Contents

Contributors *x*
Preface *xix*
Acknowledgments *xxiii*

Part I Introduction *1*

1 What Is Pharmacoepidemiology? *3*
Brian L. Strom

2 Basic Principles of Clinical Pharmacology Relevant to Pharmacoepidemiologic Studies *27*
Jeffrey S. Barrett

3 Basic Principles of Clinical Epidemiology Relevant to Pharmacoepidemiologic Studies *44*
Brian L. Strom

4 Sample Size Considerations for Pharmacoepidemiologic Studies *60*
Brian L. Strom

5 When Should One Perform Pharmacoepidemiologic Studies? *71*
Brian L. Strom

Part II The Role of Pharmacoepidemiology in Different Sectors *81*

6 The Role of Pharmacoepidemiology in the Healthcare System and Academia *83*
Joshua J. Gagne and Jerry Avorn

7 The Role of Pharmacoepidemiology in Industry *98*
Nicolle M. Gatto, Rachel E. Sobel, Jamie Geier, Jingping Mo, Andrew Bate, and Robert F. Reynolds

8 **The Role of Pharmacoepidemiology in Regulatory Agencies** *126*
Gerald J. Dal Pan, June Raine, and Shinobu Uzu

9 **Pharmacoepidemiology and the Law** *140*
Aaron S. Kesselheim and Kerstin N. Vokinger

Part III Sources of Data for Pharmacoepidemiology Research *165*

Part IIIa Spontaneous Reporting *167*

10 **Postmarketing Spontaneous Pharmacovigilance Reporting Systems** *169*
Gerald J. Dal Pan, Marie Lindquist, and Kate Gelperin

Part IIIb Electronic Data Systems *203*

11 **Overview of Electronic Databases in Pharmacoepidemiology** *205*
Brian L. Strom

12 **Encounter Databases** *211*
Tobias Gerhard, Yola Moride, Anton Pottegård , and Nicole Pratt

13 **Electronic Health Record Databases** *241*
Daniel B. Horton, Harshvinder Bhullar, Lucy Carty, Francesca Cunningham, Alexis Ogdie, Janet Sultana, and Gianluca Trifirò

14 **Inpatient Databases** *290*
James A. Feinstein, Peter K. Lindenauer, Chris Feudtner, and Brian T. Fisher

Part IIIc Studies Involving *Ad Hoc* Data Collection *305*

15 **Event Monitoring in the UK** *307*
Vicki Osborne and Saad A.W. Shakir

16 **Primary Data Collection for Pharmacoepidemiology** *342*
Nancy A. Dreyer, Ana Filipa Macedo, and Priscilla Velentgas

Part IIId Choosing a Data Source *355*

17 **Choosing among the Available Data Sources for Pharmacoepidemiology Research** *357*
Brian L. Strom

Part IV Selected Applications of Pharmacoepidemiology *373*

18 Studies of Drug Utilization *375*
Björn Wettermark, Vera Vlahović-Palčevski, David Lee, and Ulf Bergman

19 Evaluating and Improving Physician Prescribing *411*
Christine Y. Lu, the late Sumit R. Majumdar, Helene Lipton, and Stephen B. Soumerai

20 Pharmacoepidemiologic Studies of Vaccine Safety *437*
Robert T. Chen, Jason M. Glanz, and Tom T. Shimabukuro

21 Epidemiologic Studies of Medical Devices: Methodologic Considerations for Implantable Devices *496*
Danica Marinac-Dabic, Sharon-Lise Normand, Art Sedrakyan, and Thomas P. Gross

22 Research on the Effects of Medications in Pregnancy and in Children *524*
Daniel B. Horton, Sonia Hernandez-Diaz, Tamar Lasky, and Krista F. Huybrechts

23 Study of Biologics and Biosimilars *561*
Jeffrey R. Curtis and James D. Lewis

24 Risk Management *581*
Claudia Manzo, Emil Cochino, Lubna Merchant, and Giampiero Mazzaglia

25 Distributed Networks of Databases Analyzed Using Common Protocols and/or Common Data Models *617*
Sengwee Toh, Nicole Pratt, Olaf Klungel, Joshua J. Gagne, and Robert W. Platt

26 Comparative Effectiveness Research *639*
Soko Setoguchi and Ian Chi Kei Wong

27 Data Mining and Other Informatics Approaches to Pharmacoepidemiology *675*
Andrew Bate, Gianluca Trifirò, Paul Avillach, and Stephen J.W. Evans

28 Pharmacoepidemiologic Research on Drugs of Abuse *701*
Jana McAninch, Alex Secora, Cynthia Kornegay, and Judy Staffa

Part V Selected Special Methodologic Issues in Pharmacoepidemiology *723*

29 Assessing Causation from Case Reports *725*
Judith K. Jones, Bernard Bégaud, and Elyse Kingery

30 Molecular Pharmacoepidemiology *746*
Christine Y. Lu and Stephen E. Kimmel

31 Bioethical Issues in Pharmacoepidemiologic Research *772*
Laura E. Bothwell, Annika Richterich, and Jeremy Greene

32 The Use of Randomized Controlled Trials in Pharmacoepidemiology *792*
Robert F. Reynolds, Samuel M. Lesko, Nicolle M. Gatto, Tjeerd P. van Staa, and Allen A. Mitchell

33 The Use of Pharmacoepidemiology to Study Beneficial Drug Effects *813*
Brian L. Strom and the late Kenneth L. Melmon

34 Pharmacoeconomics: The Economics of Pharmaceuticals *837*
Kevin A. Schulman

35 Benefit–Risk Assessments of Medical Treatments *867*
Bennett Levitan, Rachael DiSantostefano, and Scott Evans

36 The Use of Metaanalysis in Pharmacoepidemiology *897*
Jesse A. Berlin, Brenda J. Crowe, H. Amy Xia, and Stephen J.W. Evans

37 Validity of Drug and Diagnosis Data in Pharmacoepidemiology *948*
Mary Elizabeth Ritchey, Suzanne L. West, and George Maldonado

38 Studies of Medication Adherence *991*
Julie Lauffenburger, Trisha Acri, and Robert Gross

39 Risk Evaluation and Communication *1010*
Susan J. Blalock, Rebecca Dickinson, and Peter Knapp

40 Methods for Studying the Health Effects of Drug–Drug Interactions *1030*
Sean Hennessy, Charles E. Leonard, Joshua J. Gagne, James H. Flory, Colleen M. Brensinger, and Warren B. Bilker

41 The Pharmacoepidemiology of Medication Errors *1046*
Hanna M. Seidling and David W. Bates

42 Patient Engagement and Patient-Reported Outcomes *1061*
Esi M. Morgan

43 Advanced Approaches to Controlling Confounding in Pharmacoepidemiologic Studies *1078*
Sebastian Schneeweiss and Samy Suissa

Part VI Conclusion *1109*

44 The Future of Pharmacoepidemiology *1111*
Brian L. Strom, Stephen E. Kimmel, and Sean Hennessy

Appendix A Sample Size Tables *1123*

Appendix B Glossary *1141*

Index *1155*

Preface

> If the whole materia medica, as now used, could be sunk to the bottom of the sea, it would be all the better for mankind, and all the worse for the fishes.
>
> Oliver Wendell Holmes
> *Comments and Counter-Currents in Medical Science*

The history of drug regulation in the United States is largely a history of political responses to epidemics of adverse drug reactions, each adverse reaction of sufficient public health importance to lead to political pressure for regulatory change.

The initial law, the Pure Food and Drug Act, was passed in 1906. It was a response to the excessive adulteration and misbranding of foods and drugs. The 1938 Food, Drug, and Cosmetic Act was passed in reaction to an epidemic of renal failure resulting from a brand of elixir of sulfanilamide formulated with diethylene glycol. The 1962 Kefauver–Harris Amendment to the Food, Drug, and Cosmetic Act was enacted in response to the infamous "thalidomide disaster," in which children exposed to thalidomide *in utero* were born with phocomelia; that is, with flippers instead of limbs. The resulting regulatory changes led, in part, to the accelerated development of the field of clinical pharmacology, which is the study of the effects of drugs in humans.

Subsequent decades continued to see an accelerating series of accusations about major adverse events possibly associated with drugs. Those discussed in the first edition of this book included liver disease caused by benoxaprofen, subacute myelo-optic-neuropathy (SMON) caused by clioquinol, oculomucocutaneous syndrome caused by practolol, acute flank pain and renal failure caused by suprofen, liver disease caused by ticrynafen, and anaphylactoid reactions caused by zomepirac. Added in the second edition were cardiac arrhythmias from astemizole and terfenadine; hypertension, seizures, and strokes from postpartum use of bromocriptine; deaths from fenoterol; suicidal ideation from fluoxetine; hypoglycemia from human insulin; birth defects from isotretinoin; cancer from depot-medroxyprogesterone; multiple illnesses from silicone breast implants; memory and other central nervous system disturbances from triazolam; and hemolytic anemia and other adverse reactions from temafloxacin. Further added in the third edition were liver toxicity from amoxicillin-clavulanic acid; liver toxicity from bromfenac; cancer and myocardial infarction from calcium channel blockers; cardiac arrhythmias with cisapride; primary pulmonary hypertension and cardiac valvular disease from dexfenfluramine and fenfluramine; gastrointestinal bleeding, postoperative bleeding, deaths, and many other adverse reactions associated with ketorolac; multiple drug interactions with mibefradil; thrombosis from newer oral contraceptives; myocardial infarction from sildenafil; seizures with tramadol; eosinophilia myalgia from tryptophan; anaphylactic

reactions from vitamin K; and liver toxicity from troglitazone. Added in the fourth edition were ischemic colitis from alosetron; myocardial infarction from celecoxib, naproxen, and rofecoxib; rhabdomyolysis from cerivastatin; cardiac arrhythmias from grepafloxacin; stroke from phenylpropanolamine; bronchospasm from rapacuronium; and many others. Added in the fifth edition were progressive multifocal leukoencephalopathy from natalizumab; hepatotoxicity from pamoline and from lumiracoxib; serious cardiovascular complications from rosiglitazone, tegaserod, sibutramine, rimonabant, valdecoxib, pergolide, and propoxyphene; fatal adverse reactions when used with alcohol from palladone; and serious and sometimes fatal brain infections from efalizumab. New in the sixth edition are serious infections of the genital area from sodium-glucose Cotransporter-2 (SGLT2) inhibitors; serious low blood sugar levels and mental health side effects from fluoroquinolones; increased risk of heart-related death and death from all causes from gout medicine febuxostat; increased risk of leg and foot amputations from canagliflozin; possible increased risk of bladder cancer from pioglitazone; heart failure risk from saxagliptin and alogliptin; possible increased risk of heart attack and stroke from testosterone; and potentially fatal heart rhythms from azithromycin. Some of these resulted in drug withdrawals. Published data also suggest that adverse drug reactions could be as much as the fourth leading cause of death. These and other serious but uncommon drug effects have led to the development of new methods to study drug effects in large populations. Academic investigators, the pharmaceutical industry, regulatory agencies, and the legal profession have turned for these methods to the field of epidemiology, the study of the distribution and determinants of disease in populations.

Major new changes have been made in drug regulation and organization, largely in response to a series of accusations about myocardial infarction and stroke caused by analgesics, each detected in long-term prevention trials rather than in normal use of the drugs. For example, the pharmacoepidemiology group at the US Food and Drug Administration (FDA) was doubled in size; the FDA was given new regulatory authority after drug marketing, and was also charged with developing the Sentinel Initiative, a program to conduct medical product safety surveillance in a population to exceed 100 million. Further, the development since January 1, 2006 of Medicare Part D, a US federal program to subsidize prescription drugs for Medicare recipients, introduces to pharmacoepidemiology a new database with a stable population of 25 million, as well as the interest of what may be the largest healthcare system in the world. These developments have brought about major changes for our field.

The bridging of the fields of clinical pharmacology and epidemiology resulted in the development of a new field: pharmacoepidemiology, the study of the use of and effects of drugs in large numbers of people. Pharmacoepidemiology applies the methods of epidemiology to the content area of clinical pharmacology. This new field became the science underlying postmarketing drug surveillance, studies of drug effects that are performed after a drug has been released to the market. In recent years, pharmacoepidemiology has expanded to include many other types of studies as well.

The field of pharmacoepidemiology has grown enormously since the publication of the first edition of this book. The International Society of Pharmacoepidemiology, an early idea when the first edition was written, has grown into a major international scientific force, with over 1476 members from 63 countries, an extremely successful annual meeting attracting more than 1800 attendees, a large number of very active committees and special interest groups, and its own journal. In addition, a number of established journals have targeted pharmacoepidemiology manuscripts as desirable.

As new scientific developments occur within mainstream epidemiology, they are rapidly adopted, applied, and advanced within our field too. We have also become institutionalized as a subfield within the field of clinical pharmacology, with a Drug Utilization and Outcomes community within the American Society for Clinical Pharmacology and Therapeutics, and with pharmacoepidemiology a required part of the clinical pharmacology board examination.

Most of the major international pharmaceutical companies have founded dedicated units to organize and lead their efforts in pharmacoepidemiology, pharmacoeconomics, and quality-of-life studies. The continuing parade of drug safety crises continues to emphasize the need for the field, and some foresighted manufacturers have begun to perform "prophylactic" pharmacoepidemiology studies, so as to have data in hand and available when questions arise, rather than waiting to begin collecting data after a crisis has developed. Pharmacoepidemiologic data are now routinely used for regulatory decisions, and many governmental agencies have been developing and expanding their own pharmacoepidemiology programs. Risk management programs are now required by regulatory bodies with the marketing of new drugs, as a means of improving drugs' benefit/risk balance. Requirements that a drug be proven to be cost-effective have been added to national, local, and insurance healthcare systems, either to justify reimbursement or even to justify drug availability. A number of schools of medicine, pharmacy, and public health have established research programs in pharmacoepidemiology, and a few of them have also established pharmacoepidemiology training programs in response to a desperate need for a bigger pharmacoepidemiology labor force. Pharmacoepidemiologic research funding is now more plentiful, and even support for training is now available, albeit limited.

In the United States, drug utilization review programs are required, by law, of each of the 50 state Medicaid programs, and have been implemented as well in many managed care organizations. However now, years later, the utility of drug utilization review programs has been questioned. In addition, the Joint Commission currently requires that every hospital in the US has an adverse drug reaction monitoring program and a drug use evaluation program, turning every hospital into a mini-pharmacoepidemiology laboratory. Stimulated in part by the interests of the World Health Organization and the Rockefeller Foundation, there is even substantial interest in pharmacoepidemiology in the developing world. Yet, throughout the world, the public's increased concern about privacy has made pharmacoepidemiologic research much more difficult.

In the first edition of this book, the goal was to help introduce this new field to the scientific world. The explosion in interest in the area, the rapid scientific progress that has been made, and the unexpectedly good sales of the first edition led to the second. The continued maturation of what used to be a novel field, the marked increase in sales of the second edition over the first, and the many requests from people all over the world led to the third edition. Thereafter, much in the field has changed, and the fourth edition was prepared. We also produced a textbook version, which has been widely used. Now, seven years after the fifth edition, the field continues to rapidly change, so it is time for a new edition.

In the process, most chapters in the new edition have been thoroughly revised. New chapters have been added, along with many fresh authors. With reorganization of some sections and careful pruning of old chapters, the net size of the book has been kept the same.

As in earlier editions, Part I provides background information on what is included in the field of pharmacoepidemiology, a description of the study designs it uses, a consideration of its unique problem – the requirement for very large sample sizes – and a discussion about when one would want to perform a pharmacoepidemiology

study. Also included is a chapter providing basic principles of clinical pharmacology. Part II presents a series of discussions on the need for the field, the contributions it can make, and some of its problems, from the perspectives of academia, industry, and regulatory agencies. Part III describes the systems that have been developed to perform pharmacoepidemiologic studies, and how each approaches the problem of gathering large sample sizes of study subjects in a cost-effective manner. We no longer attempt to include all the databases in the field, as they have continued to multiply. Instead, in this edition we have combined databases into categories, rather than dedicating a separate chapter to each. Part IV describes selected special opportunities for the application of pharmacoepidemiology to address major issues of importance. These are of particular interest as the field continues to turn its attention to questions beyond just those of adverse drug reactions. Part V presents state-of-the-art discussions of some particular methodologic issues that have arisen in the field. Finally, Part VI provides our personal speculations about the future of pharmacoepidemiology.

This book is not intended as a textbook of adverse drug reactions; that is, a compilation of drug-induced problems organized either by drug or by problem. Nor is it intended primarily as a textbook for use in introductory pharmacoepidemiology courses (for which *Textbook of Pharmacoepidemiology* might be more appropriate). Rather, it is intended to elucidate the methods of investigating adverse drug reactions, as well as other questions of drug effects. It is also not intended as a textbook of clinical pharmacology, organized by disease or by drug, or a textbook of epidemiology, but rather as a text describing the overlap between the two fields.

It is our hope that this book can serve both as a useful introduction to pharmacoepidemiology and as a reference source for the growing number of people interested in this field, in academia, in regulatory agencies, in industry, and in the law. It will also hopefully be useful as a reference text for the numerous courses now underway in this subject. We have been excited by the rapid progress and growth that our field has seen, and delighted that this book has played a small role in assisting this. With this new edition, it will document the major changes that have occurred. In the process, we hope that it can continue to serve to assist in the development of pharmacoepidemiology.

Brian L. Strom, MD, MPH
Stephen E. Kimmel, MD, MSCE
Sean Hennessy, PharmD, PhD

Acknowledgments

There are many individuals and institutions to whom we owe thanks for their contributions to our efforts in preparing this book. Mostly, we thank the contributors who wrote the chapters within it. We greatly enjoyed interacting with them and are grateful for all that we have learned in the process. Over the years, our own pharmacoepidemiology work has been supported mostly by grants, contracts, and cooperative agreements from the US government, especially multiple different institutes of the National Institutes of Health, the Agency for Healthcare Research and Quality, the Food and Drug Administration, and the Department of Veterans Affairs, as well as the Patient Centered Outcomes Research Institute. Other significant funders of our work include private foundations and pharmaceutical companies. Also, we would like to thank the University of Pennsylvania Perelman School of Medicine and Rutgers University. While none of this funding was specifically intended to support the development of this book, without the assistance we would not have been able to develop our careers in pharmacoepidemiology. In addition, we would like to thank Wiley, our publisher, for assistance and insights, both in support of this book and in support of the field's journal, *Pharmacoepidemiology and Drug Safety*.

Chris Rowan's contributions to this book were enormous, encompassing both the role of Managing Editor and reviewing all of the chapters, editing them thoughtfully, and posing additional questions and issues for the authors to address. Finally, Jennifer Hardy provided superb help communicating with the authors and preparing the chapters for submission to Wiley.

BLS would like to thank Steve Kimmel and Sean Hennessy for joining him as co-editors in this and the prior edition. They are two very special and talented men. It has been BLS's pleasure to help to train them, now too many years ago, to help them cultivate their own careers, and to see them blossom into star pharmacoepidemiologists in their own right, now extremely effective and successful. It is a wonderful to be able to share with them this book, which has been an important part of BLS's life and career.

BLS would also like to thank his late parents for the support and education that were critical to his being able to be successful in his career. He would like to thank the late Paul D. Stolley, MD, MPH, and the late Kenneth L. Melmon, MD, for their direction, guidance, and inspiration in the formative years of his career. He would like to thank his trainees, from whom he learns at least as much as he teaches. Last, but certainly not least, BLS would like to thank his family – Lani, Shayna, and Jordi – for accepting the time demands of the book, for tolerating his endless hours working at home on it, and for their ever-present love and support.

SEK expresses his sincere gratitude to BLS for his almost 30 years as a mentor and colleague and for the chance to work on this book, to his parents for providing the foundation for all of his work, and to his family – Alison, David, Benjamin, and Jonathan – for all their support and patience while Dad worked on the book.

SH also thanks BLS, his longtime friend and career mentor, and all of his students, mentees, and collaborators. Finally, he thanks his parents, and his family – Kristin, Landis, and Bridget – for their love and support.

Part I

Introduction

1

What Is Pharmacoepidemiology?

Brian L. Strom

Rutgers Biomedical and Health Sciences, Newark, NJ, USA

> *A desire to take medicine is, perhaps, the great feature which distinguishes man from other animals.*
>
> Sir William Osler, 1891

In recent decades, modern medicine has been blessed with a pharmaceutical armamentarium that is much more powerful than it had before. Although this has given healthcare providers the ability to provide better medical care for their patients, it has resulted too in the ability to do much greater harm. It has also generated an enormous number of product liability suits against pharmaceutical manufacturers, some appropriate and others inappropriate. In fact, the history of drug regulation parallels the history of major adverse drug reaction "disasters." Each change in pharmaceutical law was a political reaction to an epidemic of adverse drug reactions. A 1998 study estimated that 100 000 Americans die each year from adverse drug reactions, and 1.5 million US hospitalizations each year result from adverse drug reactions; yet, 20–70% of adverse drug reactions may be preventable [1]. The harm that drugs can cause has also led to the development of the field of pharmacoepidemiology, which is the focus of this book. More recently, the field has expanded its focus to include in addition many issues other than adverse reactions.

To clarify what is, and what is not, included within the discipline of pharmacoepidemiology, this chapter will begin by defining pharmacoepidemiology, differentiating it from other related fields. The history of drug regulation will then be briefly and selectively reviewed, focusing on the US experience as an example, demonstrating how it has led to the development of this new field. Next, the current regulatory process for the approval of new drugs will be outlined, in order to place the use of pharmacoepidemiology and postmarketing drug surveillance into proper perspective. Finally, the potential scientific and clinical contributions of pharmacoepidemiology will be discussed.

Definition of Pharmacoepidemiology

Pharmacoepidemiology is the study of the use of and the effects of drugs in large numbers of people. The term pharmacoepidemiology obviously contains two components: "pharmaco" and "epidemiology." In order to better appreciate

Pharmacoepidemiology, Sixth Edition. Edited by Brian L. Strom, Stephen E. Kimmel and Sean Hennessy.

and understand what is and what is not included in this new field, it is useful to compare its scope to that of other related fields. The scope of pharmacoepidemiology will first be compared to that of clinical pharmacology, and then to that of epidemiology.

Pharmacoepidemiology versus Clinical Pharmacology

Pharmacology is the study of the effects of drugs. *Clinical pharmacology* is the study of the effects of drugs in humans (see also Chapter 2). Pharmacoepidemiology obviously can be considered, therefore, to fall within clinical pharmacology. In attempting to optimize the use of drugs, one central principle of clinical pharmacology is that therapy should be individualized, or tailored, to the needs of the particular patient at hand. This individualization of therapy requires the determination of a risk/benefit ratio specific to the patient. Doing so requires a prescriber to be aware of the potential beneficial and harmful effects of the drug in question and to know how elements of the patient's clinical status might modify the probability of a good therapeutic outcome. For example, consider a patient with a serious infection, serious liver impairment, and mild impairment of his or her renal function. In considering whether to use gentamicin to treat the infection, it is not sufficient to know that gentamicin has a small probability of causing renal disease. A good clinician should realize that a patient who has impaired liver function is at a greater risk of suffering from this adverse effect than one with normal liver function [2]. Pharmacoepidemiology can be useful in providing information about the beneficial and harmful effects of any drug, thus permitting a better assessment of the risk/benefit balance for the use of any particular drug in any particular patient.

Clinical pharmacology is traditionally divided into two basic areas: pharmacokinetics and pharmacodynamics. *Pharmacokinetics* is the study of the relationship between the dose administered of a drug and the serum or blood level achieved. It deals with drug absorption, distribution, metabolism, and excretion. *Pharmacodynamics* is the study of the relationship between drug level and drug effect. Together, these two fields allow one to predict the effect one might observe in a patient from administering a certain drug regimen. Pharmacoepidemiology encompasses elements of both of these fields, exploring the effects achieved by administering a drug regimen. It does not normally involve or require the measurement of drug levels. However, pharmacoepidemiology can be used to shed light on the pharmacokinetics of a drug when used in clinical practice, such as exploring whether aminophylline is more likely to cause nausea when administered to a patient who is simultaneously taking cimetidine. However, to date this is a relatively novel application of the field.

Specifically, the field of pharmacoepidemiology has primarily concerned itself with the study of adverse drug effects. Adverse reactions have traditionally been separated into those which are the result of an exaggerated but otherwise usual pharmacologic effect of the drug, sometimes called *type A reactions*, versus those which are aberrant effects, so called *type B reactions* [3]. Type A reactions tend to be common, dose-related, predictable, and less serious. They can usually be treated by simply reducing the dose of the drug. They tend to occur in individuals who have one of three characteristics. First, the individuals may have received more of a drug than is customarily required. Second, they may have received a conventional amount of the drug, but they may metabolize or excrete it unusually slowly, leading to drug levels that are too high (see also Chapter 2). Third, they may have normal drug levels, but for some reason are overly sensitive to the drug.

In contrast, type B reactions tend to be uncommon, not related to dose, unpredictable,

and potentially more serious. They usually require cessation of the drug. They may be due to what are known as hypersensitivity reactions or immunologic reactions. Alternatively, type B reactions may be some other idiosyncratic reaction to the drug, either due to some inherited susceptibility (e.g., glucose-6-phosphate dehydrogenase deficiency) or due to some other mechanism. Regardless, type B reactions are the most difficult to predict or even detect, and represent the major focus of many pharmacoepidemiologic studies of adverse drug reactions.

One typical approach to studying adverse drug reactions has been the collection of spontaneous reports of drug-related morbidity or mortality (see Chapter 10), sometimes called pharmacovigilance (although other times that term is used to refer to all of pharmacoepidemiology). However, determining causation in case reports of adverse reactions can be problematic (see Chapter 29), as can attempts to compare the effects of drugs in the same class (see Chapter 26). Further, drug–drug interactions, predicted based on pharmacokinetic data (see Chapter 2), require massive sample sizes to confirm in people (see Chapter 40). This has led academic investigators, industry, the US Food and Drug Administration (FDA), and the legal community to turn to the field of epidemiology. Specifically, *studies of adverse effects* have been supplemented with *studies of adverse events*. In the former, investigators examine case reports of purported adverse drug reactions and attempt to make a subjective clinical judgment on an *individual* basis about whether the adverse outcome was actually caused by the antecedent drug exposure. In the latter, controlled studies are performed examining whether the adverse outcome under study occurs more often in an exposed *population* than in an unexposed population. This marriage of the fields of clinical pharmacology and epidemiology has resulted in the development of a further field: pharmacoepidemiology.

Pharmacoepidemiology versus Epidemiology

Epidemiology is the study of the distribution and determinants of diseases in populations (see Chapter 3). Since pharmacoepidemiology is the study of the use of and effects of drugs in large numbers of people, it obviously falls within epidemiology as well. Epidemiology is also traditionally subdivided into two basic areas. The field began as the study of infectious diseases in large populations; that is, epidemics. It has since been expanded to encompass the study of chronic diseases. The field of pharmacoepidemiology uses the techniques of chronic disease epidemiology to study the use of and the effects of drugs. Although application of the methods of pharmacoepidemiology can be useful in undertaking the clinical trials of drugs that are performed before marketing [4], the major application of these principles is after drug marketing. This has primarily been in the context of postmarketing drug surveillance, although in recent years the interests of pharmacoepidemiologists have broadened considerably. Now, as will be made clearer in future chapters, pharmacoepidemiology is considered of importance in the whole life cycle of a drug, from the time it is first discovered or synthesized through to when it is no longer sold as a drug.

Thus, pharmacoepidemiology is a relatively new applied field, bridging between clinical pharmacology and epidemiology. From clinical pharmacology, pharmacoepidemiology borrows its focus of inquiry. From epidemiology, pharmacoepidemiology borrows its methods of inquiry. In other words, it applies the methods of epidemiology to the content area of clinical pharmacology. In the process, multiple special logistical approaches have been developed and multiple special methodologic issues have arisen. These are the primary foci of this book.

Historical Background

Early Legislation

The history of drug regulation in the US is similar to that in most developed countries, and reflects the growing involvement of governments in attempting to insure that only safe and effective drug products were available and that appropriate manufacturing and marketing practices were used. The initial US law, the Pure Food and Drug Act, was passed in 1906, in response to excessive adulteration and misbranding of the food and drugs available at that time. There were no restrictions on sales or requirements for proof of the efficacy or safety of marketed drugs. Rather, the law simply gave the federal government the power to remove from the market any product that was adulterated or misbranded. The burden of proof was on the federal government.

In 1937, over 100 people died from renal failure as a result of the marketing by the Massengill Company of elixir of sulfanilimide dissolved in diethylene glycol [5]. In response, Congress passed the 1938 Food, Drug, and Cosmetic Act. Preclinical toxicity testing was required for the first time. In addition, manufacturers were required to gather clinical data about drug safety and to submit these data to FDA before drug marketing. The FDA had 60 days to object to marketing or else it would proceed. No proof of efficacy was required.

Little attention was paid to adverse drug reactions until the early 1950s, when it was discovered that chloramphenicol could cause aplastic anemia [6]. In 1952, the first textbook of adverse drug reactions was published [7]. In the same year, the American Medical Association (AMA) Council on Pharmacy and Chemistry established the first official registry of adverse drug effects, to collect cases of drug-induced blood dyscrasias [8]. In 1960, the FDA began to collect reports of adverse drug reactions and sponsored new hospital-based drug-monitoring programs. The Johns Hopkins Hospital and the Boston Collaborative Drug Surveillance Program developed the use of in-hospital monitors to perform cohort studies to explore the short-term effects of drugs used in hospitals [9,10]. This approach was later to be transported to the University of Florida–Shands Teaching Hospital as well [11].

In the winter of 1961, the world experienced the infamous "thalidomide disaster." Thalidomide was marketed as a mild hypnotic, and had no obvious advantage over other drugs in its class. Shortly after its marketing, a dramatic increase was seen in the frequency of a previously rare birth defect, phocomelia: the absence of limbs or parts of limbs, sometimes with the presence instead of flippers [12]. Epidemiologic studies established its cause to be *in utero* exposure to thalidomide. In the UK, this resulted in the establishment in 1968 of the Committee on Safety of Medicines. Later, the World Health Organization (WHO) established a bureau to collect and collate information from this and other similar national drug-monitoring organizations (see Chapter 10).

The US had never permitted the marketing of thalidomide and so was fortunately spared this epidemic. However, the "thalidomide disaster" was so dramatic that it resulted in regulatory change in the US as well. Specifically, in 1962 the Kefauver–Harris Amendments were passed. These amendments strengthened the requirements for proof of drug safety, requiring extensive preclinical pharmacologic and toxicologic testing before a drug could be tested in humans. The data from these studies were required to be submitted to the FDA in an Investigational New Drug (IND) application before clinical studies could begin. Three explicit phases of clinical testing were defined, which are described in more detail later in this chapter. In addition, a new requirement was added to the clinical testing, for "substantial evidence that the drug will have the effect it purports or is represented to have." "Substantial evidence" was defined as "adequate and well-controlled investigations,

including clinical investigations." Functionally, this has generally been interpreted as requiring randomized clinical trials to document drug efficacy before marketing. This new procedure also delayed drug marketing until the FDA explicitly gave approval. With some modifications, these are the requirements still in place in the US today. In addition, the amendments required the review of all drugs approved between 1938 and 1962, to determine if they too were efficacious. The resulting DESI (Drug Efficacy Study Implementation) process, conducted by the National Academy of Sciences' National Research Council with support from a contract from the FDA, was not completed until years later, and resulted in the removal from the US market of many ineffective drugs and drug combinations. The result of all these changes was a great prolongation of the approval process, with attendant increases in the cost of drug development, in what was termed the "drug lag" [13] (discussed later in the chapter). However, the drugs that do reach the market are presumably much safer and more effective.

Drug Crises and Resulting Regulatory Actions

Despite the more stringent process for drug regulation, subsequent years have seen a series of major adverse drug reactions. Subacute myelo-optic-neuropathy (SMON) was found in Japan to be caused by clioquinol, a drug marketed in the early 1930s but not discovered to cause this severe neurologic reaction until 1970 [14]. In the 1970s, clear cell adenocarcinoma of the cervix and vagina and other genital malformations were found to be due to *in utero* exposure to diethylstilbestrol two decades earlier [15]. The mid-1970s saw the UK discovery of the oculomucocutaneous syndrome caused by practolol, five years after drug marketing [16]. In 1980, the drug ticrynafen was noted to cause deaths from liver disease [17]. In 1982, benoxaprofen was noted to do the same [18]. Subsequently the use of zomepirac, another nonsteroidal anti-inflammatory drug, was noted to be associated with an increased risk of anaphylactoid reactions [19]. Serious blood dyscrasias were linked to phenylbutazone [20]. Small intestinal perforations were noted to be caused by a particular slow-release formulation of indomethacin [21]. Bendectin®, a combination product indicated to treat nausea and vomiting in pregnancy, was removed from the market because of litigation claiming it was a teratogen, despite the absence of valid scientific evidence to justify this claim [22] (see Chapter 22). Acute flank pain and reversible acute renal failure were noted to be caused by suprofen [23]. Isotretinoin was almost removed from the US market because of the birth defects it causes [24,25]. The Eosinophilia-Myalgia syndrome was linked to a particular brand of L-tryptophan [26]. Triazolam, thought by The Netherlands in 1979 to be subject to a disproportionate number of central nervous system side effects [27], was discovered by the rest of the world to be problematic in the early 1990s [28–30]. Silicone breast implants, inserted by the millions in the US for cosmetic purposes, were accused of causing cancer, rheumatologic disease, and many other problems, and restricted from use except for breast reconstruction after mastectomy [31]. Human insulin was marketed as one of the first of the new biotechnology drugs, but soon thereafter was accused of causing a disproportionate amount of hypoglycemia [32–36]. Fluoxetine was marketed as a major new, important and commercially successful psychiatric product, but then lost a large part of its market due to accusations about its association with suicidal ideation [37,38]. An epidemic of deaths from asthma in New Zealand was traced to fenoterol [39–41], and later data suggested that similar, although smaller, risks might be present with other beta-agonist inhalers [42]. The possibility was raised of cancer from depot-medroxyprogesterone, resulting in initial refusal to allow its marketing for this purpose in the US

[43], multiple studies [44,45], and ultimate approval. Arrhythmias were linked to the use of the antihistamines terfenadine and astemizole [46,47]. Hypertension, seizures, and strokes were noted from postpartum use of bromocriptine [48,49]. Multiple different adverse reactions were linked to temafloxacin [50]. Other examples include liver toxicity from amoxicillin-clavulanic acid [51]; liver toxicity from bromfenac [52,53]; cancer, myocardial infarction, and gastrointestinal bleeding from calcium channel blockers [54–61]; arrhythmias with cisapride interactions [62–65]; primary pulmonary hypertension and cardiac valvular disease from dexfenfluramine and fenfluramine [66–68]; gastrointestinal bleeding, postoperative bleeding, deaths, and many other adverse reactions associated with ketorolac [69–72]; multiple drug interactions with mibefradil [73]; thrombosis from newer oral contraceptives [74–77]; myocardial infarction from sildenafil [78]; seizures from tramadol [79,80]; anaphylactic reactions from vitamin K [81]; liver toxicity from troglitazone [82–85]; and intussusception from rotavirus vaccine [86].

Later drug crises have occurred due to allegations of ischemic colitis from alosetron [87]; rhabdomyolysis from cerivastatin [88]; bronchospasm from rapacuronium [89]; torsades de pointes from ziprasidone [90]; hemorrhagic stroke from phenylpropanolamine [91]; arthralgia, myalgia, and neurologic conditions from Lyme vaccine [92]; multiple joint and other symptoms from anthrax vaccine [93]; myocarditis and myocardial infarction from smallpox vaccine [94]; and heart attack and stroke from rofecoxib [95].

Major adverse drug reactions continue to plague new drugs, and in fact have been as common if not more common in the last several decades. In total, 36 different oral prescription drug products have been removed from the US market since 1980 alone (alosetron, 2000; aprotinin, 2007; astemizole, 1999; benoxaprofen, 1982; bromfenac, 1998; cerivastatin, 2001; cisapride, 2000; dexfenfluramine, 1997; efalizumab, 2009; encainide, 1991; etretinate, 1998; fenfluramine, 1998; flosequinan, 1993; grepafloxin, 1999; levomethadyl, 2003; lumiracoxib, 2007; mibefradil, 1998; natalizumab, 2005; nomifensine, 1986; palladone, 2005; pemoline, 2005; pergolide, 2010; phenylpropanolamine, 2000; propoxyphene, 2010; rapacuronium, 2001; rimonabant, 2010; rofecoxib, 2004; sibutramine, 2010; suprofen, 1987; tegaserod, 2007; terfenadine, 1998; temafloxacin, 1992; ticrynafen, 1980; troglitazone, 2000; valdecoxib, 2007; zomepirac, 1983). The licensed vaccines against rotavirus [86] and Lyme [92] were also withdrawn because of safety concerns (see Chapter 20). Further, between 1990 and 2004, at least 15 noncardiac drugs, including astemizole, cisapride, droperidol, grepafloxacin, halofantrine, pimozide, propoxyphene, rofecoxib, sertindole, sibutramine, terfenadine, terodiline, thioridazine, vevacetylmethadol, and ziprasidone, were subject to significant regulatory actions because of cardiac concerns [96].

Since 1993, trying to deal with drug safety problems, the FDA morphed its extant spontaneous reporting system into the MedWatch program of collecting spontaneous reports of adverse reactions (see Chapters 8 and 10), as part of that issuing monthly notifications of label changes. Compared to the 20–25 safety-related label changes that were being made every month by mid-1999, between 19 and 57 safety-related label changes (boxed warnings, warnings, contraindications, precautions, adverse events) were made every month in 2009 [97]. From January of 2010 to July of 2016, there were 3324 safety-related label changes, with a range per month of 19–87 (median 41). Among all safety-related label changes (January 2010 to July 2016), 8%, 13%, 56%, and 65% were boxed warnings, contraindications, warnings, and precautions, respectively [97].

According to a study from a number of years ago by the US Government Accountability Office, 51% of approved drugs have serious

adverse effects not detected before approval [98]. Further, there is recognition that the initial dose recommended for a newly marketed drug is often incorrect, and needs monitoring and modification after marketing [99–101].

In some of the examples given, the drug was never convincingly linked to the adverse reaction, yet many of these accusations led to the removal of the drug involved from the market. Interestingly, however, this withdrawal was not necessarily performed in all of the different countries in which each drug was marketed. Most of these discoveries have led to litigation as well, and a few have even resulted in criminal charges against the pharmaceutical manufacturer and/or some of its employees (see Chapter 9).

Legislative Actions Resulting from Drug Crises

Through the 1980s, there was concern that an underfunded FDA was approving drugs too slowly, and that the US suffered, compared to Europe, from a "drug lag" [102]. To provide additional resources to the FDA to help expedite the drug review and approval process, Congress passed in 1992 the Prescription Drug User Fee Act (PDUFA), allowing the FDA to charge manufacturers a fee for reviewing new drug applications [103,104]. This legislation was reauthorized by Congress three more times: PDUFA II, also called the Food and Drug Modernization Act of 1997; PDUFA III, also called the Public Health Security and Bioterrorism Preparedness and Response Act of 2002; and PDUFA IV, also called the Food and Drug Administration Amendments (FDAAA-PL 110-85) of 2007. The goals for PDUFA I–IV were to enable the FDA to complete review of over 90% of priority drug applications in 6 months, and complete review of over 90% of standard drug applications in 12 months (under PDUFA I) or 10 months (under PDUFA II–IV). In addition to reauthorizing the collection of user fees from the pharmaceutical industry, PDUFA II allowed the FDA to accept a single well-controlled clinical study under certain conditions, to reduce drug development time. The result was a system where more than 550 new drugs were approved by the FDA in the 1990s [105].

However, whereas 1400 FDA employees in 1998 worked with the drug approval process, only 52 monitored safety; FDA spent a mere $2.4 million on extramural safety research. This state of affairs coincided with the growing numbers of drug crises already cited. With successive reauthorizations of PDUFA, this markedly changed. PDUFA III for the first time allowed the FDA to use a small portion of the user fees for postmarketing drug safety monitoring, to address safety concerns.

Nevertheless, there now was growing concern, in Congress and among the US public, that perhaps the FDA was approving drugs too *fast* [106,107]. There were also calls for the development of an independent drug safety board, analogous to the National Transportation Safety Board [108,109], with a mission much wider than the FDA's regulatory mission, to complement the latter. For example, such a board could investigate drug safety crises such as those discussed, looking for ways to prevent them, and could deal with issues such as improper physician use of drugs, the need for training, and the development of new approaches to the field of pharmacoepidemiology.

Recurrent concerns about the FDA's management of postmarketing drug safety issues led to a systematic review of the entire drug risk assessment process. In 2006, the US General Accountability Office issued its report of a review of the organizational structure and effectiveness of FDA's postmarketing drug safety decision-making [100], followed in 2007 by the Institute of Medicine's independent assessment [110]. Important weaknesses were noted in the current system, including failure of the FDA's Office of New Drugs and Office of Drug Safety to communicate with each other on safety issues, failure of the FDA to track ongoing postmarketing studies, the ambiguous role of the

FDA's Office of Drug Safety in scientific advisory committees, limited authority by the FDA to require the pharmaceutical industry to perform studies to obtain needed data, concerns about culture problems at the FDA where recommendations by members of its drug safety staff were not followed, and concerns about conflicts of interest involving advisory committee members. This Institute of Medicine report was influential in shaping PDUFA IV.

Indeed, with the passage of those amendments, the FDA's authority was substantially increased, with the ability, for example, to require postmarketing studies and levy heavy fines if these requirements were not met. Further, its resources were substantially increased, with a specific charge to (i) fund epidemiology best practices and data acquisition ($7 million in fiscal 2008, increasing to $9.5 million in fiscal 2012); (ii) fund new drug trade name review ($5.3 million in fiscal 2008, rising to $6.5 million in fiscal 2012); and (iii) fund risk management and communication ($4 million in fiscal 2008, rising to $5 million in fiscal 2012) [111] (see also Chapter 24). In addition, in another use of the new PDUFA funds, the FDA plans to develop and implement agency-wide and special-purpose postmarket information technology (IT) systems, including the MedWatch Plus Portal, the FDA Adverse Event Reporting System, the Sentinel System (a virtual national medical product safety system; see Chapter 25), and the Phonetic and Orthographic Computer Analysis System to find similarities in spelling or sound between proposed proprietary drug names that might increase the risk of confusion and medication errors [111].

The Food and Drug Administration Safety and Innovation Act of 2012 (FDASIA), the fifth authorization of PDUFA, expanded the FDA's authority with the ability to safeguard and advance public health by: (i) "giving the authority to collect user fees from industry to fund reviews of innovator drugs, medical devices, generic drugs and biosimilar biological products"; (ii) "promoting innovation to speed patient access to safe and effective products"; (iii) "increasing stakeholder involvement in FDA processes"; and (iv) "enhancing the safety of the drug supply chain" [112]. Also enacted in 2012, the Generic Drug User Fee Amendments (GDUFA) permitted the FDA to assess industry user fees with the intention of increasing the predictability and timeliness of generic drug application reviews [113]. The Biosimilar User Fee Act (BsUFA), also enacted in 2012, authorized the FDA to collect fees directly from biosimilar drug product applicants to expedite the review of biosimilar applications [114]. The FDA Reauthorization Act of 2017 (FDARA) reauthorized PDUFA, GDUFA, and BsUFA through fiscal year 2022.

Among other aims, the 21st Century Cures Act (enacted in December 2016) was intended to expedite the process by which new drugs and devices are approved by easing the requirements put on drug companies looking for FDA approval on new products or new indications on existing drugs. It calls for the use of "data summaries" to support the approval of certain drugs for new indications, rather than full clinical trial data. It also allows drug companies to promote off-label uses to insurance companies, enabling them to expand their markets. Of particular relevance to pharmacoepidemiology, it permits the use of "real world evidence" rather than just clinical trial results [115]. Depending on how these new rules are interpreted, this could massively change drug development in the US, and in particular the role of pharmacoepidemiology in that drug development.

Intellectual Development of Pharmacoepidemiology Emerging from Drug Crises

Several developments in the 1960s can be thought to have marked the beginning of the field of pharmacoepidemiology. The Kefauver–Harris Amendments that were introduced in

1962 required formal safety studies for new drug applications. The DESI program that was undertaken by the FDA as part of those amendments required formal efficacy studies for old drugs that were approved earlier. These requirements created a demand for new expertise and new methods. In addition, the mid-1960s saw the publication of a series of drug utilization studies [116–120]. These provided the first descriptive information on how physicians use drugs, and began a series of investigations of the frequency and determinants of poor prescribing (see also Chapters 18 and 19).

In part in response to concerns about adverse drug effects, the early 1970s saw the development of the Drug Epidemiology Unit, now the Slone Epidemiology Center, which extended the hospital-based approach of the Boston Collaborative Drug Surveillance Program by collecting lifetime drug exposure histories from hospitalized patients and using these to perform hospital-based case–control studies [121] (see Chapter 16). The year 1976 saw the formation of the Joint Commission on Prescription Drug Use, an interdisciplinary committee of experts charged with reviewing the state of the art of pharmacoepidemiology at that time, as well as providing recommendations for the future [122]. The Computerized Online Medicaid Analysis and Surveillance System (COMPASS®) was first developed in 1977, using Medicaid billing data to perform pharmacoepidemiologic studies [123] (see Chapter 12). The Drug Surveillance Research Unit, now called the Drug Safety Research Trust, was developed in the UK in 1980, with its innovative system of prescription event monitoring [124] (see Chapter 15). Each of these represented major contributions to the field of pharmacoepidemiology, and together with newer approaches are reviewed in Part III of this book.

In the examples of drug crises mentioned earlier, there were serious but uncommon drug effects, and these experiences led to an accelerated search for new methods to study drug effects in large numbers of patients. This resulted in a shift from adverse effect studies to adverse event studies, with a concomitant increasing use of new data resources and new methods to study adverse reactions. The American Society for Clinical Pharmacology and Therapeutics issued, in 1990, a position paper on the use of purported postmarketing drug surveillance studies for promotional purposes [125], and the International Society for Pharmacoepidemiology (ISPE) issued, in 1996, Guidelines for Good Epidemiology Practices for Drug, Device, and Vaccine Research in the United States [126], which were updated in 2007 [127] and 2015. Since the late 1990s, pharmacoepidemiologic research has also been increasingly burdened by concerns about patient confidentiality [128–132] (see also Chapter 31).

There is also increasing recognition that most of the risk from most drugs to most patients occurs from known reactions to old drugs. As an attempt to address concerns about underuse, overuse, and adverse events of medical products and medical errors that may cause serious impairment to patient health, a new program of Centers for Education and Research on Therapeutics (CERTs) was authorized under the FDA Modernization Act of 1997 (as part of the same legislation that reauthorized PDUFA II). Starting in 1999 and incrementally adding more centers in 2002, 2006, and 2007, the Agency for Healthcare Research and Quality (AHRQ) that was selected to administer this program had funded up to 14 CERTs [133], although the program ended in 2016 (see also Chapter 6).

The research and education activities sponsored by AHRQ through the CERTs program since the late 1990s take place in academic centers. The CERTs conduct research on therapeutics, exploring new uses of drugs, ways to improve the effective uses of drugs, and the risks associated with new uses or combinations of drugs. They also develop educational modules and materials for disseminating the research

findings about medical products. With the development of direct-to-consumer advertising of drugs since the mid-1980s in the US, the CERTs' role in educating the public and healthcare professionals by providing evidence-based information has become especially important.

Another impetus for research on drugs resulted from one of the mandates (in Sec. 1013) of the Medicare Prescription Drug, Improvement, and Modernization Act of 2003 to provide beneficiaries with scientific information on the outcomes, comparative clinical effectiveness, and appropriateness of healthcare items and services [134]. In response, the AHRQ created in 2005 the DEcIDE (Developing Evidence to Inform Decisions about Effectiveness) Network to support in academic settings the conduct of studies on the effectiveness, safety, and usefulness of drugs and other treatments and services [135]. This too ended, in 2012.

Another major new initiative of close relevance to pharmacoepidemiology is risk management. There is increasing recognition that the risk/benefit balance of some drugs can only be considered acceptable with active management of their use, to maximize their efficacy and/or minimize their risk. In response, in the late 1990s, new initiatives ranged from FDA requirements for risk management plans to an FDA Drug Safety and Risk Management Advisory Committee, and the issuing of risk minimization and management guidance in 2005. More information is provided in Chapters 8 and 24.

Another initiative closely related to pharmacoepidemiology is the Patient Safety movement. In the Institute of Medicine's report, "To Err Is Human: Building a Safer Health System," the authors note that (i) "even apparently single events or errors are due most often to the convergence of multiple contributing factors"; (ii) "preventing errors and improving safety for patients requires a systems approach in order to modify the conditions that contribute to errors"; and (iii) "the problem is not bad people; the problem is that the system needs to be made safer" [136]. In this framework, the concern is not about substandard or negligent care, but rather about errors made by even the best trained, brightest, and most competent professional health caregivers and/or patients. From this perspective, the important research questions ask about the conditions under which people make errors, the types of errors being made, and the types of systems that can be put into place to prevent errors altogether when possible. Errors that are not prevented must be identified and corrected efficiently and quickly, before they inflict harm. Turning specifically to medications, from 2.4% to 6.5% of hospitalized patients suffer adverse drug effects, prolonging hospital stays by 2 days, and increasing costs by $2000–2600 per patient [137–140]. Over 7000 US deaths were attributed to medication errors in 1993 [141]. Although these estimates have been disputed [142–147], the overall importance of reducing these errors has not been questioned. In recognition of this problem, the AHRQ launched a major new grant program of over 100 projects at its peak with over $50 million/year of funding. While only a portion of this is dedicated to medication errors, they are clearly a focus of interest and relevance to many. More information is provided in Chapter 41.

The 1990s and especially the 2000s saw another shift in the field, away from its exclusive emphasis on drug utilization and adverse reactions, to the inclusion of other interests as well, such as the use of pharmacoepidemiology to study beneficial drug effects, the application of health economics to the study of drug effects, quality-of-life studies, meta-analysis, studies of biologics, data mining, studies of drugs of abuse, drug interactions, and so on. These new foci are discussed in more detail in Parts IV and V of this book.

Moreover, with the publication of the results from the Women's Health Initiative indicating that combination hormone replacement therapy

causes an increased risk of myocardial infarction rather than a decreased risk [148,149], there has been increased concern about reliance solely on nonexperimental methods to study drug safety after marketing [150–153]. This led to increased use of massive randomized clinical trials as part of postmarketing surveillance (see Chapter 32). This is especially important because often the surrogate markers used for drug development cannot necessarily be relied upon to map completely to true clinical outcomes [154].

Finally, with the advent of the Obama administration in the US, there was enormous interest in comparative effectiveness research (CER). CER was defined in 2009 by the Federal Coordinating Council for Comparative Effectiveness Research as "the conduct and synthesis of research comparing the benefits and harms of different interventions and strategies to prevent, diagnose, treat and monitor health conditions in "real world" settings. The purpose of this research is to improve health outcomes by developing and disseminating evidence-based information to patients, clinicians, and other decision-makers, responding to their expressed needs, about which interventions are most effective for which patients under specific circumstances" [155]. By this definition, CER includes three key elements: (i) evidence synthesis, evidence generation, and evidence dissemination. Typically, CER is conducted through observational studies of either large administrative or medical record databases (see Part IIIb), or large naturalistic clinical trials (see Chapter 32). In many ways, the UK has been focusing on CER for years via its National Institute for Health and Clinical Excellence (NICE), an independent organization responsible for providing national guidance on promoting good health and preventing and treating ill health [156]. However, the Obama administration included $1.1 billion for CER in its federal stimulus package, and had plans for hundreds of millions of dollars of support per year thereafter. While CER does not overlap completely with pharmacoepidemiology, the scientific approaches are very close. Pharmacoepidemiologists evaluate the use and effects of medications. CER investigators compare, in the real world, the safety and benefits of one treatment to those of another. CER extends beyond pharmacoepidemiology in that it can include more than just drugs; pharmacoepidemiology extends beyond CER in that it includes studies comparing exposed to unexposed patients, not just alternative exposures. However, to date, most work done in CER has been in pharmacoepidemiology. See Chapter 26 for more discussion.

The Current Drug Approval Process

Drug Approval in the US

Until the early 1990s, there was a decline in the number of novel drugs approved per year [101,157], while the cost of bringing a drug to market has risen sharply [158]. The total cost of drug development to the pharmaceutical industry increased from $24 billion in 1999, to $32 billion in 2002 [159], and to $65.2 billion on research and development in 2008 [160]. The cost to discover and develop a drug that successfully reached the market rose from over $800 million in 2004 [161] to an estimated $1.3–1.7 billion currently [162]. In addition to the sizable costs of research and development, a substantial part of the total cost is determined also by the regulatory requirement to test new drugs during several premarketing and postmarketing phases, as will be reviewed next.

The current drug approval process in the US and most other developed countries includes preclinical animal testing followed by three phases of clinical testing. Phase I testing is usually conducted in just a few normal volunteers, and represents the initial trials of the drug in

humans. Phase I trials are generally conducted by clinical pharmacologists, to determine the metabolism of the drug in humans, a safe dosage range in humans, and to exclude any extremely common toxic reactions that are unique to humans.

Phase II testing is also generally conducted by clinical pharmacologists, on a small number of patients who have the target disease. Phase II testing is usually the first time patients are exposed to the drug. Exceptions are drugs that are so toxic that it would not normally be considered ethical to expose healthy individuals to them, like cytotoxic drugs. For these, patients are used for Phase I testing as well. The goals of Phase II testing are to obtain more information on the pharmacokinetics of the drug and on any relatively common adverse reactions, and to obtain initial information on its possible efficacy. Specifically, Phase II is used to determine the daily dosage and regimen to be tested more rigorously in Phase III.

Phase III testing is performed by clinician-investigators in a much larger number of patients, in order to rigorously evaluate the drug's efficacy and provide more information on its toxicity. At least one of the Phase III studies needs to be a randomized clinical trial (see Chapter 3). To meet FDA standards, at least one of the randomized clinical trials usually needs to be conducted in the US. Generally between 500 and 3000 patients are exposed to a drug during Phase III, even if drug efficacy can be demonstrated with much smaller numbers, in order to be able to detect less common adverse reactions. For example, a study including 3000 patients would allow one to be 95% certain of detecting any adverse reactions that occur in at least 1 exposed patient out of 1000. At the other extreme, a total of 500 patients would allow one to be 95% certain of detecting any adverse reactions that occur in 6 or more patients out of every 1000 exposed. Adverse reactions that occur less commonly than these are less likely to be detected in these premarketing studies. The sample sizes needed to detect drug effects are discussed in more detail in Chapter 4. Nowadays, with the increased focus on drug safety, premarketing dossiers are sometimes being extended well beyond 3000 patients. However, as one can tell from the sample size calculations in Chapter 4 and Appendix A, by itself these larger numbers lead to little additional information being gained about adverse drug reactions, unless one were to increase to perhaps 30 000 patients, well beyond the scope of most premarketing studies.

Finally, Phase IV testing is the evaluation of the effects of drugs after general marketing. The bulk of this book is devoted to such efforts.

Drug Approval in Other Countries

Outside the US, national systems for the regulation and approval of new drugs vary greatly, even among developed countries and especially between developed and developing countries. While in most developed countries at least the general process of drug development is very analogous to that in the US, its implementation varies widely. A WHO comparative analysis of drug regulation in 10 countries found that not all even have a written national drug policy document [163]. Regulation of medicines in some countries is centralized in a single agency that performs the gamut of functions, involving product registration, licensing, product review, approval for clinical trials, postmarketing surveillance, and inspection of manufacturing practice. Examples for this are Health Canada [164], the China Food and Drug Administration (CFDA) [165], the Medicines Agency in Denmark [166], the Medicines Agency in Norway [167], the Center for Drug Administration in Singapore [168], and the Medicines and Medical Devices Safety Authority in New Zealand [169]. In other countries, regulatory functions are distributed among different agencies. An example of the latter is The Netherlands, where the Ministry of Health,

Welfare and Sports performs the functions of licensing; the Healthcare Inspectorate checks on general manufacturing practice; and the Medicines Evaluation Board performs the functions of product assessment and registration and adverse drug reaction monitoring [163]. As another example, in Singapore two independent agencies (the Center for Pharmaceutical Administration and the Center for Drug Evaluation) were previously responsible for medicinal regulation and evaluation, but are currently merged into a single agency (the Center for Drug Administration) [168].

Another dimension on which countries may vary is the degree of autonomy of regulatory decisions from political influence. Drug regulation in most countries is performed by a department within the executive branch (Australia, Cuba, Cyprus, Tunisia, and Venezuela are examples cited by the WHO report, and Denmark [166], India [170], and New Zealand [169] are other examples). In other countries, this function is performed by an independent commission or board. An example of the latter arrangement is The Netherlands, where members of the Medicines Evaluation Board are appointed directly by the Crown, thereby enabling actions that are independent of interference by other government authorities, such as the Ministry of Health [163]. All 10 countries examined by the WHO require registration of pharmaceutical products, but they differ on the documentation requirements for evidence of safety and efficacy [163]. Some countries carry out independent assessments while others, especially many developing countries, rely on WHO assessments or other sources [163]. With the exception of Cyprus, the remaining nine countries surveyed by the WHO were found to regulate the conduct of clinical trials, but with varying rates of participation of healthcare professionals in reporting adverse drug reactions [163]. Another source noted that countries also differ on the extent of emphasis on quantitative or qualitative analysis for assessing pre- and postmarketing data [171].

Further, within Europe, each country has its own regulatory agency, for instance the UK Medicines and Healthcare Products Regulatory Agency (MHRA), formed in 2003 as a merger of the Medicines Control Agency (MCA) and the Medical Devices Agency (MDA). In addition, since January 1998, some drug registration and approval within the European Union (EU) has shifted away from the national licensing authorities of EU members to the centralized authority of the European Medicines Evaluation Agency (EMEA), which was established in 1993 [172]. To facilitate this centralized approval process, the EMEA pushed for harmonization of drug approvals. While the goals of harmonization are to create a single pharmaceutical market in Europe and to shorten approval times, concerns were voiced that harmonized safety standards would lower the stricter standards that were favored by some countries such as Sweden, and would compromise patient safety [173]. Now called the European Medicines Agency (EMA), this is a decentralized EU body responsible for the scientific evaluation and supervision of medicines. These functions are performed by the EMA's Committee for Medicinal Products for Human Use (CHMP). EMA authorization to market a drug is valid in all EU countries, but individual national medicines agencies are responsible for monitoring the safety of approved drugs and sharing this information with the EMA [174].

Potential Contributions of Pharmacoepidemiology

The potential contributions of pharmacoepidemiology are now well recognized, even though the field is still relatively new. However, some contributions are already apparent (see Table 1.1). In fact, in the 1970s the FDA requested postmarketing research at the time of approval for about one third of drugs, compared to over 70% in the 1990s [175]. Since the passage

Table 1.1 Potential contributions of pharmacoepidemiology.

- A) Information which supplements the information available from premarketing studies – better quantitation of the incidence of known adverse and beneficial effects
  - 1) Higher precision
  - 2) In patients not studied prior to marketing, e.g., the elderly, children, pregnant women
  - 3) As modified by other drugs and other illnesses
  - 4) Relative to other drugs used for the same indication
- B) New types of information not available from premarketing studies
  - 1) Discovery of previously undetected adverse and beneficial effects
    - i) Uncommon effects
    - ii) Delayed effects
  - 2) Patterns of drug utilization
  - 3) The effects of drug overdoses
  - 4) The economic implications of drug use
- C) General contributions of pharmacoepidemiology
  - 1) Reassurances about drug safety
  - 2) Fulfillment of ethical and legal obligations

of PDUFA IV, the FDA has the right to require that such studies be completed. In this section of this chapter, we will first review the potential for pharmacoepidemiologic studies to supplement the information available prior to marketing, and then review the new types of information obtainable from postmarketing pharmacoepidemiologic studies, but not obtainable prior to drug marketing. Finally, we will review the general, and probably most important, potential contributions such studies can make. In each case, the relevant information available from premarketing studies will be briefly examined first, to clarify how postmarketing studies can supplement it.

Supplementary Information

Premarketing studies of drug effects are necessarily limited in size. After marketing, nonexperimental epidemiologic studies can be performed, evaluating the effects of drugs administered as part of ongoing medical care. These allow the cost-effective accumulation of much larger numbers of patients than those studied prior to marketing, resulting in a more precise measurement of the incidence of adverse and beneficial drug effects (see Chapter 4). For example, at the time of drug marketing, prazosin was known to cause a dose-dependent first dose syncope [176,177], but the FDA requested that the manufacturer conduct a postmarketing surveillance study of the drug in the US to quantitate its incidence more precisely [122]. In recent years, there has even been an attempt, in selected special cases, to release critically important drugs more quickly by taking advantage of the work that can be performed after marketing. Probably the best-known early example was zidovudine [178,179]. More recently, this has been the case with a number of cancer drugs, including at least one where initial expectations of efficacy were not confirmed in definitive trials after marketing, and were then proven again later in a subgroup, leading to the product being removed from the market and then marketed again. As already noted, the increased sample size available after marketing also permits a more precise determination of the correct dose to be used [99,101,180,181]. The study of drug interactions, as previously discussed, is analogous (see also Chapter 40).

Premarketing studies also tend to be very artificial. Important subgroups of patients are not typically included in studies conducted before drug marketing, usually for ethical reasons. Examples include the elderly, children, and pregnant women. Studies of the effects of drugs in these populations generally must be conducted after drug marketing [182]. (See also Chapter 22.)

Additionally, for reasons of statistical efficiency, premarketing clinical trials generally seek subjects who are as homogenous as possible, in order to reduce unexplained variability in the outcome variables measured and increase

the probability of detecting a difference between the study groups, if one truly exists. For these reasons, certain patients are often excluded, including those with other illnesses or those who are receiving other drugs. Postmarketing studies can explore how factors such as other illnesses and other drugs might modify the effects of the drugs, as well as looking at the effects of differences in drug regimen, adherence, and so on [183]. For example, after marketing, the ophthalmic preparation of timolol was noted to cause many serious episodes of heart block and asthma, resulting in more than 10 deaths. These effects were not detected prior to marketing, as patients with underlying cardiovascular or respiratory disease were excluded from the premarketing studies [184].

Finally, to obtain approval to market a drug, a manufacturer needs to evaluate its overall safety and efficacy, but does not need to evaluate its safety and efficacy relative to any other drugs available for the same indication. To the contrary, with the exception of illnesses that could not ethically be treated with placebos, such as serious infections and malignancies, it is generally considered preferable, or even mandatory, to have studies with placebo controls. There are a number of reasons for this preference. First, it is easier to show that a new drug is more effective than a placebo than to show that it is more effective than another effective drug. Second, one cannot actually prove that a new drug is as effective as a standard drug. A study showing that a new drug is no worse than another effective drug does not provide assurance that it is better than a placebo; one simply could have failed to detect that it was in fact worse than the standard drug. One could require a demonstration that a new drug is more effective than another effective drug, but this is a standard that does not and should not have to be met. Yet, optimal medical care requires information on the effects of a drug relative to the alternatives available for the same indication. This information must often await studies conducted after drug marketing. Indeed, as noted, this is a major component of the new focus on CER (see Chapter 26).

New Types of Information Not Available from Premarketing Studies

As already mentioned, premarketing studies are necessarily limited in size (see also Chapter 4). The additional sample size available in postmarketing studies permits the study of drug effects that may be uncommon but important, such as drug-induced agranulocytosis [185].

Premarketing studies are also necessarily limited in time; they must come to an end, or the drug could never be marketed. In contrast, postmarketing studies permit the study of delayed drug effects, such as the unusual clear cell adenocarcinoma of the vagina and cervix, which occurred two decades later in women exposed *in utero* to diethylstilbestrol [15].

The patterns of physician prescribing and patient drug utilization often cannot be predicted prior to marketing, despite pharmaceutical manufacturers' best attempts to predict when planning for drug marketing. Studies of how a drug is actually being used, and determinants of changes in these usage patterns, can only be performed after drug marketing (see Chapters 18 and 19).

In most cases, premarketing studies are performed using selected patients who are closely observed. Rarely are there any significant overdoses in this population. Thus, the study of the effects of a drug when ingested in extremely high doses is rarely possible before drug marketing. Again, this must await postmarketing pharmacoepidemiologic studies [186].

Finally, it is only in the past decade or two that pharmacoepidemiologists have become more sensitive to the costs of medical care, and the techniques of health economics been applied to evaluate the cost implications of drug use [187]. It is clear that exploration of the costs of drug use requires consideration of more than just the

costs of the drugs themselves. The costs of a drug's adverse effects may be substantially higher than the cost of the drug itself, if these adverse effects result in additional medical care and possibly even hospitalizations [188]. Conversely, a drug's beneficial effects could reduce the need for medical care, resulting in savings that could be much larger than the cost of the drug itself. As with studies of drug utilization, the economic implications of drug use can be predicted prior to marketing, but can only be rigorously studied after marketing (see Chapter 34).

General Contributions of Pharmacoepidemiology

Lastly, it is important to review the general contributions that pharmacoepidemiology can make. As an academic or a clinician, one is most interested in the new information about drug effects and drug costs that can be gained from pharmacoepidemiology. Certainly, these are the findings that receive the greatest public and political attention. However, often no new information is obtained, particularly about new adverse drug effects. This is not a disappointing outcome, but in fact a very reassuring one, and this reassurance about drug safety is one of the most important contributions that pharmacoepidemiologic studies can make. Related to this is the reassurance that the sponsor of the study, whether manufacturer or regulator, is fulfilling its organizational duty ethically and responsibly by looking for any undiscovered problems that may exist. In an era of product liability litigation, this is an important assurance. One cannot change whether a drug causes an adverse reaction, and the fact that it does will hopefully eventually become evident. What can be changed is the perception about whether a manufacturer did everything possible to detect it and was not negligent in its behavior.

Basic Principles of Clinical Pharmacology Relevant to Pharmacoepidemiologic Studies

Jeffrey S. Barrett

Bill and Melinda Gates Medical Research Institute, Cambridge, MA, USA

Generally, pharmacology deals with the study of drugs, while clinical pharmacology deals with the study of drugs in humans. More specifically, clinical pharmacology evaluates the characteristics, effects, properties, reactions, and uses of drugs. Of particular interest is their therapeutic value in humans, including their toxicology, safety, pharmacodynamics, and pharmacokinetics. While the foundation of the discipline is underpinned by basic pharmacology (i.e., the study of the interactions that occur between a living organism and exogenous chemicals that alter normal biochemical function), the important emphasis is the application of pharmacologic principles and methods in the care of patients. It has a broad scope, from the discovery of new target molecules and molecular targets to the evaluation of clinical utility in specific populations. Clinical pharmacology bridges the gap between laboratory science and medical practice. Its main objective is to promote the safe and effective use of drugs, maximizing beneficial drug effects while minimizing harmful side effects. It is important that caregivers are skilled in areas of drug information, medication safety, and other aspects of pharmacy practice related to clinical pharmacology. Clinical pharmacology is an important bridging discipline that necessitates knowledge about dose exposure (pharmacokinetics), exposure response (pharmacodynamics), and response outcomes to define the therapeutic window (i.e., the dosage of a medication between the amount that produces the desired or beneficial effect and the amount that produces more adverse effects than desired effects) of a drug in various patient populations. Likewise, clinical pharmacology principles also guide dose modifications in various patient subpopulations (pediatrics, pregnancy, the elderly, and those with organ impairment) and/or dose adjustments for various lifestyle factors (food, time of day, drug interactions).

The discovery and development of new medicines are reliant upon clinical pharmacology research. Scientists in academic, regulatory, and industrial settings participate in this research as part of the overall drug development process. Likewise, the output from clinical pharmacology investigation appears in the drug monograph or package insert of all new medicines, and forms the basis of how drug dosing information is communicated to healthcare providers.

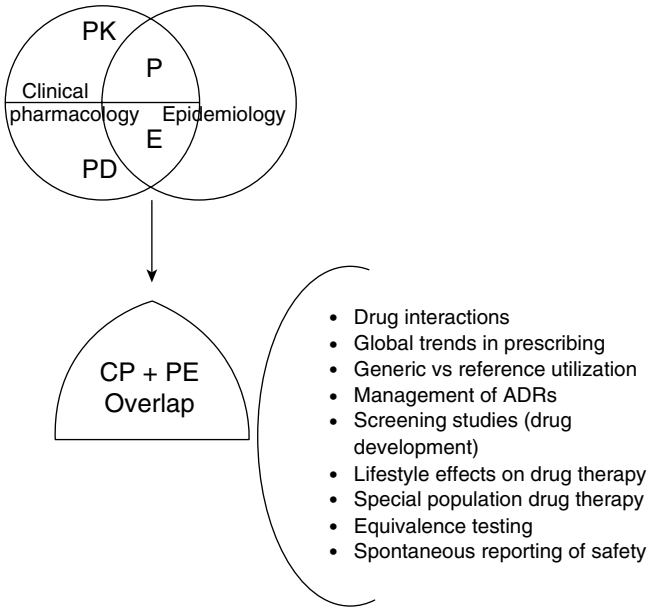
Pharmacoepidemiology, Sixth Edition. Edited by Brian L. Strom, Stephen E. Kimmel and Sean Hennessy.

Clinical Pharmacology and Pharmacoepidemiology

Pharmacoepidemiology is the study of the utilization and effects of drugs in large numbers of people (see Chapter 1). To accomplish this, pharmacoepidemiology borrows from both clinical pharmacology and epidemiology. Thus, pharmacoepidemiology can also be called a bridging science spanning both clinical pharmacology and epidemiology. Part of the task of clinical pharmacology is to provide a risk–benefit assessment for the effect of drugs in patients. Studies that estimate the probability of beneficial effects in populations, or the probability of adverse effects in populations, will benefit from using epidemiologic methods. Pharmacoepidemiology then can also be defined as the application of epidemiologic methods to the content area of clinical pharmacology. Figure 2.1 illustrates the relationship between clinical pharmacology and pharmacoepidemiology, as well as some of the specific research areas reliant on both disciplines.

Basics of Clinical Pharmacology

Clinical pharmacology encompasses drug composition, drug biopharmaceutic properties, interactions, toxicology, and effects (both desirable and undesirable) that can be used in therapy of diseases. As described earlier, underlying the discipline of clinical pharmacology are the fields of pharmacokinetics and pharmacodynamics, and each of these disciplines can be further defined by the unique processes that dictate composite pathways (e.g., absorption, distribution, metabolism, elimination). Clinical pharmacology is essential both to our understanding of how drugs work as well as how to guide their administration. Individual



Pharmacoepidemiology borrows from both clinical pharmacology and epidemiology. Thus, pharmacoepidemiology can also be called a bridging science spanning both clinical pharmacology and epidemiology. Part of the task of clinical pharmacology is to provide a risk-benefit assessment for the effect of drugs in patients.

Figure 2.1 Relationship between clinical pharmacology and pharmacoepidemiology, illustrating the overlapping areas of interest. ADRs, adverse drug reactions; CP, clinical pharmacology; PD, pharmacodynamics; PE, pharmacoepidemiology; PK, pharmacokinetics.

pharmacotherapy can be challenging due to physiologic factors that may alter drug kinetics (age, size, etc.), pathophysiologic differences that may alter pharmacodynamics, disease subpopulations that may differ from the "mainstream population," and other factors that may result in great variation in safety and efficacy outcomes. The situation becomes even more difficult when one considers critically ill populations and the paucity of well-controlled clinical trials in vulnerable populations. Likewise, healthcare providers who prescribe medications to the critically ill and other difficult-to-manage patients must have some understanding of the basic processes that govern the current dosing recommendations for their patients.

Pharmacokinetics

Pharmacokinetics refers to the study of the mechanisms of absorption and distribution of an administered drug, the chemical changes of the substance in the body (metabolism), and the effects and routes of excretion of the metabolites of the drug (elimination). Each of these subprocesses is defined in greater detail.

Absorption

Absorption is the process of drug transfer from the site of administration to the bloodstream. The rate and efficiency of absorption depend on the route of administration. For intravenous administration, absorption is complete; the total dose reaches the systemic circulation. Drugs administered enterally may be absorbed by either passive diffusion or active transport. The **bioavailability** (F) of a drug is defined by the fraction of the administered dose that reaches the systemic circulation. If a drug is administered intravenously, then the bioavailability is 100% and F = 1.0. When drugs are administered by routes other than intravenously, the bioavailability is usually less. Bioavailability is reduced by incomplete absorption, first-pass metabolism, and distribution into other tissues.

Volume of Distribution

The **volume of distribution** (Vd) is a hypothetical volume of fluid through which a drug is dispersed. A drug rarely disperses solely into the water compartments of the body. Instead, the majority of drugs disperse to several compartments, including adipose tissue and plasma proteins. The total volume into which a drug disperses is called the apparent volume of distribution. This volume is not a physiologic space, but instead a conceptual parameter. It relates the total amount of drug in the body to the concentration of the drug (C) in the blood or plasma: Vd = Drug/C.

Figure 2.2 represents the fate of a drug after intravenous administration. After administration, a maximal plasma concentration is achieved, and the drug is immediately distributed. The plasma concentration then decreases over time. This initial phase is called the alpha (α) phase of drug distribution, where the decline in plasma concentration is due to the distribution of the drug. Once a drug is distributed, it undergoes metabolism and elimination. The second phase is called the beta (β) phase, where the decline in plasma concentration is due to drug metabolism and clearance. The terms A and B are intercepts with the Y axis. The extrapolation of the beta phase defines B. The dotted line is generated by subtracting the extrapolated line from the original concentration line. This second line defines alpha and A. The plasma concentration can be determined using the formula $C = Ae^{-\alpha t} + Be^{-\beta t}$. The distribution and elimination half-lives can be determined by $t_{1/2\alpha} = 0.693/\alpha$ and $t_{1/2\beta} = 0.693/\beta$, respectively [1]. For drugs in which distribution is homogenous along the varied physiologic spaces, the distinction between the alpha and beta phases may be subtle, and essentially a single phase best describes the decline in drug concentration.

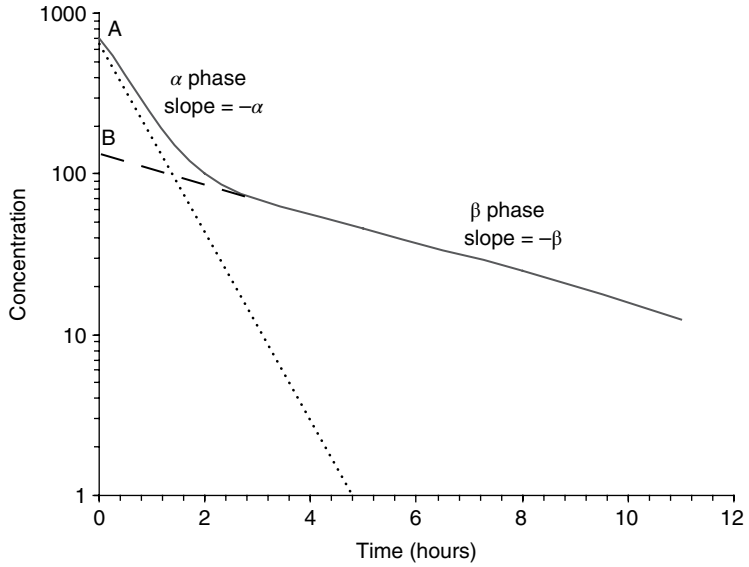


Figure 2.2 Semi-logarithmic plot of concentration vs. time after an intravenous administration of a drug that follows two-compartment pharmacokinetics.

Metabolism

The **metabolism** of drugs is catalyzed by enzymes, and most reactions follow Michaelis Menten kinetics: V(rate of drug metabolism) = [((Vmax)(C)/Km) + (C)], where C is the drug concentration and Km is the Michaelis Menten constant [1]. In most situations, the drug concentration is much less than Km and the equation simplifies to V = (Vmax)(C)/Km. In this case, the rate of drug metabolism is directly proportional to the concentration of free drug and follows first-order kinetics. A constant percentage of the drug is metabolized over time, and the rate of elimination is proportional to the amount of drug in the body.

Most drugs used in the clinical setting are eliminated in this manner. A few drugs, such as aspirin, ethanol, and phenytoin, are used in higher doses, resulting in higher plasma concentrations. In these situations, C is much greater than Km, and the equation reduces to V(rate of drug metabolism) = (Vmax)(C)/(C) = Vmax. The enzyme system becomes saturated by a high free-drug concentration, and the rate of metabolism is constant over time. This is called zero-order kinetics, and a constant amount of drug is metabolized per unit of time. A large increase in serum concentration can result from a small increase in dose for drugs that follow zero-order elimination.

The liver is the principal organ of drug metabolism. Other organs that display considerable metabolic activity include the gastrointestinal tract, the lungs, the skin, and the kidneys. Following oral administration, many drugs are absorbed intact from the small intestine and transported to the liver via the portal system, where they are metabolized. This process is called first-pass metabolism, and may greatly limit the bioavailability of orally administered drugs. In general, all metabolic reactions can be classified as either Phase I or Phase II biotransformations. Phase I reactions usually convert the parent drug to a polar metabolite by introducing or unmasking a more polar site (-OH, $-NH_2$). If Phase I metabolites are sufficiently polar, they may be readily excreted. However, many Phase I metabolites undergo a subsequent reaction in which endogenous substances such as glucuronic acid, sulfuric acid, or an amino

acid combine with the metabolite to form a highly polar conjugate. Many drugs undergo these sequential reactions. However, Phase II reactions may precede Phase I reactions, as in the case of isoniazid.

Phase I reactions are usually catalyzed by enzymes of the cytochrome P450 system. These drug-metabolizing enzymes are located in the lipophilic membranes of the endoplasmic reticulum of the liver and other tissues. Three gene families, CYP1, CYP2, and CYP3, are responsible for most drug biotransformations. The CYP3A subfamily accounts for more than 50% of Phase I drug metabolism, predominantly by the CYP3A4 subtype. CYP3A4 is responsible for the metabolism of drugs commonly used in the intensive care setting, including acetaminophen, cyclosporine, diazepam, methadone, midazolam, spironolactone, and tacrolimus. Most other drug biotransformations are performed by CYP2D6 (e.g., clozapine, codeine, flecainide, haloperidol, oxycodone), CYP2C9 (e.g., phenytoin, S-warfarin), CYP2C19 (e.g., diazepam, omeprazole, propranolol), CYP2E1 (e.g., acetaminophen, enflurane, halothane), and CYP1A2 (e.g., acetaminophen, caffeine, theophylline, warfarin).

Drug biotransformation reactions may be enhanced or impaired by multiple factors, including age, enzyme induction or inhibition, pharmacogenetics, and the effects of other disease states [2]. For example, the metabolic pathways for acetaminophen have been well studied. Approximately 95% of the metabolism occurs via conjugation to glucuronide (50–60%) and sulfate (25–35%). Most of the remainder of acetaminophen is metabolized via the cytochrome P450 forming N-acetyl-p-benzoquinone imine (NAPQI), which is thought to be responsible for hepatotoxicity. This minor but important pathway is catalyzed by CYP 2E1, and to a lesser extent by CYP 1A2 and CYP 3A4. NAPQI is detoxified by reacting with either glutathione directly or through a glutathione transferase catalyzed reaction. When the hepatic synthesis of glutathione is overwhelmed, manifestations of toxicity appear, producing centrilobular necrosis. In the presence of a potent CYP 2E1 inhibitor, disulfiram, there was a 69% reduction in the urinary excretion of these 2E1 metabolic products, which supports the assignment of a major role for 2E1 in the formation of NAPQI [3]. Studies of inhibitors of other CYP pathways (e.g., 1A2 and 3A4) have failed to document a significant effect on the urinary excretion of glutathione conjugates [4]; thus, 2E1 appears to be the primary pathway overwhelmingly responsible for NAPQI. CYP 2E1 is unique among the CYP gene families in its ability to produce reactive oxygen radicals through a reduction of O_2, and is the only CYP system strongly induced by alcohol, which is itself a substrate. In addition to alcohol, isoniazid acts as an inducer and a substrate. Ketoconazole and other imidazole compounds are inducers but not substrates. Barbiturates and phenytoin, which are nonspecific inducers, have no role as CYP 2E1 inducers, nor are they substrates for that system. Phenytoin in fact may be hepatoprotective, because it is an inducer of the glucuronidation metabolic pathway for acetaminophen, thus shunting metabolism away from NAPQI production [5].

Elimination

Elimination is the process by which a drug is removed or "cleared" from the body. Clearance (CL) is usually referred to as the amount of blood from which all drug is removed per unit of time (volume/time). The main organs responsible for drug clearance are the kidneys and the liver. The total body clearance of a drug is equal to the sum of the clearances from all mechanisms. Typically, this is partitioned into renal and nonrenal clearance. Most elimination by the kidneys is accomplished by glomerular filtration. The amount of drug that is filtered is determined by glomerular integrity, the size and charge (electrostatic force of a molecule related

to whether it has gained or lost electrons, positive or negative respectively) of the drug, water solubility, and the extent of protein binding. Highly protein-bound drugs are not readily filtered. Therefore, estimation of the glomerular filtration rate (GFR) has traditionally served as an approximation of renal function.

In addition to glomerular filtration, drugs may be eliminated from the kidneys via active secretion. Secretion occurs predominantly at the proximal tubule, where active transport systems secrete primarily organic acids and bases. Organic acids include most cephalosporins, loop diuretics, methotrexate, nonsteroidal anti-inflammatories, penicillin, and thiazide diuretics. Organic bases include ranitidine and morphine. As drugs move toward the distal convoluting tubule, their concentration increases. High urine flow rates decrease the concentration of the drug in the distal tubule, decreasing the likelihood that the drug will diffuse from the lumen. For both weak acids and bases, the nonionized form of the drug is reabsorbed more readily. Altering the pH (ion trapping) can minimize reabsorption, by placing a charge on the drug and preventing its diffusion. For example, salicylate is a weak acid. In case of salicylate toxicity, urine alkalization places a charge on the molecule, and increases its elimination. The liver also contributes to elimination through metabolism or excretion into the bile. After a drug is secreted in the bile, it may then be either excreted into the feces or reabsorbed via enterohepatic recirculation [6].

The **half-life of elimination** is the time it takes to clear half of the drug from plasma. It is directly proportional to the Vd, and inversely proportional to CL: $t_{1/2\beta} = (0.693)\,(Vd)/CL$.

Special Populations

The term "special populations" as applied to drug development refers to discussions in the early 1990s among industry, academic, and regulatory scientists struggling with the then current practice that early drug development was focused predominantly on young, Caucasian male populations. Representatives from the US, Europe, and Japan jointly issued regulatory requirements for drug testing and labeling in "special populations" (namely the elderly) in 1993. In later discussions, this generalization was expanded to include four major demographic segments (women, the elderly, pediatric, and major ethnic groups); despite the large size of each of these population segments, pharmaceutical research had been limited in each of these areas. Current appreciation for these populations also benefits from a greater understanding of the heterogeneity of the eventual marketplace for many new chemical entities. More importantly, these "special populations" also represent diverse subpopulations of patients in whom dosing guidance is often needed, and likewise targeted clinical pharmacology research is essential.

Elderly

There are many physical signs consistent with aging, including wrinkles, change of hair color to gray or white, hair loss, lessened hearing, diminished eyesight, slower reaction times, and decreased agility. In clinical pharmacology, we are more concerned with how aging affects physiologic processes that dictate drug pharmacokinetics and pharmacodynamics. Advancing age is characterized by impairment in the function of the many regulatory processes that provide functional integration between cells and organs. Under these circumstances, failure to maintain homeostasis under conditions of physiologic stress can exist. This can often explain, at least in part, the increased interindividual variability that occurs as people age.

Cardiac structure and function, renal and gastrointestinal systems, and body composition are the physiologic systems most often implicated when pharmacokinetic or pharmacodynamic

differences are observed between elderly and young populations. Table 2.1 lists the primary physiologic factors affected by aging [7]. Recognition of these factors is important for predicting the implications of aging for drug pharmacokinetics especially.

With respect to absorption, the impact of age is unclear, and many conflicting results exist. While many studies have not shown significant age-related differences in absorption rates for specific drugs, the absorption of vitamin B_{12}, iron, and calcium is slower through reduced active transport mechanisms [8,9]. A reduction in first-pass metabolism is associated with aging, most likely due to a reduction in liver mass and blood flow. Likewise, drugs undergoing a significant first-pass effect experience an increase in bioavailability with age. This is the case for drugs like propranolol and labetalol. Conversely, drugs administered as prodrugs and requiring activation in the liver (e.g., ACE [angiotensin converting enzyme] inhibitors enalapril and perindopril) are likely to experience reduction in this phase and likewise reduced exposure of the active species.

Based on age-related changes in body composition, polar drugs, which are primarily water soluble, often exhibit smaller volumes of distribution, resulting in higher plasma concentrations in older patients. This is the case for agents including ethanol, theophylline, digoxin, and gentamicin [7,10]. Conversely, nonpolar compounds are often lipid soluble and exhibit larger volumes of distribution in older patients. The impact of the larger Vd is prolongation of half-life with age. This is the case for drugs such as chlormethiazole and thiopentone [11,12]. Conflicting results have been reported with

Table 2.1 Physiologic systems affected during aging that influence drug pharmacokinetic and/or pharmacodynamic behavior.

Physiologic System	Impact of Aging
Cardiac structure and function	• Reduced elasticity and compliance of the aorta and great arteries (higher systolic arterial pressure, increased impedance to left ventricular hypertrophy, and interstitial fibrosis) • Decrease in rate of myocardial relaxation • Left ventricle stiffens and takes longer to relax and fill in diastole • Isotonic contraction is prolonged and velocity of shortening reduced • Reduction in intrinsic heart rate and increased sinoatrial node conduction time
Renal system	• Renal mass decreases (reduction in nephrons) • Reduced blood flow in the afferent arterioles in the cortex • Renal plasma flow and glomerular filtration rate decline • Decrease in ability to concentrate the urine during water deprivation • Impaired response to water loading
Gastrointestinal system	• Secretion of hydrochloric acid and pepsin is decreased under basal conditions • Reduced absorption of several substances in the small intestine, including sugar, calcium, and iron • Decrease in lipase and trypsin secretion in the pancreas • Progressive reduction in liver volume and liver blood flow
Body composition	• Progressive reduction in total body water and lean body mass, resulting in a relative increase in body fat

respect to age effects on protein binding [13,14], making generalization difficult.

Several drug classes, including water-soluble antibiotics, diuretics, water-soluble beta-adrenoceptor blockers, and nonsteroidal anti-inflammatory drugs [7,15], exhibit changes in clearance with age as a result of declining renal function. With respect to hepatic metabolism, studies have shown that significant reductions in clearance with age are observed for Phase I pathways in the liver [16–18].

From the standpoint of a clinical trial, age categories are necessary to define the inclusion and exclusion criteria for the population targeted for enrollment. Most developed world countries have accepted the chronological age of 65 years as a definition of "elderly" or an older person. The salient point is that pharmaceutical sponsors are increasingly encouraged to include a broader range of ages in their pivotal trials than before, or specifically to target an elderly subpopulation in a separate trial, consistent with Food and Drug Administration (FDA) guidance. The FDA guideline for studies in the elderly is directed principally toward new molecular entities likely to have significant use in that population, either because the disease intended to be treated is characteristically a disease of aging (e.g., Alzheimer's disease) or because the population to be treated is known to include substantial numbers of geriatric patients (e.g., hypertension).

Pediatrics

As children develop and grow, changes in body composition, development of metabolizing enzymes, and maturation of renal and liver function all have impacts on drug disposition [19,20] (see also Chapter 22).

Renal

Renal function in the premature and full-term neonate, both glomerular filtration and tubular secretion, is significantly reduced compared to older children. Maturation of renal function is a dynamic process that begins during fetal life and is complete by early childhood. Maturation of tubular function is slower than that of glomerular filtration. The glomerular filtration rate is approximately 2–4 ml/minute/1.73 m^2 in full-term neonates, but it may be as low as 0.6–0.8 ml/minute/1.73 m^2 in preterm neonates. The glomerular filtration rate increases rapidly during the first two weeks of life and continues to rise until adult values are reached at 8–12 months of age. For drugs that are renally eliminated, impaired renal function decreases clearance, increasing the half-life. Therefore, for drugs that are primarily eliminated by the kidney, dosing should be performed in an age-appropriate fashion that takes into account both maturational changes in kidney function [21].

Hepatic

Hepatic biotransformation reactions are substantially reduced in the neonatal period. At birth, the cytochrome p450 system is 28% of that of the adult [22]. The expression of Phase I enzymes such as the P-450 cytochromes changes markedly during development. CYP3A7, the predominant CYP isoform expressed in the fetal liver, peaks shortly after birth and then declines rapidly to levels that are undetectable in most adults. Within hours after birth, CYP2E1 activity increases, and CYP2D6 becomes detectable soon thereafter. CYP3A4 and CYP2C appear during the first week of life, whereas CYP1A2 is the last hepatic CYP to appear, at 1–3 months of life [22,23]. The ontogeny of Phase II enzymes is less well established than the ontogeny of reactions involving Phase I enzymes. Available data indicate that the individual isoforms of glucuronosyltransferase (UGT) have unique maturational profiles with pharmacokinetic consequences. For example, the glucuronidation of acetaminophen (a substrate for UGT1A6 and, to a lesser extent, UGT1A9) is decreased in newborns and young children compared with adolescents and adults.

Glucuronidation of morphine (a UGT2B7 substrate) can be detected in premature infants as young as 24 weeks of gestational age [24,25].

Gastrointestinal

Overall, the rate at which most drugs are absorbed is slower in neonates and young infants than in older children. As a result, the time required to achieve maximal plasma levels is longer in the very young. The effect of age on enteral absorption is not uniform and is difficult to predict [19,23]. Gastric emptying and intestinal motility are the primary determinants of the rate at which drugs are presented to and dispersed along the mucosal surface of the small intestine. At birth, the coordination of antral contractions improves, resulting in a marked increase in gastric emptying during the first week of life. Similarly, intestinal motor activity matures throughout early infancy, with consequent increases in the frequency, amplitude, and duration of propagating contractions [26,27]. Changes in the intraluminal pH in different segments of the gastrointestinal tract can directly affect both the stability and the degree of ionization of a drug, thus influencing the relative amount of the drug available for absorption. During the neonatal period, intragastric pH is relatively elevated (greater than 4). Thus, oral administration of acid-labile compounds such as penicillin G produces greater bioavailability in neonates than in older infants and children [28]. In contrast, drugs that are weak acids, such as phenobarbital, may require larger oral doses in the very young in order to achieve therapeutic plasma levels. Other factors that affect the rate of absorption include age-associated development of villi, splanchnic blood flow, changes in intestinal microflora, and intestinal surface area [27].

Body Composition

Age-dependent changes in body composition alter the physiologic spaces into which a drug may be distributed. The percentage of total body water drops from about 85% in premature infants to 75% in full-term infants to 60% in the adult. Extracellular water decreases from 45% in the infant to 25% in the adult. Total body fat in the premature infant can be as low as 1%, compared to 15% in the normal, term infant. Many drugs are less bound to plasma proteins in the neonate and infant than in the older child [29]. Limited data in neonates suggest that the passive diffusion of drugs into the central nervous system is age dependent, as reflected by the progressive increase in the ratios of brain phenobarbital to plasma phenobarbital from 28 to 39 weeks of gestational age, demonstrating the increased transport of phenobarbital into the brain [30].

Pregnancy

The FDA classifies drugs into five categories of safety for use during pregnancy – that is, normal pregnancy, labor, and delivery – as outlined in Table 2.2 (see also Chapter 22). Few well-controlled studies of therapeutic drugs

Table 2.2 FDA categories of drug safety during pregnancy.

Category	Description
A	Controlled human studies show no fetal risks; these drugs are the safest
B	Animal studies show no risk to the fetus and no controlled human studies have been conducted, or animal studies show a risk to the fetus but well-controlled human studies do not
C	No adequate animal or human studies have been conducted, or adverse fetal effects have been shown in animals but no human data are available
D	Evidence of human fetal risk exists, but benefits may outweigh risks in certain situations (e.g., life-threatening disorders, serious disorders for which safer drugs cannot be used or are ineffective)
X	Proven fetal risks outweigh any possible benefit

have been conducted in pregnant women. Most information about drug safety during pregnancy is derived from animal studies and uncontrolled studies in people (e.g., postmarketing reports).

Observational studies have documented that pregnant women take a variety of medicines during pregnancy [31]. While changes in drug exposure during pregnancy are well documented, a mechanistic understanding of these effects is not clear [32]. The few studies that have been conducted suggest that bioavailability is not altered during pregnancy, though increased plasma volume and protein binding changes can alter the apparent volume of distribution of some drugs [32]. Likewise, changes in volume of distribution and clearance during pregnancy can cause increases or decreases in the terminal elimination half-life of drugs. Renal excretion of unchanged drugs is increased during pregnancy [32] and hence these agents may require dose increases. Likewise, the metabolism of drugs via select P450-mediated pathways (3A4, 2D6, and 2C9) and UGT isoenzymes is increased during pregnancy, necessitating increased dosages of drugs metabolized by these pathways [32,33]. In contrast, CYP1A2 and CYP2C19 activity is decreased during pregnancy, suggesting dosing reductions for agents metabolized via these pathways. The effect of pregnancy on transport proteins is unknown. These data are limited and, hence, more clinical evidence-based studies to determine the effect of pregnancy on the pharmacokinetics and pharmacodynamics of commonly used drugs are sorely needed (see also Chapter 22).

Organ Impairment

Renal Dysfunction

Renal failure can affect the pharmacokinetics of drugs. In renal failure, the binding of acidic drugs to albumin is decreased, because of competition with accumulated organic acids and uremia-induced structural changes in albumin, which decrease drug binding affinity, altering the volume of distribution [15]. Drugs that are more than 30% eliminated unchanged in the urine are likely to have significantly diminished clearance in the presence of renal insufficiency [15].

Hepatic Dysfunction

Drugs that undergo extensive first-pass metabolism may have a significantly higher oral bioavailability in patients with liver failure than in normal subjects. Gut hypomotility may delay the peak response to enterally administered drugs in these patients. Hypoalbuminemia or altered glycoprotein levels may affect the fractional protein binding of acidic or basic drugs, respectively. Altered plasma protein concentrations may affect the extent of tissue distribution of drugs that are normally highly protein bound. The presence of significant edema and ascites may alter the volume of distribution of highly water-soluble agents, such as aminoglycoside antibiotics. The capacity of the liver to metabolize drugs depends on hepatic blood flow and liver enzyme activity, both of which can be affected by liver disease. In addition, some p450 isoforms are more susceptible than others to liver disease, impairing drug metabolism [18].

Cardiac Dysfunction

Circulatory failure, or shock, can alter the pharmacokinetics of drugs frequently used in the intensive care setting. Drug absorption may be impaired because of bowel wall edema. Passive hepatic congestion may impede first-pass metabolism, resulting in higher plasma concentrations. Peripheral edema inhibits absorption by intramuscular parenteral routes. The balance of tissue hypoperfusion versus increased total body water with edema may unpredictably alter the volume of distribution. In addition, liver hypoperfusion may alter drug-metabolizing enzyme function, especially flow-dependent drugs such as lidocaine [34,35].

Drug Interactions

Patients are often treated with more than one drug, and often many, increasing the chance of a drug–drug interaction (see also Chapter 40). These interactions can alter absorption, distribution, metabolism, and clearance. Drug interactions can affect absorption through formation of drug–drug complexes (e.g., significantly increased bioavailability of fexofenadine in the presence of St. John's wort [36]), alterations in gastric pH, and changes in gastrointestinal motility. This can have a substantial impact on the bioavailability of enterally administered agents. The volume of distribution may be altered with competitive plasma protein binding and subsequent changes in free drug concentrations [13,14,37].

Drug biotransformation reactions vary greatly among individuals and are susceptible to drug–drug interactions. Induction is the process by which enzyme activity is increased by exposure to a certain drug, resulting in an increase in the metabolism of other drugs and lower plasma concentrations. Common inducers include barbiturates, carbamazepine, isoniazid, and rifampin. In contrast, inhibition is the process by which enzyme activity is decreased by exposure to a certain drug, resulting in a decrease in the metabolism of other drugs, and subsequent higher plasma concentrations. Common enzyme inhibitors include ciprofloxacin, fluconazole, metronidazole, quinidine, and valproic acid [2]. Inducers and inhibitors of Phase II enzymes have been less extensively characterized, but some clinical applications of this information have emerged, including the use of phenobarbital to induce glucuronyl transferase activity in icteric neonates. Water-soluble drugs are eliminated unchanged in the kidneys. The clearance of drugs that are excreted entirely by glomerular filtration is unlikely to be affected by other drugs. Organic acids and bases are renally secreted, and can compete with one another for elimination, resulting in unpredictable drug disposition [15].

Pharmacodynamics

Pharmacodynamics, in general terms, seeks to define what a drug does to the body (i.e., the effects or response to drug therapy). Pharmacodynamic modeling attempts to characterize measured, physiologic parameters before and after drug administration, with the effect defined as the change in a physiologic parameter relative to its pre-dose or baseline value. Baseline is defined as the physiologic parameter without drug dosing, and may be complicated in certain situations due to diurnal variations. Efficacy can be defined numerically as the expected sum of all beneficial effects following treatment (see also Chapter 33). In this case we refer to clinical and not necessarily economic benefits, though there clearly may be concordance (see also Chapter 34). Similarly, toxicity can be characterized either by the time course of a specific toxic event or the composite of toxic responses attributed to a common toxicity.

Overview

Pharmacodynamic response to drug therapy evolves only after active drug molecules reach their intended site(s) of action. Hence, the link between pharmacokinetic and pharmacodynamic processes is implicit. Likewise, the respective factors that influence various subprocesses (absorption, distribution, tolerance, etc.) are relevant and may necessitate separate study. Differences in pharmacodynamic time course among drug entities can be broadly associated with the nature of the concentration–effect relationship as being direct (effect is directly proportional to concentration at the site of measurement, usually the plasma) or indirect (effect exhibits some type of temporal delay with respect to drug concentration, either because of differences between site of action and measurement, or because the effect

of interest results after other physiologic or pharmacologic conditions are satisfied).

Direct effect relationships are easily observed with cardiovascular agents whose site of action is the vascular space. Pharmacologic effects such as blood pressure, ACE inhibition, and inhibition of platelet aggregation can be characterized by direct response relationships. Such relationships can usually be defined by three typical patterns: linear, hyperbolic (E_{max}), and sigmoid E_{max} functions [38]. These are shown in Figure 2.3. In each case, the plasma concentration and drug concentration at the effect site are proportional. Likewise, the concentration–effect relationship is assumed to be independent of time.

Other drugs exhibit an indirect relationship between concentration and response. In this case, the concentration–effect relationship is time dependent. One explanation for such effects is hysteresis, which refers to the phenomenon where there is a time lapse between a cause and its effect. With respect to pharmacodynamics, this most often indicates a situation in which there is a delay in equilibrium between plasma drug concentration and the concentration of active substance at the effect site (thiopental,

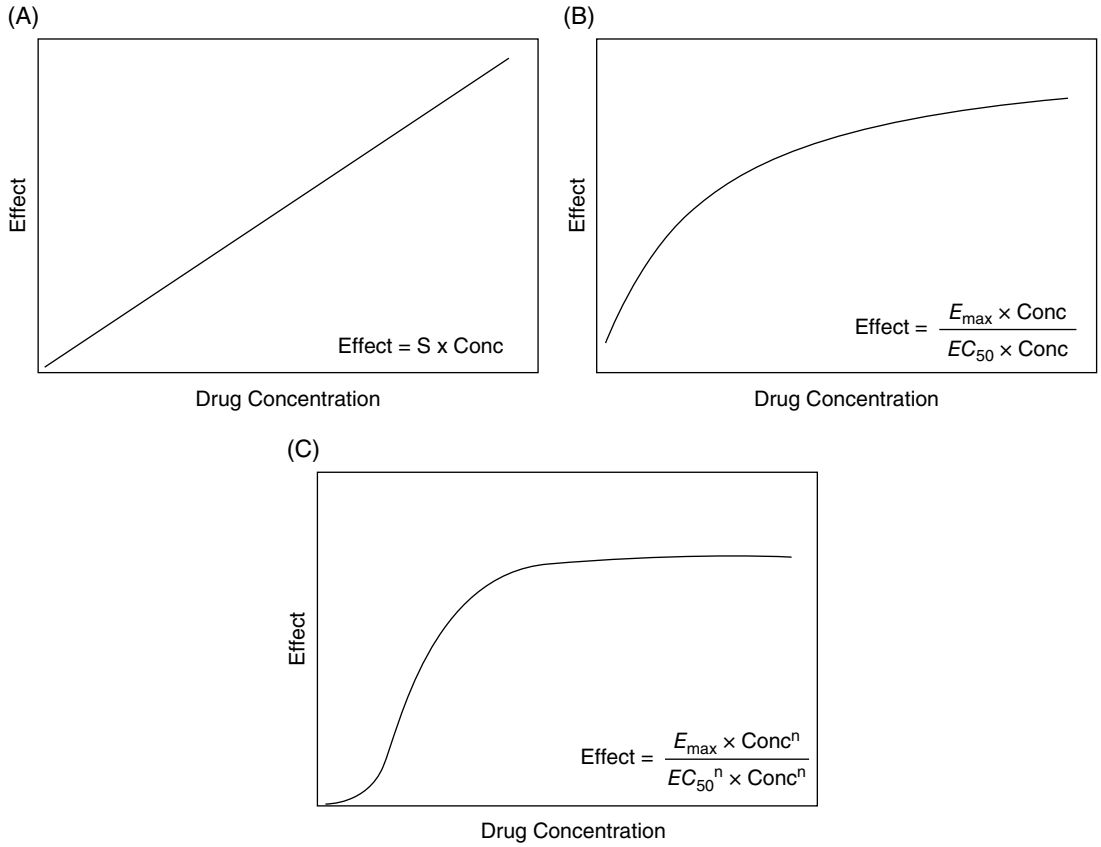

Figure 2.3 Representative pharmacodynamic relationships for drugs that exhibit direct responses: (A) linear, (B) hyperbolic, and (C) Sigmoid-E_{max} relationships are shown. S is the slope of the linear response; E_{max} refers to the maximum effect observed; EC_{50} refers to the concentration at which 50% of the maximal response is achieved; and n is the degree of sigmoidicity or shape factor (sometimes referred to as the Hill coefficient).

fentanyl, and many others). Three conditions predominate: the biophase (actual site of drug action) is not in the central compartment, the mechanism of action involves protein synthesis, and/or active metabolites are present. One can conceptualize a hypothetical effect compartment (a physical space where drug concentrations are directly correlated with drug actions) such that the relationships defined in Figure 2.4 are only observed when the effect site concentration (Ce) is used as opposed to the plasma concentration (Cp). In this situation, a hysteresis loop is observed when plotting Ce versus Cp (see Figure 2.4).

More complicated models (indirect response models) have been used to express the same observations, but typically necessitate a greater understanding of the underlying physiologic process (e.g., cell trafficking, enzyme recruitment, etc.) [38]. The salient point is that pharmacodynamic characterization and likewise dosing guidance derived from such investigation stand to be more informative than drug concentrations alone. Likewise, pharmacodynamics may be the discriminating characteristic that defines dose adjustment in special populations. This is the case for the observed markedly enhanced sensitivity in infants compared with

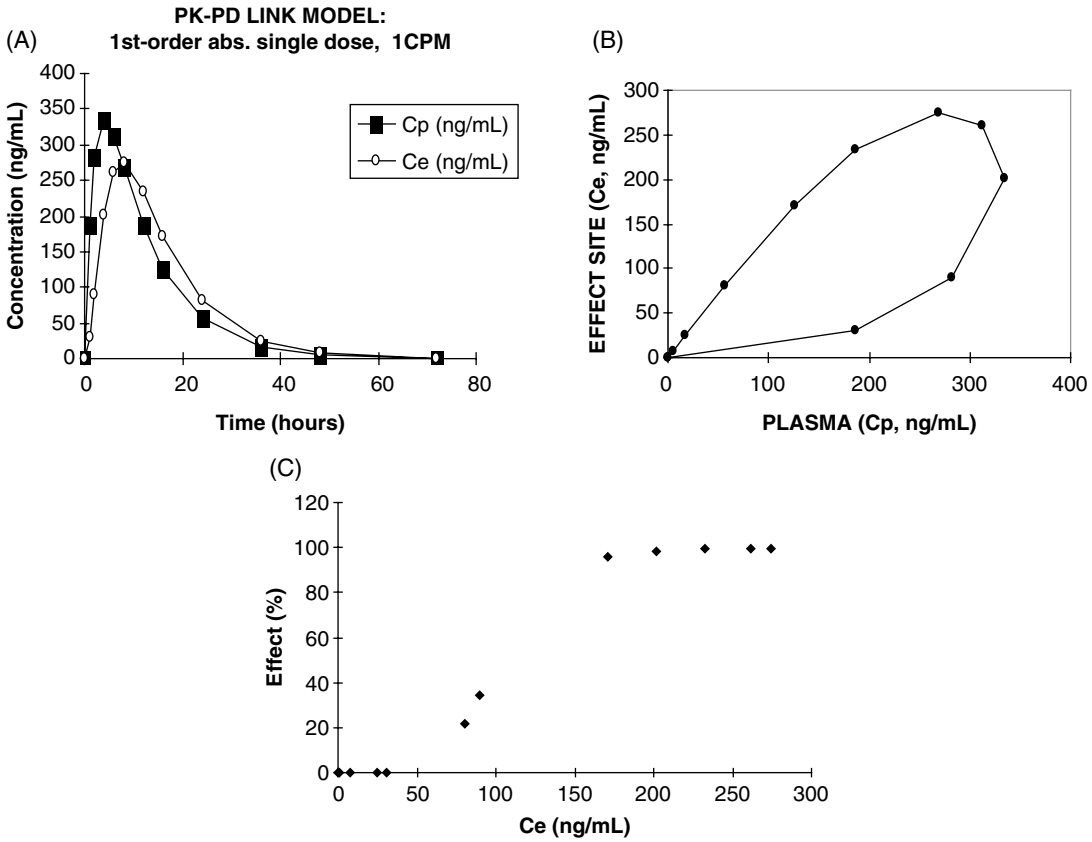

Figure 2.4 (A) Concentration–time, (B) hysteresis, and (C) effect–concentration plots, illustrating the use of an effect compartment to explain observed hysteresis. older children and adults with respect to the immunosuppressive effects of cyclosporine [39], and for calcium channel blocking effects on the PR interval in the elderly [40,41].

Pharmacogenomics

Pharmacogenomics is the study of how an individual's genetic inheritance affects the body's response to drugs (see also Chapter 30). Pharmacogenomics holds the promise that drugs might one day be tailored to individuals and adapted to each person's own genetic makeup. Environment, diet, age, lifestyle, and state of health all can influence a person's response to medicines, but understanding an individual's genetic composition is thought to be the key to creating personalized drugs with greater efficacy and safety. Pharmacogenomics combines traditional pharmaceutical sciences, such as biochemistry, with annotated knowledge of genes, proteins, and single nucleotide polymorphisms (SNPs). Genetic variations, or SNPs, in the human genome can be a diagnostic tool to predict a person's drug response. For SNPs to be used in this way, a person's DNA must be sequenced for the presence of specific SNPs. SNP screenings will benefit drug development and those people whose pharmacogenomic screening shows that the drug being tested would be harmful or ineffective for them would be excluded from clinical trials. Prescreening clinical trial subjects might also allow clinical trials to be smaller, faster, and therefore less expensive. Finally, the ability to assess an individual's reaction to a drug before it is prescribed will increase confidence in prescribing the drug and the patient's confidence in taking the drug, which in turn should encourage the development of new drugs tested in a like manner. For example, the major enzyme responsible for tacrolimus metabolism is CYP3A. CYP3A5 genes have multiple SNPs. One study found that at 3, 6, and 12 months after heart transplantation, there was a significant difference in tacrolimus blood concentrations per dose/kg/day between the CYP3A5 *1/*3 (CYP3A5 expresser) and the *3/*3 (nonexpresser) genotypes, with the *1/*3 patients requiring larger tacrolimus doses to achieve the same blood concentration. It was concluded that specific genotypes of CYP3A5 in pediatric heart transplant patients require larger tacrolimus doses to maintain their tacrolimus blood concentration, and that this information could be used prospectively to manage patients' immunosuppressive therapy. (See also Chapter 30 for molecular pharmacoepidemiology.)

Model-Informed Drug Development

One of the more recent developments in the evolution of clinical pharmacology in the facilitation of early stage drug development is in the implementation of model-informed drug development (MIDD) principles by many pharmaceutical and biotech companies. The approach is also endorsed by the global regulatory community, including the European Medicines Agency (EMA) and the FDA. The use of modeling and simulation approaches to derisk decision making in drug development is not new, but the systematic integration of the unique model assets in an evolving computing environment that expands with knowledge about candidate molecules and/or vaccines is still a work in progress for many pharmaceutical sponsors. However, feedback from early adopters suggests that the approach can reduce both time and cost in drug development when conducted in an appropriate manner. Figure 2.5 highlights many of the common early drug development decision milestones, in conjunction with the various model types and methodologies that represent key stage-gate milestones.

Many of these milestones represent contributions from clinical pharmacology and the

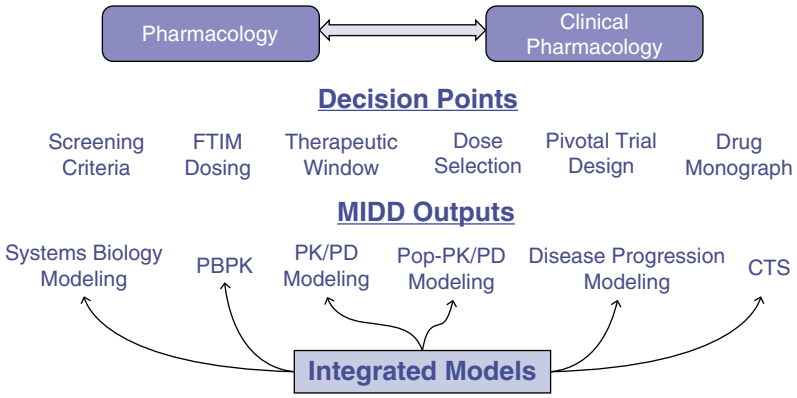

Figure 2.5 The model-informed drug development (MIDD) approach learns and confirms key characteristics of new molecular entities in a quantitative manner, with the goal of providing explicit, reproducible, and predictive evidence for optimizing drug development plans and enabling critical decisions. CTS, clinical trial simulation; FTIM, first time in man; PBPK, physiologically based pharmacokinetics; PD, pharmacodynamics; PK, pharmacokinetics.

supportive quantitative disciplines which collaborate in the MIDD effort (e.g., bioinformatics, system pharmacology, drug metabolism and pharmacokinetics [DMPK], pharmacometrics, and biostatistics). As Figure 2.5 suggests, many of these milestones are not only critical to the progression of drug and/or vaccine candidates, but also represent critical go/no go criteria requiring quantitative definition around the pace of potential outcomes. The MIDD likewise is effective at generating scenarios that explore the space of potential outcomes, either through direct experimentation or model-based projection (i.e., simulation).

In addition to the utility of MIDD in the decision-making process, MIDD implementation generates modeling assets that can be used in later stages of drug development. These can represent inputs to epidemiologic modeling and simulation exercises that explore the utility of projecting candidate attributes on target populations of interest, and also accommodate the complexity of the existing standard of care, population, and subpopulation differences influenced by socioeconomic and lifestyle factors. This represents a new frontier for these disciplines to further interact and inform each other.

Conclusion

Clinical pharmacology serves an important role in the development of new drugs and the management of pharmacotherapy. It is essential knowledge that must inform the drug developer, the investigator or trialist, the regulator, and the caregiver in their respective settings. In the context of pharmacoepidemiologic investigations, clinical pharmacology also provides a fundamental backbone for understanding the expected associations between drug therapy and clinical benefit, as well as potential toxicity. The pharmacoepidemiologist must also have intimate knowledge of clinical pharmacology, as the projection of performance (clinical and economic), the connection between utilization, compliance, and the complexities of multimodal therapy, and the associations of drug behavior with disease- or population-specific indices must be defined relative to the known clinical pharmacologic principles that govern how we expect drugs to behave in humans. In an era in which more holistic approaches are sought to maintain homeostasis and clinical strategies engage more preventive approaches, clinical pharmacology will be an essential discipline to discriminate options that are truly beneficial.

Basic Principles of Clinical Epidemiology Relevant to Pharmacoepidemiologic Studies

Brian L. Strom

Rutgers Biomedical and Health Sciences, Newark, NJ, USA

Pharmacoepidemiology applies the methods of epidemiology to the content area of clinical pharmacology. Chapter 2 reviewed the basic principles of clinical pharmacology. Therefore, in order to understand the approaches and methodologic issues specific to the field of pharmacoepidemiology, the basic principles of epidemiology must be understood as well. To that end, this chapter will begin with an overview of the scientific method in general. This will be followed by a discussion of the different types of errors one can make in designing a study. Next, the chapter will review the criteria for the causal nature of an association, which are how one can decide whether an association demonstrated in a particular study is, in fact, a causal association. Finally, the specific study designs available for epidemiologic studies, or in fact for any clinical studies, will be reviewed. The next chapter discusses a specific methodologic issue which needs to be addressed in any study, but which is of particular importance for pharmacoepidemiologic studies: the issue of sample size. These two chapters are intended to be an introduction to the field of epidemiology for the neophyte. More information on these principles can be obtained from any textbook on epidemiology or clinical epidemiology [1–24].

Overview of the Scientific Method

The scientific method to investigate a research question involves a three-stage process (see Figure 3.1). In the first stage, one selects a group of subjects for study. These subjects may be patients or animals or biologic cells, and are the sources for the data sought by the study to answer a question of interest. Second, one uses the information obtained in this sample of study subjects to generalize and draw a conclusion about a population in general. This conclusion is referred to as an association. Third, one generalizes again, drawing a conclusion about a scientific theory or causation. Each will be discussed in turn.

Any given study is performed on a selection of individuals, who represent the *study subjects*. These study subjects should theoretically represent a random sample of some defined population. For example, one might perform a randomized clinical trial of the efficacy of enalapril in lowering blood pressure, randomly allocating a total of 40 middle-aged hypertensive men to receive either enalapril or placebo and observing their blood pressure six weeks later. One might expect to see the blood

Pharmacoepidemiology, Sixth Edition. Edited by Brian L. Strom, Stephen E. Kimmel and Sean Hennessy.

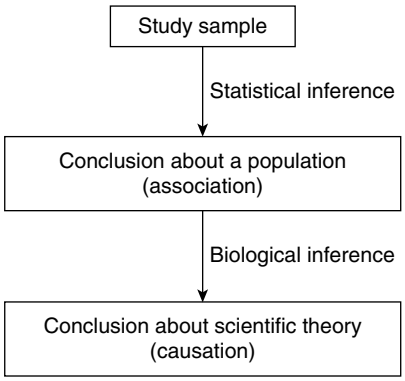

Figure 3.1 Overview of the scientific method.

pressure of the 20 men treated with the active drug decrease more than the blood pressure of the 20 men treated with a placebo. In this example, the 40 study subjects would represent the study sample, theoretically a random sample of middle-aged hypertensive men. In reality, the study sample is almost never a true random sample of the underlying target population, because it is logistically impossible to identify every individual who belongs in the target population and then randomly choose from among them. However, the study sample is usually treated as if it were a random sample of the target population.

At this point, one would be tempted to make a generalization that enalapril lowers blood pressure in middle-aged hypertensive men. However, one must explore whether this observation could have occurred simply by chance; that is, due to random variation. If the observed outcome in the study was simply a chance occurrence, then the same observation might not have been seen if one had chosen a different sample of 40 study subjects. Perhaps more importantly, it might not exist if one were able to study the entire theoretical population of all middle-aged hypertensive men. In order to evaluate this possibility, one can perform a statistical test, which allows an investigator to quantitate the probability that the observed outcome in this study (i.e., the difference seen between the two study groups) could have happened simply by chance. There are explicit rules and procedures for how one should properly make this determination: the science of statistics. If the results of any study under consideration demonstrate a "statistically significant difference" (i.e., ruling out the probability of a chance occurrence), then one is said to have an *association*. The process of assessing whether random variation could have led to a study's findings is referred to as *statistical inference*, and represents the major role for statistical testing in the scientific method.

If there is no statistically significant difference, then the process in Figure 3.1 stops. If there is an association, then one is tempted to generalize the results of the study even further, to state that enalapril is an antihypertensive drug in general. This is referred to as *scientific or biologic inference*, and the result is a conclusion about *causation*, that the drug really does lower blood pressure in a population of treated patients. To draw this type of conclusion, however, requires one to generalize to populations other than that included in the study, including types of people who were not represented in the study sample, such as women, children, and the elderly. Although it may be apparent in this example that this is in fact appropriate, that may well not always be the case. Unlike statistical inference, there are no precise quantitative rules for biologic inference. Rather, one needs to examine the data at hand in light of all other relevant data in the rest of the scientific literature, and make a subjective judgment. To assist in making that judgment, however, one can use the criteria for the causal nature of an association described later in the chapter. First, however, we will place causal associations into proper perspective by describing the different types of errors that can be made in performing a study and the different types of associations in which each results.

Types of Errors That One Can Make in Performing a Study

There are four basic types of associations that can be observed in a study (Table 3.1). The basic purpose of research is to differentiate among them.

First, of course, one could have no association.

Second, one could have an *artifactual association*; that is, a spurious or false association. This can occur by either of two mechanisms: chance or bias. Chance is unsystematic, or random, variation. The purpose of statistical testing in science is to evaluate this, estimating the probability that the result observed in a study could have happened purely by chance.

The other possible mechanism for creating an artifactual association is bias. Epidemiologists' use of the term bias is different from that of the lay public. To an epidemiologist, *bias* is systematic variation, a consistent manner in which two study groups are treated or evaluated differently. This consistent difference can create an apparent association where one actually does not exist. Of course, it also can mask a true association.

There are many different types of potential biases [25]. For example, consider an interview study in which the research assistant is aware of the investigator's hypothesis. Attempting to please the boss, the research assistant might probe more carefully during interviews with one study group than during interviews with the other. This difference in how carefully the interviewer probes could create an apparent but false association, which is referred to as interviewer bias. Another example would be a study of drug-induced birth defects that compares children with birth defects to children without birth defects. A mother of a child with birth defect, when interviewed about any drugs she took during her pregnancy, may be likely to remember drug ingestion during pregnancy with greater accuracy than a mother of a healthy child, because of the unfortunate experience she has undergone. The improved recall in the mothers of the children with birth defects may result in false apparent associations between drug exposure and birth defects. This systematic difference in recall is referred to as recall bias [26].

Table 3.1 Types of associations between factors under study.

1) None (independent)
2) Artifactual (spurious or false)
a) Chance (unsystematic variation)
b) Bias (systematic variation)
3) Indirect (confounded)
4) Causal (direct or true)

Note that biases, once present, cannot be corrected. They represent errors in the study design that can result in incorrect results in the study. It is important to note that a *statistically significant result is no protection against a bias*; one can have a very precise measurement of an incorrect answer! The only protection against biases is proper study design. (See Chapter 43 for more discussion about biases in pharmacoepidemiologic studies.)

Third, one can have an indirect, or confounded, association. A *confounding variable*, or *confounder*, is a variable, other than the risk factor and other than the outcome under study, which is related independently to both the risk factor and the outcome and which may create an apparent association or mask a real one. For example, a study of risk factors for lung cancer could find a very strong association between having yellow fingertips and developing lung cancer. This is obviously not a causal association, but an indirect association, confounded by cigarette smoking. Specifically, cigarette smoking causes both yellow fingertips and lung cancer. Although this example is transparent, most examples of confounding are not. In designing a study, one must consider every variable that can be associated with the risk factor under study or the outcome variable under study, in order to

Table 3.2 Approaches to controlling confounding.

1) Random allocation
2) Subject selection
a) Exclusion
b) Matching
3) Data analysis
a) Stratification
b) Mathematical modeling

plan to deal with it as a potential confounding variable. Preferably, one will be able to specifically control for the variable, using one of the techniques listed in Table 3.2. (See Chapters 33 and 43 for more discussion about confounding in pharmacoepidemiologic studies.)

Fourth, and finally, there are true, causal associations.

Thus, there are three possible types of errors that can be produced in a study: random error, bias, and confounding. The probability of random error can be quantitated using statistics. Bias needs to be prevented by designing the study properly. Confounding can be controlled either in the design of the study or in its analysis. If all three types of errors can be excluded, then one is left with a true, causal association.

Criteria for the Causal Nature of an Association

The "criteria for the causal nature of an association" were first put forth by Sir Austin Bradford Hill [27], but have been described in various forms since, each with some modification. Probably the best known description of them was in the first Surgeon General's Report on Smoking and Health [28], published in 1964. These criteria are presented in Table 3.3, in no particular order. No one of them is absolutely necessary for an association to be a causal association. Analogously, no one of them is sufficient for an association to be considered a causal association. Essentially, the more criteria that are present, the more likely it is that an association is a causal association. The fewer criteria that are met, the less likely it is that an association is a causal association. Each will be discussed in turn.

Table 3.3 Criteria for the causal nature of an association.

1) Coherence with existing information (biologic plausibility)
2) Consistency of the association
3) Time sequence
4) Specificity of the association
5) Strength of the association
a) Quantitative strength
b) Dose–response relationship
c) Study design

The first criterion listed in Table 3.3 is *coherence with existing information* or *biological plausibility*. This refers to whether the association makes sense, in light of other types of information available in the literature. These other types of information could include data from other human studies, data from studies of other related questions, data from animal studies, or data from *in vitro* studies, as well as scientific or pathophysiologic theory. To use the example provided earlier, it clearly was not biologically plausible that yellow fingertips could cause lung cancer, and this provided the clue that confounding was present. Using the example of the association between cigarettes and lung cancer, cigarette smoke is a known carcinogen, based on animal data. In humans, it is known to cause cancers of the head and neck, the pancreas, and the bladder. Cigarette smoke also goes down into the lungs, directly exposing the tissues in question. Thus, it certainly is biologically plausible that cigarettes could *cause* lung cancer [29]. It is much more reassuring if an association found in a particular study makes sense, based on previously available information, and this leads one to be more comfortable that it

might be a causal association. Clearly, however, one could not require that this criterion always be met, or one would never have a major breakthrough in science.

The second criterion listed in Table 3.3 is the *consistency of the association*. A hallmark of science is reproducibility: if a finding is real, one should be able to reproduce it in a different setting. This could include different geographic settings, different study designs, different populations, and so on. For example, in the case of cigarettes and lung cancer, the association has now been reproduced in many different studies, in different geographic locations, using different study designs [30]. The need for reproducibility is such that one should never believe a finding reported only once; there may have been an error committed in the study, which is not apparent to either the investigator or the reader.

The third criterion listed is the *time sequence*: a cause must precede an effect. Although this may seem obvious, there are study designs from which this cannot be determined. For example, if one were to perform a survey in a classroom of 200 medical students, asking each if they were currently taking diazepam and also whether they were anxious, one would find a strong association between the use of diazepam and anxiety, but this does not mean that diazepam causes anxiety! Although this is obvious, as it is not a biologically plausible interpretation, one cannot differentiate from this type of cross-sectional study which variable came first and which came second. In the example of cigarettes and lung cancer, obviously the cigarette smoking usually precedes the lung cancer, as a patient would not survive long enough to smoke much if the opposite were the case.

The fourth criterion listed in Table 3.3 is *specificity*. This refers to the question of whether the cause ever occurs without the presumed effect, and whether the effect ever occurs without the presumed cause. This criterion is almost never met in biology, with the occasional exception of infectious diseases. Measles never occurs without the measles virus, but even in this example, not everyone who becomes infected with the measles virus develops clinical measles. Certainly, not everyone who smokes develops lung cancer, and not everyone who develops lung cancer was a smoker. This is one of the major points the tobacco industry stresses when it attempts to make the claim that cigarette smoking has not been proven to cause lung cancer. Some authors even omit this as a criterion, as it is so rarely met. When it is met, however, it provides extremely strong support for a conclusion that an association is causal.

The fifth criterion listed in Table 3.3 is the *strength of the association*. This includes three concepts: its quantitative strength, dose–response, and the study design. Each will be discussed in turn.

The *quantitative strength* of an association refers to the effect size. To evaluate this, one asks whether the magnitude of the observed difference between the two study groups is large. A quantitatively large association can only be created by a causal association or a large error, which should be apparent in evaluating the methods of a study. A quantitatively small association may still be causal, but it could be created by a subtle error, which would not be apparent in evaluating the study. Conventionally, epidemiologists consider an association with a relative risk of less than 2.0 a weak association. Certainly, the association between cigarette smoking and lung cancer is a strong association: studies show relative risks ranging between 10.0 and 30.0 [30].

A *dose–response relationship* is an extremely important and commonly used concept in clinical pharmacology and is used similarly in epidemiology. It exists when an increase in the intensity of an exposure results in an increased risk of the disease under study. Equivalent to this is a *duration–response relationship*, which exists when a longer exposure causes an increased risk of the disease. The presence of either relationship strongly implies that an

association is, in fact, a causal association. Certainly in the example of cigarette smoking and lung cancer, it has been shown repeatedly that an increase in either the number of cigarettes smoked each day or in the number of years of smoking increases the risk of developing lung cancer [30].

Finally, *study design* refers to two concepts: whether the study was well designed, and which study design was used in the studies in question. The former refers to whether the study was subject to one of the three errors described earlier in this chapter, namely random error, bias, and confounding. Table 3.4 presents the study designs typically used for epidemiologic studies, or in fact for any clinical studies. They are organized in a hierarchical fashion. As one advances from the designs at the bottom of the

Table 3.4 Advantages and disadvantages of epidemiologic study designs.

Study design	Advantages	Disadvantages
Randomized clinical trial (experimental study)	Most convincing design Only design which controls for unknown or unmeasurable confounders	Most expensive Artificial Logistically most difficult Ethical objections
Cohort study	Can study multiple outcomes Can study uncommon exposures Selection bias less likely Unbiased exposure data Incidence data available	Possibly biased outcome data More expensive If done prospectively, may take years to complete
Case–control study	Can study multiple exposures Can study uncommon diseases Logistically easier and faster Less expensive	Control selection problematic Possibly biased exposure data
Analyses of secular trends	Can provide rapid answers	No control of confounding
Case series	Easy quantitation of incidence	No control group, so cannot be used for hypothesis testing
Case reports	Cheap and easy method for generating hypotheses	Cannot be used for hypothesis testing

table to those at the top, studies get progressively harder to perform, but are progressively more convincing. In other words, associations shown by studies using designs at the top of the list are more likely to be causal associations than associations shown by studies using designs at the bottom of the list. The association between cigarette smoking and lung cancer has been reproduced in multiple well-designed studies, using analyses of secular trends, case–control studies, and cohort studies. However, it has not been shown using a randomized clinical trial, which is the "Cadillac" of study designs, as will be discussed later in the chapter. This is the other major defense the tobacco industry employs. Of course, it would not be ethical or logistically feasible to randomly allocate individuals to smoke or not to smoke and expect to follow them for 20 years to observe the outcome in each group.

The issue of causation is discussed more in Chapter 10 as it relates to the process of spontaneous reporting of adverse drug reactions, and in Chapter 29 as it relates to determining causation in case reports.

Epidemiologic Study Designs

In order to clarify the concept of study design further, each of the designs in Table 3.4 will be discussed in turn, starting at the bottom of the list and working upward.

Case Reports

Case reports are simply reports of events observed in single patients. As used in pharmacoepidemiology, a case report describes a single patient who was exposed to a drug and experiences a particular, usually adverse, outcome. For example, one might see a published case report about a young woman who was taking oral contraceptives and who suffered a pulmonary embolism.

Case reports are useful for raising hypotheses about drug effects, to be tested with more rigorous study designs. However, in a case report one cannot know if the patient reported is either typical of those with the exposure or typical of those with the disease. Certainly, one cannot usually determine whether the adverse outcome was due to the drug exposure or would have happened anyway. As such, it is very rare that a case report can be used to make a statement about causation. One exception to this would be when the outcome is so rare and so characteristic of the exposure that one knows that it was likely to be due to the exposure, even if the history of exposure were unclear. An example of this is clear cell vaginal adenocarcinoma occurring in young women exposed *in utero* to diethylstilbestrol [31]. Another exception would be when the disease course is very predictable and the treatment causes a clearly apparent change in this disease course. An example would be the ability of penicillin to cure streptococcal endocarditis, a disease that is nearly uniformly fatal in the absence of treatment. Case reports can be particularly useful to document causation when the treatment causes a change in disease course which is reversible, such that the patient returns to their untreated state when the exposure is withdrawn, can be treated again, and when the change returns upon repeat treatment. Consider a patient who is suffering from an overdose of methadone, a long-acting narcotic, and is comatose. If this patient is then treated with naloxone, a narcotic antagonist, and immediately awakens, this would be very suggestive that the drug indeed is efficacious as a narcotic antagonist. As the naloxone wears off the patient would become comatose again, and then if they were given another dose of naloxone they would awaken again. This, especially if repeated a few times, would represent strong evidence that the drug is indeed effective as a narcotic antagonist. This type of challenge–rechallenge situation is relatively uncommon, however, as physicians generally will avoid

exposing a patient to a drug if the patient experienced an adverse reaction to it in the past. This issue is discussed in more detail in Chapters 10 and 29.

Case Series

Case series are collections of patients, all of whom have a single exposure, whose clinical outcomes are then evaluated and described. Often they are from a single hospital or medical practice. Alternatively, case series can be collections of patients with a single outcome, looking at their antecedent exposures. For example, one might observe 100 consecutive women under the age of 50 who suffer from a pulmonary embolism, and note that 30 of them had been taking oral contraceptives.

After drug marketing, case series are most useful for two related purposes. First, they can be useful for quantifying the incidence of an adverse reaction. Second, they can be useful for being certain that any particular adverse effect of concern does not occur in a population which is larger than that studied prior to drug marketing. The so-called Phase IV postmarketing surveillance study of prazosin was conducted for the former reason, to quantitate the incidence of first-dose syncope from prazosin [32]. The Phase IV postmarketing surveillance study of cimetidine [33] was conducted for the latter reason. Metiamide was an H-2 blocker, which was withdrawn after marketing outside the US because it caused agranulocytosis. Since cimetidine is chemically related to metiamide, there was a concern that cimetidine too might cause agranulocytosis [32]. In both examples, the manufacturer asked its sales representatives to recruit physicians to participate in the study. Each participating physician then enrolled the next series of patients for whom the drug was prescribed.

In this type of study, one can be more certain that the patients are probably typical of those with the exposure or with the disease, depending on the focus of the study. However, in the absence of a control group, one cannot be certain which features in the description of the patients are unique to the exposure or outcome. As an example, one might have a case series from a particular hospital of 100 individuals with a certain disease, and note that all were men over the age of 60. This might lead one to conclude that this disease seems to be associated with being a man over the age of 60. However, it would be clear that this would be an incorrect conclusion once one noted that the hospital this case series was drawn from was a Veterans Administration hospital, where most patients are men over the age of 60. In the previous example of pulmonary embolism and oral contraceptives, 30% of the women with pulmonary embolism had been using oral contraceptives. However, this information is not sufficient to determine whether this is higher, the same as, or even lower than would have been expected. For this reason, case series are also not very useful in determining causation, but provide clinical descriptions of a disease or of patients who receive an exposure.

Analyses of Secular Trends

Analyses of secular trends, also called "ecologic studies," examine trends in an exposure that is a presumed cause and trends in a disease that is a presumed effect and test whether the trends coincide. These trends can be examined over time or across geographic boundaries. In other words, one could analyze data from a single region and examine how the trend changes over time, or one could analyze data from a single time period and compare how the data differ from region to region or country to country. Vital statistics are often used for these studies. As an example, one might look at sales data for oral contraceptives and compare them to death rates from venous thromboembolism, using recorded vital statistics. When such a study was actually performed, mortality rates from venous

thromboembolism were seen to increase in parallel with increasing oral contraceptive sales, but only in women of reproductive age, not in older women or in men of any age [34].

Analyses of secular trends are useful for rapidly providing evidence for or against a hypothesis. However, these studies lack data on individuals; they utilize only aggregated group data (e.g., annual sales data in a given geographic region in relation to annual cause-specific mortality in the same region). As such, they are unable to control for confounding variables. Thus, among exposures whose trends coincide with that of the disease, analyses of secular trends are unable to differentiate which factor is likely to be the true cause. For example, lung cancer mortality rates in the US have been increasing in women, such that lung cancer is now the leading cause of cancer mortality in women [35]. This is certainly consistent with the increasing rates of cigarette smoking observed in women until the mid-1960s [36], and so appears to be supportive of the association between cigarette smoking and lung cancer. However, it would also be consistent with an association between certain occupational exposures and lung cancer, as more women in the US are now working outside the home.

Case–Control Studies

Case–control studies compare cases with a disease to controls without the disease, looking for differences in antecedent exposures. As an example, one could select cases of young women with venous thromboembolism and compare them to controls without venous thromboembolism, looking for differences in antecedent oral contraceptive use. Several such studies have been performed, generally demonstrating a strong association between the use of oral contraceptives and venous thromboembolism [37].

Case–control studies can be particularly useful when one wants to study multiple possible causes of a single disease, as one can use the same cases and controls to examine any number of exposures as potential risk factors. This design is also particularly useful when one is studying a relatively rare disease, as it guarantees a sufficient number of cases with the disease. Using case–control studies, one can study rare diseases with markedly smaller sample sizes than those needed for cohort studies (see Chapter 4). For example, the classic study of diethylstilbestrol and clear cell vaginal adenocarcinoma required only 8 cases and 40 controls [31], rather than the many thousands of exposed subjects that would have been required for a cohort study of this question.

Case–control studies generally obtain their information on exposures retrospectively; that is, by recreating events that happened in the past. Information on past exposure to potential risk factors is generally obtained by abstracting medical records or by administering questionnaires or interviews. As such, case–control studies are subject to limitations in the validity of retrospectively collected exposure information. In addition, the proper selection of controls can be a challenging task and appropriate control selection can lead to a selection bias, which may lead to incorrect conclusions. Nevertheless, when case–control studies are done well, subsequent well-done cohort studies or randomized clinical trials, if any, will generally confirm their results. As such, the case–control design is a very useful approach for pharmacoepidemiologic studies.

Cohort Studies

Cohort studies identify subsets of a defined population and follow them over time, looking for differences in their outcome. Cohort studies generally are used to compare exposed patients to unexposed patients, although they can also be used to compare one exposure to another. For example, one could compare women of reproductive age who use oral contraceptives to users of other contraceptive methods, looking

for the differences in the frequency of venous thromboembolism. When such studies were performed, they in fact confirmed the relationship between oral contraceptives and thromboembolism, which had been noted using analyses of secular trends and case–control studies [38,39]. Cohort studies can be performed either prospectively, that is simultaneous with the events under study, or retrospectively, that is after the outcomes under study had already occurred, by recreating those past events using medical records, questionnaires, or interviews.

The major difference between cohort and case–control studies is the basis upon which patients are recruited into the study (see Figure 3.2). Patients are recruited into case–control studies based on the presence or absence of a disease, and their antecedent exposures are then studied. Patients are recruited into cohort studies based on the presence or absence of an exposure, and their subsequent disease course is then studied.

Cohort studies have the major advantage of being free of the major problem that plagues case–control studies: the difficult process of selecting an undiseased control group. In addition, prospective cohort studies are free of the problem of the questionable validity of retrospectively collected data. For these reasons, an association demonstrated by a cohort study is more likely to be a causal association than one demonstrated by a case–control study. Furthermore, cohort studies are particularly useful when one is studying multiple possible outcomes from a single exposure, especially a relatively uncommon exposure. Thus, they are especially useful in postmarketing drug surveillance studies, which are looking at any possible effect of a newly marketed drug. However, cohort studies can require extremely large sample sizes to study relatively uncommon outcomes (see Chapter 4). In addition, prospective cohort studies can require a prolonged time period to study delayed drug effects.

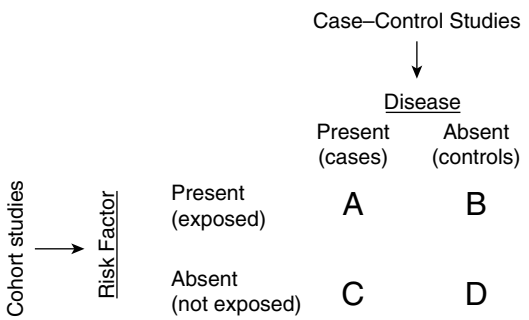

Figure 3.2 Cohort and case–control studies provide similar information, but approach data collection from opposite directions. *Source:* Strom BL. Medical databases in post-marketing drug surveillance. *Trends Pharmacol Sci* 1986; **7**: 377–80.

Analysis of Case–Control and Cohort Studies

As can be seen in Figure 3.2, both case–control and cohort studies are intended to provide the same basic information; the difference is how this information is collected. The key statistic reported from these studies is the *relative risk*, the ratio of the incidence rate of an outcome in the exposed group to the incidence rate of the outcome in the unexposed group. A relative risk of greater than 1.0 means that exposed subjects have a *greater* risk of the disease under study than unexposed subjects, or that the exposure appears to cause the disease. A relative risk of less than 1.0 means that exposed subjects have a *lower* risk of the disease than unexposed subjects, or that the exposure seems to protect against the disease. A relative risk of 1.0 means that exposed subjects and unexposed subjects have the same risk of developing the disease, or that the exposure and the disease appear unrelated.

One can calculate a relative risk directly from the results of a cohort study. However, in a case–control study one cannot determine the size of either the exposed population or the unexposed population from which the diseased cases and undiseased controls were drawn. The results of a case–control study do not provide

information on the incidence rates of the disease in exposed and unexposed individuals. Therefore, relative risks cannot be calculated directly from a case–control study. Instead, in reporting the results of a case–control study one generally reports the *odds ratio*, which is a close estimate of the relative risk when the disease under study is relatively rare. Since case–control studies are generally used to study rare diseases, there generally is very close agreement between the odds ratio and the relative risk, and the results from case–control studies are often loosely referred to as relative risks, although they are in fact odds ratios.

Both relative risks and odds ratios can be reported with *P values*. These P values allow one to determine if the relative risk is statistically significantly different from 1.0; that is, whether the differences between the two study groups are likely to be due to random variation or are likely to represent real associations.

Alternatively, and probably preferably, relative risks and odds ratios can be reported with *confidence intervals*, which are an indication of the range of relative risks within which the true relative risk for the entire theoretical population is most likely to lie. As an approximation, a 95% confidence interval around a relative risk means that we can be 95% confident that the true relative risk lies in the range between the lower and upper limits of this interval. If a 95% confidence interval around a relative risk excludes 1.0, then the finding is statistically significant with a P value of less than 0.05. A confidence interval provides much more information than a P value, however. As an example, a study that yields a relative risk (95% confidence interval) of 1.0 (0.9–1.1) is clearly showing that an association is very unlikely. A study that yields a relative risk (95% confidence interval) of 1.0 (0.1–100) provides little evidence for or against an association. Yet, both could be reported as a relative risk of 1.0 and a P value greater than 0.05. As another example, a study that yields a relative risk (95% confidence interval) of 10.0 (9.8–10.2) precisely quantifies a 10-fold increase in risk that is also statistically significant. A study that yields a relative risk (95% confidence interval) of 10.0 (1.1–100) says little, other than that an increased risk is likely. Yet, both could be reported as a relative risk of 10.0 ($P<0.05$). As a final example, a study yielding a relative risk (95% confidence interval) of 3.0 (0.98–5.0) is strongly suggestive of an association, whereas a study reporting a relative risk (95% confidence interval) of 3.0 (0.1–30) would not be. Yet, both could be reported as a relative risk of 3.0 ($P>0.05$).

Finally, another statistic that one can calculate from a cohort study is the excess risk, also called the risk difference or, sometimes, the attributable risk. Whereas the relative risk is the ratio of the incidence rates in the exposed group versus the unexposed groups, the excess risk is the arithmetic difference between the incidence rates. The relative risk is more important in considering questions of causation. The excess risk is more important in considering the public health impact of an association, as it represents the increased rate of disease due to the exposure. For example, oral contraceptives are strongly associated with the development of myocardial infarction in young women [37]. However, the risk of myocardial infarction in nonsmoking women in their 20s is so low, that even a fivefold increase in that risk would still not be of public health importance. In contrast, women in their 40s are at higher risk, especially if they are cigarette smokers as well. Thus, oral contraceptives should not be as readily used in these women [37].

As with relative risks, excess risks cannot be calculated from case–control studies, as incidence rates are not available. As with the other statistics, P values can be calculated to determine whether the differences between the two study groups could have occurred just by chance. Confidence intervals can be calculated around excess risks as well, and would be interpreted analogously.

Randomized Clinical Trials

Finally, *experimental studies* are studies in which the investigator controls the therapy that is to be received by each participant. Generally, an investigator uses that control to randomly allocate patients between or among the study groups, performing a *randomized clinical trial*. For example, one could theoretically randomly allocate sexually active women to use either oral contraceptives or no contraceptives, examining whether they differ in their incidence of subsequent venous thromboembolism. The major strength of this approach is random assignment, which is the only way to make it likely that the study groups are comparable in potential confounding variables that are either unknown or unmeasurable. For this reason, associations demonstrated in randomized clinical trials are more likely to be causal associations than those demonstrated using one of the other study designs reviewed here.

However, even randomized clinical trials are not without their problems. The randomized clinical trial just outlined, allocating women to receive contraceptives or no contraceptives, demonstrates the major potential problems inherent in the use of this study design. It would obviously be impossible to perform, ethically and logistically. In addition, randomized clinical trials are expensive and artificial. Inasmuch as they have already been performed prior to marketing to demonstrate each drug's efficacy, they tend to be unnecessary after marketing. They are likely to be used in pharmacoepidemiologic studies mainly for supplementary studies of drug efficacy [40]. However, they remain the "gold standard" by which the other designs must be judged. Indeed, with the publication of the results from the Women's Health Initiative indicating that combination hormone replacement therapy causes an increased risk of myocardial infarction rather than a decreased risk [41–44], there has been increased concern about reliance solely on nonexperimental methods to study drug safety after marketing [45–47], and we are seeing the use of massive randomized clinical trials as part of postmarketing surveillance (see Chapter 32).

Discussion

Thus, a series of different study designs are available (Table 3.4), each with their respective advantages and disadvantages. Case reports, case series, analyses of secular trends, case–control studies, and cohort studies have been referred to collectively as *observational study designs* or *nonexperimental study designs*, in order to differentiate them from experimental studies. In nonexperimental study designs the investigator does not control the therapy, but simply observes and evaluates the results of ongoing medical care. Case reports, case series, and analyses of secular trends have also been referred to as *descriptive studies*. Case–control studies, cohort studies, and randomized clinical trials all have control groups, and have been referred to as *analytic studies*. The analytic study designs can be classified in two major ways: by how subjects are selected into the study and by how data are collected for the study (see Table 3.5). From the perspective of how subjects are recruited into the study, case–control studies can be contrasted with cohort studies. Specifically, case–control studies select subjects into the study based on the presence or absence of a disease, while cohort studies select subjects into the study based on the presence or absence of an exposure. From this perspective, randomized clinical trials can be viewed as a subset of cohort studies, a type of cohort study in which the investigator controls the allocation of treatment, rather than simply observing ongoing medical care. From the perspective of timing, data can be collected *prospectively*, that is simultaneously with the events under study, or *retrospectively*, that is after the events under

study had already developed. In the latter situation, one recreates events that happened in the past using medical records, questionnaires, or interviews. Data can also be collected using *cross-sectional studies*, studies that have no time sense, as they examine only one point in time. In principle, either cohort or case–control studies can be performed using any of these time frames, although prospective case–control studies are unusual. Randomized clinical trials must be prospective, as this is the only way an investigator can control the therapy received.

The terms presented in this chapter, which are those that will be used throughout the book, are probably those used by a majority of epidemiologists. Unfortunately, however, other terms have been used for most of these study designs as well. Table 3.5 presents several of the synonyms that have been used in the medical literature. The same term is sometimes used by different authors to describe different concepts. For example, in this book we are reserving the use of the terms "retrospective study" and "prospective study" to refer to a time sense. As is apparent from Table 3.5, however, in the past some authors have used the term "retrospective study" to refer to a case–control study and "prospective study" to refer to a cohort study, confusing the two concepts inherent in the classification schemes presented in the table. Other authors use the term "retrospective study" to refer to any nonexperimental study, while others appear to use it to refer to any study they do not like, as a term of derision! Unfortunately, when reading a scientific paper, there is no way of determining which usage the author intended. More important than the terminology, however, are the concepts underlying the terms. Once they understand these concepts, readers can choose to use whatever terminology they are comfortable with.

Table 3.5 Epidemiologic study designs.

A) Classified by how subjects are recruited into the study
1) Case–control (case-history, case-referent, retrospective, trohoc) studies
2) Cohort (follow-up, prospective) studies
3) Experimental studies (clinical trials, intervention study)
B) Classified by how data are collected for the study
1) Retrospective (historical, nonconcurrent, retrolective) studies
2) Prospective (prolective) studies
3) Cross-sectional studies

Conclusion

From the material presented in this chapter, it is hopefully now apparent that each study design has an appropriate role in scientific progress. In general, science proceeds from the bottom of Table 3.4 upward, from case reports and case series that are useful for suggesting an association to analyses of trends and case–control studies that are useful for exploring these associations. Finally, if a study question warrants the investment and can tolerate the delay until results become available, then cohort studies and randomized clinical trials can be undertaken to assess these associations more definitively.

For example, regarding the question of whether oral contraceptives cause venous thromboembolism, an association was first suggested by case reports and case series, then was explored in more detail by analyses of trends and a series of case–control studies [37]. Later, because of the importance of oral contraceptives, the number of women using them, and the fact that users were predominantly healthy women, the investment was made in two long-term, large-scale cohort studies [38,39]. This question might even be worth the investment of a randomized clinical trial, except it would not be feasible or ethical. In contrast, when thalidomide was marketed, it was

not a major breakthrough; other hypnotics were already available. Case reports of phocomelia in exposed patients were followed by case–control studies [48] and analyses of secular trends [49]. Inasmuch as the adverse effect was so terrible and the drug was not of unique importance, the drug was then withdrawn, without the delay that would have been necessary if cohort studies and/or randomized clinical trials had been awaited. Ultimately, a retrospective cohort study was performed, comparing those exposed during the critical time period to those exposed at other times [50].

In general, however, clinical, regulatory, commercial, and legal decisions need to be made based on the best evidence available at the time of the decision. To quote Sir Austin Bradford Hill [27]:

> All scientific work is incomplete—whether it be observational or experimental. All scientific work is liable to be upset or modified by advancing knowledge. That does not confer upon us a freedom to ignore the knowledge we already have, or to postpone the action that it appears to demand at a given time. Who knows, asked Robert Browning, but the world may end tonight? True, but on available evidence most of us make ready to commute on the 8:30 next day.

Sample Size Considerations for Pharmacoepidemiologic Studies

Brian L. Strom

Rutgers Biomedical and Health Sciences, Newark, NJ, USA

Chapter 1 pointed out that between 500 and 3000 subjects are usually exposed to a drug prior to marketing, in order to be 95% certain of detecting adverse effects that occur in between 1 and 6 in 1000 exposed individuals. While this seems like a reasonable goal, it poses some important problems that must be taken into account when planning pharmacoepidemiologic studies. Specifically, such studies must generally include a sufficient number of subjects to add significantly to the premarketing experience, and this requirement for large sample sizes raises logistical obstacles to cost-effective studies. This central special need for large sample sizes is what has led to the innovative approaches to collecting pharmacoepidemiologic data that are described in Part III of this book.

The approach to considering the implications of a study's sample size is somewhat different depending on whether a study is already completed or is being planned. After a study is completed, if a real finding was statistically significant, then the study had a sufficient sample size to detect it, by definition. If a finding was not statistically significant, then one can use either of two approaches. First, one can examine the resulting confidence intervals in order to determine the smallest differences between the two study groups that the study had sufficient sample size to exclude [1]. Alternatively, one can approach the question in a manner similar to the way one would approach it if one were planning the study *de novo*. Nomograms can be used to assist a reader in interpreting negative clinical trials in this way [2].

In contrast, in this chapter we will discuss in more detail how to determine a proper study sample size, from the perspective of one who is designing a study *de novo*. Specifically, we will begin by discussing how one calculates the minimum sample size necessary for a pharmacoepidemiologic study, to avoid the problem of a study with a sample size that is too small. We will first present the approach for cohort studies, then for case–control studies, and then for case series. For each design, one or more tables will be presented to assist the reader in carrying out these calculations.

Pharmacoepidemiology, Sixth Edition. Edited by Brian L. Strom, Stephen E. Kimmel and Sean Hennessy.

Sample Size Calculations for Cohort Studies

The sample size required for a cohort study depends on what you are expecting from the study. To calculate sample sizes for a cohort study, one needs to specify five variables (see Table 4.1) [3,4].

The first variable to specify is the *alpha* (α) *or type I error* that one is willing to tolerate in the study. Type I error is the probability of concluding that there is a difference between the groups being compared when in fact a difference does not exist. Using diagnostic tests as an analogy, a type I error is a false positive study finding. The more tolerant one is willing to be of type I error, the smaller the sample size required. The less tolerant one is willing to be of type I error, the smaller one would set alpha, and the larger the sample size that would be required. Conventionally alpha is set at 0.05, although this certainly does not have to be the case. Note that alpha needs to be specified as either one-tailed or two-tailed. If only one of the study groups could conceivably be more likely to develop the disease and one is interested in detecting this result only, then one would specify alpha to be one-tailed. If either of the study groups may be likely to develop the disease and either result would be of interest, then one would specify alpha to be two-tailed. To decide whether alpha should be one-tailed or two-tailed, investigators should consider what their reaction would be to a result that is statistically significant in a direction opposite to the one expected. For example, what if one observed that a drug increased the frequency of dying from coronary artery disease instead of decreasing it, as expected? If the investigator's response to this would be "Boy, what a surprise, but I believe it," then a two-tailed test should be performed. If the investigator's response would be "I don't believe it, and I will interpret this simply as a study that does not show the expected decrease in coronary artery disease in the group treated with the study drug," then a one-tailed test should be performed. The more conservative option is the two-tailed test, assuming that the results could turn out in either direction. This is the option that is usually, although not always, chosen.

Table 4.1 Information needed to calculate a study's sample size.

For cohort studies	For case–control studies
1) Alpha, or type I error, considered tolerable, and whether it is one-tailed or two-tailed	1) Alpha, or type I error, considered tolerable, and whether it is one-tailed or two-tailed
2) Beta, or type II error, considered tolerable	2) Beta, or type II error, considered tolerable
3) Minimum relative risk to be detected	3) Minimum relative risk to be detected
4) Incidence of the disease in the unexposed control group	4) Prevalence of the exposure in the undiseased control group
5) Ratio of unexposed controls to exposed study subjects	5) Ratio of undiseased controls to diseased study subjects

The second variable that needs to be specified to calculate a sample size for a cohort study is the *beta* (β) *or type II error* that one is willing to tolerate in the study. A type II error is the probability of concluding that there is no difference between the groups being compared when in fact a difference does exist. In other words, a type II error is the probability of missing a real difference. Using diagnostic tests as an analogy, a type II error is a false negative study finding. The complement of beta is the power of a study; that is, the probability of detecting a difference if a difference really exists. Power is calculated as 1-β. Again, the more tolerant one is willing to be of type II errors – that is, the higher the beta – the smaller the sample size required. The beta is conventionally set at 0.1 (i.e., 90% power) or 0.2 (i.e., 80% power), although again this need not be the case. Beta is always one-tailed.

The third variable one needs to specify in order to calculate sample sizes for a cohort study is the minimum effect size one wants to be able to detect. For a cohort study, this is expressed as a relative risk. The smaller the relative risk that one wants to detect, the larger the sample size required. Note that the relative risk often used by investigators in this calculation is the relative risk the investigator is expecting from the study. This is *not correct*, as it will lead to inadequate power to detect relative risks that are smaller than expected, but still clinically important to the investigator. In other words, if one chooses a sample size that is designed to detect a relative risk of 2.5, one should be comfortable with the thought that, if the actual relative risk turns out to be 2.2, one may not be able to detect it as a statistically significant finding.

In a cohort study one selects subjects based on the presence or absence of an exposure of interest and then investigates the incidence of the disease of interest in each of the study groups. Therefore, the fourth variable one needs to specify is the expected incidence of the study outcome in the unexposed control group. Again, the more one asks of a study (e.g., the power to detect very small differences), the larger the sample size needed. Specifically, the rarer the outcome of interest, the larger the sample size needed.

The fifth variable one needs to specify is the number of unexposed control subjects to be included in the study for each exposed study subject. A study has the most statistical power for a given number of study subjects if it has the same number of exposed and unexposed subjects (controls). However, sometimes the number of exposed subjects is limited and, therefore, inadequate to provide sufficient power to detect a relative risk of interest. In that case, additional power can be gained by increasing the number of controls alone. Doubling the number of controls – that is, including two controls for each exposed subject – results in a modest increase in the statistical power, but it does not double it. Including three controls for each exposed subject increases the power further. However, the increment in power achieved by increasing the ratio of control subjects to exposed subjects from 2:1 to 3:1 is smaller than the increment in power achieved by increasing the ratio from 1:1 to 2:1. Each additional increase in the size of the control group increases the power of the study further, but with progressively smaller gains in statistical power. Thus, there is rarely a reason to include more than three or four controls per study subject. For example, one could design a study with an alpha of 0.05 to detect a relative risk of 2.0 for an outcome variable that occurs in the control group with an incidence rate of 0.01. A study with 2319 exposed individuals and 2319 controls would yield a power of 0.80, or an 80% chance of detecting a difference of that magnitude. With the same 2319 exposed subjects, ratios of control subjects to exposed subjects of 1:1, 2:1, 3:1, 4:1, 5:1, 10:1, and 50:1 would result in statistical powers of 0.80, 0.887, 0.913, 0.926, 0.933, 0.947, and 0.956, respectively.

It is important to differentiate between the number of controls (as has been discussed and illustrated) and the number of control groups. It is not uncommon, especially in case–control studies where the selection of a proper control group can be difficult, to choose more than one control group (for example, a group of hospital controls and a group of community controls). This is done for reasons of validity, not for statistical power, and it is important that these multiple control groups not be aggregated in the analysis. In this situation, the goal is to insure that the comparison of the exposed subjects to each of the different control groups yields the same answer, not to increase the available sample size. As such, the comparison of each control group to the exposed subjects should be treated as a separate study. The comparison of the exposed group to each control group requires a separate sample size calculation.

Once the five variables outlined have been specified, the sample size needed for a given study can be calculated. Several different formulas have been used for this calculation, each of which gives slightly different results. The formula that is probably most often used is modified from Schlesselman [3]:

$$N = \frac{1}{\left[p(1-R)^2\right]}\left[Z_{1-\alpha}\sqrt{\left(1+\frac{1}{K}\right)U(1-U)} + Z_{1-\beta}\sqrt{pR(1-Rp)+\frac{p(1-p)}{K}}\right]^2$$

where p is the incidence of the disease in the unexposed, R is the minimum relative risk to be detected, α is the type I error rate which is acceptable, β is the type II error rate which is acceptable, $Z_{1-\alpha}$ and $Z_{1-\beta}$ refer to the unit normal deviates corresponding to α and β, K is the ratio of number of unexposed control subjects to the number of exposed subjects, and

$$U = \frac{Kp+pR}{K+1}$$

$Z_{1-\alpha}$ is replaced by $Z_{1-\alpha/2}$ if one is planning to analyze the study using a two-tailed alpha. Note that K does not need to be an integer.

A series of tables are presented in Appendix A, which were calculated using this formula. In Tables A1–A4 we have assumed an alpha (two-tailed) of 0.05, a beta of 0.1 (90% power), and control to exposed ratios of 1:1, 2:1, 3:1, and 4:1, respectively. Tables A5–A8 are similar, except they assume a beta of 0.2 (80% power). Each table presents the number of exposed subjects needed to detect any of several specified relative risks, for outcome variables that occur at any of several specified incidence rates. The total study size will be the sum of exposed subjects (as listed in the relevant table) plus the controls.

For example, what if one wanted to investigate a new nonsteroidal anti-inflammatory drug that is about to be marketed, but premarketing data raised questions about possible hepatotoxicity? This would presumably be studied using a cohort study design and, depending upon the values chosen for alpha, beta, the incidence of the disease in the unexposed population, the relative risk one wants to be able to detect, and the ratio of control to exposed subjects, the sample sizes needed could differ markedly (see Table 4.2). For example, what if your goal was to study hepatitis that occurs, say, in 0.1% of all unexposed individuals? If one wanted to design a study with one control per exposed subject to detect a relative risk of 2.0 for this outcome variable, assuming an alpha (two-tailed) of 0.05 and a beta of 0.1, one could look in Table A1 and see that it would require 31 483 exposed subjects, as well as an equal number of unexposed controls. If one were less concerned with missing a real finding, even if it were there, one could change beta to 0.2, and the required sample size would drop to 23 518 (see Table 4.2 and Table A5). If one wanted to minimize the number of exposed subjects needed for the study, one could include up to four controls for each exposed subject (Table 4.2 and Table A8). This would result in a sample size of 13 402, with four times as many controls, a total of 67 010 subjects. Finally, if one considers it inconceivable that this new drug could *protect* against liver disease and one is not interested in that outcome, then one might use a one-tailed alpha, resulting in a somewhat lower sample size of 10 728, again with four times as many controls. Much smaller sample sizes are needed to detect relative risks of 4.0 or greater; these are also presented in Table 4.2.

In contrast, what if one's goal was to study elevated liver function tests, which, say, occur in 1% of an unexposed population? If one wants to detect a relative risk of 2 for this more common outcome variable, only 3104 subjects would be needed in each group, assuming a two-tailed alpha of 0.05, a beta of 0.1, and one control per

Table 4.2 Examples of sample sizes needed for a cohort study.

Hypothetical disease	Incidence rate assumed in unexposed	Alpha	Beta	Relative risk to be detected	Control : exposed ratio	Sample size needed in exposed group	Sample size needed in control group
Abnormal liver function tests	0.01	0.05 (2-tailed)	0.1	2	1	3104	3104
	0.01	0.05 (2-tailed)	0.2	2	1	2319	2319
	0.01	0.05 (2-tailed)	0.2	2	4	1323	5292
	0.01	0.05 (1-tailed)	0.2	2	4	1059	4236
	0.01	0.05 (2-tailed)	0.1	4	1	568	568
	0.01	0.05 (2-tailed)	0.2	4	1	425	425
	0.01	0.05 (2-tailed)	0.2	4	4	221	884
	0.01	0.05 (1-tailed)	0.2	4	4	179	716
Hepatitis	0.001	0.05 (2-tailed)	0.1	2	1	31 483	31 483
	0.001	0.05 (2-tailed)	0.2	2	1	23 518	23 518
	0.001	0.05 (2-tailed)	0.2	2	4	13 402	53 608
	0.001	0.05 (1-tailed)	0.2	2	4	10 728	42 912
	0.001	0.05 (2-tailed)	0.1	4	1	5823	5823
	0.001	0.05 (2-tailed)	0.2	4	1	4350	4350
	0.001	0.05 (2-tailed)	0.2	4	4	2253	9012
	0.001	0.05 (1-tailed)	0.2	4	4	1829	7316
Cholestatic jaundice	0.0001	0.05 (2-tailed)	0.1	2	1	315 268	315 268
	0.0001	0.05 (2-tailed)	0.2	2	1	235 500	235 500
	0.0001	0.05 (2-tailed)	0.2	2	4	134 194	536 776
	0.0001	0.05 (1-tailed)	0.2	2	4	107 418	429 672
	0.0001	0.05 (2-tailed)	0.1	4	1	58 376	58 376
	0.0001	0.05 (2-tailed)	0.2	4	1	43 606	43 606
	0.0001	0.05 (2-tailed)	0.2	4	4	22 572	90 288
	0.0001	0.05 (1-tailed)	0.2	4	4	18 331	73 324

exposed subject. Alternatively, if one wanted to detect the same relative risk for an outcome variable that occurred as infrequently as 0.0001, perhaps cholestatic jaundice, one would need 315 268 subjects in each study group.

Obviously, cohort studies can require very large sample sizes to study uncommon diseases. A study of uncommon diseases is often better performed using a case–control study design, as described in the previous chapter.

Sample Size Calculations for Case–Control Studies

The approach to calculating sample sizes for case–control studies is similar to the approach for cohort studies. Again, there are five variables that need to be specified, the values of which depend on what the investigator expects from the study (see Table 4.1). Three of these are alpha, or the type I error one is willing to tolerate; beta, or the type II error one is willing to tolerate; and the minimum odds ratio (an approximation of the relative risk) one wants to be able to detect. These are defined and described in the section on cohort studies.

In addition, in a case–control study one selects subjects based on the presence or absence of the disease of interest, and then investigates the prevalence of the exposure of interest in each study group. This is in contrast to a cohort study, in which one selects subjects based on the presence or absence of an exposure, and then studies whether or not the disease of interest develops in each group. Therefore, the fourth variable to be specified for a case–control study is the expected prevalence of the exposure in the undiseased control group, rather than the incidence of the disease of interest in the unexposed control group of a cohort study.

Finally, analogous to the consideration in cohort studies of the ratio of the number of unexposed control subjects to the number of exposed study subjects, one needs to consider in a case–control study the ratio of the number of undiseased control subjects to the number of diseased study subjects. The principles in deciding upon the appropriate ratio to use are similar in both study designs. Again, there is rarely a reason to include a ratio greater than 3:1 or 4:1. For example, if one were to design a study with a two-tailed alpha of 0.05 to detect a relative risk of 2.0 for an exposure which occurs in 5% of the undiseased control group, a study with 516 diseased individuals and 516 controls would yield a power of 0.80, or an 80% chance of detecting a difference of that size. Studies with the same 516 diseased subjects and ratios of controls to cases of 1:1, 2:1, 3:1, 4:1, 5:1, 10:1, and 50:1 would result in statistical powers of 0.80, 0.889, 0.916, 0.929, 0.936, 0.949, and 0.959, respectively.

The formula for calculating sample sizes for a case–control study is similar to that for cohort studies (modified from [3]):

$$N = \frac{1}{(p-V)^2}\left[Z_{1-\alpha}\sqrt{\left(1+\frac{1}{K}\right)U(1-U)} + Z_{1-\beta}\sqrt{p(1-p)/K + V(1-V)}\right]^2$$

where R, α, β, $Z_{1-\alpha}$, and $Z_{1-\beta}$ are as earlier, p is the prevalence of the exposure in the control group, and K is the ratio of undiseased control subjects to diseased cases,

$$U = \frac{p}{K+1}\left[K + \frac{R}{1+p(R-1)}\right]$$

and

$$V = \frac{pR}{1+p(R-1)}$$

Again, a series of tables that provide sample sizes for case–control studies is presented in Appendix A. In Tables A9–A12, we have assumed an alpha (two-tailed) of 0.05, a beta of 0.1 (90% power), and control to case ratios of 1:1, 2:1, 3:1, and 4:1, respectively. Tables A13–A16 are similar, except they assume a beta of 0.2 (80% power). Each table presents the number of diseased subjects needed to detect any of a number of specified relative risks, for a number of specified exposure rates.

For example, what if again one wanted to investigate a new nonsteroidal anti-inflammatory drug that is about to be marketed, but premarketing data raised questions about possible hepatotoxicity? This time, however, one is attempting to use a case–control study design.

Again, depending upon the values chosen of alpha, beta, and so on, the sample sizes needed could differ markedly (see Table 4.3). For example, what if one wanted to design a study with one control (undiseased subject) per diseased subject, assuming an alpha (two-tailed) of 0.05 and a beta of 0.1? The sample size needed to detect a relative risk of 2.0 for any disease would vary, depending upon the prevalence of use of the drug being studied. If one optimistically assumed that the drug will be used nearly as commonly as ibuprofen, by perhaps 1% of the population, then one could look in Table A9 and see that it would require 3210 diseased subjects and an equal number of undiseased controls. If one were less concerned with missing a real association, even if it existed, one could opt for a beta of 0.2, and the required sample size would drop to 2398 (see Table 4.3 and Table A13). If one wanted to minimize the number of diseased subjects needed for the study, one could include up to four controls for each diseased subject (Table 4.3 and Table A16). This would result in a sample size of 1370, with four times as many controls. Finally, if one considered it inconceivable that this new drug could *protect* against liver disease, then one might use a one-tailed alpha, resulting in a somewhat lower sample size of 1096, again with four times as many controls. Much smaller sample sizes are needed to detect relative risks of 4.0 or greater and are also presented in Table 4.3.

In contrast, what if one's estimates of the new drug's sales were more conservative? If one wanted to detect a relative risk of 2.0 assuming sales to 0.1% of the population, perhaps similar to tolmetin, then 31 588 subjects would be needed in each group, assuming a two-tailed alpha of 0.05, a beta of 0.1, and one control per diseased subject. In contrast, if one estimated the drug would be used in only 0.01% of the population (i.e., in controls without the study disease of interest), perhaps like phenylbutazone, one would need 315 373 subjects in each study group.

Obviously, case–control studies can require very large sample sizes to study relatively uncommonly used drugs. In addition, each disease of interest requires a separate case group and, thereby, a separate study. As such, as described in Chapter 3, studies of uncommonly used drugs and newly marketed drugs are usually better done using cohort study designs, whereas studies of rare diseases are better done using case–control designs.

Sample Size Calculations for Case Series

As described in Chapter 3, the utility of case series in pharmacoepidemiology is limited, as the absence of a control group makes causal inference difficult. Despite this, however, this is a design that has been used repeatedly. There are scientific questions that can be addressed using this design, and the collection of a control group equivalent in size to the case series would add considerable cost to the study. Case series are usually used in pharmacoepidemiology to quantitate better the incidence of a particular disease in patients exposed to a newly marketed drug. For example, in the "Phase IV" postmarketing drug surveillance study conducted for prazosin, the investigators collected a case series of 10 000 newly exposed subjects recruited through the manufacturer's sales force, to quantitate better the incidence of first-dose syncope, which was a well-recognized adverse effect of this drug [5,6]. Case series are normally used to determine whether a disease occurs more frequently than some predetermined incidence in exposed patients. Most often, the predetermined incidence of interest is zero, and one is looking for any occurrences of an extremely rare illness. As another example, when cimetidine was first marketed, there was concern over whether it could cause agranulocytosis, since it was closely related chemically to metiamide,

Table 4.3 Examples of sample sizes needed for a case–control study.

Hypothetical drug	Prevalence rate assumed in undiseased	Alpha	Beta	Odds ratio to be detected	Control : case ratio	Sample size needed in case group	Sample size needed in control group
Ibuprofen	0.01	0.05 (2-tailed)	0.1	2	1	3210	3210
	0.01	0.05 (2-tailed)	0.2	2	1	2398	2398
	0.01	0.05 (2-tailed)	0.2	2	4	1370	5480
	0.01	0.05 (1-tailed)	0.2	2	4	1096	4384
	0.01	0.05 (2-tailed)	0.1	4	1	601	601
	0.01	0.05 (2-tailed)	0.2	4	1	449	449
	0.01	0.05 (2-tailed)	0.2	4	4	234	936
	0.01	0.05 (1-tailed)	0.2	4	4	190	760
Tolmetin	0.001	0.05 (2-tailed)	0.1	2	1	31 588	31 588
	0.001	0.05 (2-tailed)	0.2	2	1	23 596	23 596
	0.001	0.05 (2-tailed)	0.2	2	4	13 449	53 796
	0.001	0.05 (1-tailed)	0.2	2	4	10 765	43 060
	0.001	0.05 (2-tailed)	0.1	4	1	5856	5856
	0.001	0.05 (2-tailed)	0.2	4	1	4375	4375
	0.001	0.05 (2-tailed)	0.2	4	4	2266	9064
	0.001	0.05 (1-tailed)	0.2	4	4	1840	7360
Phenylbutazone	0.0001	0.05 (2-tailed)	0.1	2	1	315 373	315 373
	0.0001	0.05 (2-tailed)	0.2	2	1	235 579	235 579
	0.0001	0.05 (2-tailed)	0.2	2	4	134 240	536 960
	0.0001	0.05 (1-tailed)	0.2	2	4	107 455	429 820
	0.0001	0.05 (2-tailed)	0.1	4	1	58 409	58 409
	0.0001	0.05 (2-tailed)	0.2	4	1	43 631	43 631
	0.0001	0.05 (2-tailed)	0.2	4	4	22 585	90 340
	0.0001	0.05 (1-tailed)	0.2	4	4	18 342	73 368

another H-2 blocker, which had been removed from the market in Europe because it caused agranulocytosis. This study also collected 10 000 subjects. It found only two cases of neutropenia, one in a patient who was also receiving chemotherapy. There were no cases of agranulocytosis [7].

To establish drug safety, a study must include a sufficient number of subjects to detect an elevated incidence of a disease, if it exists. Generally, this is calculated by assuming that the frequency of the event in question is vanishingly small, so that the occurrence of the event follows a Poisson distribution, and then one generally calculates 95% confidence intervals around the observed results.

Table A17 in the Appendix is useful for making this calculation [8]. In order to apply this table, one first calculates the incidence rate observed from the study's results; that is, the

number of subjects who develop the disease of interest during the specified time interval, divided by the total number of individuals in the population at risk. For example, if three cases of liver disease were observed in a population of 1000 patients exposed to a new nonsteroidal anti-inflammatory drug during a specified period of time, the incidence would be 0.003. The number of subjects who develop the disease is the "Observed number on which estimate is based (n)" in Table A17. In this example, it is 3. The lower boundary of the 95% confidence interval for the incidence rate is then the corresponding "Lower limit factor (L)" multiplied by the observed incidence rate. In this example, it would be 0.206 × 0.003 = 0.000618. Analogously, the upper boundary would be the product of the corresponding "Upper limit factor (U)" multiplied by the observed incidence rate. In the example, this would be 2.92 × 0.003 = 0.00876. In other words, the incidence rate (95% confidence interval) would be 0.003 (0.000618–0.00876). Thus, the best estimate of the incidence rate would be 30 per 10 000, but there is a 95% chance that it lies between 6.18 per 10 000 and 87.6 per 10 000.

In addition, a helpful simple guide is the so-called rule of threes, useful in the common situation where no events of a particular kind are observed [8]. Specifically, if no events of a particular type (i.e., the events of interest to the study) are observed in a study of X individuals, then one can be 95% certain that the event occurs no more often than 3/X. For example, if 500 patients are studied prior to marketing a drug, then one can be 95% certain that any event which does not occur in any of those patients may occur with a frequency of 3 or less in 500 exposed subjects, or that it has an incidence rate of less than 0.006. If 3000 subjects are exposed prior to drug marketing, then one can be 95% certain that any event which does not occur in this population may occur in no more than 3 in 3000 subjects, or the event has an incidence rate of less than 0.001. Finally, if 10 000 subjects are studied in a postmarketing drug surveillance study, then one can be 95% certain that any events which are not observed may occur in no more than 3 in 10 000 exposed individuals, or that they have an incidence rate of less than 0.0003. In other words, events not detected in the study may occur less often than in 1 in 3333 subjects in the general population.

Discussion

The discussions about sample size determinations in cohort and case–control studies assume that one is able to obtain information on each of the five variables that factor into these sample size calculations. Is this realistic? Four of the variables are, in fact, totally in the control of the investigators, subject to their specification: alpha, beta, the ratio of control subjects to study subjects, and the minimum relative risk to be detected. Only one of the variables requires data derived from other sources. For cohort studies, this is the expected incidence of the disease in the unexposed control group. For case–control studies, it is the expected prevalence of the exposure in the undiseased control group. In considering this needed information, it is important to realize that the entire process of sample size calculation is approximate, despite its mathematical sophistication. There is certainly no compelling reason why an alpha should be 0.05, as opposed to 0.06 or 0.04. The other variables specified by the investigators are similarly arbitrary. As such, only an approximate estimate is needed for this missing variable. Often the needed information is readily available from some existing data source, for example vital statistics or commercial drug utilization data sources. If not, one can search the medical literature for one or more studies that have collected these data for a defined population, either deliberately or as a by-product of their data-collecting effort, and assume that the population one will study will be similar. If this is not an

appropriate assumption, or if no such data exist in the medical literature, one is left with two alternatives. The first, and better, alternative is to conduct a small pilot study within one's population, in order to measure the information one needs. The second is simply to guess. In the second case, one should consider what a reasonable higher guess and a reasonable lower guess might be as well, to see if the sample size should be increased to take into account the imprecision of the estimate.

Finally, what if one is studying multiple outcome variables (in a cohort study) or multiple exposure variables (in a case–control study), each of which differs in the frequency one expects in the control group? In that situation, an investigator might base the study's sample size on the variable that leads to the largest requirement, and note that the study will have even more power for the other outcome (or exposure) variables. Regardless, it is usually better to have a somewhat larger sample size than the minimum, to allow some leeway if any of the underlying assumptions were wrong. This also will permit subgroup analyses with adequate power. In fact, if there are important subgroup analyses that represent *a priori* hypotheses that one wants to be able to evaluate, one should perform separate sample size calculations for those subgroups. In this situation, one should use the incidence of disease or prevalence of exposure that occurs in the subgroups, not that which occurs in the general population.

Note that sample size calculation is often an iterative process. There is nothing wrong with performing an initial calculation, realizing that it generates an unrealistic sample size, and then modifying the underlying assumptions accordingly. What is important is that investigators examine their final assumptions closely, asking whether, given the compromises made, the study is still worth undertaking.

Note also that this discussion was restricted to sample size calculations for dichotomous variables; that is, variables with only two options: a study subject either has a disease or does not have a disease. Information was not presented on sample size calculations for continuous outcome variables; that is, variables that have some measurement, such as height, weight, blood pressure, or serum cholesterol. Overall, the use of a continuous variable as an outcome variable, unless the measurement is extremely imprecise, will result in a marked increase in the power of a study. Details about this are omitted because epidemiologic studies unfortunately do not usually have the luxury of using such variables. Readers who are interested in more information on this can consult a textbook of sample size calculations [9].

All of the previous discussions have focused on calculating a minimum necessary sample size. This is the usual concern. However, two other issues specific to pharmacoepidemiology are important to consider as well. First, one of the main advantages of postmarketing pharmacoepidemiologic studies is the increased sensitivity to rare adverse reactions that can be achieved, by including a sample size larger than that used prior to marketing. Since between 500 and 3000 patients are usually studied before marketing, most pharmacoepidemiologic cohort studies are designed to include at least 10 000 exposed subjects. The total population from which these 10 000 exposed subjects would be recruited would need to be very much larger, of course. Case–control studies can be much smaller, but generally need to recruit cases and controls from a source population of equivalent size as for cohort studies. These are not completely arbitrary figures, but are based on the principles described in this chapter, applied to the questions which remain of great importance to address in a postmarketing setting. Nevertheless, these figures should not be rigidly accepted, but should be reconsidered for each specific study. Some studies will require fewer subjects, many will require more. To accumulate these sample sizes while performing cost-effective studies, several special techniques have

been developed, which are described in Part III of this book.

Second, because of the development of these new techniques and the development of large electronic data systems (see Part IIIb), pharmacoepidemiologic studies have the potential for the relatively unusual problem of *too large* a sample size. It is even more important than usual, therefore, when interpreting the results of studies that use these data systems, to examine their findings, differentiating clearly between statistical significance and clinical significance. With a very large sample size, one can find statistically significant differences that are clinically trivial. In addition, it must be kept in mind that subtle findings, even if statistically and clinically important, could easily have been created by biases or confounders (see Chapter 3). Subtle findings should not be ignored, but should be interpreted with caution.

When Should One Perform Pharmacoepidemiologic Studies?

Brian L. Strom

Rutgers Biomedical and Health Sciences, Newark, NJ, USA

As discussed in the previous chapters, pharmacoepidemiologic studies apply the techniques of epidemiology to the content area of clinical pharmacology. This chapter will review when pharmacoepidemiologic studies should be performed. It will begin with a discussion of the various reasons why one might perform pharmacoepidemiologic studies. Central to many of these is one's willingness to tolerate risk. Whether one's perspective is that of a manufacturer, regulator, academician, or clinician, one needs to consider the risk of adverse reactions that one considers tolerable. Thus, the chapter will continue with a discussion of the difference between safety and risk. It will conclude with a discussion of the determinants of one's tolerance of risk.

Reasons to Perform Pharmacoepidemiologic Studies

The decision to conduct a pharmacoepidemiologic study can be viewed as similar to the regulatory decision about whether to approve a drug for marketing or the clinical decision about whether to prescribe a drug. In each case, decision-making involves weighing the costs and risks of a therapy against its benefits.

The main costs of a pharmacoepidemiologic study are obviously the costs (monetary, effort, time) of conducting the study itself. These costs clearly will vary, depending on the questions posed and the approach chosen to answer them. Generally, the cost per patient in a postmarketing study, with the exception of postmarketing randomized clinical trials, is likely to be at least an order of magnitude less than the cost of a premarketing study. Other costs to consider are the opportunity costs of other research that might be left undone if this research is performed.

One risk of conducting a pharmacoepidemiologic study is the possibility that it could identify an adverse outcome as associated with the drug under investigation when in fact the drug does not cause this adverse outcome. Another risk is that it could provide false reassurances about a drug's safety. Both these risks can be minimized by appropriate study designs, skilled researchers, and appropriate and responsible interpretation of the results obtained.

The benefits of pharmacoepidemiologic studies could be conceptualized in four different categories: regulatory, marketing, clinical, and

Pharmacoepidemiology, Sixth Edition. Edited by Brian L. Strom, Stephen E. Kimmel and Sean Hennessy.

legal (see Table 5.1). Each will be of importance to different organizations and individuals involved in deciding whether to initiate a study. Any given study will usually be performed for several of these reasons, which will be discussed in turn.

Regulatory

Perhaps the most obvious and compelling reason to perform a postmarketing pharmacoepidemiologic study is regulatory: a plan for a postmarketing pharmacoepidemiologic study is required before the drug will be approved for marketing. Requirements for postmarketing research have become progressively more frequent in recent years. For example, in the 1970s the US Food and Drug Administration (FDA) required postmarketing research at the time of approval for about one third of drugs, a requirement which increased to over 70% in the 1990s [1]. Many of these required studies have been randomized clinical trials, designed to clarify residual questions about a drug's efficacy. Others focus on questions of drug toxicity. Often it is unclear whether the pharmacoepidemiologic study was undertaken in response to a regulatory requirement or in response to merely a "suggestion" by the regulator, but the effect is essentially the same. Early examples of studies conducted to address regulatory questions include the "Phase IV" cohort studies performed of cimetidine [2] and prazosin [3], discussed in Chapters 1 and 3. Now that the FDA has the authority to require such studies, such requirements are becoming more common.

Sometimes a manufacturer may offer to perform a pharmacoepidemiologic study with the hope that the regulatory agency might thereby expedite drug approval. If the agency believed that any new serious problem would be detected rapidly and reliably after marketing, it could feel more comfortable about releasing the drug sooner. Although it is difficult to assess the impact of volunteered postmarketing studies on regulatory decisions, the very large economic impact of an earlier approval has motivated some manufacturers to initiate such studies. In addition, in recent years regulatory authorities have occasionally released a particularly important drug after essentially only Phase II testing,

Table 5.1 Reasons to perform pharmacoepidemiologic studies.

- A) Regulatory
  - 1) Required
  - 2) To obtain earlier approval for marketing
  - 3) As a response to question by regulatory agency
  - 4) To assist application for approval for marketing elsewhere
- B) Marketing
  - 1) To assist market penetration by documenting the safety of the drug
  - 2) To increase name recognition
  - 3) To assist in repositioning the drug
    - a) Different outcomes, e.g., quality of life and economic
    - b) Different types of patients, e.g., the elderly
    - c) New indications
    - d) Less restrictive labeling
  - 4) To protect the drug from accusations about adverse effects
- C) Legal
  - 1) In anticipation of future product liability litigation
- D) Clinical
  - 1) Hypothesis testing
    - a) Problem hypothesized on the basis of drug structure
    - b) Problem suspected on the basis of preclinical or premarketing human data
    - c) Problem suspected on the basis of spontaneous reports
    - d) Need to better quantitate the frequency of adverse reactions
  - 2) Hypothesis generating – need depends on:
    - a) whether it is a new chemical entity
    - b) the safety profile of the class
    - c) the relative safety of the drug within its class
    - d) the formulation
    - e) the disease to be treated, including:
      - i) its duration
      - ii) its prevalence
      - iii) its severity
      - iv) whether alternative therapies are available

with the understanding that additional data would be gathered during postmarketing testing. For example, zidovudine was released for marketing after only limited testing, and not until later were additional data gathered on both safety and efficacy, data which indicated, among other things, that the doses initially recommended were too large [4].

Some postmarketing studies of drugs arise in response to case reports of adverse reactions reported to the regulatory agency. One response to such a report might be to suggest a labeling change. Often a more appropriate response, clinically and commercially, would be to propose a pharmacoepidemiologic study. This study would explore whether this adverse event in fact occurs more often in those exposed to the drug than would have been expected in the absence of the drug and, if so, how large is the increased risk of the disease. As an example, a Medicaid database was used to study hypersensitivity reactions to tolmetin [5], following reports about this problem to the FDA's Spontaneous Reporting System [6].

Finally, drugs are obviously marketed at different times in different countries. A postmarketing pharmacoepidemiologic study conducted in a country which marketed a drug relatively early could be useful in demonstrating the safety of the drug to regulatory agencies in countries which have not yet permitted its marketing. This is becoming increasingly feasible, as both the industry and the field of pharmacoepidemiology are becoming more international, and regulators are collaborating more.

Marketing

As will be discussed later in this chapter, pharmacoepidemiologic studies are performed primarily to obtain the answers to clinical questions. However, it is clear that a major underlying reason for some pharmacoepidemiologic studies is the potential marketing impact of those answers. In fact, some companies make the marketing branch of the company responsible for pharmacoepidemiology, rather than the medical branch.

Because of the known limitations in the information available about the effects of a drug at the time of its initial marketing, many physicians are appropriately hesitant to prescribe a drug until a substantial amount of experience in its use has been gathered. A formal postmarketing surveillance study can speed that process, as well as clarify advantages or disadvantages a drug has compared to its competitors.

A pharmacoepidemiologic study can also be useful to improve product name recognition. The fact that a study is underway will often be known to prescribers, as will its results once it is publicly presented and published. This increased name recognition will presumably help sales. An increase in a product's name recognition is likely to result particularly from pharmacoepidemiologic studies that recruit subjects for the study via prescribers. However, while this technique can be useful in selected situations, it is extremely expensive and less likely to be productive of scientifically useful information than most other alternatives available. In particular, the conduct of a purely marketing exercise under the guise of a postmarketing surveillance study, not designed to collect useful scientific information, is to be condemned [7]. It is misleading and could endanger the performance of future scientifically useful studies, by resulting in prescribers who are disillusioned and, thereby, reluctant to participate in future studies.

Pharmacoepidemiologic studies can also be useful to reposition a drug that is already on the market; that is, to develop new markets for the drug. One could explore different types of outcomes resulting from the use of the drug for the approved indication, for example the impact of the drug on the cost of medical care (see Chapter 34) and on patients' quality of life (see Chapter 42). One could also explore the use of the drug for the approved indication in types of patients other than those included in premarketing studies, for example in children, in the

elderly, or in patients with multiple comorbidities and/or taking many concomitant medications. By exploring unintended beneficial effects, or even drug efficacy (see Chapter 33), one could obtain clues to and supporting information for new indications for drug use. Finally, whether because of questions about efficacy or questions about toxicity, drugs are sometimes approved for initial marketing with restrictive labeling. For example, bretylium was initially approved for marketing in the US only for the treatment of life-threatening arrhythmias. Approval for more widespread use requires additional data. These data can often be obtained from pharmacoepidemiologic studies.

Finally, and perhaps most importantly, pharmacoepidemiologic studies can be useful to protect the major investment made in developing and testing a new drug. When a question arises about a drug's toxicity, it often needs an immediate answer, or else the drug may lose market share or even be removed from the market. Immediate answers are often unavailable, unless the manufacturer had the foresight to perform pharmacoepidemiologic studies in anticipation of this problem. Sometimes these problems can be specifically foreseen and addressed. More commonly, they are not. However, the availability of an existing cohort of exposed patients and a control group will often allow a much more rapid answer than would have been possible if the study had to be conducted *de novo*. One example of this is provided by the experience of Pfizer Pharmaceuticals, when the question arose about whether piroxicam (Feldene®) was more likely to cause deaths in the elderly from gastrointestinal bleeding than the other nonsteroidal anti-inflammatory drugs. Although Pfizer did not fund studies in anticipation of such a question, it was fortunate that several pharmacoepidemiologic research groups had data available on this question because of other studies that they had performed [8]. McNeil was not as fortunate when questions were raised about anaphylactic reactions caused by zomepirac. If the data it eventually was able to have [9] had been available at the time of the crisis, they might not have removed the drug from the market. Later, Syntex recognized the potential benefit, and the risk, associated with the marketing of parenteral ketorolac, and chose to initiate a postmarketing surveillance cohort study at the time of the drug's launch [10–12]. Indeed, the drug was accused of multiple different adverse outcomes, and it was only the existence of this study, and its subsequently published results, that saved the drug in its major markets.

Legal

Postmarketing surveillance studies can theoretically be useful as legal prophylaxis, in anticipation of eventually having to defend against product liability suits (see Chapter 9). One often hears the phrase "What you don't know, won't hurt you." However, in pharmacoepidemiology this view is shortsighted and, in fact, very wrong. All drugs cause adverse effects; the regulatory decision to approve a drug and the clinical decision to prescribe a drug both depend on a judgment about the relative balance between the benefits of a drug and its risks. From a legal perspective, to win a product liability suit using a legal theory of negligence, a plaintiff must prove causation, damages, and negligence. A pharmaceutical manufacturer that is a defendant in such a suit cannot change whether its drug causes an adverse effect. If the drug does, this will presumably be detected at some point. The manufacturer also cannot change whether the plaintiff suffered legal damages from the adverse effect; that is, whether the plaintiff suffered a disability or incurred expenses resulting from a need for medical attention. However, even if the drug did cause the adverse outcome in question, a manufacturer certainly could document that it was performing state-of-the-art studies to attempt to detect whatever toxic effects the drug had. In addition, such studies could make easier the

defense of totally groundless suits, in which a drug is blamed for producing adverse reactions it does not cause.

Clinical

Hypothesis Testing

The major reason for most pharmacoepidemiologic studies is hypothesis testing. The hypotheses to be tested can be based on the structure or the chemical class of a drug. For example, the cimetidine study mentioned earlier [2] was conducted because cimetidine was chemically related to metiamide, which had been removed from the market in Europe because it caused agranulocytosis. Alternatively, hypotheses can also be based on premarketing or postmarketing animal or clinical findings. For example, the hypotheses can come from spontaneous reports of adverse events experienced by patients taking the drug in question. The tolmetin [5], piroxicam [8], zomepirac [9], and ketorolac [10–12] questions mentioned are all examples of this. Finally, an adverse effect may clearly be due to a drug, but a study may be needed to quantitate its frequency. An example would be the postmarketing surveillance study of prazosin, performed to quantitate the frequency of first-dose syncope [3]. Of course, the hypotheses to be tested can involve beneficial drug effects as well as harmful drug effects, subject to some important methodologic limitations (see Chapter 33).

Hypothesis Generating

Hypothesis-generating studies are intended to screen for previously unknown and unsuspected drug effects. In principle, all drugs could, and perhaps should, be subjected to such studies. However, some drugs may require these studies more than others. This has been the focus of a formal study, which surveyed experts in pharmacoepidemiology [13].

For example, it is generally agreed that new chemical entities are more in need of study than what are called "me too" drugs. This is because the lack of experience with related drugs makes it more likely that the new drug has possibly important, unsuspected effects.

The safety profile of the class of drugs should also be important to the decision about whether to conduct a formal screening postmarketing surveillance study for a new drug. Previous experience with other drugs in the same class can be a useful predictor of what the experience with the new drug in question is likely to be. For example, with the finding that troglitazone had an increased risk of liver disease [14], that became a concern as well with the later thiazolidinediones, pioglitazone and rosiglitazone [15]. Similarly, with the finding that rofecoxib was associated with myocardial infarction, that became a concern as well with celecoxib [16].

The relative safety of the drug within its class can also be helpful. A drug that has been studied in large numbers of patients before marketing and appears safe relative to other drugs within its class is less likely to need supplementary postmarketing surveillance studies. An extension of this approach, of course, is comparative effectiveness research (see Chapter 26).

The formulation of the drug can be considered a determinant of the need for formal screening pharmacoepidemiologic studies. A drug that will, because of its formulation, be used mainly in institutions, where there is close supervision, may be less likely to need such a study. When a drug is used under these conditions, any serious adverse effect is likely to be detected, even without any formal study.

The disease to be treated is an important determinant of whether a drug needs additional postmarketing surveillance studies. Drugs used to treat chronic illnesses are likely to be used for a long period of time. As such, it is important to know their long-term effects. This cannot be addressed adequately in the relatively brief time available for each premarketing study. Also, drugs used to treat common diseases are important to study, as many patients are likely to be exposed to them. Drugs used to treat mild or

self-limited diseases need careful study too, because serious toxicity is less acceptable. This is especially true for drugs used by healthy individuals, such as contraceptives. On the other hand, when one is using a drug to treat individuals who are very ill, one is more tolerant of toxicity, assuming the drug is efficacious.

Finally, it is important to know whether alternative therapies are available. If a new drug is not a major therapeutic advance, since it will be used to treat patients who would have been treated with the old drug, one needs to be more certain of its relative advantages and disadvantages. The presence of significant adverse effects, or the absence of beneficial effects, is less likely to be tolerated for a drug that does not represent a major therapeutic advance.

Safety versus Risk

Clinical pharmacologists are used to thinking about drug "safety": the statutory standard that must be met before a drug is approved for marketing in the US is that it needs to be proven to be "safe and effective under conditions of intended use." It is important, however, to differentiate safety from risk. Virtually nothing is without some risks. Even staying in bed is associated with a risk of acquiring bed sores! Certainly no drug is completely safe. Yet, the unfortunate misperception by the public persists that drugs mostly are and should be without any risk at all. Use of a "safe" drug, however, still carries some risk. It would be better to think in terms of *degrees of safety*. Specifically, a drug "is safe if its risks are judged to be acceptable" [17]. Measuring risk is an objective but probabilistic pursuit. A judgment about safety is a personal and/or social value judgment about the acceptability of that risk. Thus, assessing safety requires two extremely different kinds of activities: measuring risk and judging the acceptability of those risks [17]. The former is the focus of much of pharmacoepidemiology and most of this book. The latter is the focus of the following discussion. More detail is presented in Chapter 39.

Risk Tolerance

Whether or not to conduct a postmarketing surveillance pharmacoepidemiologic study also depends on one's willingness to tolerate risk. From a manufacturer's perspective, one can consider this risk in terms of the risk of a potential regulatory or legal problem that may arise. Whether one's perspective is that of a manufacturer, regulator, academician, or clinician, one needs to consider the risk of adverse reactions that one is willing to accept as tolerable. There are several factors that can affect one's willingness to tolerate the risk of adverse effects from drugs (see Table 5.2). Some of these factors are related to the adverse outcome being studied. Others are related to the exposure and the setting in which the adverse outcome occurs.

Features of the Adverse Outcome

The severity and reversibility of the adverse reaction in question are of paramount importance to its tolerability. An adverse reaction that is severe is much less tolerable than one that is mild, even at the same incidence. This is especially true for adverse reactions that result in permanent harm, for example birth defects or death.

Another critical factor that affects the tolerability of an adverse outcome is the frequency of the adverse outcome in those who are exposed. Notably, this is *not* a question of the relative risk of the disease due to the exposure, but a question of the excess risk attributed to the drug of interest (see Chapter 3). Use of tampons is extraordinarily strongly linked to toxic shock: prior studies have shown relative risks of between 10 and 20. However, toxic shock is sufficiently uncommon that even a 10- to 20-fold increase in the risk of the disease still contributes an

Table 5.2 Factors affecting the acceptability of risks.

A) Features of the adverse outcome
1) Severity
2) Reversibility
3) Frequency
4) "Dread disease"
5) Immediate versus delayed
6) Occurs in all people vs. just in sensitive people
7) Known with certainty or not
B) Characteristics of the exposure
1) Essential versus optional
2) Present vs. absent
3) Alternatives available
4) Risk assumed voluntarily
5) Drug use will be as intended vs. misuse is likely
C) Perceptions of the evaluator

extraordinarily small excess risk of toxic shock syndrome in those who use tampons [18].

In addition, the particular disease caused by the drug is important to one's tolerance of its risks. Certain diseases are considered by the public to be "dread diseases," those that generate more fear and emotion than others. Examples are AIDS and cancer. It is less likely that the risk of a drug will be considered acceptable if it causes one of these diseases.

Another relevant factor is whether the adverse outcome is immediate or delayed. Most individuals are less concerned about delayed risks than immediate risks. This is one of the factors that have probably slowed the success of antismoking efforts. In part this is a function of denial; delayed risks seem as if they may never occur. In addition, the economic concept of "discounting" plays a role here. An adverse event in the future is less bad than the same event today, and a beneficial effect today is better than the same beneficial effect in the future. Something else may occur between now and then that could make that delayed effect irrelevant or, at least, mitigate its impact. Thus, a delayed adverse event may be worth incurring if it can bring about beneficial effects today.

It is also important whether the adverse outcome is a type A reaction or a type B reaction. As described in Chapter 1, type A reactions are the result of an exaggerated but otherwise usual pharmacologic effect of a drug. Type A reactions tend to be common, but they are dose related, predictable, and less serious. In contrast, type B reactions are aberrant effects of a drug. Type B reactions tend to be uncommon, are not related to dose, and are potentially more serious. They may be due to hypersensitivity reactions, immunologic reactions, or some other idiosyncratic reaction to the drug. Regardless, type B reactions are the more difficult to predict or even detect. If one can predict an adverse effect, then one can attempt to prevent it. For example, in order to prevent aminophylline-induced arrhythmias and seizures, one can begin therapy at lower doses and follow serum levels carefully. For this reason, all other things being equal, type B reactions are usually considered less tolerable.

Finally, the acceptability of a risk also varies according to how well established it is. The same adverse effect is obviously less tolerable if one knows with certainty that it is caused by a drug than if it is only a remote possibility.

Characteristics of the Exposure

The acceptability of a risk is very different depending upon whether an exposure is essential or optional. Major adverse effects are much more acceptable when one is using a therapy that can save or prolong life, such as chemotherapy for malignancies. On the other hand, therapy for self-limited illnesses must have a low risk to be acceptable. Pharmaceutical products intended for use in healthy individuals, such as vaccines and contraceptives, must be exceedingly low in risk to be considered acceptable.

The acceptability of a risk is also dependent on whether the risk is from the presence of a treatment or its absence. One could conceptualize deaths from a disease that can be treated by

a drug that is not yet on the market as an adverse effect from the absence of treatment. For example, the six-year delay in introducing beta-blockers into the US market has been blamed for resulting in more deaths than all recent adverse drug reactions combined [19]. As a society, we are much more willing to accept risks of this type than risks from the use of a drug that has been marketed prematurely. Physicians are taught *primum non nocere* – first do no harm. This is somewhat analogous to our willingness to allow patients with terminal illnesses to die from these illnesses without intervention, while it would be considered unethical and probably illegal to perform euthanasia. In general, we are much more tolerant of sins of omission than sins of commission.

Whether any alternative treatments are available is another determinant of the acceptability of risks. If a drug is the only available treatment for a disease, particularly a serious disease, then greater risks will be considered acceptable. This was the reason zidovudine was allowed to be marketed for the treatment of AIDS, despite its toxicity and the limited testing that had been performed [4]. Analogously, studies of toxic shock syndrome associated with the use of tampons were of public health importance, despite the infrequency of the disease, because consumers could choose among other available tampons that were shown to carry different risks [18].

Whether a risk is assumed voluntarily is also important to its acceptability. We are willing to accept the risk of death in automobile accidents more than the much smaller risk of death in airline accidents, because we control and understand the former and accept the attendant risk voluntarily. Some people even accept the enormous risks of death from tobacco-related disease, but would object strongly to being given a drug that was a small fraction as toxic. In general, it is agreed that patients should be made aware of possibly toxic effects of drugs they are prescribed. When a risk is higher than it is with the usual therapeutic use of a drug, as with an invasive procedure or an investigational drug, one usually asks the patient for formal informed consent. The fact that fetuses cannot make voluntary choices about whether or not to take a drug contributes to the unacceptability of drug-induced birth defects.

Finally, from a societal perspective, one needs to be concerned about whether a drug will be and is used as intended or whether misuse is likely. Misuse, in and of itself, can represent a risk of the drug. For example, a drug is considered less acceptable if it is addicting and, so, is likely to be abused. In addition, the potential for overprescribing by physicians can decrease the acceptability of the drug. For example, in the controversy about birth defects from isotretinoin, there was no question that the drug was a powerful teratogen, and that it was a very effective therapy for serious cystic acne refractory to other treatments. There was no question either about its effectiveness for less severe acne. However, that effectiveness led to its widespread use, including in individuals who could have been treated with less toxic therapies, and a larger number of pregnancy exposures, abortions, and birth defects than otherwise would have occurred [20].

Perceptions of the Evaluator

Finally, much depends ultimately upon the perceptions of the individuals who are making the decision about whether a risk is acceptable. In the US, there have been more than a million deaths from traffic accidents over the past 30 years; tobacco-related diseases kill the equivalent of three jumbo jet loads every day; and 3000 children are born each year with embryopathy from their mothers' use of alcohol in pregnancy [21]. Yet, these deaths are accepted with little concern, while the uncommon risk of an airplane crash or being struck by lightning generates fear. The decision about whether to allow isotretinoin to remain on the market hinged on whether the efficacy of the drug for a small number of people

who had a disease which was disfiguring but not life threatening was worth the birth defects that would result in some other individuals. There is no way to remove this subjective component from the decision about the acceptability of risks. Indeed, much more research is needed to elucidate patients' preferences in these matters. However, this subjective component is part of what makes informed consent so important. Most people feel that the final subjective judgment about whether an individual should assume the risk of ingesting a drug should be made by that individual, after education by their physician. However, as an attempt to assist that judgment, it is useful to have some quantitative information about the risks inherent in some other activities. Some such information is presented in Table 5.3.

Table 5.3 Annual risks of death from some selected hazards.

Hazard	Annual death rate (per 100 000 exposed individuals)
Heart disease (US, 1985)	261.4
Sport parachuting	190
Cancer (US, 1985)	170.5
Cigarette smoking (age 35)	167
Hang gliding (UK)	150
Motorcycling (US)	100
Power boat racing (US)	80
Cerebrovascular disease (US, 1985)	51
Scuba diving (US)	42
Scuba diving (UK)	22
Influenza (UK)	20
Passenger in motor vehicle (US)	16.7
Suicide (US, 1985)	11.2
Homicide (US, 1985)	7.5
Cave exploration (US)	4.5
Oral contraceptive user (age 25–34)	4.3
Pedestrian (US)	3.8
Bicycling (US)	1.1
Tornados (US)	0.2
Lightning (US)	0.05

Conclusion

This chapter reviewed when pharmacoepidemiologic studies should be performed. After beginning with a discussion of the various reasons why one might perform pharmacoepidemiologic studies, it reviewed the difference between safety and risk. It concluded with a discussion of the determinants of one's tolerance of risk. Now that it is hopefully clear when one might want to perform a pharmacoepidemiologic study, the next part of the book will provide perspectives on pharmacoepidemiology from some of the different fields that use it.

Part II

The Role of Pharmacoepidemiology in Different Sectors

6

The Role of Pharmacoepidemiology in the Healthcare System and Academia

Joshua J. Gagne and Jerry Avorn

Division of Pharmacoepidemiology and Pharmacoeconomics, Department of Medicine, Brigham and Women's Hospital and Harvard Medical School, Boston, MA, USA

Every year prescribers and patients have more medications at their disposal, each with its own efficacy, side effects, and cost. When a new drug is introduced, its benefit/risk relationship is often understood in only a preliminary way, as is its cost-effectiveness. This provides a limited perspective on how it ideally should be used. High-profile withdrawals of drugs for safety reasons, along with prominent warnings about widely used medications that remain on the market, have caused physicians, patients, and policymakers to become more aware of drug safety concerns. At the same time, healthcare systems all over the globe are struggling with how to provide the most appropriate care in the face of rising costs and increasingly tight fiscal constraints. Pharmacoepidemiology can serve as a key tool for helping to address all of these concerns. These issues are growing throughout the healthcare system, and particularly in academic medical centers.

Once a drug is approved for marketing, it enters a complex healthcare system in which its prescription, its use by patients, and its outcomes often go largely unassessed. Until recently, scant attention has been paid to systematic surveillance of these actions, except for the atypical settings of some integrated healthcare delivery systems. The prevailing view has been that after the US Food and Drug Administration (FDA) or comparable national authority approves a drug, it is used at the discretion of the clinician, with little formal follow-up of the appropriateness or consequences of such decisions. The problem is made more acute by the fact that many regulatory agencies purposely (and often by statute) do not base their approval decisions on a medication's clinical or economic value compared to similar products; often superiority over placebo is sufficient for a drug to be approved. In addition, it is generally no one's responsibility (other than the harried prescriber) to determine how faithfully patients are adhering to the prescribed regimen. Increasingly, more attention is being paid to assessing the outcomes of medication use on a population level, considering what its useful and harmful outcomes are when it is taken by hundreds, thousands, or even millions of patients rather than by single individuals in a clinical trial or in routine practice. It is now widely appreciated that some adverse events can be identified and their risk quantified only by observing a drug's use in large numbers of patients. The best perspective on the impact of a medication on the health of the public requires measuring those outcomes in the healthcare

Pharmacoepidemiology, Sixth Edition. Edited by Brian L. Strom, Stephen E. Kimmel and Sean Hennessy.

system itself, rather than for one person at a time. It is here that the insights of pharmacoepidemiology are playing an increasingly central role.

Driven by the pressures just noted, this situation is evolving, with growing appreciation of several important problems, each of which can be informed by the methods and tools of pharmacoepidemiology: (i) medications that seem acceptably safe on approval may prove to have important risks which were underappreciated at the time of approval; (ii) in typical practice, clinicians often make prescribing decisions that do not reflect the best evidence base or guideline recommendations; (iii) even this evidence base is often thinner than it should be because head-to-head comparisons of drug effectiveness or safety – either trial based or observational – have not been done [1]; (iv) as a result, inadequate information is available to inform decisions about which drugs work best, or most cost-effectively, for specific indications; and (v) patients frequently fail to take their medications as directed.

Pharmacoepidemiology is the core discipline required for a rigorous understanding of each of these areas, and to guide the development and evaluation of programs to address them. Many of these topics are discussed in detail in the chapters that follow; this chapter provides an overview of how the field and its methods can contribute to these larger themes in medical care delivery and health services research, from the perspective of academia.

The Drug Approval Process

Each national healthcare system must grapple with the following inherent paradox of pharmacology: a new therapy must be evaluated for approval when the available data on its benefits and harms are still modest. Yet, waiting until "all the evidence is in" can pose its own public health threat, if this prevents an important new treatment from being used by patients who need it. Since any medication that is effective is bound to have some adverse effect in some organ system in some patients at some doses, any approval must by definition be based on a judgment that a drug's efficacy is "worth it" in light of the known risks of the treatment. However, the trials conducted by a given drug manufacturer to win approval are often powered statistically (see Chapter 4) to demonstrate success for that single product in achieving a prespecified therapeutic endpoint. Especially when this is demonstration of superiority over placebo, and/or when the required endpoint is reaching a surrogate outcome – for example, a change in a laboratory test such as hemoglobin A1c or low-density lipoprotein (LDL) cholesterol – the number of subjects required for these exercises and the duration of the studies are often inadequate to reveal important safety problems if they are present. This is exacerbated by the extensive exclusion criteria for study participation, a particular problem for high-risk populations such as the frail elderly, pregnant women, and children (see also Chapter 22) [2].

As a result, additional methods need to be applied even to preapproval data to aggregate adverse events from multiple study populations to provide the power needed to assess safety. Meta-analysis (see Chapter 36) of adverse effects data from multiple preapproval trials represents the first opportunity to use these tools to inform the appropriate use of medications. This makes it possible to combine findings from different, smaller studies – many of them conducted before the drug in question was approved – to produce evidence of potential harm for drugs such as rofecoxib (cardiovascular harm) [3], rosiglitazone (myocardial infarction) [4], or the selective serotonin reuptake inhibitors (SSRIs) used in children (suicidality) [5].

These shortcomings of premarketing trials are likely to become even more salient as

regulators move toward alternative drug approval processes. The European Medicines Agency recently completed a pilot project to explore approval via adaptive pathways, which are intended to provide earlier and progressive patient access to new drugs. The US FDA maintains several expedited regulatory pathways. Postapproval monitoring of drugs approved through these pathways is even more critical, because safety information is more likely to emerge in the postmarketing setting for drugs approved by these pathways compared to conventional pathways [6,7]. In 2016 the US Congress enacted the 21st Century Cure Act, which included, among other sections, provisions that modify the data required for FDA approval. In particular, the law promotes the use of biomarkers and surrogate measures to support the approval of new drugs as well as "real-world evidence" from observational data to support supplemental indications for existing products [8]. As these new provisions are implemented, pharmacoepidemiology will have an even greater role in generating the real-world evidence for supplemental indications [9], and will be increasingly relied upon to evaluate the impact on clinical outcomes, both beneficial and harmful, of new drugs approved on less rigorous evidence.

Prescribing Practices

Once a drug has entered the healthcare delivery system, a growing literature documents several areas in which prescribing falls short of existing knowledge. These issues can also be elucidated using the tools of pharmacoepidemiology. First, and often neglected, is the issue of *underprescribing*. Studies of many important chronic diseases such as hypertension, hypercholesterolemia, and diabetes reveal that many patients with these conditions have not been diagnosed by their physicians, and, when they have, they are often not prescribed an adequate regimen to control their risks, or even any regimen at all [10]. Even with a database that includes only drug utilization information, pharmacoepidemiology makes it possible to achieve a good first approximation of the problem of undertreatment by measuring the age- and gender-adjusted prevalence of use of medications to manage specific chronic conditions by a given clinician, or a given practice or health system (see Chapter 18). When patterns of use are combined with other research on prescriber characteristics and decision-making, it becomes possible to identify more clearly when and how prescribing falls short, insights which can then be used to shape programs to improve care (see later discussion) [11].

When medications are used, there is good evidence that clinicians frequently do not prescribe regimens that are optimal, based on the available clinical evidence, or prescribe medications that may interact with other drugs a patient takes, or choose more expensive drugs when comparable generic preparations would work as well and be much more affordable. Pharmacoepidemiology makes it possible to assess the distribution of drugs used for a given indication by clinician, practice, or system, even if only drug utilization datasets are available, though it is necessary to take into account whether a given prescriber is a specialist who may see in referral most of the refractory patients cared for by colleagues.

When diagnostic data are also available, a more sophisticated approach can also take into account contraindications and compelling indications related to specific drug choices, to refine the assessment of the appropriateness of prescribing in an entire healthcare system, or for individual clinicians (see Chapter 19). Numerous studies have documented these shortfalls in several domains of care. For example, one study assessed all hypertension-related medication use and diagnoses in one large state-funded program of medications for the

elderly. The availability of clinical information made it possible to determine how well the regimen of each patient conformed to the recommendations of the then-current guidelines of the Joint National Committee (JNC) on Prevention, Detection, and Treatment of High Blood Pressure. This study found that a substantial proportion of treated hypertensive patients were not receiving a regiment consistent with JNC guidelines [12]. Often, such suboptimal prescribing involved omissions of an indicated class (e.g., angiotensin-converting enzyme inhibitors in patients with diabetes mellitus), or use of a calcium channel blocker when a beta-blocker would have been more appropriate (e.g., in a hypertensive patient who has had a myocardial infarction). Another analysis reviewed all clinical encounters of patients who had filled prescriptions for clopidogrel and found that about half did not have any evidence of conditions (such as coronary artery stenting) for which the drug had an approved indication, or any other evidence-based reasons for its use [13].

Moving up an additional level in database detail, more sophisticated health records systems are becoming available each year that integrate pharmacy data with information from clinical laboratories, electronic health records, registries, and sources of patient-reported information to measure the adequacy of use of cholesterol-lowering agents, diabetes drugs, antihypertensives, and other drugs. This makes it possible to assess the effectiveness of prescribing outcomes for a given clinician (or practice or system), by measuring how well target metrics such as normotension or goal LDL cholesterol or hemoglobin A1c are being achieved. In all these analyses, pharmacoepidemiology makes it possible to evaluate the appropriateness of medication use in selected populations, even if it cannot with certainty determine whether a given prescription in a particular patient was the best choice.

Evaluation of Patients' Use of Drugs in the Healthcare System

Even when a medication is appropriately prescribed, patients may underuse it or use it in unsafe ways. Underuse of needed drugs by patients is one of the most common medication-related problems, and one that can be readily identified by pharmacoepidemiology (see also Chapter 38) [14]. Although it is less striking than obvious drug-induced adverse events, underuse is probably responsible for at least as much morbidity and mortality, if not more. To be fully understood, this requires the kind of denominator-grounded population orientation of a pharmacoepidemiologic perspective, which is still lacking in many healthcare systems [15]. The clinical trialist or the treating physician focuses on patients who are assigned to receive a drug in a study, or who are prescribed a drug in practice, respectively. But by expanding the view to the larger population of people of which those study subjects or patients make up a subsample, the pharmacoepidemiologist can also take into account all those people with a particular diagnosis who are *not* taking a given drug or drug class, perhaps because their clinician did not prescribe treatment, or because the patient did not have access to the medication, or had stopped treatment because of side effects.

The failure of a patient to fill a prescribed medication has been described using various terms, each with its own sociocultural baggage. (In fact, even the word "failure" is loaded in this way.) The word *compliance* has been criticized because it is seen as depicting a master–subservient relationship between doctor and patient, implying that a "noncompliant" patient is engaging in a kind of misbehavior. Many prefer the term *adherence*, which is more neutral. *Persistence* refers to the degree to which a patient sticks with a prescribed regimen over time. *Intelligent nonadherence* (or intelligent noncompliance) describes a situation in which a patient stops a therapy because it is producing

excessively burdensome side effects or failing to relieve symptoms effectively. Until around 1990, the field of adherence research was understudied, and most clinicians assumed that after they wrote a prescription, a patient filled it and took it more or less as directed. Once large-scale computerized pharmacy claims datasets and the methods of pharmacoepidemiology made it possible to readily measure the prescription-filling behavior of large numbers of people, it became clear that this simple assumption was often false (see Chapter 38) [16,17].

Datasets based on the complete paid-claims files of drug benefit programs (see Chapter 12) provided the first means of studying adherence in defined populations. Because such a claim is usually necessary before the pharmacy can be paid, and because insured patients are unlikely to pay out of pocket to fill prescriptions outside the system, such datasets provide an excellent record of what medications are actually dispensed [18]. When such datasets are analyzed, a grim fact emerges: averaging across studies, about half of all medications prescribed for the treatment of chronic conditions such as hypercholesterolemia, elevated blood pressure, osteoporosis, glaucoma, and so on are not taken [19]. This causes a massive and still underappreciated shortfall – at both the clinical and public health levels – in the benefit that these regimens could generate in preventing myocardial infarction, strokes, fractures, or visual loss, respectively [20]. The full magnitude of this problem is still not completely appreciated by clinicians or policymakers.

Because many assessments of underuse are based on pharmacy-generated data on filled prescriptions, it is sometimes difficult to know whether nonuse of an indicated drug was the result of a failure of the patient to fill a prescription, or the failure of the clinician to write it. Electronic prescribing makes it possible to define this problem more precisely. As bad as the problem of low refill rates is, these newer analyses have made it clear that the situation is even worse [21]. One large study found that a fourth of initial prescriptions written electronically were never picked up at the pharmacy [22]. As a result, the approximately 50% rate of nonadherence seen over time in pharmacoepidemiologic datasets based on filled prescriptions is a best-case scenario, as it does not even take into account the additional millions of regimens that are not initiated by the patient. Terminology has evolved to define the two aspects of this problem: *secondary nonadherence* refers to the failure by a patient to continue to use a medication already begun; *primary nonadherence* occurs when a clinician writes a prescription that the patient does not even fill once. The magnitude of both primary and secondary nonadherence is substantial, and varies by drug class as well as by country [23–26].

These findings about adherence have implications for other aspects of pharmacoepidemiologic studies. First, they raise important concerns about the validity of large databases (such as the UK Clinical Practice Research Database and other electronic health record databases) that define drug exposure in terms of what a clinician prescribed, as opposed to what the patient actually obtained from the pharmacy (see Chapters 13 and 37). Second, the very high rates of nonuse in typical practice settings cast doubt on randomized trial-based assumptions about the clinical benefit, public health impact, and cost-effectiveness of many regimens in widespread use. This issue points up the value of the "real-world" analyses performed by pharmacoepidemiologists using data from typical practice settings (see Chapters 11–14).

Many pharmacoepidemiologic studies have attempted to identify risk factors for poor adherence, with the goal of helping prescribers to spot proactively which patients are likely to be nonadherent [27]. Yet this literature has identified remarkably few such predictors. High drug cost has been one, especially in patients without adequate pharmacy benefit insurance. Such studies have also demonstrated that

insured patients prescribed a higher-cost medication adhere less well to their regimens than those prescribed a lower-cost generic in the same therapeutic class [28,29]. Several studies have identified claims-based measures of patients' prior adherence to other medications as a strong predictor of their future adherence to a new medication, likely reflecting their general willingness or ability to adhere to prescribed treatments [30,31]. Another consistent risk factor has been race, suggesting an important problem in physician–patient communication and/or trust for nonwhite patients [32]. However, other variables such as physician characteristics, or patient age, level of education, or morbidity, have not consistently been found to be associated with poor medication adherence, making the management of this common problem even more difficult.

Assessment of the Quality and Outcomes of Medication Use in Populations

Much attention is now being paid to assessment of the outcomes of medication use in typical real-world populations. This perspective is based on the difference between *efficacy,* the effect of a medication in the rigorous but idealized setting of a clinical trial, and its *effectiveness,* a measure of its outcomes in typical practice settings (see Chapter 33). These often differ. For example, one important conventional randomized trial demonstrated convincingly that the addition of spironolactone to the regimen of patients with congestive heart failure substantially improved their clinical status and reduced mortality [33]. However, a population-based analysis later established that when these findings were applied in routine practice by typical physicians treating a much larger number of typical patients, there was a significant increase in hyperkalemia-associated morbidity and mortality [34]. By contrast, an analysis of prescribers' responses to a different study that provided new evidence about the optimal management of atrial fibrillation demonstrated a more positive change in practice [35].

Other "lost in translation" analyses document that despite overwhelming randomized trial evidence showing the efficacy of warfarin use in preventing stroke in patients with atrial fibrillation, population-based studies of older patients living in nursing homes revealed a surprisingly low prevalence of use of this therapy [36]. Such underuse was found to be associated with physicians' recent experience with adverse events caused by the drug [37], as well as by their perceptions of and attitudes to risks and benefits [38]. Other pharmacoepidemiologic studies of medication use in nursing homes have documented similar dramatically low use of other well-documented medications in these high-risk populations, such as drugs to treat osteoporosis, even in patients who have already had a hip fracture [39]. This kind of real-world population research can lay the foundation for enlightened interventions to address such nonuse, by taking on its underlying causes.

Pharmacoepidemiologic methods can also be used to track the diffusion of new medication classes into practice [40], as well as the reaction of practitioners in various settings to new information about the comparative benefits and risks of drugs, as in the case of warnings about the cardiovascular toxicity of rosiglitazone [41]. Acknowledging the gap between the characteristics of clinical trial participants and those who often use a medication in practice, methods are also being developed and applied to generalize trial results to more typical patient populations. For example, the newer oral anticoagulant, dabigatran, was approved on the basis of a large randomized trial comparing it to warfarin, an older oral anticoagulant. A simulation-based approach was used to assess how the comparative benefits and risks would translate to cohorts of patients who use these drugs outside of the

randomized trial and in usual routine care [42]. Such an approach preserves the strengths of the randomized trial, but makes the results more useful to patients and clinicians.

Policy Analysis

Usually, policy changes are implemented in the healthcare system with no systematic plans for their evaluation, and no follow-up studies of their impact; this can be hyperbolically but poignantly characterized as a form of large-scale, sloppy human experimentation without informed consent. Such changes in benefit design are often applied to medication use. However, even if a policy is changed in a way that does not anticipate an evaluation, population-based observational studies after the fact can still yield important conclusions concerning its effects, both good and bad. For example, when the Canadian province of British Columbia implemented a reference-pricing policy for antihypertensive medications in which it reimbursed only the cost of an effective generic drug in several classes, critics charged that any savings would come at the cost of increased morbidity and healthcare utilization. However, a careful time-series analysis of all medication use, physician visits, and hospital care in the province before and after policy implementation provided compelling evidence that the new reimbursement system produced no important clinical downsides, but did achieve substantial savings for the provincial healthcare budget [43]. Such observational methods have also been combined with population-based randomized policy trials, and were found to yield similar results [43].

Similarly, one large US employer introduced a change in its drug benefit plan that reduced or eliminated patient co-payment requirements for cholesterol-lowering drugs and an expensive antiplatelet agent. While this new policy seemed intuitively appealing, no plan had been put in place to determine whether the additional costs incurred by the employer would result in patient benefit. A pharmacoepidemiologic analysis compared adherence rates to these medications by employees of that company with rates for comparable people insured by similar employers with less generous drug benefit plans, and found that the change in benefit design significantly improved adherence [44]. A similar policy was later tested by randomizing patients in a large health insurance plan who had recently been discharged from the hospital with myocardial infarction to either their usual drug benefit plan or to no co-payments for their postdischarge statins, beta-blockers, angiotensin-converting enzyme inhibitors, or angiotensin-receptor blockers [45]. The elimination of co-payments improved adherence without increasing total health spending, and also reduced the incidence of subsequent cardiac events. The tools of pharmacoepidemiology have also been used to evaluate other interventions to improve medication adherence, such as automated refill programs [46], automated and live reminder calls from pharmacists [47], and medication synchronization programs, which are designed to align patients' prescription refills on the same date to reduce the number of pharmacy visits per month [48].

Not all such policy interventions are as well conceived. Hard-pressed governmental programs such as Medicaid must often resort to prior approval requirements for certain costly drugs, which require prescribers to seek permission from the program before a given medication is dispensed. Sometimes the criteria that determine whether permission is granted are evidence based and plausible; other times they are not [49,50]. The methods of pharmacoepidemiology are increasingly used to assess the clinical and economic consequences of such policies [51–53]. One study documented an increase in the use of clopidogrel in one Canadian province after a highly restrictive policy was replaced with a more lenient one; this

change was associated with a significant concomitant reduction in adverse cardiovascular outcomes [54].

Interventional Pharmacoepidemiology

Once the tools of pharmacoepidemiology make it possible to define patterns of suboptimal use such as poor drug choices, underuse, overuse, problematic dosing, and concomitant use of interacting drugs, such surveillance can be employed to identify problems amenable to interventions to improve utilization. Although epidemiology is traditionally seen as a merely observational discipline, it can also be used for what might be called "interventional epidemiology" – in this case, using the tools of pharmacoepidemiology to define baseline medication use, to direct the implementation of programs to improve such use, and then to employ the same rigorous ascertainment of practice patterns and clinical events to evaluate the effectiveness of those interventions.

One example of such interventional pharmacoepidemiology has been the development, testing, and widespread deployment of the form of educational outreach known as "academic detailing," discussed in greater detail in Chapter 19. This approach was designed to address observational data showing that prescribing patterns often appear to be shaped by the promotional efforts of drug manufacturers more strongly than by evidence-based guidelines. This is in large part because drug companies are much more effective in communicating their messages about what clinicians should prescribe than are academics. Much of industry's successful behavior change results from the activities of pharmaceutical sales representatives, known as "detailers," who go to the physician's office and engage in interactive conversations with the clinician that are specifically designed to change prescribing behavior. By contrast, most traditional continuing medical education offered by the academic world is far more passive: the physician is expected to come to a central location to attend a didactic presentation, usually with little interaction or feedback, and no clear-cut behavioral goal.

In the early 1980s, the academic detailing approach was developed, which used the engaging interactive outreach of the pharmaceutical industry, but put it in the service of transmitting messages based solely on evidence-based recommendations of optimal prescribing, developed by academic physicians [55]. Building on pharmacoepidemiologic assessment of overall prescribing patterns in a given area, the method was then tested in several population-based randomized trials in which it was shown to be effective in improving prescribing, as well as in reducing unnecessary medication expenditures [56–58].

The first academic detailing programs represent some of the earliest uses of population-based medication use datasets (in this case, from US Medicaid programs) to define medication use by large and well-defined populations of practitioners and patients. The availability of complete data on actual claims from the pharmacy datasets made possible a rigorous assessment of the interventions' efficacy as well as of their cost-effectiveness. Based on these initial observations, such programs have been subjected to over 60 subsequent randomized trials, and are now in widespread use globally.

As computerized drug and medical data have matured, their role has expanded to support large-scale, multicenter, pragmatic randomized trials of medications themselves [59]. In the Salford Lung Study, investigators randomized over 4000 typical patients with asthma to receive an inhaled combination of a beta-agonist and a corticosteroid or to usual care [60]. The trial was conducted in more than 70 general practice clinics in the UK, using an integrated electronic health record system that

enabled the investigators to collect study data during the course of the trial, with little additional interaction required between patients and trial staff.

Economic Assessment of Medication-Related Issues

Using population-based datasets that contain information on expenditures as well as utilization makes it possible to assess the economic impact of such prescribing issues as well (see Chapter 34). The previously mentioned study of patients treated for hypertension, for example, found that better adherence to the JNC guideline recommendations would not only have led to more evidence-based prescribing (and therefore better clinical outcomes), it would also have resulted in savings of $1.2 billion annually if the findings were projected nationally [12]. Similarly, the clopidogrel use study suggested that if aspirin had been substituted in patients who lacked an evidence-based or FDA-approved indication for use of the more costly drug, it would have saved $1.5 billion at a national level [13].

Another important application of pharmacoepidemiology to the economic assessment of medications builds on its capacity to model the effects of clinical trials well beyond their often brief duration [61]. For example, although statins usually must be taken for a lifetime, many randomized trials demonstrating their benefit have lasted for a much shorter time, often under two years. Epidemiologic methods make it possible to project the likely trajectories of simulated study subjects in both the experimental and control arms of a study. Based on differences observed during the trial itself, and some assumptions about their durability – assumptions which should be both transparent and conservative – it becomes possible to estimate the lifelong benefits, risks, and costs of use of such treatments [62].

The Academic Medical Center

The academic medical center represents a special case of inquiry for pharmacoepidemiology, and one where the field can make particularly useful contributions. These centers are the home base for many researchers in the field, and such settings are more likely than many routine practices to have available the electronic datasets that make such analyses possible. In recent years, the Institute of Medicine has been promoting the idea of a Learning Healthcare System in which the data generated within a medical center are analyzed and used to improve the delivery of care within the system. The science of pharmacoepidemiology is central to the collection, analysis, and interpretation of the data generated and used in this continuous feedback loop for several reasons, including its capacity to rigorously specify treatment exposures and outcomes, and its perspective that takes into account the concept of "population at risk" [63].

The application of population-based approaches can make it possible to subject problematic prescribing in an academic medical center to data-guided interventions, particularly if a computer-based order-entry system is being used (see Chapter 41) [64]. Until recently, this was possible only in advanced comprehensive healthcare organizations. However, in any institution in which prescriptions are written on a computerized order-entry system, prompts can be installed to propose more evidence-based medication use [65]. In addition, academic detailing programs or other interventions can then be deployed to address specific prescribing problems, and evaluated using the same order-entry data [57]. For academic medical centers that evolve in the coming years to become the hubs of comprehensive accountable care organizations, the availability of such data and investigator teams will make it possible to use these epidemiologic tools to study – and improve – the patterns of use and outcomes of medications across the entire inpatient–outpatient continuum of care.

Consortia of Academic Medical Center Programs for Pharmacoepidemiologic Research

As the field of pharmacoepidemiology matures, new collaborations are emerging to enhance the capacity of the healthcare delivery system and of academic centers to address important questions in medication use. Such collaborations can bring together large groups of patients for study, increasing the size of populations available for research, as well as their diversity and representativeness (see Chapter 25). Equally importantly, such consortia can bring together the expertise of several groups whose skills may be complementary in addressing the difficult methodologic issues inherent in observational studies of drug use and outcomes. The European Medicines Agency has created ENCePP, the European Network of Centres for Pharmacoepidemiology and Pharmacovigilance [66]. The project has developed an inventory of European research centers and data sources in pharmacoepidemiology and pharmacovigilance, and provides a public index of such resources. ENCePP has also developed an electronic register of studies that provides a publicly accessible means of identifying all registered ongoing projects in pharmacoepidemiology and pharmacovigilance. In order to be registered and receive formal ENCePP approval, study investigators must agree to a Code of Conduct [67], which sets forth a set of principles for such studies concerning methodologic practices and transparency; they must also agree to adhere to a checklist of methodologic standards [68].

Examples in the US include the FDA's Sentinel, the Center for Disease Control and Prevention's (CDC) Vaccine Safety Datalink (VSD), and the Patient-Centered Outcome Research Institute's (PCORI) PCORnet. Sentinel is the FDA's national monitoring system that brings together a large number of electronic healthcare data providers and academic investigators to conduct postapproval safety surveillance of FDA-regulated medical products. The VSD, which is a collaborative project between the CDC and healthcare organizations that provide data and scientific expertise, is a precursor to Sentinel that focuses on vaccine safety surveillance, such as monitoring the safety of the seasonal influenza vaccine. A product of the healthcare reform program enacted in 2010, PCORI was designed to provide funding for comparative effectiveness research (CER), which was to include the study of medications, often by means of observational studies (see Chapter 26). PCORnet is PCORI's collaborative network of health systems, clinicians, researchers, patients, and data intended to foster patient-centered research across various health systems. However, those who expected PCORI to function as a CER resource that would fund trial or observational studies comparing relevant treatment options head to head have been surprised at what a small proportion of its activities have supported such work.

The Future

The continuing evolution of healthcare systems in both the industrialized and developing worlds will bring about a growing role for pharmacoepidemiology in multiple settings. Many new medications have novel efficacy but also daunting risks of toxicity, and often enormous costs. Healthcare systems all over the world face pressures to provide only those interventions that have the best efficacy and safety, but also at a price. To accomplish this will require relying on more than manufacturers' assessments of the utility, safety, or economic value of their own products, and more than clinicians' received wisdom or traditional prescribing habits. Nor will the interest of some insurers in promoting use of the most inexpensive medications necessarily

lead to optimal outcomes clinically, economically, or ethically. Pharmacoepidemiology (and its related discipline, pharmacoeconomics) can provide the tools for rigorous assessment of the good and harm that specific medications provide, and hold the promise of applying science to therapeutic decisions that are still too dominated by other forces.

Epidemiology is recognized as a key component of risk management and safety assessment activities during pre- and postapproval drug development. In addition to risk management, epidemiology contributes to several other important functions within a biopharmaceutical company, including portfolio development, studies of beneficial drug effects, the commercialization of drugs, and benefit–risk assessments. The use of epidemiology to support the appropriate marketing of drugs, including studies of beneficial drug effects, health economics, quality-of-life measures, and benefit–risk assessment, are discussed elsewhere in this book (see Chapters 26, 33, 34, 35, and 42). The most consistent contribution of epidemiology in the biopharmaceutical industry is arguably drug safety evaluation, including the contextualization and refinement of safety signals, and examination of specific research hypotheses. To meet these aims, epidemiologists design and implement background epidemiology studies among indicated populations, risk management interventions and evaluations, and postapproval safety studies. Additionally, epidemiologists contribute content, expertise, and strategy to regulatory documents such as global risk management plans (RMP), pediatric investigation plans (PIP), and orphan drug applications, and are key contributors in interactions with regulatory authorities.

This chapter discusses the specific application of pharmacoepidemiology to safety assessment throughout the development life cycle, from the perspective of epidemiologists working within the biopharmaceutical industry. Throughout this chapter we will refer as an example to the epidemiology strategy implemented to support the development, approval, and postapproval activities for Xeljanz® (tofacitinib), a Janus kinase (JAK) inhibitor for treatment of rheumatoid arthritis (RA).

The views expressed are those of the authors, which are not necessarily those of Pfizer Inc.

Pharmacoepidemiology, Sixth Edition. Edited by Brian L. Strom, Stephen E. Kimmel and Sean Hennessy.

Regulatory and Industry Focus on Risk Management and Epidemiology

Biopharmaceutical risk management (see also Chapter 24) is fundamentally concerned with preserving an appropriate benefit–risk balance among patients using a medicine, vaccine, or device. There are many tools by which this goal can be achieved, but *risk assessment* and *risk mitigation* are the two primary components of risk management. Epidemiologists play a vital role in the quantification and interpretation of risk. Preapproval, they contextualize risks emerging from clinical studies by understanding the background rates of disease occurrence in the indicated population. Postapproval, they assess the safety of drugs as used in actual clinical practice. Epidemiologists' training in observational research, data analysis and interpretation, and survey and program design also contributes to effective risk mitigation program planning and assessment.

The Evolution of Biopharmaceutical Risk Management

The guidance and regulations around risk management have evolved since the 1990s. Public pressure to speed up drug approvals for HIV and cancer drugs led to the Prescription Drug User Fee Act (PDUFA) in the US. Ten years later, concern that speed might come at the expense of fully evaluating safety led to the inclusion of a risk management framework for safety assessment in PDUFA III in 2002. For the first time, dedicated funding was provided to the Food and Drug Administration (FDA) for risk management resources. In response to this regulation, the FDA issued three guidance documents in 2005: (i) Pre-Marketing Risk Assessment, (ii) Pharmacovigilance and Pharmacoepidemiology, and (iii) Risk Minimization Action Plans (RiskMAPs).

After a number of widely used drugs were withdrawn in 2004 and 2005 for safety reasons, the public questioned the effectiveness of the FDA's methods of assessing and approving drugs. The Institute of Medicine (IOM) was tasked with evaluating the US drug safety system and making recommendations for improvements to risk assessment, safety surveillance, and the safer use of drugs. The IOM committee made numerous recommendations, several of which pertained to epidemiologists, including that the FDA receive additional funding and staff; improve communications on drug safety, incorporating a larger role for drug safety staff; and, most importantly, be given additional authority and enforcement tools [1].

As a result of the IOM report and other stakeholder research and advocacy, Congress passed the Food and Drug Administration Amendment Act (FDAAA) in 2007, which further strengthened the FDA's oversight of risk management activities. With FDAAA, the FDA was granted the ability to mandate postapproval studies (postmarketing requirements, or PMR) and risk evaluation and mitigation strategies (REMS; see the later section for further information) by imposing substantial fines for noncompliance or denial/revocation of drug approval. FDAAA also allowed for voluntary postmarketing commitments (PMC); that is, studies that may not necessarily be required, but could provide important public health information. Observational studies could be either PMRs or PMCs, and are further described in the FDA Guidance for Industry Postmarketing Studies and Clinical Trials [2].

Europe passed similar legislation in 2005, the Rules Governing Medicinal Products in the European Union, Volume 9A, which provide guidelines on pharmacovigilance and risk management between companies and the European Medicines Agency (EMA) [3]. European Union (EU) law requires companies to submit a formal RMP with each marketing authorization application (MAA). Following a review of the

European system of safety monitoring as well as extensive public consultation, a Directive and Regulation (also called the new EU pharmacovigilance legislation) were adopted by the European Parliament and Council of Ministers in December 2010, which became effective in July 2012, bringing about significant changes in the safety monitoring of medicines across the EU. The new EU pharmacovigilance legislation introduced a pharmacovigilance system master file (PSMF), required RMPs for all new products, enhanced postauthorization measures with legally binding postauthorization safety studies (PASS), including evaluation of the effectiveness of additional risk minimization measures (aRMMs), and postauthorization efficacy studies (PAES). The new EU pharmacovigilance legislation also introduced clarity in the oversight by the authorities for noninterventional studies: the national competent authority is responsible for nationally authorized products; EMA and its Pharmacovigilance and Risk Assessment Committee (PRAC) has oversight responsibility when more than one member state is involved. To facilitate the performance of pharmacovigilance in accordance with the new EU legislation, the EMA developed good pharmacovigilance practices (GVP) modules. The modules that are most relevant to epidemiologists are Module VIII – Post-authorization safety studies [4] and Module XVI – Risk minimization measures: selection of tools and effectiveness [5].

Besides the US and EU, regulations on risk management planning, including postapproval safety studies, are evolving in other parts of the world, such as Asia and Latin America. In Japan, postmarketing surveillance (PMS) is required for newly approved medicine and must be conducted in according with good postmarketing study practice (GPSP), a set of standards unique to Japan. The GPSP ordinance mandates PMS studies, commonly known as drug use results surveys (DURS), and defines the approach for the conduct of DURS. There is a little flexibility in design and format, and protocol finalization and approval are usually streamlined processes. Japan's Pharmaceuticals and Medical Devices Agency (PMDA) has been working to strengthen its drug safety assessment framework. The Medical Information for Risk Assessment Initiative (MIHARI) project was initiated in 2009 with the aim of utilizing large-scale electronic health information databases as novel information sources for pharmacoepidemiologic drug safety assessments in Japan. After conducting extensive pilot studies, the framework was implemented in practical applications in 2014, and is expected to play an important role in Japan's pharmacovigilance and risk management in the future.

In China, policies for postapproval safety studies, known as *intensive monitoring,* are still evolving, and the available guidance and overall approach are not as comprehensive as in the US, EU, or Japan. However, the basis for intensive monitoring has evolved over the past decade, and provisions for the ideas of postmarketing reevaluation and reregistration are delineated in China's Food and Drug Administration regulations.

In Mexico, the Federal Commission for Protection against Health Risks (COFEPRIS) is the regulatory authority for pharmaceuticals. The National Center of Pharmacovigilance within COFEPRIS is responsible for the oversight of all pharmacovigilance activities, in addition to setting local policies in line with national and international pharmacovigilance guidelines. The main standard guideline governing pharmacovigilance, including PMS studies, in Mexico is the Installation and Operation of Pharmacovigilance (2013).

Epidemiology has become increasingly important to risk management over the last three decades with the evolution of pharmacovigilance regulation globally, which has further solidified epidemiology's role in informing the benefit–risk assessment of medicines throughout the development lifecycle.

Epidemiology in Drug Safety Evaluation

Background

The safety profile of any drug reflects an evolving body of knowledge, extending from preclinical investigations through to the postapproval life cycle of the product. Drug manufacturers traditionally relied on two major sources for information on the safety of drugs: the clinical trials supporting the new drug application (NDA) and, once the drug was marketed, spontaneous reports received throughout the world (see Chapter 10). Clinical trials and spontaneous reports are useful and have a unique place in assessing drug safety (e.g., signal detection). However, both sources have limitations that can be addressed, in part, by the proper use of observational epidemiology. Epidemiologic studies complement these two sources of data to refine the safety signals they generate and to provide a more comprehensive and pragmatic picture of the safety profile of a drug as it is used in clinical practice.

Pharmacoepidemiology Study Designs

Pharmacoepidemiologic analyses can be descriptive or analytic in nature; may involve existing data, primary data collection, or a hybrid of secondary and primary data; and may be used to generate, refine, or examine hypotheses. Industry epidemiologists compile drug safety information from published epidemiologic literature, pooled clinical trials, trial extensions, electronic health records (e.g., insurance claims data or electronic medical records), existing registries, and *de novo* observational studies. Commonly used study designs include the cohort study, case–control study, and cross-sectional study (see also Chapter 3).

In addition to typical epidemiologic designs, depending on the specific safety research hypothesis, epidemiologists design and implement active surveillance studies, pragmatic trials (including the most naturalistic version, the large simple trial), and self-controlled designs such as the case-crossover study and self-controlled case series. Active surveillance studies can be defined as descriptive studies intended to solicit information on adverse events among a specified population, such that the numerator and denominator are as complete as possible, potentially allowing calculation of incidence. An example describing the active surveillance program established for juvenile idiopathic arthritis can be found later in this chapter in the section on pediatrics.

Purely observational epidemiologic studies may not always be the most appropriate method of evaluating safety signals or comparing the safety profile of different medications, especially when there are concerns of confounding by indication. Confounding by indication occurs when the risk of an adverse event is related to the indication for medication use, such that in the absence of the medication, those actually exposed are at higher or lower risk of the adverse event than those unexposed. As with any other form of confounding, one can, in theory, control for its effects if the severity of the underlying illness (i.e., any conditions specified as labeled indications or contraindications, or included in the precautions or warnings) can be validly measured (see Chapter 43). Confounding by indication is more of an issue when a particular property of the drug is very likely to affect the type of patient it is used by or prescribed to. In these cases, studies using randomization to treatment may be necessary. A pragmatic clinical trial (PCT) is a randomized clinical trial with one or more pragmatic elements, and a large simple trial (LST) is a type of PCT that combines randomization to treatment with observational follow-up of patients. The LST design allows for a theoretical balance of known and unknown confounding factors, while maintaining more real-world safety assessment than typical

clinical trials. By maintaining simplicity in study procedures, including the study's inclusion/exclusion criteria, patients' use of concomitant medications, and the frequency of patient monitoring, LSTs approximate real-life practice. Further, the large study size provides the power needed to evaluate small absolute and relative risks. The characteristics of LSTs are further described in Chapter 32.

Self-controlled designs, in which each case serves as its own control, were developed to assess effects of intermittent exposures on abrupt-onset events or diseases (see also Chapter 43). The case-crossover study is one form of self-controlled design, analogous to a traditional matched case–control design. The risk window is defined as a time period just before the outcome occurred and the control window(s) is (are) defined as other (nonoverlapping) time periods before the outcome occurred. For example, the case-crossover design was used to evaluate whether PDE5 inhibitors (i.e., sildenafil, vardenafil, and tadalafil), as a class, triggered the onset of acute nonarteritic anterior ischemic optic neuropathy (NAION) [6,7]. NAION is a rare condition, necessitating a design that identifies patients based on their disease status. However, identifying appropriate controls was deemed very challenging with a standard case–control study design. Furthermore, the case-crossover study was ideally suited to this research question, since PDE5 inhibitors are taken on an as-needed basis, which constitutes an intermittent exposure; acute NAION is characterized by sudden onset and is experienced by the patient as an abrupt visual change, often first detected upon awakening; and each case subject is effectively matched to him- or herself, such that the potential effects of confounders that do not vary over the study period, such as age, diabetes, and hypertension, are effectively held constant.

In the self-controlled case series design (SCCS), originally developed to study vaccine safety (see Chapter 20), the risk and control windows are defined within some observation period of interest. The risk window is defined as a time period after the exposure of interest occurs (among those exposed) and the control windows are all other time periods before and after the risk window (among those exposed), or all time periods (for those unexposed) within the observation period. The SCCS was used to evaluate the global risk of Guillain–Barré syndrome (GBS) following vaccination against Influenza A (H1N1) [8]. In this case, the SCCS design was chosen because it does not require the infrastructure needed to establish complete population denominators. In addition, the study design requirements were met, for instance H1N1 vaccine was an intermittent exposure, GBS is rare and has an abrupt onset, and the likelihood of H1N1 vaccine exposure was not expected to be impacted by the development of GBS [9].

Data Sources for Pharmacoepidemiology Studies

In order to respond rapidly and responsibly to safety issues, high-quality and valid data resources must be available. As a result of this need, the development and use of record linkage and automated databases, including hospital databases, have grown considerably over the past several decades (see also Chapters 11–14). These databases offer several advantages over primary data collection epidemiology studies or randomized trials (see Chapters 15, 16, and 32). First, automated databases are usually large in size, ranging from hundreds of thousands to millions of patients, often with many years of "observation." A second advantage is speed: since information on study subjects is already computerized, the data can be accessed quickly rather than waiting years for the results of studies in which patients are identified and followed over time. The third advantage is cost relative to primary data collection studies. Primary data collection observational studies and randomized trials can cost tens to hundreds of

millions of dollars, compared to hundreds of thousands of dollars for database studies.

Considerable progress has been made in the development of new and existing research databases containing information on drug usage and health-related outcomes. This progress is advantageous, as a variety of data sources are necessary for research in pharmacoepidemiology. The limitations of many automated datasets are well established and need to be considered before conducting a study on a newly marketed medication. Each data source will have its own strengths and limitations, which are usually related to important factors: the reasons for collecting the data (e.g., research, monitoring clinical practice, or reimbursement); the type of data collected; the coding systems used; the resources devoted to evaluating and monitoring the research quality of the data; and national or regional variations in medical practice. Many data collection systems were designed for administrative, rather than research, purposes. As a result, information needed to assess a specific safety issue may be unavailable and the quality of medical information may be inadequate. Validation of outcomes based on diagnostic or procedural codes used for reimbursement purposes (or algorithms based on these codes) against at least a subset of medical records is often desirable, as the usefulness of this type of research to answer an important safety question may be limited if the data are not properly validated. For some databases, medical record review may not be feasible due to laws and/or policies regarding patient confidentiality or anonymity. Continuing studies of the research validity of these databases are crucial, and should be pursued when feasible [10–14]. Further information on specific data sources can be found in Chapters 11–17.

Another common research limitation of automated data sources is that sufficient numbers of users may not yet be recorded, or the medication may not be marketed in the country where the database is located. Some data resources suffer from a considerable "lag time" between data entry and availability for research purposes. Further, even though many health maintenance organizations and national patient registries have a very large number of unique persons (often millions), these numbers may be inadequate to study potential drug risks of extremely rare outcomes. Finally, results from these sources are often limited in their generalizability.

Epidemiologic studies with primary data collection are considered when it is not feasible to address safety issues using existing databases. The NAION case-crossover studies described earlier and the ziprasidone LST (described in Chapter 32) are examples of epidemiology studies that involved primary data collection. These types of studies take a relatively long time for data collection and are more costly. In some instances, it is possible to conduct a hybrid primary–secondary data collection study by identifying patients or physicians in automated databases, and supplementing the existing data source with information collected directly from patients or physicians through telephone interviews or via electronic communications [15,16].

To address any specific product safety concerns, it is important to consider the validity and feasibility of all potential study design and data source options to enable selection of the most appropriate, and to implement epidemiologic studies in accordance with relevant guidelines such as the Guidelines for Good Pharmacoepidemiology Practices (GPP) [17], the EMA's European Network of Centres for Pharmacoepidemiology and Pharmacovigilance (ENCePP) Guide on Methodological Standards in Pharmacoepidemiology [18], and the FDA Guidance for Industry and FDA Staff: Best Practices for Conducting and Reporting of Pharmacoepidemiologic Safety Studies Using Electronic Healthcare Data Sets [19].

Contributions of Preapproval Epidemiology

Before evaluation of a potential medicine can begin, extensive preclinical research is con-

ducted, involving lengthy *in vitro* and *in vivo* testing. Preclinical safety studies evaluate and identify potential toxic effects of the drug, which include assessing whether a medicine is carcinogenic, mutagenic, or teratogenic. Although the information generated from preclinical studies provides guidance on the selection of a safe starting dose for the first administration-to-human study, the limited predictability of animal studies to the toxicity of drugs in human is well recognized. However, these studies can provide important information about hypothetical drug risks.

Randomized clinical trials (RCTs) provide abundant high-quality data about identified and hypothetical risks, but have limitations. Preapproval RCTs typically involve highly selected subjects, followed for a short period of time, and in the aggregate include at most a few thousand patients. These studies are generally sufficiently large to provide evidence of a beneficial clinical effect, exclude large increases in risk of common adverse events, and identify the most common and acutely occurring adverse events. However, they are rarely large enough to detect small differences in the risk of common adverse events or to reliably estimate the risk of rare events. Using the "rule of three," where the sample size needed is roughly three times the reciprocal of the frequency of the event, at least 300 patients would be required in a trial in order to observe at least one adverse event that occurs at a rate of 1/100. Likewise, a sample of 3000 is needed to observe at least one adverse event with 95% probability if the frequency of the event is 1/1000. (See Chapter 4 for more discussion of the sample sizes needed for studies.) Increasingly, preapproval studies – particularly in rare diseases or where long-term placebo treatments are unethical – include unbalanced randomization or treatment arms with a short duration of placebo or active comparator, or use noncontemporaneous controls. While clinical trials are not intended or designed to address all potential safety issues related to a particular drug [20], like preclinical studies, they often give rise to signals that cannot be adequately addressed from trial data alone.

Preapproval epidemiology complements safety data from preclinical and clinical studies and provides a context for signals arising from clinical trials. Comprehensive reviews of the epidemiologic literature are complemented by epidemiologic studies to establish among patients expected to use the new medication (i.e., indicated populations) the background epidemiology (e.g., incidence, prevalence, mortality) of the indication; the expected prevalence/incidence of risk factors, co-morbidities, and complications; patterns of healthcare utilization and prescribing of currently approved treatments; and background rates of mortality and serious nonfatal events.

Epidemiologic studies conducted before or during the clinical development program are often critical to place the incidence of adverse events observed in clinical trials in perspective. Data are often lacking on the expected rates of events in the population likely to be treated. For example, studies examining the risk factors for and rates of sudden unexplained death among people with epilepsy were able to provide reassurance that the rates observed in a clinical development program were within the expected range for individuals with comparably severe disease [21–23]. Epidemiologists use information from the published literature, descriptive epidemiologic studies, and standing cohorts (i.e., open cohorts of indicated populations which are updated over time and queried for incidence of safety events and other data as needed) to support regulatory filings and to complete epidemiology sections of key regulatory documents (e.g., risk management and pediatric investigation plans, orphan drug applications). These background epidemiology data can also be a key component for internal decision making, such as trial design, data monitoring committee decisions to stop/continue trials, decisions to move/not move to the next phase

of development, risk management decisions, and risk mitigation planning.

During development, in addition to summarizing the existing relevant literature and designing and executing background epidemiology studies, industry epidemiologists are often involved in safety signal evaluation, observational analyses of RCT data (e.g., as treated or observed versus expected analyses), and designing postapproval epidemiology studies and risk minimization planning. Planning for successful postapproval epidemiology studies often begins well before approval. During the periapproval phase, epidemiologists may conduct feasibility assessments for planned postapproval studies, start key operational aspects of postapproval studies (e.g., identifying key external partners such as contract research organizations and scientific steering committee members for the design and conduct of the study), and contribute to regulatory submissions, responses, and negotiations (e.g., responding to regulatory inquiries related to epidemiology, participate in regulatory meetings).

There are several other areas where epidemiologists are increasingly providing their expertise to support preapproval development. In the context of risk minimization planning, the epidemiologist may conduct research to test the comprehension and utility of educational materials, evaluate the proposed risk minimization tools and processes to assess their burden on the healthcare system and patients, pilot and/or user test assessment materials such as surveys, and generally contribute to the design and implementation of these programs. Furthermore, many regulatory agencies are utilizing various benefit–risk assessment frameworks in their reviews. Epidemiologists can provide inputs or lead both quantitative and qualitative benefit–risk assessments such as multicriteria decision analysis (MCDA) [24], stochastic multicriteria acceptability analysis (SMAA) [25], and the PhRMA Benefit-Risk Action Team (BRAT) framework [26], among others (see Chapter 35). Lastly, several accelerated/conditional approval pathways and regulations exist in the EU, and are anticipated for the US and other regions, which have requirements for real-world data and evidence (RWD/RWE) to complement the incomplete or uncertain data from abbreviated development programs in areas of high unmet need. Epidemiologists' expertise in regulatory-quality RWD/RWE generation is often critical to the success of these accelerated options.

Example: Tofacitinib Preapproval Epidemiology Strategy

The epidemiologic strategy for tofacitinib incorporated several distinct but complementary efforts for risk characterization, including literature reviews, meta-analyses, and a standing cohort within a US-based registry of patients with RA (see Figure 7.1). While all RCTs in the tofacitinib RA development program included at least one control group (placebo or active), the size of the control groups and duration of treatment did not permit precise comparative assessments for adverse events with low frequency or long latency. Long-term extension (LTE) studies provided greater exposure in patients taking tofacitinib. However, the lack of a control group within the LTE studies precluded direct comparative risk assessment; interpretation, therefore, was difficult, in that no data were collected that could provide evidence of the expected rates in a concurrent and directly comparable patient population. The use of indirect comparative methods via external patient cohorts provided such context, while taking into account key potential differences in the populations compared, whose baseline demographic characteristics, disease course, and treatment history varied. Data from multiple sources (i.e., observational studies, RCTs with other agents, and cohorts of patients stratified by RCT inclusion/exclusion criteria) were used to provide these indirect comparisons, drawing from the strengths of each data source while balancing their weaknesses. The output of the analyses was used to assess the rates of

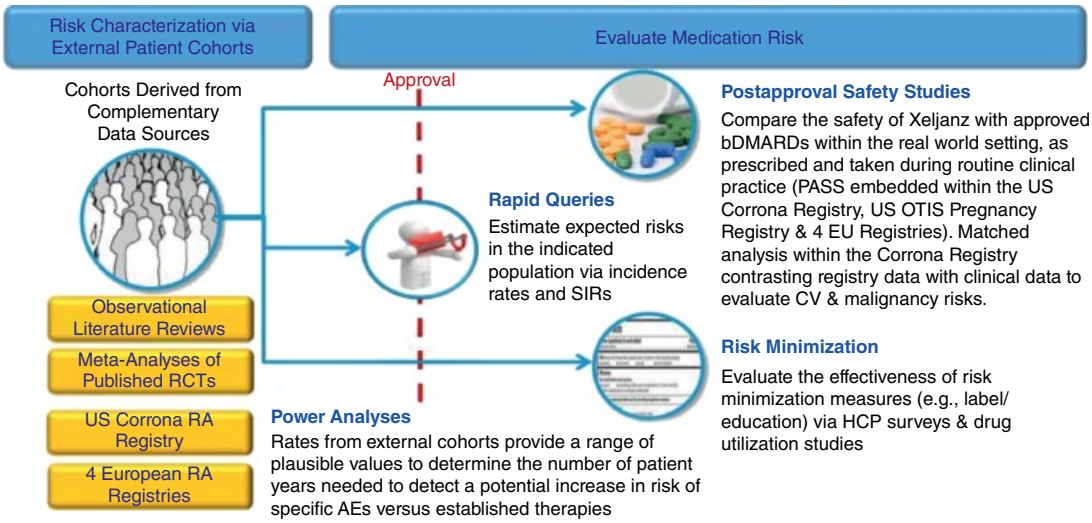

Figure 7.1 Harnessing the power of real-world evidence: Pharmacoepidemiology strategy for Xeljanz® (tofacitinib). AE, adverse event; CV, cardiovascular; HCP, healthcare professional; RA, rheumatoid arthritis; RCT, randomized controlled trial; SIR, standardized incidence rate.

identified and potential risks of interest in the tofacitinib clinical program compared with those from cohorts of RA patients treated with biologic disease-modifying antirheumatic drugs (bDMARDs). These efforts were articulated within regulatory documents, including the NDA for the FDA and the briefing document (i.e., summary of clinical safety [SCS], clinical overview [CO], etc.) for the EMA, and the data were also presented at the FDA Advisory Committee Meeting for tofacitinib (May 2012).

Due to the timing of approvals and regulatory interactions in the EU, these descriptive analyses were expanded to include four EU-based database studies. The strategy and accompanying power analysis were presented in several meetings with European national regulatory authorities and key EMA decision-makers. After deliberations, the EMA agreed to the inclusion of an integrated summary of the risk characterization work and key findings within the submission dossier (with analysis-specific component reports as appendices). The collective body of evidence (including interim data from the US-based registry study) provided substantial additional context to rates of selected adverse events observed in the tofacitinib clinical trial program, and therefore addressed the uncertainties related to the potential risks previously expressed by the EMA. Tofacitinib was approved in the EU in March 2017.

Contributions of Postapproval Epidemiology

The need for a postapproval epidemiology study can be known and devised preapproval or can arise once a new drug is marketed. Postapproval signals may come from clinical trial extension data (e.g., LTE studies), spontaneous reports, published case series, or signal detection of electronic healthcare data. Postapproval, epidemiologists execute postapproval commitments (e.g., epidemiology studies, active surveillance studies, other registries, REMS/aRMM evaluations, PIP observational studies, etc.); conduct studies evaluating the effectiveness of risk mitigation activities; perform signal detection in

existing cohorts (e.g., via claims or electronic patient record data); and design and implement new studies as additional signals arise (e.g., from spontaneous reports, signal detection, or other sources). Epidemiologists also communicate scientific findings through oral and poster presentations at scientific conferences and peer-reviewed publications.

Spontaneous reporting systems are the most commonly used pharmacovigilance method to generate signals on new or rare adverse events not discovered in clinical trials (see Chapter 10). However, there are several important limitations in interpreting spontaneous report data. Due to the lack of complete numerator (number of cases) data and the need to estimate the denominator (total number of patients actually exposed to the drug), it is not possible to determine the incidence of a particular event from spontaneous reports. Further evaluation of an apparent association between a drug and an adverse reaction usually requires postapproval epidemiologic studies.

Likewise, the nature of preapproval clinical trials often necessitates further safety evaluation through postapproval epidemiology. In addition to the limited sample size and length of follow-up of preapproval RCTs, with respect to drug safety an additional limitation of these studies lies in the common strict inclusion/exclusion criteria. Patients included in preapproval clinical studies may be the healthiest segment of that patient population. Special groups such as the elderly, pregnant women, or children are frequently excluded from trials. Patients in clinical trials also tend to be treated for well-defined indications, have limited and well-monitored concomitant drug use, and are closely followed for early signs and symptoms of adverse events which may be reversed with proper treatment.

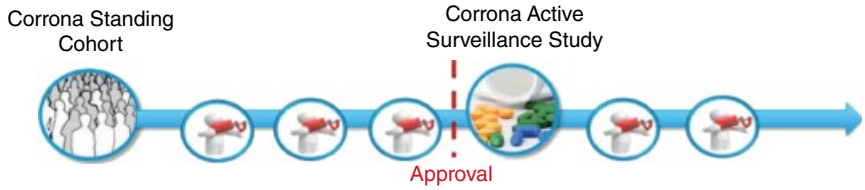
In contrast, once a drug is marketed, it is used in a real-world clinical context. Patients using the drug may have multiple co-morbidities for which they are being treated simultaneously. Patients may also be taking over-the-counter medications, "natural" remedies, or illicit drugs, unbeknown to the prescribing physician. The interactions of various drugs and treatments may result in a particular drug having a different safety profile in a postmarketing setting compared to the controlled premarketing environment. An example is the drug mibefradil, which was voluntarily withdrawn from the market by the manufacturer after less than a year as a result of new information about multiple potentially serious drug interactions. Adherence to medications also often differs between closely monitored trials and general postapproval use, as is the case with antihypertensives.

Because of the logistical complexity, high cost, and low external validity, large controlled trials have not been widely used for the postmarketing evaluation of drugs. Regulators and the medical community have communicated a desire for safety data from the populations that actually use the drugs in real-world clinical practice. This has led to a greater emphasis on the use of observational methods to understand the safety profile of new medications after they are marketed.

Tofacitinib Postapproval Epidemiology Strategy

As a condition for the approval of tofacitinib in the US, two observational postapproval safety studies were initiated: (i) an active surveillance study within the Corrona RA registry (ENCEPP/SDPP/5708) (see Figure 7.2), and (ii) a pregnancy outcome study within the OTIS registry (ENCEPP/SDPP/5703). Both studies were designed with the goal of characterizing the safety of tofacitinib within the real-world or clinical practice setting. In February 2018, both studies were in their fifth year.

Similarly, to assess the safety of tofacitinib in the EU postapproval setting, four five-year surveillance studies embedded within existing registries were proposed as a commitment to the EMA (i.e., ARTIS, BIOBADASER, BSRBR, and



- Broad patient population
- Tofa patients with 2 age- and gender-matched comparator groups
- ~5-year study with quarterly reports
- Complements the PMR RCT
- Analyses include evaluation of benefits and risks
- Starts with simple descriptive statistics, can include formal comparisons over time as data accumulate
- Multidisciplinary/cross-functional study team and internal steering committee

Figure 7.2 A closer look at the Xeljanz® (tofacitinib) postapproval Corrona active surveillance study. PMR, postmarketing requirements; RCT, randomized controlled trial.

RABBIT). The objective of the surveillance program is to evaluate any excess risk in the occurrence of known or potential adverse events, after accounting for confounding factors including disease severity and concomitant therapy. These studies, in addition to the aRMM-related work (i.e., HCP survey and drug utilization study) and ongoing pharmacovigilance (i.e., spontaneous reports, etc.), serve to address regulatory concerns regarding drug safety among European patients receiving care in the real world.

Drug Safety Evaluation in Special Populations

As already noted, most trials are conducted in populations that reflect a broad representation of the intended user to achieve regulatory approval. However, there are often populations of special interest, such as the elderly or children, who were omitted or insufficiently studied in these trials, necessitating additional research on these targeted populations.

In what follows we describe some additional examples of epidemiology studies in these special populations, and outline some of the unique challenges to and potential solutions for performing observational research in these groups.

Pregnancy and Birth Outcomes

The safety of a medicine when used during pregnancy is often unknown at the time of marketing approval (see also Chapter 22). Unless a medication is being developed specifically to treat a pregnancy-related condition or a vaccine is developed for maternal immunization, pregnant women are generally excluded from clinical trials for ethical reasons, due to potential risks to the developing fetus and newborn. In addition, most clinical trials that enroll women cease study of pregnant women upon detection of pregnancy. Thus, at the time of introduction to market, the effects of many medications on pregnancy are not well known, with the foundation of drug safety during pregnancy often resting largely on animal reproductive toxicology studies, whose extrapolation to humans is questionable. The paucity of data is potentially a serious concern for public health, particularly if the medication will be used by many women of

childbearing potential, since approximately half of all pregnancies in the US are unplanned [27] and more than half of all pregnant women in Western countries take medication during pregnancy [28]. While postmarketing spontaneous adverse event reporting of pregnancy outcomes may be helpful for identifying extremely rare outcomes associated with medication use during gestation, the limitations of these data are well established. Therefore, well-designed observational studies have become the primary way of generating evidence on the benefit and risk of medication use in pregnant women and their offspring.

In certain circumstances, registries are used to obtain information about the safety of new medications during pregnancy. A pregnancy exposure registry is typically prospective and observational, conducted to actively collect information about medication exposure during pregnancy and subsequent pregnancy outcome. The FDA and EMA issued guidelines regarding the circumstances when it is appropriate to establish a pregnancy registry [29,30]. The FDA's Office of Women's Health maintains an online list of pregnancy exposure registries [31], including some for HIV/AIDS medications, the human papillomavirus (HPV) and hepatitis B vaccines, and medications for cancers, depression, migraine, diabetes, and other conditions. Such registries differ from passive postmarketing surveillance systems, in that they collect data from women prior to knowledge of pregnancy outcomes, which has the effect of minimizing recall bias. The prospective nature of properly designed pregnancy registries also allows them to examine multiple pregnancy outcomes within a single study. Ideally, a pregnancy registry will allow for increased generalizability by being population based. It may aid the study of a cause–effect assessment between drug exposure and outcome by being prospective in nature; by collecting information on the timing of drug exposure, detailed treatment schedule, and dosing; by using standard and predefined definitions for pregnancy outcomes and malformations; and by recording these data in a systematic manner. The registry will ideally also follow offspring of medication-exposed women for a prolonged period after birth, to allow for detection of any delayed malformations in children who seem normal at birth.

Although pregnancy registries have advantages over passive surveillance methods, there are a number of major limitations that should be carefully considered. One of the major challenges of a pregnancy registry is a low level of enrollment. For example, the pharmaceutical company GlaxoSmithKline sponsored four international registries, but none of them reached the enrollment milestone of 1000 pregnancies during the first 10 years of data collection, considered by the European Medicines Agency Committee for Medical Products for Human Use to be necessary to be representative of widespread exposure [32,33]. The voluntary nature of enrollment can result in selection bias if women opting to enroll differ from those who do not, in terms of factors associated with the underlying risk of the outcome being studied. Pregnancy registries may also suffer from referral bias, with healthcare professionals being more or less likely to enroll women based on their disease severity. Sometimes more than one-third of pregnancies are then lost to follow-up, which makes the representativeness of the study population questionable [34]. Further, pregnancy registries often rely on self-reported medication exposures, which may result in misclassification of exposures, and often do not capture data on pregnancy losses (especially early losses). Another major challenge of a pregnancy registry is to establish an appropriate comparator group, especially when there is a possibility that the medical condition being treated may itself be associated with the outcome of interest, such as diabetes or epilepsy. Ideally, a pregnancy registry should allow for effects of the medication on pregnancy outcome to be distinguished from the effects of the

disease state warranting the treatment, if applicable, on pregnancy outcome. This can be achieved by enrolling two comparator groups: pregnant women who are disease free and not on the medication under study, and pregnant women with the disease who are not undergoing treatment or who are on a different treatment. In practice, however, it is usually not feasible to have comparator groups within pregnancy registries, because it is difficult to enroll pregnant women who are disease free or not using medication. Thus, in many cases, only pregnant women with the disease using the drug of interest, or other treatments for the disease, are enrolled and followed.

Given the limitations of pregnancy registries and the rapid development of large computerized healthcare databases, electronic healthcare databases are increasingly being used to evaluate the safety of medicine exposure during pregnancy, due to their ability to identify large populations in a timely, efficient manner. Using electronic healthcare databases for pregnancy studies can minimize selection bias by identifying all pregnant women who are exposed to a medication, and can avoid recall bias by using prescription data that are independently recorded by prescribers or claims. Internal comparator groups can be identified that represent the general population or women with the same underlying condition exposed to no medication or other medications within the class of interest. However, there is a lack of information on whether the women actually took the medicine and the precise timing of exposure. In addition, over-the-counter medication exposure is not captured in these databases.

There are three main types of electronic healthcare databases: national population-based registers in Nordic countries (Denmark, Sweden, Norway, Iceland, and Finland), electronic patient medical records, and administrative claims for reimbursement of medical treatment and prescriptions (see Chapters 11–14). Each type of data source has its own unique strengths and limitations, in addition to the general strengths and limitations of electronic healthcare databases already discussed. A key strength of national population-based registers in Nordic countries is the mandatory reporting of all live births and stillbirths within a country, which allows the capture of exposure and outcomes data from a representative sample of women, alleviating any concerns about the generalizability of study findings. These registers routinely collect information on gestational age at birth, birth weight, congenital malformations, mother's reproductive history, type of birth, delivery characteristics, and complications. Data on body mass index, smoking status, and alcohol intake are collected in most registers.

However, there are a few unique challenges that are not seen in other types of epidemiologic studies when using administrative claims databases to evaluate the safety of medication use during pregnancy. First, the information from the mother and that from the infant must be linked to each other. Researchers have used a variety of methods to establish the mother–infant linkage, such as unique family identification numbers included in the health plan enrollment data, date of birth and delivery date, or co-insurance information of the newborn, with reported linkage rates ranging from 63% to 88% [35–38]. Secondly, data on gestational age, an important variable for determining the timing of exposure during pregnancy, is not directly recorded in claims data. Pregnancy-related diagnosis and procedure codes can be used to estimate trimesters and weeks of gestation in administrative claims databases. A number of algorithms have been validated against the gestational age information on birth certificates or in medical records [39,40]. Claims data contain information on a number of confounding factors, such as maternal demographics, medical conditions that require medical attention, and concomitant medication exposure. However, information on mother's reproductive history,

body mass index, smoking status, and alcohol intake are typically not available or documented completely.

The large number of pregnancies captured within electronic healthcare databases and the fact that the data are routinely collected make them a valuable tool for evaluation of the benefit and risk of medicine use during pregnancy. Even with the large populations of electronic healthcare databases, a single data source may not have enough pregnancies or outcomes of interest, depending on the prevalence of the medical condition being studied and the frequency of use of the medication being prescribed. Therefore, pooling of multiple data sources for specific pregnancy studies is often needed to achieve sufficient statistical power. For example, national register data from five Nordic countries were pooled to assess whether maternal use of selective serotonin reuptake inhibitors increases the risk of persistent pulmonary hypertension in the newborn [41]; automated data from three healthcare claims databases and one electronic medical record database were used to evaluate topiramate use in pregnancy and the prevalence of oral clefts [42]; and recently, a planned study to examine the safety of Trumenba® vaccine exposure during pregnancy using electronic data from multiple healthcare systems in the US, all of which participate in the Sentinel distributed network [43].

Pediatrics

In the context of drug development, children are considered a special population (see also Chapter 22). This categorization is due to the unique physiologic characteristics of children: developing organ systems often result in different and unpredictable pharmacokinetic and pharmacodynamic profiles compared to adults, beyond standard adjustments for smaller body size and weight. The special population designation is also a result of the special ethical issues associated with testing unapproved substances in this vulnerable population, who cannot provide true informed consent.

There is drug development legislation specifically for pediatrics in both the EU and US. They differ slightly in their requirements and timing, but they both focus on early preparation of pediatric development plans and early submission (typically in Phase II) of these plans to regulatory authorities for review and approval. Similar to the EU RMP, the paediatric investigation plan (PIP) in Europe and the pediatric study plan (PSP) in the US require extensive information on the background epidemiology of the disease in children by age and other demographic and geographic subgroups; epidemiologists may play an important role in providing this information. Waiver requests, because of insufficient numbers of pediatric patients or because the disease does not exist in pediatrics, are another area that epidemiologists may support. The EU PIP process also requires that the adult RMP be expanded to include pediatric indications and to expand or conduct relevant safety studies, if applicable. In both regions, separate pediatric observational safety studies as conditions of approval are fairly common, given the lack of long-term safety data that is typically available in this population.

An important consequence of the US and EU pediatric legislation is that companies are now required to integrate pediatric planning much earlier in development than before. It also requires that epidemiologists become more familiar with general pediatric research issues, as well as pediatric population sources and research networks, since any patent-protected or patent-eligible drug or biologic with a European filing, regardless of the point in its life cycle, must submit a PIP. The regulatory changes in the US and general attention to active safety monitoring of vulnerable populations have also strengthened the need for postapproval observational safety studies in pediatrics.

Unlike drug development programs in adults, which typically encompass thousands of

individuals treated prior to approval, many pediatric drug development programs comprise a single pivotal clinical study of several hundred children. This small study size may be due to the lower incidence/prevalence of the disease in children, or the reluctance of parents to expose their children to experimental therapies. The small sample sizes drive the need for and increased focus on adequate long-term safety monitoring beyond traditional passive surveillance (i.e., spontaneous reports) in pediatrics, yet raise interesting methodologic challenges for epidemiologists studying the safety of drugs in children. One is frequently faced with assessing both a very rare exposure and a very rare outcome of interest. This conundrum necessitates observational approaches, because a traditional RCT cannot be feasibly conducted, but also may require creative approaches to design and data source selection that would not be necessary in adult populations. Utilizing existing registries or creating a new one, active surveillance programs using either primary or secondary data collection modalities, or collaborations with pediatric specialty research networks are just a few potential solutions.

Pediatric rheumatology, pediatric oncology, and many rare diseases represent common therapeutic areas that face these methodologic and ethical issues with several examples from which to draw [44–47]. In other instances, children are the primary target or vector for disease, as in many common infectious diseases. The primary methodologic limitation facing the epidemiologist may no longer be adequate sample size, but instead finding an unexposed comparator group, such as when studying a vaccine that is part of a universal vaccination campaign. More information on the nuances of vaccine safety evaluation is available in Chapter 20. Both situations highlight the need for novel approaches and methodologies to better support long-term safety monitoring of biopharmaceuticals in children.

Epidemiology in Evaluation of Risk Mitigation Interventions

Epidemiology not only plays an important role in evaluation of the drug safety profile pre- and postapproval, but, as noted earlier, also makes significant contributions to the evaluation of the effectiveness of risk mitigation intervention measures (see also Chapter 24). This component of biopharmaceutical risk management has grown considerably in the last decade, with the US, EU members, Taiwan, Egypt, Australia, and a number of other countries implementing legislation that supports risk mitigation interventions.

Under FDAAA, the FDA can require a sponsor to submit a proposed REMS as part of its initial application, if the FDA finds that a REMS is necessary to ensure the benefits of the drug or biologic product outweigh the risks [48]. The FDA may also require a REMS postapproval based on new safety information. The FDAAA has defined this as any information obtained during the initial review process, as a result of postapproval studies, or from spontaneous reports [48]. REMS are intended to be utilized to reduce known or hypothetical risks when traditional minimization approaches (i.e., the product label) are insufficient. These tools generally fall into three categories: enhanced education, that is patient labeling (including Medication Guides) or communication plans such as prescriber training programs; elements to assure safe use (ETASU), such as requiring documentation of laboratory tests before each prescription, or restricting distribution only to those who are certified prescribers; and an implementation system to monitor and evaluate ETASU. A critical addition to this legislation that was particularly relevant to epidemiologists within industry was the requirement to perform assessments of the effectiveness of these risk minimization tools and to submit these to the

FDA for review at prescribed time points, generally at 18 months, 3 years, and 7 years. The FDA draft guidances on REMS assessments and survey design were issued in January 2019, and it is unknown when these will be finalized. The EU has similar legislation to require sponsors to implement aRMMs where necessary to ensure that the benefits outweigh the risks, and a similar requirement to assess the effectiveness of the aRMMs, although without defined timelines. These aRMM programs and assessments are described in the EU RMP [4,5,49].

Epidemiologists play a critical role in the design and implementation of these assessments because of their expertise in observational study design, survey design, data analysis, and program evaluation. For example, using an automated healthcare or claims database, assessments may measure compliance with monitoring guidelines or whether a contraindicated population is prescribed the drug. Assessments may also examine the frequency of occurrence of an adverse event of interest before and after implementation of the risk minimization tool. Most commonly, however, assessments measure prescriber, pharmacist, or patient comprehension of risk information or self-reported adherence to risk minimization behaviors, and require the epidemiologist to craft cross-sectional surveys specific to each recipient, drug, and associated unique risk profile, since standardized or validated questionnaires that measure these concepts do not exist. An example of a comprehensive Tysabri® REMS program is shown in Box 7.1.

The implementation of the REMS and aRMM legislation has highlighted a number of difficulties. The mandated assessments may be difficult to achieve, or to achieve within the US legislative timelines, for many reasons: the need to develop and pilot knowledge/comprehension surveys unique to each drug subject to a REMS; the requirement to design, implement, and assess complex safe use programs; the scarcity of patients treated with the drug of interest; or difficulties in identifying such patients through automated channels. The fractured healthcare and prescription delivery system in the US and the wide variety of health systems, legal and privacy requirements, and attitudes to these programs and research participation across Europe present a barrier to the efficient distribution of educational materials, to the implementation of many safe use elements, and to the scientifically valid evaluation of these programs overall. Unfortunately, there is relatively little scholarly work published on how best to assess these burdensome but important risk mitigation programs, how best to define success, and, where necessary, how best to improve them [54–57]. Knowledge in these areas continues to mature as more companies and the regulatory agencies garner additional experience, and we expect that existing guidance [5] will evolve. Risk mitigation evaluation is thus still an emerging area for epidemiologists in industry, but one that complements our specialized training and expertise.

Tofacitinib Risk Mitigation Evaluation

The US REMS for tofacitinib was originally approved on November 6, 2012 and consisted of a Medication Guide, a communication plan, and a timetable for submission of REMS assessment (i.e., surveys at 18 months, 3 years, and 7 years). The FDA deemed the 18-month REMS epidemiologic assessment adequate, citing that the survey data demonstrated that patients understood the risks associated with therapy. Therefore, in accordance with Section 505-1(g)(4)(B) of the Food, Drug, and Cosmetic Act, the FDA determined that maintaining the Medication Guide as part of the approved labeling was sufficient to address safety-related concerns. As such, it was no longer necessary to include the Medication Guide as an element of the approved REMS, and the survey of patient knowledge and understanding was removed.

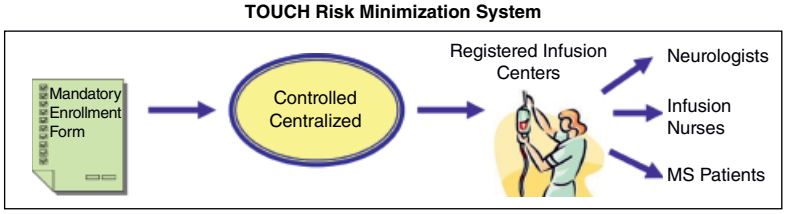
As a condition of approval within the EU, aRMMs were implemented within the EU,

Box 7.1 Tysabri® risk evaluation and mitigation strategies (REMS) case study

The FDA approved Tysabri (natalizumab), the first humanized monoclonal antibody for the treatment of relapsing multiple sclerosis (MS), via accelerated approval in November 2004. Approximately three months later, in February of 2005, Biogen/IDEC voluntarily suspended all sales and ongoing clinical studies due to two cases of progressive multifocal leukoencephalopathy (PML), one of which was fatal, in MS patients in long-term extension studies. Although no spontaneous reports had yet been reported to either the Sponsors or the FDA, the suspension was driven by the concern that the association between PML and natalizumab use was unclear, that PML is almost universally fatal, and that other patients may have undetected early-stage PML who would otherwise continue to receive the medication [50]. A third fatal case was identified in a Crohn's disease patient shortly thereafter [51].

At the time of suspension, little was known about the risk of PML in the general or MS population. In the general population, PML is extremely rare, and seldom occurs in immunocompetent individuals. It is estimated that 1–5% of AIDS patients may be diagnosed during their lifetime. PML also occurs in organ transplant recipients and cancer patients who have received immunosuppressive medications, but no cases in MS patients had previously been documented [50]. The Sponsors designed a comprehensive program to better understand the risk factors associated with PML development and developed a comprehensive RiskMAP program (later converted to a "Deemed REMS" under FDAAA) called the TOUCH™ (Tysabri Outreach: Unified Commitment to Health) Prescribing Program [52, 53]. The goals of TOUCH™ are as follows:

The program entails all REMS elements: a patient medication guide; additional physician education and accompanying assessments of knowledge and behavior; prescriber and patient attestation of risk understanding at enrollment; restricted distribution of the drug; and mandatory certification of physicians and infusion centers.



Based on this comprehensive program and a FDA Advisory Committee review in 2006, the clinical hold was lifted and natalizumab was reintroduced to the market in June of that year. Biogen/I DEC and regulatory agencies continue to closely monitor the incidence of PML potentially associated with natalizumab use (approximately 1 in 1000 in clinical trials) and communicate the updated safety information monthly to all stakeholders (e.g., neurologists, nurses, regulatory agencies). Additional research on risk factors and risk stratification, such as the impact of duration of use, the total number of infusions, and

the role of JC-virus infection, continue to be evaluated. The program has demonstrated a high degree of PML awareness and compliance with the requirements; most importantly, the fatality and disability rates appear lower than observed in clinical trials and the literature. Natalizumab was approved by the FDA in January 2008 for another indication, Crohn's disease, further supporting the effectiveness of the risk mitigation program [51, 53].

Key Points:

- Comprehensive risk assessment and mitigation plans (REMS) can preserve a positive benefit–risk balance in appropriate patient populations.
- Effective programs combine strict controls and tailored education, yet are dynamic (i.e., evolve as information becomes available and clinical practice and treatment options change over time).
- Transparent and frequent communication involving all stakeholders is critical, even if the safety profile is unknown or emerging.

consisting of an educational program intended to enhance the communication of the risks and risk minimization practices to patients and healthcare professionals (HCP). The elements of the aRMM include:

- Xeljanz® HCP brochure
- Xeljanz® HCP treatment initiation checklist
- Xeljanz® HCP treatment maintenance checklist
- Educational website
- Xeljanz® patient alert card

Under the purview of epidemiology, two studies were designed and implemented to evaluate the effectiveness of the aRMM. The studies are underway as of this writing and include a survey of HCPs and a drug utilization study.

Big Data and the Future of Pharmacoepidemiology

In recent years, the concept of "Big Data" has become more relevant to pharmacoepidemiology, with increases in the size and type of data available, as well as the computational capability to rapidly execute analyses across large datasets. Big Data is typically characterized by at least "3 Vs": velocity, variety, and volume; some commentators posit that veracity, variability, or value should be added to the list. However defined, Big Data and its associated analytic and machine learning techniques are having impacts on how pharmacoepidemiology is applied to drug development and safety assessment today. In the near future, we expect its use by industry to broaden across multiple functional activities, and its importance for decision making to increase within industry pharmacovigilance functions.

The greatest change in pharmacovigilance analytics being applied today, and the one most connected to the Big Data revolution, is wider use of observational data, as evidenced by pharmacoepidemiologic studies conducted across multiple databases and the development of large networks of observational databases of electronic healthcare records in North America, Europe, and Asia [58] (see also Chapter 25). There are now hundreds of existing longitudinal observational databases (LODs) available for secondary use in epidemiologic studies in North America, Europe, and Asia, from drug or outcome registries to transactional insurance claims databases and electronic medical record (EMR) databases [59], and increasingly these are being linked.

The best-known example of a LOD network for safety assessment is the US FDA's Sentinel system, initiated in pilot form in 2009 and consisting primarily of private transactional insurance claims data. The system was specifically designed to investigate potential safety concerns [60] to respond to the perceived weaknesses of a safety surveillance system reliant on spontaneous reporting. Sentinel, now in routine use at the FDA, conducts hundreds of assessments of products, conditions, and product–outcome pairs each year (Jeff Brown, personal communication). Analyses are conducted across a distributed network of data from 16 health plans (with additional datasets coming online over time), with currently over 220 million members and over 425 million person-years of data for analysis. Partners retain physical and operational control over their data by using a common data model (CDM). Standard, executable programs are then sent to each data partner to perform analyses or create analysis files for pooling summary data, which are then returned and compiled at a coordinating center. The network routinely uses standardized, simple queries that have as fast as a one-week turnaround from query initiation to result, a rapid analysis capability not seen previously on large-scale observational data. The distributed database, which is updated quarterly, has information on over 7 billion medical encounters and 6 billion outpatient pharmacy dispensations, and is growing at nearly 1 billion encounters a year (Jeff Brown, personal communication).

The Sentinel initiative is increasingly described as a component of a national evidence generation system [61]. In practice, this means exploring a broader use of this data network by connecting it to additional data types, including disease or drug registries, and/or other data networks, such as PCORNet, a network of EMR repositories [62], resulting in data systems encompassing more than half and up to two-thirds of the US population. These systems are envisaged as having value for research other than safety assessment, such as comparative effectiveness studies (see Chapter 26), pragmatic trials, or investigational trials in real-world settings. If the Sentinel system is truly a national resource, it also means developing governance and procedures for use by stakeholders other than the FDA, naturally with appropriate safeguards in place, to study important public health and safety research questions. The Reagan-Udall Foundation's Innovation in Medical Evidence Development and Surveillance (IMEDS) program was designed to develop a process for such access by stakeholders other than the FDA. In the first pilot conducted with IMEDS by Pfizer, policies and procedures were developed and subsequently tested by two use cases: the risk of venous thromboembolism associated with oral contraceptives; and the impact of an FDA labeling change on usage patterns of proton pump inhibitors [63–65].

Similar networks for safety surveillance have been developed around the world: AsPEN in Asia [66], CNODES in Canada [67], and several multinational European networks, such as the Innovative Medicines Initiative (IMI) PROTECT project [68], ARITMO [69], and SOS [70], while other networks, for instance OMOP and OHDSI, have primarily focused on methods testing and informatics tool development [71,72]. The Japanese regulatory authorities have also created a distributed network called MID-NET that links multiple Japanese hospitals and has a structure similar to that of Sentinel [73].

Many of these networks have developed CDM-based systems. CDM use for healthcare databases has clear benefits, but also limitations. For example, as ecosystems of tools grow to support efficient use of each CDM, this can lead to discordant results across systems [74]. A CDM is not a prerequisite for a data network. The IMI project PROTECT had a work package focused on pharmacoepidemiology that executed multiple study designs for six drug–outcome pairs across several European data sources using a

common protocol executed across data sources rather than a CDM. PROTECT demonstrated that through careful epidemiologic reasoning to produce a common protocol across multiple centers and countries, analyses conducted locally yielded generally concordant and predictably discordant results across databases [68]. Naturally, the amount of concordance varied by drug–outcome pair, study design, country, and database, but in a predictable manner.

As more observational data analyses are conducted, it is essential to ensure that studies are conducted only when there is a research question appropriate for observational study designs; techniques for confounding control are expected to be reasonably good at controlling for important confounders, particularly confounding by indication and severity; and regulatory and international scientific good practice guidelines are followed. Increased transparency in the conduct and reporting of studies may support better reproducibility and replicability. Recent guidance from the joint International Society of Pharmacoepidemiology–International Society for Pharmacoeconomics and Outcomes Research (ISPE–ISPOR) task force on "Real World Evidence in Health Care Decision Making" looks to provide guidance on the design and reporting of pharmacoepidemiologic analyses of longitudinal healthcare databases [75–78]. In the coming years, we expect further improvements in the quality and variety of clinical data available and linkages in these networks. For example, to study the prevalence of congenital malformations among infants exposed and not exposed to varenicline *in utero*, Danish and Swedish medical birth registries were used to identify live-born infants, then data on maternal varenicline use and congenital malformations in offspring were obtained by linkage to nationwide registries of dispensed prescriptions and hospital admissions [78]. Similarly, a planned study for meningitis B vaccination will look to examine the safety of Trumenba® vaccine exposure during pregnancy using electronic healthcare data and linked birth certificates from multiple healthcare systems in the US, all of which participate in the Sentinel distributed network [79]. Advances in these networks will also occur through data enrichment, such as linkage to clinical disease and drug registries or other primary data collection systems, or supplementing coded data with information obtained from the free text of medical records using natural language processing (NLP) or similar automated techniques [80].

The Big Data promises that have been most clearly fulfilled are the existence of these large networked data systems, coupled with the ability to gain insights into a study question within days rather than months or years as in the past [81]. With these advances, researchers have recently explored how these healthcare databases and systems might be used for exploratory assessment, rather than the usual signal evaluation approaches applied to these data. In this approach, the goal is to capture emerging and previously unsuspected signals; that is, hypothesis-free signal detection in healthcare databases [82]. There are limitations to the data, however, that currently hamper their usefulness in signal detection, including the lack of a learned reporter that suspects a medicine–adverse event relationship and is able to provide detailed medical information and a rationale for that suspicion; incomplete linkage of data from primary, specialist, and inpatient visits; and delays in updating and making available the data for research, which take up to a year for some databases. There is now a nascent literature on comparison of healthcare databases to spontaneous reports for signal detection, where there is cautious promise, at least for outcomes with high background event rates, which are difficult to capture as safety signals in spontaneous reporting systems [83]. For now, research suggests that, at best, this approach is likely to be complementary rather than to replace spontaneous reports.

Consumer wearable technology (such as fitness devices and smartphones) and "smart" digital technology (such as thermometers, or glucose or heart monitors) have the potential to supplement these approaches by providing better, more detailed health and behavioral information than that collected routinely in electronic healthcare databases. Some of the data are collected automatically, such as a phone's (and therefore individual's) location at a particular day and time. These data can then be linked to other information known about the location, for example the weather or air pollution levels. Most of the mobile data streams, though, are collected through "apps" that are intended to collect information about subjective experience and/or objective measures, such as heart rate or number of paces. These subjective data streams are potentially more representative and systematic than social media data streams, since they are able to prompt the user to enter data and provide data summaries that are useful or of interest to the user. For example, researchers in the UK are using smartphones and linked mobile data to study the relationship between weather patterns and RA symptom severity [84]. This study collects information about the severity of pain symptoms from an app and then links it to weather information based on the patient's location at time of data entry. To encourage participation and frequent data entry, the researchers have created the app so that it is relevant to patients: patients may view their individual symptom reporting over time as well as aggregate reporting trends for the entire study population. Elsewhere, computer games are used to collect data on reaction times to better understand disease progression [85], and smartphone apps are being explored as tools to collect safety information during research studies.

The use of consumer wearable technology for pharmacoepidemiologic research is in its infancy, although some researchers argue that the line between medical devices and consumer wearable technologies is already beginning to blur [86]. If large-volume data streams are being created that may be accessible in near real time and proximal temporally to a healthcare encounter or experience following the use of a medication, the promise for pharmacoepidemiology is great, particularly as these streams increasingly focus on medical and behavioral data (e.g., heart rate, personal and family medical history, smoking status, diet, alcohol consumption, and exercise patterns). Additionally, our analytic capabilities are being advanced, as these data streams and networks of sensors make it possible to examine relationships between data types previously unknown at this scale. To give three examples, not yet to our knowledge applied to drug safety research: studies demonstrating how noncontact visual images can be used to infer muscle activity and force [87], which one could anticipate would be of value in monitoring the progression of amyotrophic lateral sclerosis (ALS); video-recorded data can be used to allow more accurate health insights and therefore treatment in asthma patients [88]; and research into food-related object recognition [89] could potentially lead to objectively recorded dietary data being linked to electronic healthcare databases.

We anticipate that patients whose healthcare is complex, with an impact on their daily life, such as the chronically ill or those who are part of active and organized patient communities, will be early adopters of sharing their information for research purposes, despite the loss of privacy. This assumes of course that these data collection tools offer value to the individual patient and, when appropriate, their healthcare providers. Privacy, the perceived risk of misuse of data, and the regulatory considerations over tools that measure objective medical data (and therefore may be considered medical devices) are current hurdles to more widespread use. While it is impossible to predict the rapidity in uptake of these types of apps, we expect it will occur faster among younger generations of

healthcare providers and patients, who are arguably more comfortable with sharing data in this way and perhaps more likely to find it valuable.

As the amount of data of potential interest to companies has grown, so have computational advances for the analysis of these data sources. This has meant that traditional analytic approaches can be employed more rapidly, and/or extended in ways that were computationally intractable previously, such as large-scale high-dimensional propensity score matching and empirical Bayesian analysis approaches for shrinkage regression. Additionally, methods that would not have been practical in previous decades are now computationally viable analytic solutions on the large datasets of interest to pharmacoepidemiology. Examples of the latter are approaches for machine learning, artificial intelligence (AI), and cognitive computing. Currently, they appear most suited to making progress on questions requiring unsupervised pattern recognition, for example unexpected cluster detection in databases or predictive modeling [90]. Other technologies loosely connected to the Big Data movement may also have enormous impacts on pharmacoepidemiologic research strategies; for example, more widespread use of blockchain technologies may change the way we collect, structure, access, and thus analyze healthcare data.

Safeguarding patient safety and wellbeing is the ultimate purpose of these efforts to analyze new data streams and apply new analytic approaches. For this reason, as we consider the steady stream of new data and technology platforms of potential reliance to pharmacoepidemiology, we need to evaluate critically the impact of innovative data sources and techniques, and whether these should complement or replace existing approaches or are redundant, adding little or no value to current routine practice. Such evaluations will need to assess performance across data streams carefully, comparing their timeliness, effectiveness, and reliability for detecting emerging safety issues. Key to these evaluations is testing compared to appropriate, established external reference sets and transparent and measurable performance criteria. Objective and reproducible performance assessments are essential if such evaluations are intended to modify or enhance or replace components of current practice. There has been a recent focus in the field of pharmacovigilance on further developing the science of measuring the impact of pharmacovigilance activity.

Conclusions

Epidemiology makes a significant contribution to the development and marketing of safe and effective biopharmaceutical products worldwide. It facilitates the regulatory process and provides a rational basis for drug safety evaluation, particularly in the postapproval phase, and the evaluation of risk mitigation interventions. Like any other discipline, it must be properly understood and appropriately utilized. Industry has an opportunity to contribute to the development of the field and the responsibility to do so in a manner that expands resources while assuring scientific validity. With the passage of the 2007 FDAAA legislation and the 2010 EMA Regulation on Pharmacovigilance, the need for scientists with training and research experience in pharmacoepidemiology has never been greater. To best support drug safety evaluation, epidemiology strategies must (i) begin early in development, (ii) continue throughout the life cycle of the drug, (iii) evolve as new safety information becomes available, and (iv) be innovative, requiring epidemiologists to be aware of new methodologies and methods specific to the disease area. Epidemiologists within industry have an opportunity to build on the successes of the last 40 years by collaborating with academics, nonprofit organizations, and regulators to advance the methods of drug safety evaluation and risk management. In the near future, we expect the use and importance of Big Data to broaden within industry pharmacovigilance functions.

The Role of Pharmacoepidemiology in Regulatory Agencies

Gerald J. Dal Pan[1], June Raine[2], and Shinobu Uzu[3]

[1] *Office of Surveillance and Epidemiology, Center for Drug Evaluation and Research, US Food and Drug Administration, Silver Spring, MD, USA*

[3] *Pharmaceuticals and Medical Devices Agency, Tokyo, Japan*

The regulation of pharmaceuticals aims at ensuring that the public has access to medicines that are effective, acceptably safe, and of high quality. A wide range of regulatory activities spans the entire life cycle of a medicine, involving laboratory-based understanding of pharmacologic action, animal testing, providing scientific and regulatory input to drug development programs, protection of human subjects during clinical trials, assuring the integrity of the manufacturing process, reviewing the dossier to support product approval or licensure, monitoring the safety of medicines after they enter the market, and many other activities. These regulatory activities are firmly rooted in science, have a strong public health focus, and are executed within a legal and regulatory framework.

The Scope of Pharmacoepidemiology throughout the Medicinal Product Life Cycle

Assessing the Need for Medicines

Pharmacoepidemiology, along with other areas of medical epidemiology, can be used in drug development long before a medicine is licensed or even tested in humans. Pharmacoepidemiologic approaches can be used to examine patterns of utilization of existing disease treatments, in order to identify and characterize disease populations and subpopulations for which unmet medical needs exist. In some cases, there may be no available therapies. In other cases, available therapy may be ineffective for or poorly tolerated by

The views expressed herein are those of the authors, and not necessarily of the US Food and Drug Administration, the European Medicines Agency, or the Japanese Pharmaceuticals and Medical Devices Agency.

Pharmacoepidemiology, Sixth Edition. Edited by Brian L. Strom, Stephen E. Kimmel and Sean Hennessy.

certain patients. In these cases, pharmacoepidemiologic approaches can be used to characterize patients who experience a suboptimal response to the medicine, and thus to define the target population for a drug development program. For example, population-based databases can be used to characterize the frequency and distribution of characteristics of patients with a specific disease, so that relevant populations can be included in the developmental clinical trials. Healthcare databases can be used to estimate the frequency of co-morbid conditions in the setting of the specific underlying disease to be treated, so that relevant background rates can be derived to place in context potential adverse events that arise during development. This is especially useful for clinical events that are seen more frequently in patients with the disease for which the new treatment is being tested, but which could also represent an adverse drug reaction. This situation, known as confounding by indication (see also Chapters 3, 33, and 43), is a well-known methodologic problem in observational pharmacoepidemiologic studies, but can also complicate the interpretation of adverse events in clinical trials, especially if the trial is not designed or powered to analyze these events. In these situations, careful understanding of background rates can be important.

Orphan Drugs

In the last decade, there has been substantial activity and progress in the development of drugs for rare diseases [1]. Orphan drug programs are designed to provide incentives to pharmaceutical manufacturers that develop medicines for rare conditions, known as "orphan drugs." In the US, an orphan drug designation is given to a drug or biologic that has shown promise as a therapy intended to treat a disease affecting fewer than 200 000 persons in the country [2]. In Japan, orphan designation is granted for drugs or medical devices if they are intended for use in fewer than 50 000 patients in the nation and for which there is a high medical need [3]. In the European Union (EU), a prevalence rate of 5 per 10 000 persons in the EU is used [4]. When all rare diseases are taken together, their public health impact is significant; approximately 25 million people in North America are affected by these diseases [5].

Medical epidemiology is central to the designation of a product as an orphan drug, as determination of prevalence is the basis for such a designation. Data sources for determining prevalence can include administrative healthcare databases, electronic medical record systems, registries, and surveys. In many cases, combining data from multiple sources will be necessary. In most cases, data from these sources, even when combined, will not cover the entire jurisdiction for which the orphan designation applies. Thus, some form of extrapolation must be performed to determine if the relevant population prevalence has been exceeded. Most orphan drug designations are for diseases or conditions whose prevalence is much lower than the 200 000 prevalence threshold in the US. A review of 25 years' experience with the orphan drug program in the US, covering 1892 orphan designations, found that the median prevalence was 39 000; the most common patient prevalence was 10 000 or fewer patients, with relatively few prevalence rates near the 200 000 threshold. For estimates of population prevalence near the threshold, care must be taken to ensure that the most rigorous methods have been used to estimate the population prevalence of a rare disease. The closer the estimated prevalence is to the threshold, the greater the precision needed to characterize the prevalence.

Planning Drug Development Programs

Despite the availability of an increasing number of medicines, there remain a substantial number of unmet medical needs. Advances in understanding the molecular pathogenesis of

cancers, rare diseases, and infectious diseases have led to a rapid rise in the number of drug development programs targeting these conditions. At the same time, the aging population across the globe has led to a need for improved treatments for widespread diseases such as diabetes, hypertension, ischemic heart disease, chronic obstructive pulmonary disease, Alzheimer disease, other neurodegenerative disorders, and many others. The continuing emergence of antibacterial resistance and the threat of new viral illnesses prompt the need for new antimicrobial agents. Infections with *Mycobacterium tuberculosis*, *Plasmodium falciparum*, human immunodeficiency virus (HIV), endemic parasitic diseases, and other agents contribute substantially to the global burden of disease and require new treatments [6].

Regulatory agencies have responded to this demand with a variety of regulatory programs and pathways designed to promote efficient development of medicines and to reduce drug development time so that these unfulfilled medical needs can be met. Some of these programs seek to optimize drug development by providing timely consultation between the regulator and the company developing a drug to clarify scientific requirements; other programs allow clinical development to be shortened by allowing the use of surrogate markers rather than clinical markers. In the US, the breakthrough therapy designation [7] allows the Food and Drug Administration (FDA) to work closely with drug sponsors to plan a development program that will efficiently generate evidence of effectiveness and safety for drugs that meet two general criteria: (i) the drug must be for a disease or condition that is serious or life-threatening; and (ii) there is preliminary evidence that the drug may demonstrate a substantial improvement over existing therapy. When breakthrough designation is granted, the agency commits to provide intensive advice on drug development, involve senior managers throughout development, review portions of the application before the complete application is submitted (a "rolling review"), and take other actions to expedite review, as necessary [8]. The European Medicines Agency (EMA) launched the PRIME (PRIority MEdicines) initiative to provide support for the development of medicines that show a potential to benefit patients with an unmet medical need. For drugs selected for PRIME, the EMA provides guidance on the overall development program as well as scientific advice at key development milestones, assigns rapporteurs from relevant EMA committees and a dedicated point of contact, and determines whether the marketing application may be eligible for accelerated assessment [9]. In Japan, the SAKIGAKE review program was introduced as part of the "Japan Revitalization Strategy" to improve access to medicines [10]. *Sakigake* is a Japanese word meaning "frontrunner" or "pioneer." The SAKIGAKE review program applies to medicines that meet four general criteria: (i) a mechanism of action different from that of other drugs; (ii) the target disease is serious and life threatening, or causes chronic disabling symptoms, for which there is no cure; (iii) there is no approved product or product anticipated to be markedly more effective than existing treatments; and (iv) there is the intent to have early development and initial approval in Japan. The SAKIGAKE designation allows for priority consultations with the Japanese Pharmaceutical and Medical Devices Agency (PMDA), rolling review, priority review, and other features that enhance sponsors' interactions with the PMDA. In each of these situations, pharmacoepidemiologic analyses can aid in the comparison of new treatments to existing treatments, especially when data on existing treatments are derived from clinical experience and not from formal clinical trials.

The goal of a drug development program is to demonstrate that a medicine has a beneficial and meaningful effect on a clinically important outcome, generally a measure of how the patient feels, functions, or survives. Clinical

trials whose primary endpoint is a direct measure of a clinically important outcome may be very long and delay patients' access to effective therapies. To allow patient access as rapidly as is feasible, and to ensure that definitive evidence of effectiveness is obtained, an alternative approach allows marketing approval for a new drug product on the basis of adequate and well-controlled clinical trials establishing that the drug product has a beneficial effect on a surrogate endpoint. A surrogate endpoint is an outcome measure that is used in place of a direct measure of a clinically meaningful outcome when the effect of treatment on the surrogate endpoint is expected to reflect changes in the clinically meaningful outcome [11]. In the context of drug development, a validated surrogate endpoint is one for which evidence exists that the effect of treatment on the surrogate endpoint predicts the effect of treatment on the clinical outcome of interest. For example, systolic blood pressure is used as a surrogate endpoint in clinical trials of antihypertensive agents, because it predicts the risk of occurrence of stroke. Similarly, HIV viral load is used as a surrogate endpoint in clinical trials of antiretroviral agents, because it predicts the development of an acquired immunodeficiency syndrome diagnosis [12]. Validated surrogate markers are widely employed to support approval of medicines.

There are, however, many serious and life-threatening conditions for which there are no validated surrogate markers, yet there is still an urgent need to bring effective therapies to patients in a timely way. For this latter situation, the concept of "accelerated approval" has been developed. Under this framework, the US FDA may grant approval to a medicine intended to treat a serious or life-threatening disease based on an unvalidated surrogate endpoint that is reasonably likely, depending on epidemiologic, therapeutic, pathophysiologic, or other evidence, to predict clinical benefit on the basis of an effect on a clinical endpoint other than survival or irreversible morbidity [13]. In these cases, postmarketing studies must be conducted to demonstrate the actual clinical benefit of the medicine [14].

A key regulatory tool in the EU to fulfill unmet medical needs is the conditional marketing authorization, which has reduced data requirements linked to a one-year, time-limited authorization, where the authorization's renewal is linked to further data submission [15]. Under the applicable regulations, manufacturers must study the drug further once it is approved, to verify and describe its clinical benefit, where there is uncertainty about the relationship of the surrogate endpoint to clinical benefit, or of the observed clinical benefit to ultimate outcome. At the time of approval, postmarketing studies would usually already be underway.

In Japan, the Pharmaceuticals, Medical Devices and Other Therapeutics Products (PMD) Act established a system of conditional and time-limited approval for regenerative medicines based on probable benefit from early clinical trials [16]. After obtaining such approval, the marketing authorization holder is required to submit a standard marketing application with additional data on safety and efficacy. Similarly, from 2017 a conditional early approval program applies to drugs offering high efficacy and clinical usefulness in the treatment of serious diseases, drugs for which conducting confirmatory studies is impracticable, and other designated drugs. One prerequisite for approval will be a commitment to complete postmarketing studies as necessary in order to reconfirm product safety and efficacy.

Understanding the relationship between a surrogate endpoint and a clinically relevant endpoint, as well as validation of the surrogate endpoint, is an opportunity for pharmacoepidemiologists to contribute to drug development. Pharmacoepidemiologists can use principles of epidemiology to distinguish simple correlation between a potential endpoint and a clinically meaningful outcome, on the one hand, from a true surrogate marker. For example, a marker of

disease status used in natural history studies may not be an adequate surrogate endpoint in a clinical trial, because it is not related to the disease mechanisms that give rise to symptoms, morbidity, and mortality [17].

Preapproval Review of Clinical Safety Data

While the traditional role of pharmacoepidemiology, from a regulatory standpoint, has been the assessment of the safety of medicines in the postlicensing period, pharmacoepidemiology can play an important role during the prelicensing review of safety data. The limitations of prelicensing clinical trials in defining the full scope of adverse drug reactions are mainly related to the fact that clinical trials are relatively small in size, compared to the population of patients that will ultimately take the medicine once it is marketed. Patients who participate in clinical trials may have fewer co-morbidities and take fewer concomitant medications than those treated in actual practice. Prelicensing clinical trials generally provide relatively little data, or no data at all, in certain populations such as children, the elderly, and pregnant women, or at-risk groups such as immunosuppressed patients. These groups, however, are treated with the medicine in the course of clinical practice once it is licensed.

The analytic methods of clinical trials are best suited for data arising from randomized, controlled, comparative trials. Many clinical trials of medicines intended for chronic or long-term use, including those trials in preapproval drug development programs, may have single-arm, open-label extensions after participants have completed the randomized portion of the trial. For data generated from this portion of the clinical trial, the techniques of observational pharmacoepidemiology may be appropriate. In addition to tallying the frequencies of specific adverse events, data from long-term extension studies can be examined to characterize patterns of adverse event onset over time. If appropriate, analyses based on person-time can be performed. In this setting, the interpretations of adverse events must take into account the prior treatment received during the randomized portion of the trial, the duration of treatment, the underlying frequency of medical outcomes in the population with the disease being treated, and other factors. Pharmacoepidemiology can inform this approach.

Planning for Postapproval Studies

At the time a medicine is approved, there are uncertainties and unknowns regarding its safety profile. In many cases, the nature of the safety issues that will unfold postapproval cannot be predicted at the time the product is brought to market. In some cases, however, a careful review of the clinical data at the time of approval can lead to a proactive approach to obtaining more safety information.

Pharmacoepidemiology can play an important role in several specific situations. First, drug development programs based on the use of unvalidated surrogate markers, as described earlier, generally require postmarketing studies to demonstrate definitively the clinical effectiveness of the product. In these situations, pharmacoepidemiologists can be involved in studies assessing the validity of the surrogate marker.

Secondly, pharmacoepidemiologists can be involved in the design and interpretation of postmarketing studies designed to assess the impact of new formulations of medicines developed to have a more favorable safety profile than earlier versions. For example, the widespread abuse of opioid-containing drug products has generated interest in the development of abuse-deterrent formulations of these products. While a variety of different physicochemical and pharmacologic mechanisms can confer the abuse-deterrent property, the true public health impact of the reformulation can be assessed only through formal epidemiologic analysis when the product is in actual use [18].

Thirdly, pharmacoepidemiologists can be involved in planning postmarketing studies when safety signals are detected prior to approval. An example of a proactive approach is the strategy the US FDA has developed to require sponsors of antidiabetic agents to characterize as fully as possible the cardiovascular risks of these medicines [19]. The strategy starts prior to approval, when data from clinical trials are examined to determine the cardiovascular risk of the new medicine to that of comparative agents. A relative risk estimate is calculated. If the upper limit of the 95% confidence limit of this estimate exceeds 1.8, the product will require a large cardiovascular outcomes clinical trial prior to approval. If the upper bound of the 95% confidence limit falls between 1.3 and 1.8, the product can be marketed, provided of course that all other criteria for approval are met, and the manufacturer will be required to conduct a postapproval clinical trial to determine the frequency of adverse cardiovascular outcomes relative to other antidiabetic agents. If the upper limit of the 95% confidence interval is below 1.3, and the product otherwise qualifies for approval, no further cardiovascular study is needed. This strategy provides a tiered approach, spanning the pre- and postapproval periods, to assessing the cardiovascular risks of antidiabetic agents, and accounts for the level of uncertainty in the preapproval data.

Monitoring Postapproval Safety

For the regulator, the postmarketing assessment of the safety of medicines involves both a proactive approach and, of necessity, a reactive approach. The International Council for Harmonisation of Technical Requirements for Pharmaceuticals for Human Use (ICH) has developed a useful and practical framework that summarizes the known safety issues of a product and can form the basis of ongoing monitoring and, as needed, specific studies [20]. The ICH framework characterizes important identified risks, important potential risks, and important missing information. This framework allows pharmacoepidemiologists and others to devise proactive strategies to design observational studies or clinical trials to address unanswered questions about the safety profile of a medicine. The approach to studying the cardiovascular risk of antidiabetic agents, already noted, is an example of a proactive step taken at the time of approval. However, the identification of knowledge gaps can occur at any time in the life cycle of a medicine, and can be based on data from clinical trials or observational studies of the medicine, or safety findings from other medicines in the same class. In these cases, careful review of the available data can allow the regulator, often working with the developer, to develop a thoughtful and rational approach to drug safety issues in the postapproval period.

Reactive approaches are also needed in regulatory pharmacoepidemiology, because the adverse effects of medicine can become recognized at any time, sometimes many years, after approval. To the extent that regulators can use proactive pharmacoepidemiologic approaches, in theory reactive approaches can be minimized. However, not all drug safety issues can be predicted, so regulators will continue to need reactive approaches. These approaches require efficient review of the existing data, careful and timely assessment of the need for immediate or near-term regulatory action, and interaction with the product's manufacturer to plan further study. Reactive approaches become necessary, for example, when new safety issues are identified from spontaneously reported suspected adverse drug reactions, or when drug safety findings are published by independent groups, and neither the regulator nor the manufacturer is aware of them beforehand. Reactive approaches may also be needed when events such as manufacturing-related product recalls result in a large number of adverse event reports that need to be reviewed in a short period of time [21].

The specific scientific approach to an individual postapproval safety issue is beyond the scope of this chapter. From the regulator's point of view, the scientific studies that form the basis of regulatory actions must be as sound and robust as possible. Importantly, these studies should be designed to address the specific drug safety issue at hand, ideally in as short a time as possible. If there are ongoing planned studies, these may serve to contextualize the newly identified safety issue.

Assessing Actual Use Patterns of a Medicine

Regulators are interested not only in whether a medicine meets the relevant regulatory standards for approval, but also in how it is actually used in clinical practice. Because the harms of medicines can result not only from their intrinsic pharmacologic properties but also from how they are used, or misused, in practice, understanding the actual usage allows regulators to assess the degree to which the medicine is used in ways that are consistent with its safe use as described in the label or marketing authorization. To do so, regulators can use a variety of pharmacoepidemiologic techniques, including administrative claims data, electronic medical records, or other public health databases.

An analysis of emergency department visits in the US found that the rate of such visits involving both opioid analgesics and benzodiazepines increased from 11.0 to 32.4 per 100 000 population between 2004 and 2011. During that same period, overdose deaths involving drugs from both classes increased from 0.6 to 1.7 per 100 000 [22]. To shed light on this finding, an analysis of trends in the concomitant prescribing of opioids and benzodiazepines in the US between 2002 and 2014 found that concomitant prescribing increased by 41%, from 6.8% to 9.6% [23]. These drug utilization data were an important component of the body of evidence that led to warnings advising against the concomitant use of benzodiazepines and opioids [24].

An analysis of outpatient electronic medical records at a university hospital in Japan compared prescribed doses of agents for rheumatoid arthritis, diabetes, high blood pressure, and depression to standard approved doses [25]. The study found notable differences in the clinical characteristics of patients between the actual practice setting and the clinical trial setting. The average prescribed doses of agents for rheumatoid arthritis and depression were lower than standard approved doses, especially in older patients. The findings also suggested that the incidence of certain adverse events may differ between actual practice and clinical trials. Findings such as these, which describe how medicines are used in practice, can form the basis of more targeted drug safety studies.

Assessing the Impact of Regulatory Actions

Because of its public health focus, drug regulation must ensure that its actions lead to the intended public health outcomes. For serious safety issues, it is not enough simply to add a warning to a product label. Such an action is in itself an intervention, and it is thus important to understand its impact. Recognizing the fundamental importance of the need for such assessments, the Pharmacovigilance Risk Assessment Committee of the EMA developed a formal strategy to measure the impact of pharmacovigilance activities. The strategy is aimed both at informing the review of individual medicines that have been the subject of major risk minimization efforts and at determining which activities are successful and which are not, in order to optimize the pharmacovigilance system. Pharmacoepidemiology is critical to this endeavor, as it can relate regulatory activities to the outcomes that those activities are intended to affect. Pharmacoepidemiologic thinking and methodologies underpin the EMA's strategy [26].

One domain of assessment of the impact of regulatory activities is an understanding of the

effectiveness of regulatory agencies' communications about the risks of medicines. A study that examined the extent to which patients understand important information about a serious risk of a medicine that they are taking considered the results of patient-directed knowledge surveys for 66 medicines for which patients were supposed to have received a Medication Guide, a type of patient-directed labeling [27]. For each Medication Guide, acceptable knowledge was defined as 80% or more of patients correctly answering questions about the medicine's primary risk. The study found that only 20 Medication Guides (30.3%) met the 80% threshold, a finding that underscores the need for improved patient-directed information.

To understand the diffusion of an emerging drug safety message, a series of studies in the US employed several complementary methodologies, including quantitative and qualitative analysis of traditional and social media, patient and prescriber interviews, a patient survey, and pharmacoepidemiologic analysis of healthcare claims data [28]. These studies, which examined drug safety communications concerning the risk of next-day drowsiness and mental impairment with the sleep aid zolpidem and a recommendation to change the starting dose from 10 mg to 5 mg, found that traditional media reported widely some of the messages in the safety communication, but reported other messages less widely [29]. Semi-structured interviews of patients and physicians, which were designed to assess awareness and understanding of the messages, found that patients and physicians use a variety of sources of drug safety information, and that some of the messages in the drug safety information were communicated effectively to patients and physicians, though none of the patients had recalled hearing all of the messages and some patients did not understand fully how the message applied to them [30]. Studies such as these allow regulators to assess the impact of their communications and thus provide an opportunity for improvement of these efforts.

Analysis of the impact of regulatory actions is not limited to the assessment of actions related to individual medicines. Rather, it can look broadly at how the functioning of a drug regulatory system contributes to the system's public health mission. Because of the rapidly changing and expanding data that inform pharmacoepidemiologic studies, studies that examine overall performance are important because they can lead to system-wide improvements. For example, an analysis of 144 safety-related actions taken in 2012 by the Japanese Ministry of Health, Labour, and Welfare (MHLW) and the PMDA found that 83.5% were based on spontaneous reports [31]. The actions were not limited to recently approved medicines, since the median duration between drug approval and the safety-related regulatory action was 8 years. While the median duration between signal detection and a tentative or final decision was relatively short (49 and 84 days, respectively), assessments involving older products or multiple products required substantially more time. Studies such as this one can point to the need for the development of pharmacoepidemiologic assessment that utilizes health information databases in addition to spontaneous reports. A new program advanced by the PMDA, known as MIHARI (Medical Information for Risk Assessment Initiative), seeks to fulfill this need, and is described later in the chapter. In Japan, pharmacoepidemiologic studies using health information databases are permissible as studies for postapproval requirement purposes under the PMD Act. In addition, the MHLW and PMDA recently launched the Clinical Innovation Network (CIN) project, which aims to promote clinical studies by the use of disease registry data.

In another example, the Food and Drug Administration Amendments Act of 2007 required the US FDA to perform a summary safety analysis of newly approved medicines

18 months after approval or after 10 000 patients had taken the drug, whichever was later. These analyses were to be performed in addition to the FDA's ongoing safety monitoring of the drug. An evaluation of these summary safety analyses revealed that of 458 products that had been approved for at least 18 months, 300 had been the subject of a summary safety analysis; many products had not reached the 10 000-patient threshold and thus were not the subject of a summary safety analysis [32]. A new safety signal that resulted in a safety-related label change was found for 11 of these products. To provide context for this findings, these 11 safety-related label changes represented less than 2% of the 713 safety-related label changes made for these products. These findings suggested that the summary safety analysis had minimal value over standard pharmacovigilance activities. The FDA's requirement for these summary safety analyses was removed in a subsequent law [33].

Advancing the Science of Pharmacoepidemiology

Pharmacoepidemiology is a complex, dynamic, and changing field. It relies on the integration of epidemiology, clinical pharmacology, pharmacy, medicine, statistics, and other disciplines for its full execution. Increasingly, the rapid advances in the availability of large, diverse, and relevant datasets have made informatics an important contributing discipline to pharmacoepidemiologic efforts. Acquiring expertise in pharmacoepidemiology thus requires an environment that provides access to experts in all the relevant disciplines. Furthermore, this discipline relies on population-based healthcare data and thus an understanding of the healthcare system in which the data were generated, which experts in the above fields may not have. As more and more drug safety questions arise that require expertise in pharmacoepidemiology as well as appropriate data, it is crucial that there be sufficient capacity, both in the form of well-trained pharmacoepidemiologists and in the availability of systems, such as networks that combine relevant data with scientific expertise, that can be used for pharmacoepidemiologic studies. Because pharmacoepidemiology is a multidisciplinary effort, there must also be appropriate mechanisms for collaboration. Regulatory agencies play a role in facilitating the reaching of these goals.

To strengthen the monitoring of marketed medicines, the EMA developed the European Network of Centres for Pharmacoepidemiology and Pharmacovigilance (ENCePP) [34]. The EMA identified available expertise and research experience in the fields of pharmacovigilance and pharmacoepidemiology across Europe, and developed a network of centers with the capacity to perform postauthorization studies focusing on safety and benefit–risk. The ENCePP's principal activities include the development of a Code of Conduct to promote scientific independence and transparency [35]; the promulgation of scientific standards and guidance, including the ENCePP Guide on Methodological Standards in Pharmacoepidemiology [36], which provides guidance on methodology that is intended to supplement that in formal textbooks and regulatory guidance, and the ENCePP Checklist of Study Protocols [37], which is intended to promote the quality of pharmacoepidemiologic studies; and the ENCePP Resources Database, which provides an index of pharmacoepidemiologic research organizations, networks, and data sources in the EU [38]. The ENCePP project illustrates one way in which a regulatory agency can be involved in building pharmacoepidemiologic capacity.

The FDA, as one of its commitments under the reauthorization of the Prescription Drug User Fee Act in 2007, was tasked with developing a guidance document, with input from academia, industry, and others, "that addresses epidemiology best practices and provides guidance on carrying out scientifically sound

observational studies using quality data resources" [39]. The guidance document [40] illustrates another mechanism through which regulatory agencies can promote the field of pharmacoepidemiology.

Because pharmacoepidemiology depends on many areas of expertise, fostering collaboration to advance the field is another potential role that regulators can play. Through a project funded by the Innovative Medicines Initiative (IMI), the EMA, along with the national drug regulatory agencies from Denmark, Spain, and the UK, partnered with a number of public and private organizations, academic organizations, and pharmaceutical companies to form IMI PROTECT (Pharmacoepidemiological Research on Outcomes of Therapeutics by a European Consortium), a consortium dedicated to strengthening the methods used to monitor the benefits and risks of medicines [41]. (See also Chapter 25.) Topic areas covered by IMI PROTECT included enhancing data collection from consumers; improving early and proactive signal detection from spontaneous reports (including comparing different signal detection algorithms), electronic health records, and clinical trials; developing, testing, and disseminating methodologic standards for the design, conduct, and analysis of pharmacoepidemiologic studies; developing methods for continuous benefit–risk monitoring of medicines; and testing and validating various methods developed in PROTECT. By fostering collaboration across multiple disciplines, IMI PROTECT generated 74 original peer-reviewed scientific publications that not only advanced important pharmacoepidemiologic methodologies, but did so in a way that considered and enabled the potential regulatory application of such work [42].

Regulatory agencies can also promote pharmacoepidemiology by collaborating with external partners to develop and implement networks that allow for the regulatory agency to conduct its own specific pharmacoepidemiologic studies. In Japan, the PMDA launched the Medical Information for Risk Assessment Initiative (MIHARI), the aim of which is to use a variety of large-scale sources of electronic health information for pharmacoepidemiologic assessments [43]. *Mihari* is a Japanese word meaning "to monitor" or "to watch over." As part of its efforts to prepare the MIHARI for full-scale deployment, the PMDA has conducted more than 40 pilot studies during the past several years that made use of several large-scale databases: a nationwide insurance claims database covering nearly the entire Japanese population; a claims database maintained by health insurers covering a substantial portion of Japan; a database of electronic medical records maintained by medical institutions (e.g., the Medical Information Database NETwork, MID-NET®, described later in the chapter); and an inpatient care database containing data in a format compatible with the Diagnosis Procedure Combination (DPC) system, a comprehensive inpatient reimbursement system. Guided by the results of these pilot studies, in 2014 the PMDA introduced a novel regulatory framework for conducting postmarketing drug safety assessments using electronic health information databases. In addition to implementing this new framework, the PMDA also published the Guidelines for Pharmacoepidemiological Studies Using Health Information Databases for Drug Safety Assessments in 2014 [44]. The MID-NET system was established jointly by the MHLW and PMDA as a new database for use in drug safety assessment operations. It is a distributed database that compiles electronic medical records, insurance claims data, and DPC-compatible inpatient care data under a common data model. As of 2018, MID-NET had provided reliable data concerning approximately 4 million patients who received medical care from 23 medical institutions. In addition, in 2018, use of MID-NET was opened to relevant members of industry and academic researchers for use in pharmacoepidemiologic

studies investigating drug product safety and effectiveness.

FDA's Sentinel initiative (see also Chapter 25) also represents an example of a program sponsored by a regulatory agency that seeks to advance pharmacoepidemiology though a collaborative effort [45]. The goal of Sentinel is to create a sustainable, linked system of electronic healthcare databases to investigate safety questions about FDA-regulated medical products. The use of healthcare data in this way raises many questions of public interest, including on governance, privacy, data standards, and public disclosure of results. In view of these issues, the FDA sought extensive stakeholder input as it worked with outside organizations to develop Sentinel. In addition to the logistic issues already discussed, the fundamental premise of Sentinel – that data from many sources can be used to address a drug safety question in a timely way – implies that a collaborative effort is needed for the success of this project. The Sentinel system, the implementation of the initiative, includes administrative claims data and electronic medical record data from several holders of such data that are transformed into a common data model across all data holders. To facilitate efficient analysis of these data, the Sentinel system uses pretested, validated, and parameterized analytic programs along with the common data model. The system is designed as a distributed database in which holders of the data retain physical and operational control over their electronic data, a feature that addresses privacy concerns [46]. The Sentinel system has been used for a variety of analyses involving drugs as well vaccines.

Pharmacoepidemiologic efforts such as ENCePP, MIHARI, and Sentinel all make use of various traditional sources of healthcare data derived from existing sources that reflect current clinical practice and actual patient experiences. While these contemporary systems often rely on large datasets and, at times, integration of datasets through networks, it is important to note that pharmacoepidemiologic research has a decades-long tradition of using observational data recorded at the point of care to describe the effects of medicines in populations, though the scope of this work has largely focused on safety issues. The emergence in recent years of additional digital health-related data, such as data generated from wearable devices and health-related applications, has given rise to the notion that the expanding variety of electronic healthcare data can be used to study the effects of medicines beyond those related to safety. To promote further progress in this emerging area, numerous regulatory agencies from around the world resolved to work together to convert real-world data into real-world evidence to support regulatory decision making at the 12th Summit of Heads of Medicines Regulatory Agencies held in October 2017 in Kyoto, Japan. As methods to develop real-world evidence move forward [47], pharmacoepidemiologists, including those in regulatory agencies, will have an important and growing role to play, particularly in supporting timely and robust public health decisions.

Pharmacoepidemiology and the Law

Aaron S. Kesselheim and Kerstin N. Vokinger

Program On Regulation, Therapeutics, And Law (PORTAL), Division of Pharmacoepidemiology and Pharmacoeconomics, Department of Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston, MA, USA

The law describes the basic rules under which people live in modern society. Tort law, for example, provides a system of corrective justice and a coherent set of principles to decide whether a person deserves compensation for an injury he or she sustained. As another example, contract law provides a structure for adjudicating agreements between parties. In both cases, the existence of governing law helps influence the way people act. In the case of tort law, knowledge about its liability rules should incentivize people to take care to prevent accidents from happening.

In their daily work, pharmacoepidemiologists encounter many different aspects of the law. Perhaps the most recognizable connection occurs when patients seek redress in tort law for adverse effects from a medical product. In such circumstances, pharmacoepidemiologic studies may provide the scientific underpinning for the claim as to the association between the drug and the claimed outcome. Often, pharmacoepidemiologists are called as expert witnesses to interpret scientific findings for judges and juries. Other basic legal principles may also have important effects on the practice of pharmacoepidemiology. For example, pharmacoepidemiologists must navigate contract law when they develop research agreements with funding sources or owners of databases. Pharmacoepidemiologists interface with property law when they attempt to secure ownership rights over their discoveries using patents (a type of "intellectual property").

This chapter outlines three of the most recognizable intersections of pharmacoepidemiology and the law: tort law, contract law, and intellectual property law. The chapter defines and describes basic legal rules in these subject areas, and uses these rules as a basis for additional discussion about practical and ethical implications for pharmacoepidemiology. In each example, US law is used as the paradigm, with some attention to alternative models in Europe. Since much of the discussion is based on principles that are generally similar in other comparable legal systems, the lessons are applicable to pharmacoepidemiologists around the world.

Tort Law and Product Liability Lawsuits

Product liability lawsuits provide an opportunity for individuals harmed by a drug to seek damages from its manufacturer. Recent widely

Pharmacoepidemiology, Sixth Edition. Edited by Brian L. Strom, Stephen E. Kimmel and Sean Hennessy.

reported cases have included the nonsteroidal anti-inflammatory drug (NSAID) rofecoxib (Vioxx®), the antidepressant paroxetine (Paxil®) and other selective serotonin reuptake inhibitors (SSRIs), olanzapine (Zyprexa®) and other atypical antipsychotics, the cholesterol-lowering agent cerivastatin (Baycol®), the antidiabetic/anti-inflammatory troglitazone (Rezulin®), and the serotoninergic anorectic drug dexfenfluramine (Redux®). In this chapter, we will review how product liability lawsuits are adjudicated according to some common law principles. A basic understanding of product liability law is essential for pharmacoepidemiologists, even for those who might never find themselves in a courtroom, because such lawsuits also exert substantial influence on the field. Tort litigation brought by government agencies and individual patients can help uncover previously unavailable data on adverse effects, questionable practices by manufacturers, and flaws in drug regulatory systems [1].

The Legal Theory of Product Liability

In the centuries-old common law tradition of England, which forms the basis for legal systems in the US and a number of other countries, a consumer injured by a defective or contaminated pharmaceutical product was not permitted a right of action unless the consumer purchased the preparation directly from the manufacturer. The emergence of product liability law altered that state of affairs, permitting consumers harmed by the many products sold widely in interstate commerce and through distributors like pharmacies to seek redress for their injuries from the original manufacturers [2]. Originally, product liability was grounded in the theory of negligence, which meant that defendants would be liable for causing plaintiffs' injuries if the defendants engaged in wrongful or unreasonable conduct, even if it was unintentional. To succeed in a claim for negligence, plaintiffs needed to show (i) that defendants had a duty to exercise reasonable care; (ii) that defendants' conduct diverged from customary practices that would be followed by other manufacturers or members of the industry; (iii) that there was a causal link between the defendants' lack of care and the outcome at issue; and (iv) that the preceding three factors led to damages.

However, negligence theory did not allow enough deserving plaintiffs to be compensated for product-related injuries they suffered, particularly in cases in which products were hazardous or dangerous. Judges rationalized that some products contained an inherent risk of harm, so manufacturers that chose to sell such products needed to bear the responsibility when the products caused injury. As a result, starting in the early 1960s, judges started applying the theory of strict liability to certain product liability cases. Strict liability merely requires demonstration that the dangerous product caused the injury; as distinguished from negligence, the question is moot as to whether the defendants followed customary practices or exercised reasonable precautions. This principle permitted plaintiffs to seek compensation for injuries merely because the product was designed a certain way, irrespective of other mitigating factors. For example, the product could have a "manufacturing defect," meaning that the product did not comply with the manufacturer's own standards, or a "design defect," meaning that the product was designed in a way that conferred inherently unreasonable risk for the consumer.

Strict product liability grew quickly in popularity. In 1965, US legal scholars proposed a consensus understanding of the area in the influential Restatement (Second) of Torts, finding that a seller of a product that is "in a defective condition unreasonably dangerous to the user or consumer" should be strictly liable even if the seller "exercised all possible care in the preparation and sale of the product" [3]. Notably, the authors commented that warnings could be employed to prevent any product from being deemed "unreasonably dangerous," although

such warnings needed to address risks that the seller "has knowledge, or by application of reasonable, developed human skill and foresight should have knowledge" [4]. Thus, strict product liability also allowed plaintiffs to bring causes of action against manufacturers based on inadequate warnings, otherwise known as a "failure to warn."

Some courts were hesitant to apply strict product liability to cases emerging from the pharmaceutical field. This reticence was reflected in the Restatement, which included an important annotation relevant to prescription drugs. In Comment k to this section of the document, the Restatement noted that a pharmaceutical product "properly prepared, and accompanied by proper directions and warning, is not defective, nor is it unreasonably dangerous" [5]. Thus, the Restatement excluded most prescription drugs from strict liability based on manufacturer or design defects. The authors separated pharmaceutical products from other products because they believed the marketing and use of pharmaceutical products "are fully justified, notwithstanding the unavoidable high degree of risk which they involve." Prominent legal scholar William Prosser summed up the justification for treating prescription drugs differently:

> The argument that industries producing potentially dangerous products should make good the harm, distribute it by liability insurance, and add the cost to the price of the product, encounters reason for pause, when we consider that two of the greatest medical boons to the human race, penicillin and cortisone, both have their dangerous side effects, and that drug companies might well have been deterred from producing and selling them. Thus far the courts have tended to hold the manufacturer to a high standard of care in preparing and testing drugs of unknown potentiality and in giving warning; but in the absence of evidence that this standard has not been met, they have refused to hold the maker liable for unforeseeable harm. [6]

Ultimately, a minority of US courts have implemented the Comment k principle and offered pharmaceutical manufacturers a blanket protection from strict liability for manufacturer or design defect claims [7]. The majority of courts charted a slightly different course. For example, in New Jersey, the state Supreme Court declined to adopt Comment k in the case of an infant who suffered severe tooth discoloration after being prescribed demeclocycline (Declomycin®), a tetracycline antibiotic. The court ruled that the Comment k shield should only apply to drugs that were "more vital to the public health and human survival than others," while less useful drugs would continue to be evaluated under strict liability [8].

In 1997, the Restatement (Third) of Torts: Product Liability tried to clarify the question about liability for design defects. It reemphasized that judicial risk–utility analysis was improper, arguing that a drug cannot be considered to have a design defect if "reasonable health care providers, knowing of such foreseeable risks and therapeutic benefits" prescribed the drug to the patient [9].

Even in jurisdictions amenable to strict product liability for pharmaceuticals, the vast majority of drugs approved by the US Food and Drug Administration (FDA) are likely to meet courts' balancing test. As a result, when a person is injured by a prescription drug, a "design defect" lawsuit based on the claim that the product was avoidably unsafe is very unlikely to succeed. Rather, plaintiffs usually seek to demonstrate "failure to warn" by the manufacturer about the adverse event at issue (nominally a strict liability claim). Alternatively, plaintiffs could sue based on a negligence theory that the manufacturer failed to take reasonable care in marketing its product, an analysis that also largely hinges on the appropriateness of the accompanying warnings. Practically speaking, the ultimate

disposition of a case filed under a strict liability failure to warn or negligence theory turns on the question of whether the warning is reasonable [10]. After these historical twists and turns in legal theory in this area, the claim for "failure to warn" has become the most common basis for litigation over pharmaceutical products. In the next section, we will review the link between the work of pharmacoepidemiologists and failure-to-warn claims.

Failure-to-Warn Claims

Whether based on strict liability or negligence, a failure-to-warn product liability action includes three main contentions: (i) knowledge of the drug risk by the manufacturer; (ii) improper warning of the drug risk; and (iii) causation of damages.

Knowledge of the Drug Risk by the Manufacturer

First, the plaintiff must demonstrate that a pharmaceutical manufacturer knew, or should have known, of the risk. Apart from the rare case decided based on a strict liability design defect, a manufacturer of a pharmaceutical product is not held accountable for risks about which it could not have known. For example, in one case, a plaintiff brought a lawsuit claiming that her oral contraceptive medication led to her having a cerebrovascular accident, or stroke [11]. The court remarked, "Dates are thus vitally important as there is no duty to warn of unknown or unforeseeable risks, and the question is whether the risk was knowable or reasonably foreseeable at the time when the plaintiff was still taking the drug." The jury found that the particular risk the plaintiff claimed could not have been known at the time the drug was prescribed, based in part on the testimony of the expert pharmacoepidemiologist who reported that "new techniques to measure these clotting effects had not then been developed" at the time of the injury. According to the court, "The warnings contained in the package inserts were adequate or … the statements contained therein were a fair representation of the medical and scientific knowledge available at the time the drug was taken by the plaintiff."

Knowledge can be actual or constructive. *Actual knowledge* is defined as literal awareness. Actual knowledge can be demonstrated by showing that the manufacturer was cognizant of reasonable information suggesting a particular risk that it did not pass on to consumers, for example when a defendant possesses data about relevant adverse events that were not disclosed. In the case of SSRIs used to treat depression, various manufacturers were found to have conducted clinical trials that showed an increased risk of suicidal ideation in adolescent patients taking the drug. Plaintiffs brought lawsuits charging that these findings were knowingly delayed for lengthy periods of time, not released, or the concerns not fairly represented [12]. For example, the largest study of paroxetine (Paxil®) in pediatric patients was conducted in the US from 1993 to 1996; it showed no benefit of the drug over placebo and 5 cases (out of 93) of suicidal ideation, as compared to 1 case out of 89 in the placebo arm and 1 case out of 95 in the comparator (non-SSRI) arm. The manufacturer, GlaxoSmithKline, allegedly sought to "effectively manage the dissemination of these data in order to minimize any potential negative commercial impact" [13]. To support this contention, plaintiffs pointed to the fact that the data were only presented in abstract form in 1998 and published in 2001 (when the authors concluded that the drug was "generally well tolerated and effective for major depression in adolescents") [14]. After the full data from this trial and others like it were made public, a new FDA health advisory in 2004 warned physicians to carefully monitor patients for "clinical worsening, as well as agitation, irritability, suicidality, and unusual changes in behavior" and emphasized that only the SSRI fluoxetine

(Prozac®) had been approved to treat pediatric major depressive disorder [15].

Constructive knowledge is sometimes called "legal knowledge," because it is knowledge that the law assumes should be present, even if it is not. Constructive knowledge is knowledge that a person did not have, but could have acquired by the exercise of reasonable care. For example, the cholesterol-lowering drug cerivastatin (Baycol®) was removed from the market in 2001 after it was linked to cases of rhabdomyolysis, a potentially fatal kidney disease. The manufacturer, Bayer, was found to possess several reports from as early as 1999 suggesting a 10-fold risk of rhabdomyolysis relative to other medications in its class, but it allegedly did not process these reports and pass them along to patients or regulators [16]. A memorandum from a Bayer official stated, "If the FDA asks for bad news, we have to give [it], but if we don't have it, we can't give it to them" [17]. In this case, Bayer could be said to have constructive knowledge of these concerns by 1999, because the company should have processed the reports and acted on them. In other cases, plaintiffs have tried to prove constructive knowledge by arguing that manufacturers should have performed different or additional analyses to better understand an important side effect of their product. The standard for constructive knowledge in these situations has been what a reasonably prudent company with expertise in this area would have undertaken.

Improper Warning of the Drug Risk

If a manufacturer has the duty to provide a warning about adverse events associated with its product, then the next question is whether an adequate warning was provided. A proper warning has certain hallmarks, including relevance, timeliness, and accuracy.

First, a warning about an adverse effect must be commensurate with the scope and extent of dangers associated with the drug. In the case of troglitazone (Rezulin®), an oral hypoglycemic approved in the US in 1997 and used by diabetic patients, the company was accused of minimizing its presentation of liver toxicity in its warning materials [18]. Elevations of hepatic enzymes in early testing were initially depicted in the descriptions of adverse effects simply as "≥3-fold." Yet, some were apparently more than 20-fold; several of those patients suffered acute liver failure. In the subsequent litigation, it was alleged that the warning was deficient because company did not initially acknowledge this clinically important difference [19].

Secondly, warnings must not be subject to undue delay. Some delays may be internal. In the case of rosiglitazone (Avandia®), another oral hypoglycemic drug, a 2007 meta-analysis linked the drug to life-threatening cardiovascular adverse events [20]. However, after a review of internal company documents, a US Senate Finance Committee report suggested that the manufacturer knew about these risks years before this article was published, but delayed warning about them and sought to limit their dissemination [21]. A primary question in lawsuits arising from the use of rosiglitazone is whether these tactics inappropriately delayed reasonable warnings about the adverse effect. Sometimes, interactions with regulators may cause delays. For example, cisapride (Propulsid®) was a pro-kinetic agent linked to potentially fatal cardiac side effects. It was reported that the manufacturer and the FDA negotiated for five years over the details of how to change the drug's label to include adverse event data that had been submitted to the agency but not made fully available to the public [22].

Thirdly, warnings must be of appropriately urgent tone. In the case of rofecoxib (Vioxx®), a new type of NSAID used for arthritis, preapproval clinical trials suggested enhanced risk of serious cardiovascular side effects, a result consistent with a later pivotal manufacturer-sponsored trial comparing the drug to naproxen, another older NSAID, in a population of patients with rheumatoid arthritis (but no

known cardiovascular disease) [23]. When the drug's official FDA label was updated in 2002 to account for these findings, subsequent lawsuits alleged that the warning was insufficiently urgent because the risk of cardiovascular events was described in vague terms and placed in the less prominent "precautions" section of the labeling [24].

Finally, a manufacturer's duty does not end with the initial warning, because it must keep up with emerging scientific data and patient reports, and warn of new side effects discovered after initial approval. In one case, plaintiffs brought a suit contending that their daughter's serious birth defects were related to a teratogenic progesterone formulation (Delalutin®) manufactured by the defendant. The court noted that the drug manufacturer is under a "continuous duty … to keep abreast of scientific developments touching upon the manufacturer's product and to notify the medical profession of any additional side effects discovered from its use" [25]. The plaintiff's expert medical witness testified that there was "sufficient scientific information and literature relative to progesterones" at the time the drug was used to "make a prudent drug manufacturer do teratogenicity studies on any progesterone agent" [25].

Causation of Damages

Another major issue in a pharmaceutical product liability case is whether the product at issue actually caused the alleged injury. Pharmacoepidemiologists may be most comfortable thinking about causation from a medical or scientific point of view. Scientists generally posit hypotheses to explain particular outcomes and then test those hypotheses by studying whether variations in the outcomes exist across populations. However, legal causation usually requires a clear causal chain from exposure to outcome, in an individual. The legal standard for causation is therefore challenged by product liability cases, in which probabilistic evidence (i.e., P values or confidence intervals) often links drugs to injuries [26]. Courts must address two types of legal causation: general and specific causation.

General causation addresses whether a product *can* cause a particular injury in the population of patients like the plaintiff. The common law standard to prove general causation is that a particular product "more likely than not" caused the damages. Some courts have held that legal causation must be demonstrated by more than an association and a mere possibility of causation, even though causal hypotheses based on such considerations are common in the scientific literature. A few courts have even gone further and defined "more likely than not" as having a relative risk of greater than 2.0, no matter how tight the confidence intervals are around a statistically significant finding of association between 1.0 and 2.0 [27]. Presumably this is based on the calculation of attributable risk in the exposed group exceeding 50%, when the relative risk exceeds 2.0. This standard has been replicated in the Federal Judicial Center's *Reference Manual on Scientific Evidence* [28] and employed in some cases to exclude epidemiologic evidence with weaker associations. For example, in the case of the antinausea drug pyridoxine/doxylamine (Bendectin®), which was claimed to be causally linked with birth defects, one court noted, "In terms of statistical proof … plaintiffs must establish not just that their mothers' ingestion of Bendectin increased somewhat the likelihood of birth defects, but that it more than doubled it – only then can it be said that Bendectin is more likely than not the source of their injury" [29]. In one case related to litigation over the link between silicone breast implants and inflammatory disease, a court excluded a study linking the product and the outcome with a relative risk of 1.24, noting that the finding was "so significantly close to 1.0" that the study "was not worth serious consideration for proving causation" [30].

However, all courts do not adhere rigidly to the 2.0 relative risk principle for general causation.

Both clinical trials and epidemiologic studies of the product at issue can establish general causation between a pharmaceutical product and an outcome. Animal studies, meta-analyses, case reports/case series, and secondary source materials (such as internal company documents) have been used in court as they are in the medical field – to help support establishing a causal link. Since pharmacoepidemiologic studies tend to assess the presence of an association, rather than directly addressing causation, courts sometimes apply the Bradford Hill criteria to connect an association with general causation (see Table 9.1 and Chapter 1).

To demonstrate *specific causation*, a plaintiff must show that the product in question caused the alleged injury in the plaintiff. This can be a particularly complex issue for pharmaceutical products. In some cases, like instantaneous allergic reactions, the causal link between a product and an outcome is clear. For more subacute or later-onset responses, however, specific causation may be hard to demonstrate. For example, in one case against Merck brought by a plaintiff who suffered a myocardial infarction shortly after starting rofecoxib, the manufacturer argued that the outcome was attributable to the plaintiff's prior existing coronary artery disease. The plaintiff countered with the fact that he was in a state of stable cardiovascular health prior to initiation of rofecoxib, that he simultaneously developed two coronary artery clots after the drug's initiation (a rare presentation for ischemic heart disease), and that many studies have confirmed the link between rofecoxib and cardiovascular disease (a point relevant to general causation) [31]. While the trial court held for the plaintiff, the decision was reversed on appeal; the appeals court ruled that, "although plaintiffs were not required to establish specific causation in terms of medical certainty, nor to conclusively exclude every other reasonable hypothesis, because [the plaintiff's] preexisting cardiovascular disease was another plausible cause of his death, the plaintiffs were required to offer evidence excluding that cause with *reasonable certainty*" [32].

Another important aspect of specific causation is that the plaintiff must demonstrate that the inadequate warnings about the adverse effect were relevant to the plaintiff's receiving the drug. If a defendant can demonstrate that even an adequate warning would have made no difference in the decision to prescribe the drug, or to monitor the patient postprescription, the case may be dismissed for lack of a proximate cause.

Table 9.1 Bradford Hill criteria.

1)	Strength of association
2)	Consistency and replication of findings
3)	Specificity with respect to both the substance and injury at issue
4)	Temporal relationship
5)	Biological gradient and evidence of a dose–response relationship
6)	Plausibility
7)	Coherence
8)	Experimental removal of exposure
9)	Consideration of alternative explanation

Learned Intermediary Defense

If a plaintiff successfully argues these issues and demonstrates a *prima facie* case of product liability based on a failure to warn, the manufacturer has a few possible defenses. The most relevant in the field of pharmaceutical law is the learned intermediary defense.

Originally, product liability law imposed on all manufacturers a duty to warn consumers about the risks of their products. However, starting in the 1960s, pharmaceutical manufacturers argued that it would be more effective for them to warn physicians, the gatekeepers of prescription

medicines [33]. Courts accepted that physicians' advanced training and direct contact with patients put them in an optimal position to understand and relay complex information about possible side effects. Physicians are also well placed to discuss risks and benefits applicable to particular clinical circumstances in their patients. The "learned intermediary" rule allows pharmaceutical manufacturers to fulfill their duty to warn by providing an accurate and adequate warning to prescribing physicians [34].

The implications of the learned intermediary defense are that the debates in plaintiffs' cases tend to focus on the propriety of the warning vis-à-vis the physician, rather than the patient. Therefore, warnings do not have to be offered about risks that should be obvious or are generally known to skilled medical practitioners [35]. However, when the information given to physicians omits, underemphasizes, misstates, or obfuscates dangers, this deficiency is legally transferred to the patient, who maintains a right of redress against the manufacturer if those dangers materialize and cause injury.

If the manufacturer imparts an appropriate warning to physicians, then the manufacturer can be insulated from liability. In such cases, the focus of the litigation then often turns to the conduct of the physician and the physician–patient interaction. For example, in one case a lawsuit was brought following the suicide of a patient who had been prescribed two antihypertensive drugs, hydrochlorothiazide (HCTZ) and reserpine (Harmonyl®). The label for HCTZ stated that it might "potentiate the action of other antihypertensive drugs," while the insert for reserpine stated that the drug should be discontinued at any sign of "despondence" and that there were reports of drug-related depression severe enough to result in suicide. Because the physician was presumed to have had constructive knowledge of both of these warnings, the court insulated the manufacturers from liability [36].

In special situations, pharmaceutical manufacturers may lose the ability to invoke the learned intermediary defense. If a manufacturer markets its product very aggressively and without sufficient attention to certain risks, courts may rule that it has essentially undone the physician–patient prescribing relationship. Direct-to-consumer advertising (DTCA) is one modality that can undercut the assumption that patients are largely ignorant of prescription drug risks and that manufacturers lack means of interacting with patients other than through physicians. DTCA is currently only permitted in two industrialized countries around the world: the US and New Zealand. The New Jersey Supreme Court has ruled that DTCA created a limited exception to the learned intermediary defense [37], and in 2007 the West Virginia Supreme Court rejected the learned intermediary defense in its entirety on this basis [38]. Nonetheless, in most jurisdictions, the learned intermediary rule still stands.

Expertise and *Daubert*

Pharmacoepidemiologists often serve as expert witnesses in product liability cases. Pharmacoepidemiologists can help judges and juries understand data about drugs and help determine whether warning information appropriately reflects the risk posed by a drug. Experts are usually called on to describe the current state of knowledge about the adverse event at issue, and may be asked to perform additional pharmacoepidemiologic analyses of available data to present before the court.

However, courts can exclude some practitioners and some analyses from trial. Traditionally, the judge is responsible for evaluating whether expert witnesses lack qualifications or espouse scientific theories out of step with accepted knowledge [39]. In the 1993 case of *Daubert v. Merrell Dow*, the US Supreme Court outlined a number of criteria for reviewing the appropriateness of expert witness testimony, including whether the theory was current and whether it had been tested or subjected to peer review and publication [40]. A subsequent case applied these

rules and further refined them in evaluating a debate over the admissibility of expert testimony suggesting that polychlorinated biphenyls (PCBs) can cause lung cancer. The research was excluded because the experts did not validate their conclusions: the epidemiologic studies did not report a statistically significant causal link between PCBs and lung cancer, lacked proper controls, and examined substances other than PCBs [41]. As federal circuit court judge Richard Posner has explained in separate circumstances, "the courtroom is not the place for scientific guesswork, even of the inspired sort" [42].

In the US, some state courts have embraced the *Daubert* guidelines, which have also been taken up by revised Federal Rules of Evidence [43]; others adhere to an alternative doctrine that excludes testimony containing theories that do not enjoy "general acceptance in the relevant scientific community" [44]. Thus, pharmacoepidemiologists seeking to present expert evidence in litigation will routinely face judicial inquiry to determine whether they are fit to serve in that role. Judicial oversight in general sets a low floor for reliable expert testimony, although it can be expected to exclude experts who lack the relevant qualifications, lack facts to back up their perspectives, lack reliable methods, or fail to apply the methods appropriately [45]. There is considerable skepticism about the effectiveness of courts as a gatekeeper for expert witnesses, with some commentators citing judges' lack of the technical knowledge needed to meaningfully evaluate medical and scientific expertise [46].

The Effect of Regulation on Product Liability Litigation in the US

In the last few years, there has been a wave of controversy about the role of government regulation of pharmaceuticals in product liability claims against drug manufacturers. Under the US Food, Drug, and Cosmetic Act, originally passed in 1938, the FDA is required to certify that prescription drugs are safe enough and show efficacy for their intended indication before being sold on the US market [47] (see also Chapters 1 and 8). At the time of approval, the FDA also endorses the official drug labeling, which presents a description of the basis for the drug's efficacy as well as safety concerns that have emerged during the preapproval testing [48]. The labeling, which is generally written by the manufacturer and approved by the FDA, has legal significance as well. For example, because the FDA restricts certain types of manufacturer communication about non-FDA-approved (or "off-label") indications, the label determines what a pharmaceutical manufacturer can communicate to physicians and the public about its product [49]. The FDA requires the manufacturer to mention important warnings that are in the official labeling when marketing its product, but does not require manufacturers to mention warnings that are not in the labeling.

For most of its history, the FDA has regulated the drugs sold in the US without any direct role in product liability litigation brought by consumers injured by FDA-approved drugs [50]. The agency's noninterventionist posture changed for the first time in September 2002 in a product liability case brought after a man was prescribed the SSRI sertraline (Zoloft®) and started experiencing agitation, confusion, and suicidal thinking, ultimately leading him to take his own life one week later [51]. The plaintiffs claimed that the manufacturer failed to warn appropriately about the risks of suicide. The manufacturer contended that such a claim could not be brought because the FDA had not included such a warning in the official label, and the Supremacy Clause of the US Constitution preempts states from imposing legal requirements (in this case, via a tort action in state court) that directly contradict federal law [52]. Driven by the political preferences of its leadership at the time, the FDA filed an amicus brief in

the case on behalf of the defendant manufacturer, arguing that imposition of product liability would "undermine the agency's authority to protect the public health" [53]. The brief claimed that an adverse court ruling would force companies to add warnings not approved by the FDA and could upset the delicate benefit/risk balancing that went into the construction of the drug labeling, which could result in overwarning and ultimately underuse of an effective drug.

The major deficiency in the logic of those favoring FDA preemption in this area is that these arguments inappropriately regard the FDA's official label as the final word on drug safety. In fact, preapproval clinical trials necessarily involve only a limited sample of patients and are often powered to detect changes in efficacy-related endpoints, rather than rates of adverse events (see Chapter 4). The FDA will not have a complete picture of the safety of drugs, even at the time the labeling is written. After approval, the FDA lacks the resources and capability to actively monitor evolving knowledge about a drug [54]. Until the FDA Amendments Act (FDAAA) of 2007 (Public Law 110-85), the FDA had no authority to compel manufacturers to update the warnings in drug labeling. After the withdrawal of rofecoxib, Sandra Kweder, Deputy Director of the FDA's Office of New Drugs, said in testimony at a US Senate hearing, "We don't have the authority to tell a company, 'This is how your label has to look. This is the language that needs to go into your label. Here is where it goes, end of story.' We have to negotiate with the company the specific language of how things should be worded, the placement, those kinds of things" [55]. The FDAAA gave the FDA limited authority to "require" labeling changes "if the Secretary becomes aware of new safety information that the Secretary believes should be included in the labeling of the drug," but made these decisions reviewable through an alternative dispute resolution procedure [56]. Although this new authority strengthened the FDA's hand somewhat, ensuring compliance can still involve a lengthy and resource-intensive legal process. While the pathway established by FDAAA has rarely been publicly invoked in the decade since passage of the law, its existence may strengthen the FDA's position in its negotiations with manufacturers over inclusion of warning language in a drug's labeling.

Manufacturers, by contrast, are in an optimal position to learn about emerging safety concerns after FDA approval, because they closely monitor the use of their products, organize postmarketing studies, and receive spontaneous reports from physicians and other sources about adverse events arising in the course of therapy (see Chapter 7). Manufacturers have a strong financial incentive to increase sales of their products, but manufacturers may also sometimes be faced with their own safety-related data that suggest limiting use of their product, or withdrawing it from the market altogether. In such situations, manufacturers have made poor decisions that adversely affect public health. For example, when drug safety issues have emerged after approval, some manufacturers have decided to downplay reports of side effects to physicians [57] and the FDA [58,59]. Failure-to-warn litigation, therefore, serves an important supplementary regulatory function – without undermining FDA requirements – by providing a disincentive (in the form of substantial monetary penalties) for manufacturers' decisions to hide or downplay reports of safety issues that emerge after a product reaches the market. Notably, former FDA commissioners have confirmed that "Although the FDA might later disapprove of a [strengthened warning] label …, the FDA's power to disapprove does not make the manufacturer's voluntarily strengthened label a violation of federal law" [60]. At any time, a manufacturer can strengthen the labeling by adding warnings to it without first notifying the FDA and receiving approval to do so. In fact, the Code of Federal Regulations states, "The labeling shall be revised to include a warning as

soon as there is reasonable evidence of an association of a serious hazard with a drug; a causal relationship need not have been proved" [61].

Despite these considerations, the FDA's amicus brief argument was repeated in subsequent failure-to-warn cases, and a few courts expressly adopted the position [62]. In 2006, the FDA attempted to solidify its position further in a surprise preamble to a set of regulations regarding the format of the label, in which it reiterated its new contention that any FDA-approved labeling, "whether it be in the old or new format, preempts … decisions of a court of law for purposes of product liability litigation" [63]. The FDA suggested that preemption should apply even if a manufacturer failed to warn adequately about a known risk, unless a patient could prove that the company intentionally committed fraud on the FDA, which is a very difficult legal standard to meet [64].

Ultimately, the US Supreme Court reviewed the legal foundation of the claimed FDA preemption of product liability related to prescription drugs. The pivotal case, *Wyeth v. Levine*, was based on a lawsuit from a patient who was treated with an intravenous antinausea medication for her migraine headache. The product extravasated and caused gangrene in her forearm, leading to amputation. The patient sued the drug manufacturer for inadequately warning on the label about the known risks of certain intravenous uses of its medication. A Vermont jury determined after fully considering the record that the label did not sufficiently describe the drug's known risks with intravenous drip administration. The manufacturer appealed the verdict, and the Vermont Supreme Court affirmed, finding that the jury's verdict did not conflict with the FDA's labeling requirements, which "create a floor, not a ceiling, for state regulation" [65].

The manufacturer appealed again to the Supreme Court, arguing that it was impossible to comply with the federally approved label and that the state court judgment would obstruct the purpose of federal drug laws. The manufacturer charged that the FDA, not the drug manufacturer, had the primary responsibility for the drug label. In a 6–3 decision, the Supreme Court upheld the Vermont decision and struck down the notion of federal preemption in this field [66]. Justice John Paul Stevens, writing for the majority, noted, "It has remained a central premise of drug regulation that the manufacturer bears responsibility for the content of its label at all times."

After *Wyeth v. Levine*, there remains no controversy about whether FDA approval of a drug label preempts failure-to-warn claims. However, the decision did leave open the possibility that preemption could be invoked if the FDA had "consider[ed] and reject[ed] a stronger warning." That is, if the FDA reviews all the data surrounding a particular safety issue and makes a specific statement that a strong warning is not necessary, such an action could be invoked by a defendant to support preemption of a failure-to-warn lawsuit.

Product Liability Law in Europe

The European Union (EU) is a political and economic coalition that currently consists of 28 countries in Europe. The main sources of EU law are regulations, directives, and decisions. Regulations are immediately enforceable in member states when they come into force and automatically override conflicting local provisions. By contrast, directives usually leave member states discretion as to how they are to be adopted [67].

Product liability has been called an "American invention" [68], and the general product liability directive for the EU (85/374/EEC) was originally enacted in 1985. A liability action arising under this directive includes the following contentions: (i) defective product; (ii) causation of damage' and (iii) no exclusion of liability.

A product is defective if it does not provide the safety that a person is entitled to expect, taking all circumstances in account, including the presentation of the product, the use reasonably expected of the product, and the time when the product was put into circulation. However, a product may not be considered defective simply because a better product was subsequently put into circulation [69].

Product liability in non-EU European countries is defined by country-specific laws, although the approach is similar to that in the EU. In Switzerland (a non-EU country), for example, there is no specific legislation covering drug liability. Nonetheless, the generally applicable Product Liability Act requires a showing of (i) damage (design defect or failure to warn); (ii) causation of damage; and (iii) no exclusion of liability.

Like in the US, most product liability lawsuits in EU and non-EU countries in Europe are based on failure-to-warn claims about the adverse event at issue, rather than design defects. One of the exclusions of liability, as in US, is the learned intermediary defense. For example, in Switzerland, a 16-year-old patient was prescribed the oral contraceptive medication drospirenone/ethinylestradiol (Yasmin) and experienced a thromboembolism with a subsequent stroke. The patient sued the manufacturer based on a failure-to-warn claim. The labelling states that there is a higher risk for thrombosis and in the information letter to the physician, the risk for a thromboembolism is reported to double with the intake of the contraceptive medication. The Supreme Court ruled that this information was sufficient [70]. As previously discussed, since DTCA is not available in Europe, it is not possible for that practice to undermine the learned intermediary defense.

Within the EU, because the product liability rule is a directive, member states retain some flexibility in implementing aspects of it, such as whether they permit compensation for noneconomic damages (e.g., pain and suffering) or which manufacturer defenses they seek to incorporate [71]. As a result of this flexibility, there is substantial diversity across EU countries in how product liability cases are adjudicated [72]. Still, countries can be limited by the directive. For example, in a series of cases, the European Court of Justice prevented France, Spain, and Denmark from enacting provisions considered to be too friendly to the damaged party [73].

Product liability related to prescription drugs in Germany bears special attention, since this is the only EU country that has implemented (even prior to the enactment of the EU liability directive) particular rules in this field via its Medicines Act. This is the consequence of the international thalidomide birth defect public health crisis of the late 1950s and early 1960s, which affected approximately 7000 children in Germany alone [74]. Liability exists if, when used in accordance with the intended purpose, the drug has harmful effects which exceed the limits considered tolerable in the light of current medical knowledge (i.e., a design defect), or the damage has occurred as a result of labelling that does not comply with current medical knowledge (i.e., a failure to warn) [75]. However, determining liability is based on a strict liability model that requires only demonstration of (i) damages; (ii) causation of damages; and (iii) no exclusions from liability (e.g., the learned intermediary defense) [76]. Another characteristic of German drug liability is the limitation of the amount of compensation for damages. In a case of death of or injury to a person, the pharmaceutical company is liable only for a capital amount of up to €600 000 or an annuity of up to €36 000 per year. In a case of death of or injury to several persons by the same drug, the pharmaceutical company shall be liable for a capital amount of up to €120 million or an annuity of up to €7.2 million per year [77].

German law also provides an interesting case example about the labeling requirements covering prescription drugs in Europe. The European Medical Agency (EMA) regularly

issues guidelines that specify the content and presentation of the labeling [78], including for example categorizing the frequency of possible side effects as very often (>10%), often (1–10%), occasional (0.1–1%), rare (0.01–0.1%), and very rare (<0.01%). In addition, Section 10 of the German Medicines Act lists all categories of information that need to be placed on a drug's labeling, such as indications, dosage, duration of intake, reference to overdose, expiration date, and adverse events. In describing adverse events, manufacturers must include a description of all adverse reactions that can occur when the drug is used as intended, the countermeasures to be taken if possible in the event of adverse reactions, and an additional standard text that explicitly instructs patients to inform their physicians, pharmacists, health professionals, or the competent higher federal authority directly of every suspected adverse reaction [79]. The German Supreme Court has ruled that more detailed information must be provided as the severity and probability of a potential adverse event increase [80].

Overall, product liability law in Europe is in many ways similar to that in the US, especially with regard to the principles of strict liability and the learned intermediary defense. However, failure-to-warn claims are less likely to succeed in Europe than in the US, and damages practices and rules generally lead to lower compensation for patients. As a result, fewer drug liability claims are brought in Europe, and the outcome of a case can vary widely whether a claim is being brought to court in the US or in a European country.

Pharmacoepidemiology and Contract Law

Many studies in the field of pharmacoepidemiology emerge from collaborations among individuals at different institutions. Different researchers may bring specific types of expertise to a project or different resources [81,82]. For example, researchers may have all the computing power they need, but require access to a certain external database to address a question. Collaborations may occur among academic centers, between nonprofit and for-profit companies, or with the government. Cooperative work can allow more complex research to be performed and help advance the field of pharmacoepidemiology in several ways.

One type of collaborative work of particular public health importance is contract research. Contract research is undertaken by an individual, academic, or nonprofit investigator supported by a sponsor (usually an industry or governmental agency). Most contractual research relationships are defined by the generation of a "deliverable," which can be a database, a research report, or some other product. The contract is the centerpiece of the relationship and classically represents the full outline of the agreement between the parties. The mutually agreed-upon terms are used as evidence of the parties' intentions if the agreement later runs into trouble and ends up in court. Relationships with industry are common; one survey of clinical epidemiologists and health services researchers in the US found that about 40% reported currently being involved in such relationships, while 50% reported forming collaborations with industry leading to publications [83]. In countless cases, contract research in pharmacoepidemiology has led to important public health findings and changes in healthcare delivery.

However, contract research may pose various potential pitfalls as well. Concern about contract research generally centers around (i) trial design; (ii) access to data and data analysis; and (iii) publication of results. It has long been known that there is a statistically significant relationship between a favorable study result and the source of research funding [84,85]. These results can be explained by choices made in trial design, when subjective decisions about

comparators [86] or the inclusion or exclusion of certain variables or potential confounders in epidemiologic and economic studies can affect the ultimate results of the trial [87]. Investigators should be wary of performing contract research in which the sponsor has the right to unduly influence the design of the trial. Many sponsors prefer to retain control of the data and insert their own statistical analyses. They argue that such efforts guard against "investigators [who] want to take the data beyond where the data should go," while investigators argue that this arrangement provides the company with an opportunity to "provide the spin on the data that favors them" [88]. In one case of an experimental AIDS vaccine, after a negative trial, the sponsor demanded that its contradictory analyses be inserted into the manuscript and ultimately sued the investigators for $7 million after the article was published [89].

Access to clinical trial data is critically important for academic researchers. In the case of rosiglitazone, a clinical trial organized by the manufacturer sought to compare the product against other treatment options for diabetes, and an independent academic steering committee was organized to oversee the data analysis [90]. Company documents suggest that the clinical trial database was exclusively controlled by the company, which provided limited access to the investigators [91]. When members of the steering committee questioned the presentation of the results, their concerns were largely overlooked [77]. In reviewing this case, one commentator concluded that the absence of independent access to all of the data in the trial may allow physician-scientists to be manipulated by the sponsor, resulting in a manuscript that does not provide the most accurate assessment of the risks and benefits of the therapy [77]. Contracts should be carefully scrutinized for the way in which they delineate who controls access to the data.

Finally, there have been conflicts over so-called gag clauses that prevent contract investigators from publishing their results [92]. For example, when a University of Toronto physician identified safety issues related to an experimental drug used to treat iron overload in transfusion-dependent patients with thalassemia [93], she was not granted permission to publish her results. When she ultimately exposed her findings, she was the subject of a breach of contract lawsuit from the sponsor, on the basis that her research contract provided that the published work-product was "secret and confidential" and could not be disclosed except with the manufacturer's "prior written consent" [94]. In the case of the cholesterol-lowering drug ezetimibe (Zetia®), the outside investigator leading a large-scale clinical trial found that the drug lacked important efficacy in cardiovascular outcomes. He reportedly pressured the manufacturer to no avail to speed the release of the data, and due to contractual obligations was unable to come forward with the data on his own without such approval [95].

Such problems are not limited to private industry contracts. In the US, a report from the Association of American Universities and the Council on Government Relations found that federal agencies commonly include controls on the dissemination of research results in their sponsored contracts and grants [96]. Contracting issues related to liability, trial design, access to data and data analysis, and publication of results are also not limited to a particular country [97]. In Europe, for example, countries aware of the challenges in setting up contracts between investigators and industry in particular offer government assistance and templates to help balance the diverging interests. In Switzerland, the ethics committee provides templates for clinical trial agreements on its website [98], and the UK and the European Commission also offer such templates and guidance notes [99].

For researchers based in academic medical centers, institutional research administration offices usually handle the details of contract

negotiation with research sponsors. However, a survey of academic medical centers in 2001 found that academic institutions routinely engage in industry-sponsored research without sufficient protection for investigators [100]. For example, a median of 1% of research administration offices (interquartile range 0–21%) in US universities reported requiring that authors have access to all the data for multicenter trials. A 2005 survey found little change. Nearly half of academic institutions reported that they allowed contract provisions permitting the research sponsor to insert its own statistical analyses and draft the manuscript, while prohibiting investigators from sharing data with third parties after a trial had ended. The survey also found that 17% of academic research centers reported disputes between researchers and sponsors about control of or access to data [101].

A few expert bodies have offered recommendations on legal guidelines for the conduct of contract research [102]. The best known and most authoritative have emerged from the International Committee for Medical Journal Editors (ICMJE). Their guidelines for original research articles submitted to biomedical journals require that the investigators be independent of the sponsors' role in the research, fully accountable for the design and conduct of the trial, have independent access to all trial data, and control all editorial and publication decisions [103]. Each of these criteria must be worked out at the beginning of the contractual relationship between the sponsor and investigators.

Whether or not they receive support from research administration offices, pharmacoepidemiologists must be aware of the ICMJE guidelines and thoroughly evaluate contracts guiding research for inappropriate language regarding control of design of the trial, access to data, and reporting of results (see Table 9.2). They should also be aware that some peer-reviewed journals have even more strict standards than the ICMJE; for example, *Pharmacoepidemiology and Drug Safety* currently requires disclosure of any control the sponsor had on the study and manuscript. Problematic language includes overly broad confidentiality clauses, clauses that define and assign ownership of intellectual property,

Table 9.2 Potentially objectionable language in research contracts for pharmacoepidemiologists.

Category	Contractual terms	Critique
Control over investigator work-product	"____ shall provide confidential information to CONSULTANT for the purpose of conducting the CONSULTANT'S professional services. All information whether written or verbal provided by, or developed for _____, and all data collected during the performance of this Agreement is deemed to be the Confidential Information of _____."	Broad definition of "confidential information" seems to cover all information. Researcher's work-product becomes sponsor's confidential information.
Gag clauses	"No information regarding this Agreement or the interest of ____ or Client in the subject matter hereof shall be disclosed to any third party without the prior written consent of _____"	Prevents disclosure of existence of the contract as a financial source in publication.
Opportunity to influence outcome	Client "shall not present or publish, nor submit for publication, any work resulting from the Services without _____ prior written approval."	Contract allows sponsor to quash publication unless it approves analyses.

All examples are anonymized but otherwise unchanged excerpts from actual contracts written to cover sponsored pharmacoepidemiologic research.

and clauses that require approval from a sponsor prior to publication. It may be reasonable to allow sponsors a limited amount of time to review proposed publications for inadvertent release of proprietary company information or to contribute suggestions based on their expertise. However, researchers have an ethical obligation to ensure that contracts do not unreasonably delay the publication of potentially important results. Poorly written contracts can lead to inappropriate secrecy of results, which can have public health concerns, as well as resulting in litigation against researchers. Balancing the contractual tightrope might not be easy, but it is important. As Dr. Curt Furberg has said, "Companies can play hardball, and many investigators can't play hardball back. You send the paper to the company for comments, and that's the danger. Can you handle the changes the company wants? Will you give in a little, a little more, then capitulate? It's tricky for those who need money for more studies" [104].

Pharmacoepidemiology and Intellectual Property Law

Patent law is a field of growing importance to the practice of pharmacoepidemiology. A patent is a formal grant of market exclusivity authorized by the federal government. The concept of a patent may have originated in ancient Greece, but became a formal legal instrument in England and Europe in the fourteenth and fifteenth centuries. In the US, the original Patent Act was passed under authority from the Constitution, which permits Congress to develop laws that "promote progress of Science and the Useful Arts" [105]. Patents give inventors the right to exclude others from making, using, offering to sell, or selling the invention claimed in the patent for 20 years from the patent application date [106]. The goal of a patent is to encourage inventors to invest in the development of their ideas, because it gives them a competition-free period in which to market a successful invention. Patents can be issued for any process, machine, manufacture, or composition of matter. To be worthy of a patent, an innovation in one of these categories must be useful, novel, and nonobvious to a person of ordinary skill in the field. These criteria aim to ensure that patents cannot be awarded for inventions that already exist, or small, noninnovative improvements on those inventions. In recent years, numerous patents have been obtained on methods and techniques used in pharmacoepidemiology, including investigating characteristics of drug use and adverse events.

In filing for a patent, an inventor must fully disclose the content of the claimed invention in a patent document. This disclosure must provide clear detail about the invention and must enable any person skilled in the art to use it, including the "best mode" (if they have contemplated one) available for making the inventions work. The process for obtaining a patent involves submitting the patent document to examiners at institutions such as the European Patent Office (EPO) and the United States Patent and Trademark Office (USPTO) who have expertise in the general subject matter of the patent. An examiner checks the application for technical accuracy and evaluates the innovativeness of the claimed invention by comparing it to previous publications and issued patents (in legal terminology, publicly available documents such as these are termed the "prior art"), to see if all the basic criteria are met. This process generally involves substantial back-and-forth between the examiner and the applicant, and may take several years to complete. Inventors may submit patent applications themselves, or enlist the help of specially trained patent agents or patent attorneys.

Inventors may have numerous justifications for pursuing patents. First, patents provide an incentive for investment in research by offering an opportunity to recoup start-up costs after

dissemination of a product. Other inventors may seek a way to publish their innovative processes while still retaining control over what they consider to be their intellectual property. A patent is classically thought of as a "quid pro quo" between inventors and society [107]. The government provides its police power to protect an inventor's intellectual property for a set length of time and, in exchange, the inventor makes the invention available to the public and fully describes it, so that others can use it and potentially improve on it in subsequent innovation. However, patents can also be controversial. Patents over scientific research tools have been implicated in barriers to effective cooperation [108], enhanced secrecy among researchers [109], and restrictions on availability of the products of research to patients [110].

Patents have become increasingly visible in the practice of pharmacoepidemiology. Most fall into the "process" category, such as methods of analyzing claims data and comparing outcomes to identify adverse events. The US Supreme Court has held that patentable processes may not include fundamental principles such as "laws of nature, natural phenomena, or abstract ideas" [111], or purely mental processes [112]. However, applications of laws of nature to a particular process may still be patentable. For example, a well-known case involved a patent over a method of curing synthetic rubber that used the Arrhenius equation to calculate the optimal cure time. The process was found to be patentable because the formula was a part of a larger inventive process for curing rubber [94].

Patents related to the practice of pharmacoepidemiology have been obtained by applicants ranging from individuals (e.g., a patent covering a method for assessing the association of genomic data with drug safety adverse event data [113]) to large healthcare data collectors such as Microsoft (e.g., a patent covering a method for large-scale data collection and data mining to infer health-related observations [114]). For example, one patent was awarded to inventors and assigned to a start-up company for a "method, system, and software for analyzing pharmacovigilance data." The patent covers a process of:

> [D]etermining a sample size-independent measure of association between two conditions of interest in the dataset of pharmacovigilance data; using a hypergeometric distribution to determine a measure of statistical unexpectedness between the conditions of interest in said dataset … and displaying the measure of association with the measure of the statistical unexpectedness to identify a significant association between conditions of interest. [115]

The concept of "hypergeometric distribution" may not be patentable as an abstract idea, but in this case the USPTO clearly considered the process patentable overall despite its integral use of that principle.

There are important ethical and legal concerns related to patenting processes that provide exclusive control over various aspects of the conduct of pharmacoepidemiology and pharmacovigilance research. First, patents that are sufficiently broad could prevent others from conducting necessary research into drug outcomes and effects, unless potentially expensive third-party licenses were negotiated beforehand. In one case, an HIV researcher at Stanford faced a patent-infringement lawsuit over a publicly available database he created to help guide antiretroviral therapy based on the resistance characteristics of the disease, because searching this database may involve a similar process to one previously patented (but never implemented) by a for-profit company [116]. In another case, a patent-seeker in the field argued that researchers should patent the adverse reactions discovered in pharmacoepidemiologic studies to enhance funding from for-profit pharmaceutical companies that might be interested in novel and nonobvious processes that link drugs and adverse events [117]. However, a

proliferation of patents over processes linking drug delivery to reported adverse events could increase costs through "another layer of bureaucrats and patent attorneys" and hurt the public health, as "real information could get easily lost in a blizzard of patented factoids" [118].

The US Supreme Court has stepped into the controversy over process patents. In 2008, the Court of Appeals for the Federal Circuit, the highest US patent appeals court below the Supreme Court, revisited its interpretation of what may be considered a patentable process. The case involved a patent over a business method for reducing risk in situations of fluctuating prices. The Federal Circuit Court held that for a process to be patentable, it must be tied to a particular machine or apparatus, or transform an object into a different state or thing [119]. Notably, as pertaining to pharmacoepidemiologic patents, the Federal Circuit Court held that "in most cases, gathering data would not constitute a transformation" because "every algorithm inherently requires the gathering of data inputs" [120]. The Supreme Court in *Bilski v. Kappos* reviewed this standard and agreed that the machine-or-transformation test was one valid way of determining whether a business method was patentable, although it was not the exclusive test [121].

Despite the Supreme Court's reluctance to draw a bright line separating patentable from nonpatentable processes, the Court's support for the machine-or-transformation test may undercut certain patents related to pharmacoepidemiology and pharmacovigilance [122]. For example, the Federal Circuit Court used the test to invalidate a patent related to a method of adverse effect detection [123]. In that case, an inventor had secured a patent on a method of using adverse event data regarding vaccine administration to inform subsequent healthcare delivery. The patent at issue claimed:

> A method of determining whether an immunization schedule affects the incidence or severity of a chronic immune-mediated disorder in a treatment group of mammals, relative to a control group of mammals, which comprises immunizing mammals in the treatment group of mammals with one or more doses of one or more immunogens, according to said immunization schedule, and comparing the incidence, prevalence, frequency, or severity of said chronic immune-mediated disorder or the level of a marker of such a disorder, in the treatment group, with that in the control group. [124]

Pharmacoepidemiologists are likely to continue to come across patented methods in their daily work and be faced themselves with the question of whether to pursue patents on their research tools. This is particularly true in the US, where the *Bilski* decision left the door open for patents to be issued on processes involved in medical practice or pharmacoepidemiologic research.

Intellectual Property Law in Europe

In Europe, the European Patent Convention (EPC) provides the legal framework under which patents are granted. The establishment of patentability is framed in terms of fulfilling three prerequisites: novelty, usefulness, and an inventive step (equivalent to the "nonobviousness" requirement under US law) [125]. Like in the US, the maximum term of a European patent is 20 years from its filing date [126].

The US and European standards with regard to the patentability for methods and techniques are also close. The EPC provides a nonexhaustive list of nonpatentable inventions: discoveries, scientific theories, and mathematical methods; aesthetic creations; schemes, rules, and methods for performing mental acts, playing games, or doing business, and programs for computers; and presentations of information

[127]. Patents can be obtained on software according to the Technical Boards of Appeal of the EPO if the software produces a further technical effect when it runs on a computer

> which goes beyond the "normal" physical interactions between program (software) and computer (hardware). … Although it may be said that all computer programming involves technical considerations since it is concerned with defining a method which can be carried out by a machine, that in itself is not enough to demonstrate that the program which results from the programming has technical character; the programmer must have had technical considerations beyond "merely" finding a computer algorithm to carry out some procedure. [128]

According to the Guidelines for Examination in EPO, such a further technical effect can be found, for example, in the control of an industrial process or in the internal functioning of the computer itself or its interfaces under the influence of the program, or can affect the efficiency or security of a process. Software that implements a mathematical method that itself makes a technical contribution can also qualify as a further technical effect [129].

There are three possible routes for obtaining patent protection in Europe. One can apply for a patent directly to the national patent office of a particular country (national patent); one can apply for a patent to the EPO and designate specific EU member states where patent protection is wanted ("classical" European patent); or – as part of a new pathway intended to start in 2019 – one can apply for a patent to the EPO with the designation of a unitary patent that will be applicable for all of the EU member states where the government has ratified the Agreement on a Unified Patent Court [130].

The European patent system enables a central examination by the EPO, which is more efficient than the national patent process. However, granted European patents have to be subsequently validated individually in each country in which they are intended to take effect, and validation requirements can differ. The goal of the new unitary patent system is to reduce complexity and lower costs. Unitary patents will confer uniform protection, since the substantive patent law has been harmonized in the Agreement on a Unified Patent Court [131], which 25 EU member states have ratified (up to 2017) [132]. The member states also set up a Unified Patent Court to deal with the infringement and validity of unitary patents and European patents, intended to enhance legal certainty through harmonized case law in the area of patent infringement and validity and enable more efficient judicial procedures [133].

The choice among seeking a national patent, European patent, or unitary patent needs to be made depending on the preferences of the individual applicant. For example, applicants should weigh the need for broad geographic coverage versus protection in one (or a few) member states. Furthermore, consideration should also be given to whether the patent should be subject to the exclusive jurisdiction of the Unitary Patent Court, or if it is preferred to use national courts with a more limited geographic jurisdiction. While a classical European patent contains the costs for validation and renewal fees in each member state in which protection is required, the unitary patent does not include validation costs, except the cost for one translation during the transitional period as well as a single renewal fee [134].

Conclusion

Legal issues intersect with the practice of pharmacoepidemiology in many ways. Pharmacoepidemiologists may be involved in product liability cases brought by individuals against drug manufacturers, either as expert witnesses or on the basis of academic work they

undertake. These cases traditionally involve a claim of a failure to warn, which requires proof that the manufacturer knew of the safety issue, that any provided warnings were insufficient, and that the injury received was directly caused by use of the drug. Manufacturers can invoke a "learned intermediary" defense to deflect responsibility onto the treating physician, but in the US after *Wyeth v. Levine* can no longer argue that FDA approval of the drug labeling precludes providing additional warnings about adverse effects for cases in which the warnings are warranted by the data. While similar product liability rules apply in Europe, fewer cases are brought to court and damage compensation is lower.

Pharmacoepidemiologists may also be involved in contract research, but should carefully consider contractual requirements related to ownership of the work product and withholding publication.

Finally, both in the US and in Europe, pharmacoepidemiologists may decide to try to patent their research methods, but should weigh up the risks and benefits of this form of intellectual property.

Spontaneous Reporting

10

Postmarketing Spontaneous Pharmacovigilance Reporting Systems

Gerald J. Dal Pan[1], Marie Lindquist[2], and Kate Gelperin[1]

[1] *Center for Drug Evaluation and Research, US Food and Drug Administration, Silver Spring, MD, USA*
[2] *Uppsala Monitoring Centre, WHO Collaborating Centre for International Drug Monitoring, Uppsala, Sweden*

Potential signals for adverse drug reactions (ADRs) or adverse drug effects most often arise from postmarketing spontaneous case reports, which are collated and analyzed by drug safety experts, evaluated as clinical case series, and considered for potential regulatory action. These efforts are not possible without input from dedicated health professionals and other concerned stakeholders. Adverse events (AEs) thought to be potentially drug related may be reported by a consumer or a health professional to a drug's manufacturer, or they may be reported directly to a health authority through programs such as MedWatch or EudraVigilance [1,2]. In addition, case reports and case series with valuable clinical details may be published in a peer-reviewed journal [3]. Concerned stakeholders – health professionals as well as consumers – are the source of the signals that can trigger hypothesis generation, hypothesis testing, and appropriate regulatory action when needed to protect the public from unnecessary risks or harms. At times, a drug causal association may seem clear due to strong temporal association between exposure to the product and onset of an adverse effect, or when there is confirmation of positive rechallenge (i.e., signs or symptoms resolve when exposure is stopped but recur when reintroduced). But more often, causality assessment is challenging (see Chapter 29), and well-designed pharmacoepidemiology or clinical studies are needed to assess the signal [4,5].

In the United States, the Food and Drug Administration (FDA) issues Drug Safety Communications (DSCs) to alert the public about emerging safety issues, such as investigations into potential safety signals that may alter the balance of therapeutic benefit and risk for a medical product [6]. Recently, the FDA launched a new web portal that enables the public to view summary charts and listings of deidentified cases from the FDA Adverse Event Reporting System (FAERS), a compilation of all postmarketing adverse event (AE) reports received by the FDA [7].

In recent years, the term "pharmacovigilance" has become widely used to denote postmarketing

Note: The views expressed in this chapter are those of the authors, and not necessarily those of the US Food and Drug Administration or the US government.

Pharmacoepidemiology, Sixth Edition. Edited by Brian L. Strom, Stephen E. Kimmel and Sean Hennessy.

safety activities, and is defined by the World Health Organization (WHO) as "the science and activities relating to the detection, assessment, understanding and prevention of adverse effects or any other possible drug-related problems" [8].

Monitoring and understanding the safety of drug and therapeutic biologic products is a process that proceeds throughout the product's life cycle, spanning the period prior to first administration to humans through the entire marketing life of the product. Throughout the product life cycle, astute clinical observations made at the point of care constitute an important source of information. While new technologies have enabled more thorough knowledge of a drug's actions, and computerized databases have enabled large-scale, population-based analyses of drug safety investigations, these advancements are adjuncts to, and not substitutes for, careful, well-thought-out clinical observations.

Preapproval drug safety assessment includes animal toxicology and pharmacologic studies, first in humans studies (Phase I), proof-of-principle studies for the disease or condition under study (Phase II), and confirmatory studies of safety and efficacy (Phase III). In each of these stages of drug development, important drug safety information is obtained.

In the preapproval review process, regulatory authorities review these safety data, along with data on the product's efficacy, to determine if the anticipated benefits of the drug are likely to outweigh any risks with its intended use. In the US, as part of the approval process, the FDA reviews the professional labeling (package insert), to ensure that the product's uses and risks are explained adequately.

Although the preapproval testing of a drug is typically rigorous, and the review of the data is thorough, there are still inevitable uncertainties about the complete safety profile of a drug when it is brought to market. Several factors contribute to these uncertainties. First, the number of patients treated with the drug prior to approval is limited, generally from several hundred to a few thousand. Second, patients in clinical trials tend to be carefully selected for inclusion in these trials, and are thus more clinically homogeneous than patients treated in the course of clinical practice once a drug is marketed. Compared to patients in clinical trials, patients treated in clinical practice may have a broader range of co-morbidities, take a wider variety of concomitant medications, and have a wider clinical severity spectrum of the underlying disease being treated. Third, additional populations of patients, such as children or older adults, who may not have been studied in large numbers in premarketing clinical trials, may be treated with the product once it is marketed. In addition, marketed drug products are often used for diseases or conditions for which they are not indicated, or at doses outside the approved range. Because of this "off-label use," patients treated in clinical practice are more diverse than those treated in clinical trials. For these reasons, a postmarketing drug pharmacovigilance reporting system is necessary.

Description

Adverse Events and Adverse Drug Reactions

A key concept in pharmacovigilance is the distinction between the closely related, but nonetheless distinct, concepts of *adverse event* and *adverse drug reaction*. The International Conference on Harmonization of Technical Requirements for Registration of Pharmaceuticals for Human Use (ICH) E2D guideline on Post-Approval Safety Data Management: Definitions and Standards for Expedited Reporting defines an adverse event as follows [9]:

> An adverse event (AE) is any untoward medical occurrence in a patient administered a medicinal product and which does not necessarily have to have a causal relationship with this treatment. An adverse event can

> therefore be any unfavorable and unintended sign (for example, an abnormal laboratory finding), symptom, or disease temporally associated with the use of a medicinal product, whether or not considered related to this medicinal product.

The same guideline describes an adverse drug reaction as follows:

> All noxious and unintended responses to a medicinal product related to any dose should be considered adverse drug reactions.
>
> The phrase "responses to a medicinal product" means that a causal relationship between a medicinal product and an adverse event is at least a possibility.
>
> A reaction, in contrast to an event, is characterized by the fact that a causal relationship between the drug and the occurrence is suspected. If an event is spontaneously reported, even if the relationship is unknown or unstated, it meets the definition of an adverse drug reaction [9].

The principal difference between an adverse event and an adverse drug reaction is that a causal relationship is suspected for the latter, but is not required for the former. In this framework, adverse drug reactions are a subset of adverse events. In some countries, postmarketing pharmacovigilance reporting systems are focused on adverse drug reactions, while in others data on adverse events are collected. In the United States, for example, the scope of reporting requirements is "[a]ny adverse event associated with the use of a drug in humans, whether or not considered drug related …" [10].

While many of the principles discussed in this chapter apply equally to adverse events and adverse drug reactions, it is important to understand the distinction between these two concepts. Specifically, some databases may contain only adverse drug reactions, while others may contain adverse events. These databases may behave differently when used for data mining. However, because many of the principles of drug safety surveillance apply to both adverse events and adverse drug reactions, we will use the term "AE/ADR" to refer to these two terms collectively in this chapter, for convenience. When needed, we will use the individual terms if a distinction between the two is required. Although the medical literature may sometimes erroneously use these terms interchangeably, there has been increasing attention to the distinction [11].

The Concept of Spontaneous AE/ADR Reporting

A core aspect of pharmacovigilance is the voluntary reporting of AEs/ADRs either directly to established national or regional centers, or alternatively to pharmaceutical manufacturers, who in turn are obligated to report pertinent information to regulators. National reporting systems are typically run by regulatory agencies (e.g., the US FDA runs the MedWatch program) [1] or by centers designated by the health ministry or the drug regulatory authority. In a few countries, the national pharmacovigilance center is run by a university or other scientific body. In the United States for example, AEs/ADRs in individual patients are generally identified at the point of care. Patients, physicians, nurses, pharmacists, or anyone else who suspects that there may be an association between an AE/ADR and a drug or therapeutic biologic product are encouraged to, but are generally not required to, report the case to either the manufacturer or the FDA.

This system of AE/ADR reporting is often referred to as a spontaneous reporting system; "spontaneous" because the person who initially reports the AE/ADR to either the reporting center or the manufacturer chooses what events to report. Sometimes, spontaneous reporting systems are also labeled as "passive," based on the argument that the reporting

center or manufacturer passively receives this information rather than actively seeking it out. However, this term does not do justice to the proactive way in which many pharmacovigilance centers seek to operate, even if resource constraints often limit the ability to interact adequately with reporters. Moreover, "spontaneous reporting" does not fit well with the reporting situation of today, when most countries have introduced or enacted legislation which mandates reporting from pharmaceutical companies. Reporting may also include canvassed or stimulated reporting of suspected reactions of particular interest.

Underlying the concept of a spontaneous postmarketing AE/ADR pharmacovigilance reporting system is the notion that clinical observations made at the point of care are often valuable pieces of information in further refining the knowledge of a drug's safety profile. This is an important, though frequently underemphasized, idea.

First, after approval, when formal study often ends and marketing of the medicine begins, there is often no further systematic way to continue the study of a medicine's safety, or even to generate drug safety hypotheses. While scientific advances and access to new data sources (e.g., electronic healthcare records) may provide some opportunity to monitor the safety of a marketed medicine, these alternative approaches to safety signal detection remain unproven. Such sophisticated methods are not widely used in many regions, and when used, may cover a limited number of drugs and outcomes. In contrast, existing pharmacovigilance reporting systems apply to all marketed medicines and are relevant to most drug safety issues of interest.

Second, when healthcare professionals, patients, and consumers want to make notification of a potentially adverse effect of a medication, it is useful for this information to be systematically organized, stored, and analyzed. A reporting system fills this need. If such information were not systematically collected, potentially valuable data about medicines would be lost.

Third, this system implies an important role for healthcare professionals in postmarketing safety assessment. Although the practices and systems for healthcare professionals to report AEs/ADRs vary from region to region, the quality of reports is always dependent on the details provided by these professionals.

Spontaneous Reports and Solicited Reports

Another key concept in understanding the contents of a pharmacovigilance database is the distinction between a "spontaneous report" and a "solicited report." While many pharmacovigilance databases are often referred to as "spontaneous report databases," the reports in them are often a mix of spontaneous and solicited reports, as well as reports from other sources. The differences between these two types of reports can explain the quantity and quality of reports in a pharmacovigilance database, and often can explain important distinctions between pharmacovigilance databases.

The ICH E2D guideline on Post-Approval Safety Data Management: Definitions and Standards for Expedited Reporting defines a spontaneous report as follows [9]:

> A spontaneous report is an unsolicited communication by a healthcare professional or consumer to a company, regulatory authority or other organization (e.g. WHO, Regional Center, Poison Control Center) that describes one or more adverse drug reactions in a patient who was given one or more medicinal products and that does not derive from a study or any organized data collection scheme. Stimulated reporting can occur in certain situations, such as notification by a "Dear Healthcare Professional" letter, publication in the press, or questioning of healthcare professionals by company representatives. These reports should be considered spontaneous. Consumer adverse reaction reports should be handled as spontaneous reports irrespective of any subsequent "medical confirmation".

> Regulatory Authorities might require medical confirmation for the purpose of expedited reporting. Emphasis should be placed on the quality of the report and not on its source. Even if reports received from consumers do not qualify for regulatory reporting, the cases should be retained.

Several features of this definition are worth noting. First, by requiring that the report be directed to a pharmaceutical company, regulatory authority, or other organization responsible for surveillance of the adverse effects of medicines, the definition implies, but does not explicitly state, that the reporter specifically intended to report a suspected adverse drug reaction. However, in current practice, most pharmacovigilance reporting systems do not consider the reporter's intent when determining if a report is a spontaneous report. For example, a patient who has been on a chronic daily medicine for hypercholesterolemia for many years may contact that medicine's manufacturer to ask if there are any known drug interactions between that medicine and another product, such as an antiinflammatory agent that may have been recently prescribed for a sprained ankle after a sports injury. The intent of the call was to seek information, not to report a suspected adverse drug reaction. Nonetheless, this report meets the definition of a spontaneous report, at least in those systems in which adverse events, and not only adverse drug reactions, are collected. The consideration of stimulated reports as spontaneous reports is consistent with this logic.

Second, and importantly for pharmacovigilance systems that require reporting of adverse events and not only adverse drug reactions, the definition does not require a causality assessment. For the purposes of meeting adverse event reporting requirements, ICH E2D notes that "spontaneous reports associated with approved drugs imply a suspected causal relationship" [9]. It is important to note that this implied causal relationship is for the purposes of regulatory reporting, and need not represent a scientific or medical conclusion.

Third, the requirement that the report not derive from a study or an organized data collection scheme necessitates existence of another category of report to describe adverse events occurring in clinical trials, other studies, and certain organized programs sponsored by pharmaceutical companies that may collect data on adverse events. CIOMS V (Council for International Organizations of Medical Sciences) recognized the need to describe those adverse event reports derived not only from formal clinical trials or other studies, but also from the increasing number of company-sponsored programs, such as marketing programs and patient-support programs, that promote interaction between the company and patients – and thus the chance for companies to learn about adverse events [12]. CIOMS V proposed the idea of "solicited" reports, which was formalized in ICH E2D as follows [9]:

> Solicited reports are those derived from organized data collection systems, which include clinical trials, registries, post-approval named patient use programs, other patient support and disease management programs, surveys of patients or healthcare providers, or information gathering on efficacy or patient compliance. Adverse event reports obtained from any of these should not be considered spontaneous.
>
> For the purposes of safety reporting, solicited reports should be classified as study reports, and therefore should have an appropriate causality assessment by a healthcare professional or an MAH. Further guidance on study-related issues, such as managing blinded therapy cases, can be found in the ICH E2A guideline.

Unlike its recommendation for spontaneous reports, ICH E2D recommends that solicited reports be subjected to a causality assessment

for regulatory reporting; in general, only those serious adverse events deemed causally related are to be reported. ICH E2D also notes other types of adverse event reports, such as reports from the medical literature, reports from the internet, reports a company obtains in accordance with contractual relationships with another company, and reports a company receives from a regulatory authority. The first two types are considered unsolicited (though not spontaneous) while the latter two are considered solicited [9].

The CIOMS [12] and ICH E2D [9] efforts were initiated to provide a framework for regulatory reporting of adverse events, and many jurisdictions have incorporated the ICH E2D principles in their directives, regulations, guidelines, and guidance documents. While a discussion of regulatory reporting requirements is beyond the scope of this chapter, an understanding of the distinction between spontaneous reports and solicited reports is important because it is essential to understanding the contents of a pharmacovigilance database. For example, if a pharmaceutical company contributes the majority of reports to a particular pharmacovigilance database, that database can be expected to have more solicited reports, as well as spontaneous reports that result from interactions between the company's sales force and healthcare professionals, than a pharmacovigilance database whose reports are derived mainly from hospital-based pharmacovigilance centers. The distinction may also be important in the comparison of adverse event reports between two products in the same pharmacovigilance database. For example, in a single pharmacovigilance database, there may be more adverse event reports for a product that is actively promoted and marketed (and thus has a large sales force and one or more patient-focused marketing programs) than a product for which such an extensive marketing program is not in place.

Overview of Pharmacovigilance Reporting Systems

The goal of a postmarketing, or postapproval, safety program is to identify drug-related AEs or ADRs that were not identified prior to approval, to refine knowledge of the known adverse effects of a drug, and to understand better the conditions under which the safe use of a drug can be assured.

The scope of pharmacovigilance is broad. The core activity is usually the identification of previously unrecognized AEs/ADRs with use of the drug. However, it is not sufficient simply to note that use of a drug can lead to an AE/ADR. Rather, an investigation into not only the potential causal role of the drug in the development of the AE/ADR, but also the conditions leading to the occurrence of the AE/ADR in one person or population and not in others must be the focus of any postmarketing drug safety effort. Factors such as dose–response relationships, drug–drug interactions, drug–disease interactions, drug–food interactions, and the possibility of medication errors must be carefully considered.

A full understanding of the factors that can lead to an AE/ADR may yield ideas for effective interventions to minimize the severity or occurrence of the AE/ADR, and thus enhance the safe use of the drug. For this reason, the approach to detecting and understanding clinically important AEs/ADRs in the postmarketing period must be as comprehensive as possible.

The identification of a new safety issue with a medicinal product often begins with a single observation. Such observations may arise from animal studies, chemical studies and assays, or observations of human experience with the medicine. In the postmarketing period, such observations are usually clinical observations, often made at the point of care in the course of clinical practice. A practitioner or patient notes the development of symptoms or signs that were not present, or were present in less severe form, prior to the patient's using the medicine.

If this sign or symptom is not listed in the product's approved labeling, patients and healthcare professionals may not think to attribute it to the medicine. If further evaluation reveals a clinically significant process (e.g., liver injury, rhabdomyolysis, agranulocytosis), it is important to keep in mind the possibility of a side effect due to a medication in the differential diagnosis of the event. If a medication side effect is not included in the differential diagnosis, a potential association between a medicine and previously unrecognized side effect will not be made, and the patient may not be treated appropriately. If, on the other hand, the practitioner believes the medicine played a role in the development of the new clinical findings, he or she can forward relevant clinical information to either the medicine's manufacturer or to a drug regulatory authority, such as the FDA in the United States or other national or regional authorities, as appropriate.

In the postmarketing period, the investigation of AEs/ADRs is a multidisciplinary effort. The analysis of a complex AE/ADR can involve the fields of medicine, pharmacology, epidemiology, statistics, pharmacy, toxicology, and others. There are several methods of clinical postmarketing safety assessment. These include the review of case reports and case series from spontaneous reporting systems, a wide variety of types of observational epidemiologic studies, and clinical trials. This chapter will focus on spontaneous pharmacovigilance reporting systems. No one method is *a priori* better than another in all settings. Rather, the choice of methods depends on the particular safety question to be answered.

Spontaneous AE/ADR reports have at times served as a necessary and sufficient basis for regulatory actions including product withdrawals. For instance, in August 2001 the manufacturer of cerivastatin withdrew the drug from marketing based on "a markedly increased reporting rate of fatal rhabdomyolysis" compared to the other drugs in the statin class [13]. Additional confirmation of the unacceptably high risk of rhabdomyolysis with cerivastatin was eventually available three years later when results of a well-designed epidemiologic study were published [14]. Clearly, that time frame would have been far too long to delay decisive action, which in retrospect was soundly based on the signal from spontaneous reports. The timely detection of this signal would not have happened without the efforts of the point-of-care clinicians who took the time to report rhabdomyolysis when it occurred in their patients. Some drug safety experts have argued that decisive action could have been taken even earlier based on clinical trial data with a higher unapproved dose of cerivastatin, coupled with early postmarketing experience [15].

Patient Reports and Healthcare Professional Reports

Spontaneous adverse event reports, by their nature, originate at the point of care. While some pharmacovigilance systems were once restricted only to reports from healthcare professionals, there has been growing recognition of the importance of reports from patients, and many systems now accept patient-generated reports. For example, Italy, Denmark, the Netherlands, and Sweden have accepted patient reports since the early 2000s, while Australia has accepted them since 1964 [16]. The United States, which has accepted adverse event reports from consumers since 1969, developed the MedWatch program [17] in 1993 to facilitate adverse event reporting from both patients and healthcare professionals. Nonetheless, as recently as 2012, some countries with highly developed regulatory systems were not actively collecting patient reports. Of 50 countries with developed drug regulatory systems surveyed in 2013, 44 had direct patient reporting systems, 17 of which were started in 2012 or 2013 [16].

There is no internationally recognized definition of a "patient report." ICH E2D defines a "consumer" as "a person who is not a healthcare professional such as a patient, lawyer, friend, or

relative of a patient" and notes that "consumers" can submit adverse event reports [9]. Of note, in 2016 approximately 1.7 million reports were entered into the US FAERS; consumers were the source of about half (845 355) of these reports, the majority of which were submitted via pharmaceutical companies [7].

Despite initial skepticism about the value of patient reports [18], there is growing evidence that they are valuable because they often contain more detail than reports generated by healthcare professionals and can serve to complement those reports [19]. A study of the United Kingdom's Yellow Card system, which allows for AE reporting by both healthcare practitioners and patients, found that reports generated by patients had a higher median number of suspected adverse drug reactions per report compared to those generated by healthcare professionals, had a higher median word count, had more detailed information about symptoms, and more description of the emotional and social impact of the adverse event [20]. A study comparing adverse event reports submitted by patients and those submitted by healthcare professionals to the Dutch National Pharmacovigilance Center Lareb found that reports from patients were comparable to those from health professionals for the purpose of causality analysis [21]. Similarly, a recent UMC-Lareb collaboration assessed the contribution of patient reports to global signal detection in VigiBase, and concluded that patient reports provide unique information valuable in signal assessment, and recommended their inclusion in signal detection processes [22].

In addition to their value in describing adverse drug reactions, patient reports contribute to signal detection. A study of signals sent from the Dutch National Pharmacovigilance Center Lareb to the Dutch Medicines Evaluation Board found that the number of patient reports that contributed to a signal increased from zero in 2003 to 31 in 2008, and that the proportion of patient reports contributing to signal generation equaled their proportion in the database [23]. In one pharmaceutical company's AE database, signals were detected earlier when patient reports were included, compared to when only reports from healthcare providers were included [24]. Experience in the UK Yellow Card system suggests that, when analyzed separately from healthcare professional reports, patient reports may generate additional signals based on disproportionality [25].

Given the potential importance of patient reporting, efforts have been made to both encourage and simplify it. In 2012, the World Health Organization published a guide for countries to use in setting up a reporting system for the general public [26], which recommends that a patient reporting system ideally be established in the setting of an existing spontaneous reporting system. The reporting form for patients may be a dedicated patient-reporting form or the same form used by health professionals, but it should be understandable by a layperson. Education of the public on the importance of patient reporting as well as training of pharmacovigilance staff in the assessment of patient reports are other elements of the WHO guideline.

At the national level, a law passed in the US in 2008 required pharmaceutical manufacturers to include the following statement in direct-to-consumer advertising: "You are encouraged to report negative side effects of prescription drugs to the FDA. Visit www.fda.gov/safety/medwatch, or call 1–800–FDA–1088." This statement, however, did little to increase patient reporting of adverse events. In a sample of 123 drugs, the average monthly increase following the implementation of this statement was 0.24 reports per drug [27]. More recently, in 2013, the FDA introduced a consumer-friendly adverse event reporting form [28], following the introduction of which patient reporting increased by 36% [29].

Because most AE/ADR reporting systems rely on healthcare professionals, patients, and consumers to submit reports voluntarily, it is

generally recognized that there is substantial underreporting of AEs/ADRs via current systems. Two survey-based studies conducted in the US in the 1980s, one in Maryland [30] and the other in Rhode Island [31], examined physician reporting to the FDA and concluded that fewer than 10% of AEs/ADRs were reported to the FDA. These studies were conducted prior to the development of the current MedWatch program [1] in 1993, and do not consider the contribution of reporting from sources other than physicians.

Calculating the proportion of adverse event reports that a reporting system receives requires that the true number of AEs/ADRs in the population be known. For most AEs/ADRs, this number is not known or readily available. In some cases, however, data are available that allow an estimate of the extent of reporting to be calculated. For example, the extent of reporting to the FDA of cases of hospitalized rhabdomyolysis associated with statin use was estimated [32] using a projected estimate of the number of such cases in the US and comparing it to the number of reports of statin-associated hospitalized rhabdomyolysis in the FAERS, a database that houses the FDA's postmarketing adverse event reports. The projected national estimate was obtained by using incidence rates from a population-based cohort study, and applying those rates to national estimates of statin use. Across four statins (atorvastatin, cerivastatin, pravastatin, and simvastatin), the estimated overall extent of AE reporting was 17.7%. For individual statins, the estimated extent of reporting ranged from 5.0% (atorvastatin) to 31.2% (cerivastatin). Further analysis revealed that the high proportion of reporting of cerivastatin cases was driven by reports received after the dissemination of a Dear Healthcare Professional letter notifying physicians of the risks of cerivastatin-associated rhabdomyolysis. The estimated extent of reporting was 14.8% before the letter and rose to 35.0% after. It is important to note that the results of this study apply only to reporting cases of statin-associated rhabdomyolysis. The extent of reporting for different drug-event pairs will be different, and cannot be estimated from the results of this study.

Once reports are received by national pharmacovigilance centers, they are entered into AE/ADR databases. These databases can then be inspected for drug safety signals, which form the basis of further study, necessary regulatory action, or both.

Report Characteristics

The individual case report is the fundamental unit of a postmarketing pharmacovigilance reporting system. The extent to which such a reporting system can address specific drug safety questions depends, in large part, on the characteristics and quality of the individual reports. Specific report formats differ across jurisdictions, though many countries and regions collect information compatible with the ICH E2B format. The updated electronic messaging standard ICH E2B (R3) [33] specifies both administrative and product identification information, as well as information on the case. The standard is designed to work with a variety of national and international systems and incorporates endorsement of standards by participating standards development organizations such as the International Standards Organization (ISO), Health Level Seven (HL7), European Committee for Standardization (CEN), and Clinical Data Interchange Standards Consortium (CDISC) to enable wider interoperability across the regulatory and healthcare communities. Although potentially comprehensive in scope, the format also allows for limited data to be submitted. The principal domains of case information in the ICH E2B standard include patient characteristics, reaction(s) or event(s), results of tests and procedures relevant to the investigation of the patient, drug(s) information, and a narrative case summary and further information.

Regardless of the specific formatting requirements across jurisdictions, there are some fundamental components of an individual safety report that are important for a thorough review.

Product identification, in as much detail as possible, is essential for an assessment of a case report. For pharmaceuticals, the identification of the active ingredient(s) is critical to product identification. However, other factors can also be important, depending on the specific safety question. For example, the formulation of the product can be important, as certain active ingredients may be present in a variety of formulations. Many opioid agents come in oral, injectable, and transdermal formulations. Because the pharmacokinetic and other pharmaceutical properties can differ across these formulations, information on the formulation is important in determining if there are formulation-specific effects, including those that may result from medication errors. Additionally, if the drug safety question involves the assessment of an AE/ADR related to a product quality defect, information on both manufacturer and lot/batch number can be very important, as product quality problems typically involve specific lots from an individual manufacturer.

Reports describing medication errors, or the potential for medication errors, ideally contain information on the product involved, the sequence of events leading up to the error, the work environment in which the error occurred, and the type of error that occurred [34].

Characteristics of a good-quality case report have been published [33,34]. As discussed below, these characteristics include adequate information on product use, patient characteristics, medical history, and concomitant treatments, and a description of the AE/ADR, including response to treatments and clinical outcome. Our experience, based on many years of reviewing case reports, is that while a substantial amount of useful clinical information can be written in a succinct narrative, most narratives are incomplete, many to the extent that they are uninterpretable. While follow-up with the reporter is sometimes feasible for drug safety analysts during case review, this has been the exception rather than the rule, often due to resource constraints. Incomplete and uninterpretable case reports limit the effectiveness of postmarket pharmacovigilance reporting systems. Attempts to improve the systems will need to address the problem of poor case report quality rather than merely increasing the number of reports. Unfortunately, it is not unusual for the FDA to receive potentially important spontaneous reports which cannot be evaluated because of missing key information. For instance, 13 (2%) of a total 675 reports of hypersensitivity AEs/ADRs associated with heparin administration during an investigation of tainted heparin were excluded from an analysis of AERS data because the reports were "not interpretable" [35].

Information on product use should include the start date(s), stop date(s), doses, frequency of use, and indication for use. Dosage information is important in exploring dose–event relationships. Duration of use is important for characterizing the time course of AEs/ADRs relative to initiation of product use. Indication for use is also an important piece of information, as many products are used for more than one indication (either on-label or off-label). Certain AEs/ADRs may be related to specific indications. Alternatively, concomitant medications and other factors related to one indication but not others may confound interpretation of the AE/ADR. For these reasons, indication for use is an important element of a case report.

Patient information should include age, gender, medical history, and concomitant medication usage. The presence of factors that could confound the relationship of the drug to the AE/ADR, especially elements of the medical history and concomitant medication usage, are critical to the interpretation of individual case safety reports.

A description of the AE/ADR that allows for independent medical assessment is critical. A simple listing of coded diagnostic and procedure

terms is generally insufficient for adequate assessment of the report. A narrative of the event that includes the temporal relationship of drug usage to the development of the AE/ADR, the clinical and diagnostic features, the clinical course, any measures instituted to treat the AE/ADR, the response to these measures, and the clinical outcome are all essential components of a high-quality case report. Results of laboratory tests, imaging, and pathology results facilitate an independent interpretation of the report. Information on dechallenge (the resolution of the AE/ADR when the medication is withdrawn) and rechallenge (the redevelopment of the AE/ADR when the drug is reintroduced), if available, can be invaluable.

Social Media

Social media are a range of computer-based technologies that allow the creation and sharing of information, ideas, photographs, and other messages via electronic communication. User-generated content is a defining feature of social media. This content can be made available to others via computer-based networks that connect one user with other users or groups to form social networks. Depending on privacy settings, which in some cases may be chosen by the user, the user's content may be widely available to other users or it may be restricted to only certain users or groups. Given the widespread use of the internet and, to a lesser degree, of social media for health-related topics, there is interest in whether social media can be a source of drug safety signals or otherwise shed light on adverse drug reactions [36]. Because social media posts describe individual experiences, they can, in theory, describe adverse reactions to medicines. The use of social media for pharmacovigilance presents both opportunities and challenges [37,38].

With an estimated 2.5 billion users of social media worldwide [39], including in parts of the world where formal pharmacovigilance programs are not highly developed, social media have the potential to be a source of patient- and consumer-generated information about adverse events [37]. The ability to tap into this potential source of information is especially relevant given the growing importance of, and attention to, patient- and consumer-generated reports in pharmacovigilance.

The challenges of identifying drug safety signals in social media include all those inherent in traditional spontaneous reporting systems (e.g., underreporting, duplicate reports, lack of relevant details, and stimulated reporting) as well as additional ones posed by the unique features of social media. These latter challenges include the general lack of structure of social media posts, the often informal nature of writing, the use of "street names" for established pharmaceuticals without corresponding use of standard brand names or active ingredient names, the use of slang or other informal language to describe symptoms or other medical concepts, and the diffuse audiences in social media. A further challenge is that while there are millions of social media posts, only a small percentage will concern adverse drug reactions. These challenges might be expected to pose more problems in large general social media sites than in smaller, health-related social media sites. For example, a study using the general social media site Twitter to identify adverse drug reactions found that of 10 822 tweets that mentioned a drug of interest, an adverse drug reaction, determined by expert annotation, was present in approximately 1200 [40]. By contrast, a similar study based in the health-related social media site DailyStrength found that approximately 24% of posts that mentioned a drug also mentioned an adverse drug reaction [41].

In traditional adverse event reporting systems, data are entered using a structured format, such as the ICH E2B standard, and drug and adverse event information are coded using standard dictionaries and terminologies. Importantly, data collection methods in these traditional systems

usually are designed to collect relevant information and have the final data structure in mind. Social media do not share these characteristics. Because most social media posts do not concern drugs or drug-related adverse events, techniques to identify adverse events in social media must first identify mentions of drugs, and then must further identify mentions of drug–adverse event pairs. Once these pairs are identified, further analyses can begin.

The use of social media for pharmacovigilance is an area of active research to address these challenges [38]. Current research focuses on the use of natural-language processing and other techniques, such as supervised machine learning, to identify drug-related adverse events in social media [42]. One of the biggest challenges in this regard is the distinction of drug mentions associated with an adverse event from those with no association to an adverse event, a task complicated by the fact that though the former group is the relevant one, it is usually notably smaller than the latter group.

Another area of research is determining the utility of social media in pharmacovigilance. In 2014, the Innovative Medicines Initiative (IMI), a public–private partnership between the European Union and the European Federation for Pharmaceutical Industries and Associations, launched WEB-RADR: Recognising Adverse Drug Reactions to develop new technical tools to facilitate the detection and analysis of potential adverse drug reactions in social media sites. It also aimed to develop a mobile phone app for the reporting of suspected ADRs to regulatory authorities in the European Union (in the context of traditional adverse event reporting). One of several planned outgrowths of these efforts is the establishment of a regulatory framework for social media mining for adverse drug reactions [43].

Preliminary results of IMI WEB-RADR, based largely on analyses of posts in Twitter, suggest that some medicines receive more attention in social media relative to their frequency in VigiBase, while others receive much less. Individual Twitter posts were deemed to be not valuable, perhaps due to Twitter's character length restrictions; however, combining information from multiple posts generated by the same user was not examined [44]. Preliminary recommendations from IMI WEB-RADR for a regulatory framework note that data from social media should be treated as a "secondary use of data," the use of social media for signal detection and validation should be optional, reporting of individual case safety reports of adverse drug reactions from social media sites should not be required, and follow-up with social media users should not be required. Rather, drug manufacturers should include insights gained from social media regarding the safety of their products in the product's periodic safety update report or risk management plan [45]. In conclusion, more work is needed to refine the methods of extracting and analyzing data from social media for detection of adverse drug reactions.

National Pharmacovigilance Systems

The organization of postmarketing safety reporting systems and national pharmacovigilance systems varies around the world. The fundamental feature is that health professionals, and in some cases patients or consumers, are encouraged to send reports of AEs/ADRs to one or more specified locations. These locations can be the drug regulatory authority, an academic or hospital-based pharmacovigilance center (often working with or on behalf of a drug regulatory authority), or the drug manufacturer. The roles of these institutions vary from country to country, and depend greatly on the regulatory and national drug monitoring system in the country.

In low- and middle-income countries, with varying regulatory infrastructure, the focus in pharmacovigilance has been different from that in the more affluent parts of the world. Reports can result from counterfeit and substandard

drugs, known ADRs and drug interactions of concern to reporters, and ADRs resulting from medical error. In some countries, responding to queries about adverse reaction incidence, diagnosis, and management is a major part of the work of pharmacovigilance centers. In developing countries, there are often deficiencies in access to up-to-date information on drug safety that need remedying. On the other hand, large donations of new drugs to combat the endemic scourges of malaria, HIV/AIDS, tuberculosis, infestations, and other diseases, along with vaccines, have led to the high priority of monitoring their use for both safety and efficacy.

However, in many low- and middle-income countries there is currently not enough capacity for effective drug safety monitoring, and the improved access to new medicines adds additional strain on already overburdened or nonexistent pharmacovigilance systems. A survey from 2010 of pharmacovigilance systems in low- and middle-income countries found that seven of 55 responding countries indicated that they had no designated system in place, and fewer than half of the respondents had a budget for pharmacovigilance [46]. Consequently, lack of funding was mentioned as a hindrance to the development of pharmacovigilance, together with lack of training and a culture that does not promote AE/ADR reporting. Suggested key developments included training for health workers and pharmacovigilance program managers; active surveillance methods, sentinel sites and registries; and better collaboration between pharmacovigilance centers and public health programs, with a designated budget for pharmacovigilance included in the latter.

The WHO is now working together with major donor organizations to address the urgent need for capacity building in low- and middle-income countries. The strategy is focused on sustainable development, covering not only the implementation of reporting systems, technical support, and training of healthcare professionals, but also improvements in governance and infrastructure to support pharmacovigilance activities in the broader context of regulatory systems strengthening.

The perceived responsibility of healthcare professionals to report AEs/ADRs often varies around the world. Because the largest gaps in drug safety knowledge are believed to be for recently approved medicines, most countries emphasize the need to report AEs/ADRs, even less serious ones, for this group of medicines. For example, in the United Kingdom, recently approved drugs containing new active ingredients are marked in the British National Formulary with a black triangle [47], a symbol used to denote a product whose active ingredient has been newly licensed for use in the UK. In some cases, drug products meeting certain additional criteria are also marked with a black triangle, even if the active ingredient has been previously approved. The aim of the black triangle program is to prompt health professionals to report all suspected adverse reactions associated with the use of these products. In some countries, it is mandatory for physicians and dentists to report cases of suspected adverse drug reactions to the regulatory authority. Most countries, however, do not have such specific programs or requirements, but health professionals are encouraged to report and the national reporting centers provide general advice to health professionals on what events to report.

In a majority of countries, including countries in the ICH regions, other high-income countries, and 33 of 55 low- and middle-income countries responding to a 2008 survey [46], pharmaceutical companies that hold marketing authorizations are obligated to report AEs or ADRs to the regulatory authority. In some countries, the event is reportable only if an attribution of causality has been made. In other countries, the event is reportable even if no attribution has been made. For example, in the United States, pharmaceutical companies are required by law to submit spontaneous reports

of AEs/ADRs, regardless of attribution of causality, on an expedited basis if they are serious and unexpected. The AE/ADR is considered serious [1] when the patient outcome is death; life-threatening; hospitalization (initial or prolonged); disability; congenital anomaly; or requires intervention to prevent permanent impairment or damage. Periodic reporting of other types of AEs/ADRs, such as those considered serious and expected (labeled), or nonserious, is typically required as well. The periodicity of such aggregate reports is determined by the length of time the drug has been marketed, with increased frequency for newly approved drugs, and decreased frequency (e.g., annual) with older drugs.

While spontaneous reports of AEs/ADRs usually originate initially from the point of care, the more proximal source of reports coming into the national pharmacovigilance centers may vary from country to country. In countries outside the ICH regions, the majority of reports are received directly from physicians in hospital and in general practice. Cumulatively over the past 40 years, most reports in the ICH region have come from the point-of-care initial reporter via the pharmaceutical companies to the regulatory authority; however, in several EU countries (e.g., all the Nordic countries), reports coming directly from health professionals to the regulatory authority greatly exceed company reports during this period. The patterns are likely to change towards a higher proportion of company reports in those many countries where pharmaceutical companies are legally obliged to report AEs/ADRs. Some countries restrict reports to those received by physicians. Other countries accept reports from pharmacists, nurses, and patients. There is a current trend towards encouraging direct patient or consumer reporting, replacing the notion held by many in the past that such reports would not be a reliable and useful source of information.

In most countries, the national pharmacovigilance center is part of the drug regulatory authority; in some, the monitoring is carried out jointly by the drug regulatory authority/Ministry of Health and an independent institution. In Germany, the Federal Institute for Drugs and Medical Devices (BfArM) maintains a joint database for recording reported adverse drug reactions, together with the Drug Commission of the German Medical Profession. According to the professional code of conduct of physicians in Germany, all adverse drug reactions should be reported to the Drug Commission. In The Netherlands, the practical responsibility for postmarketing surveillance is shared between the Medicines Evaluation Board (MEB) and the Netherlands Pharmacovigilance Centre (Lareb). The MEB handles communications with market authorization holders; the role of Lareb is to process and analyze reports from health professionals and patients.

Decentralized drug monitoring systems exist both within and outside the ICH region. In France, the French Medicines Agency coordinates the network of 31 regional centers that are connected to major university hospitals. In the UK, there are four regional centers connected to university hospitals which have the special function of encouraging reporting in their regions. The reporting system in China involves 31 regional centers reporting to the National Center for Adverse Drug Reaction Monitoring in the China Food and Drug Administration (CFDA). In India, the Pharmacovigilance Programme of India has been in operation since 2010, with the Indian Pharmacopoeia Commission (IPC) running the National Coordinating Centre. The system is now operating nationwide, with 250 local monitoring centers in medical institutes.

National and International Postmarketing Safety Databases

Once submitted to the national drug safety monitoring program, individual case safety reports are stored in computerized postmarketing safety databases. Many national drug regulatory

authorities have databases which include suspected AE/ADR reports derived from a postmarketing reporting system, as well as reports from other sources, such as the published medical literature, and sometimes certain types of serious adverse events (e.g., those considered by a clinical investigator to be potentially caused by a study drug) from clinical trials. Examples of national reporting systems and databases include the Blue Card system (Australia), Canada Vigilance (Canada), the Canadian Adverse Events Following Immunization Surveillance System (CAEFISS) database (Canada), the French Pharmacovigilance Spontaneous Reporting System database (France), the Adverse Drug Reaction Information Management System of the Pharmaceutical and Medication Devices Agency, Ministry of Health, Labor, and Welfare (Japan), the Lareb database (Netherlands), the BiSi database (Sweden), the MHRA ADR database (United Kingdom), the FDA Adverse Event Reporting System (FAERS) database (United States), and the Vaccine Adverse Event Reporting System (VAERS) database (United States). In addition, there are two international reporting and database systems: EudraVigilance [2] in the European Union (run by the European Medicines Agency, EMA) and VigiBase [48] pooling data from the more than 120 member countries of the WHO International Drug Monitoring Programme (run by the Uppsala Monitoring Centre, UMC). VigiBase is also the system used as the national database by around 70 pharmacovigilance centers around the world; reports are stored directly in VigiBase but entered, managed, and analyzed remotely through an internet-based data management tool, VigiFlow.

To understand the results of an analysis of individual case reports from a postmarketing safety database, it is necessary to understand the unique features of the database, as each large postmarketing safety database differs from the others. It is necessary to understand if, and how, the data are coded. Many databases code drugs according to a local or national standard drug dictionary, while others use a standard international dictionary, such as WHODrug [49]. Similarly, many databases code individual AE/ADR reporter verbatim terms which describe the AE/ADR according to a standard medical dictionary, such as the Medical Dictionary for Regulatory Activities (MedDRA) [50]. In the ICH regions (Europe, Japan, and the United States), use of MedDRA is mandatory for coding of AEs/ADRs.

Beyond coding, several other features of the database are important to understand. First, does the database include only reports from postmarketing systems, or does it include reports from other sources, such as the medical literature or clinical trials? Second, does the database include reports only from health professionals, or does it also include reports from patients and consumers? Third, what is the range of medical products included in the database – drugs, biologics, blood, blood products, vaccines, dietary supplements? Fourth, does the database include reports from only one country or region, or does it include reports from regions outside the jurisdiction of the regulatory authority? Fifth, does the database include both "nonserious" and "serious" AEs/ADRs; if so, what proportion of the reports have been classified by the health authority (or other database manager) as serious? Sixth, does the database include all adverse events (i.e., events which may or may not be judged to be causally related to a medicine) or does it include only adverse drug reactions (i.e., events for which a likely causal relationship has been determined prior to entering the report into the database)? Seventh, how many individual case reports are in the database? Each of these factors is important in determining the utility of a particular database in answering a specific drug safety question.

Detecting Signals from a Postmarketing Safety Database

The impetus to use a postmarketing safety database to evaluate the potential relationship of an AE/ADR to a drug may come from various

sources. For example, postapproval animal studies may suggest that a certain AE/ADR may be associated with a drug. The finding that a particular member of a drug class is associated with a specific adverse effect may prompt a search for the same reaction in other members of the class. Publication of case reports or case series, or unanticipated safety findings from ongoing clinical trials can be important sources of new safety questions for a marketed product. These stimuli for more intensive review of AE/ADR reports are external to the database.

Identifying potential associations of AEs/ADRs to drugs using only information within the database involves the detection of signals. According to the WHO, a signal is "reported information on a possible causal relationship between an adverse event and a drug, the relationship being unknown or incompletely documented previously" [51]. While there have been many definitions of a signal put forth over the years, the important underlying principle is that a signal is a hypothesis that calls for further work to be performed to evaluate that hypothesis. Signal detection is the act of looking for or identifying signals from any source.

In the setting of a relatively small number of reports, review of groups of reports or periodic summaries of reports has been a standard method of signal detection. For example, one could look at a list of all reports in which the outcome was "death" to see if this outcome was reported more frequently for some drugs than others. Summaries based on specific organ class toxicities could be reviewed to examine whether reports in one system organ class were proportionately more frequent for one drug than others. These methods depend on the ability of a drug safety specialist to recognize new or unusual patterns of case reports. While an astute specialist can identify signals using this method, this manual review is often neither practical nor reproducible for detecting signals from large postmarketing safety databases, some of which contain several million records.

In an effort to address this challenge, data mining techniques have been applied to pharmacovigilance AE/ADR databases. In broad terms, data mining refers to a process of analyzing data to find patterns. In the case of AE/ADR databases, most of these patterns would not be visible without the use of statistically based, computerized algorithms. A variety of specific algorithms have been applied to safety signal detection in AE/ADR databases (see Chapter 27) [52,53].

The fundamental feature of data mining techniques used to analyze adverse event databases is that each is based on finding "disproportionalities" in data; that is, the finding that a given AE/ADR is reported for a particular drug more often than would be expected based on the number of reports of that AE/ADR for all other drugs in the database. Several features of these methods are worth noting.

First, the methods are transparent. While the total number of reports for a drug varies over time (and may be highest in the first few years of reporting), this temporal trend will not necessarily alter the proportion of specific reactions for the drug. Thus, a given reaction may still be found to be disproportionately reported even as the total number of reports for the drug changes.

Second, these methods rely exclusively on reports within the database; no external data are needed. For this reason, understanding the characteristics of the database, as discussed above, is important. This feature has several consequences. Because the expected number of reports of a specific AE/ADR for a given drug (and thus the disproportionality of the drug–event pair) depend on the reports within the individual database, the degree of disproportionality for a given drug–event pair may vary from one database to the next. In the extreme, a given drug–event pair may have a strong signal of disproportionality in one database and no such signal in another. A second consequence is that as the background information for all drugs in the database changes, so does the expected number of reports of a specific AE/ADR for a given drug (and again the disproportionality of the drug–event pair).

Third, a signal of disproportionality is a measure of a statistical association within a collection of AE/ADR reports (rather than in a population), and it is not a measure of causality. In this regard, it is important to underscore that the use of data mining is for signal detection – that is, for hypothesis generation – and that further work is needed to evaluate the signal.

Fourth, the absence of a signal of disproportionality in a postmarketing safety database is not evidence that an important AE/ADR is not associated with a particular drug.

Data mining is sometimes done using a subset of an AE/ADR database; for example, a portion of the database limited to a specific class of drugs might be used to find relative differences in the frequencies of specific AEs/ADRs across the class [54]. Some of the data mining techniques used in pharmacovigilance have included the proportional reporting ratio, the reporting odds ratio, the Bayesian Confidence Propagation Neural Network (BCPNN), and the empirical Bayes method (also known as the Gamma Poisson Shrinker or the Multi-item Gamma Poisson Shrinker) [55]. As part of the IMI, a public-private partnership in Europe, the EMA established the Pharmacoepidemiological Research on Outcomes of Therapeutics by a European Consortium (IMI PROTECT) with a goal of conducting research to develop and test new tools for the benefit–risk assessment of marketed drugs. A range of signal detection algorithms were compared across seven spontaneous reporting databases, with no method found to be better than the others. Findings were inconsistent across databases. The choice of signaling criteria had a greater impact on signal detection performance than the choice of disproportionality methods [56,57].

Review of Case Reports

The review of individual case reports of AEs/ADRs is a complex process that has been described elsewhere [58,59,60]. It typically begins by identifying one or more case reports with the outcome of interest. Because the case reports that form a case series often come from disparate sources, it is usually necessary to develop a case definition. The case definition centers on the clinical characteristics of the event of interest, without regard to the causal role of the medicine whose relationship to the adverse event is being investigated. Once a case definition is established, each report is reviewed to determine if the event meets the case definition and if the report is to be included in the case series. Depending on the specific question(s) to be answered by the case series, other exclusion criteria may also apply. For example, one would always exclude a case in which the report suggests that the patient never took the medicine of interest. In other cases, one may restrict the case series to only certain formulations of the medicine (e.g., include case reports in which an intravenous formulation, but not an oral formulation, was used, if such exclusion is appropriate for the question at hand), or to certain age groups (e.g., limit the case series to only case reports describing the suspected adverse events in pediatric patients, if such exclusion is appropriate for the question at hand), or to certain indications for use (e.g., limit the case series to case reports in which the medicine was used for a certain off-label indication, if such exclusion is appropriate to the question at hand). Exclusion criteria for a case series must be carefully considered so that potentially relevant cases are not excluded, and all available information is fully assessed. In general, if the purpose of the case series is to examine the relationship between a medicine and a suspected AE/ADR that has not been previously associated with it, it is best to err on the side of inclusion to avoid missing clinically relevant, though incomplete, information about cases of interest.

Once the case series has been developed, it is next necessary to review each case report individually to determine whether there is a

plausible causal relationship between the medicine and the adverse event. At the level of the individual case report, it is often difficult to establish with certainty that the medicine caused the adverse event of interest (see Chapter 29) [61,62,63]. For example, if the AE/ADR of interest is already common in the population that takes the medication, establishing a causal role for the medicine in the development of the condition is generally not feasible using individual case reports or case series. For example, the incidence of Parkinson disease is much higher in persons over age 60 years than it is in persons below that age [64]. In this situation, review of a report describing a myocardial infarction in a 70-year-old patient on an antiparkinsonian agent will generally not be informative in determining if the agent played a causal role in the development of the myocardial infarction, as myocardial infarction occurs commonly in this age group. Similarly, review of a case report is not likely to shed light on the causal relationship between a medicine and an AE/ADR when the AE/ADR is a manifestation of the underlying illness which the medicine is treating. For example, review of case reports of worsening asthma in patients taking an antiasthma medication is not likely to be sufficient to establish a causal link between the worsening asthma and the medication.

Review of a case series to establish a causal relationship between a drug and an AE/ADR is most straightforward when the suspected AE/ADR: (1) is rare in the population when the medication is not used, (2) is not a manifestation of the underlying disease, (3) has a strong temporal association with drug administration, and (4) is biologically plausible as a drug reaction or is generally the result of a drug reaction based on other clinical experience. Examples of AEs/ADRs that often meet these criteria are acute hepatic failure, aplastic anemia, agranulocytosis, rhabdomyolysis, serious skin reactions such as Stevens–Johnson syndrome and toxic epidermal necrolysis, and certain arrhythmias, such as torsades de pointes.

The approach to assessing the causal role of a medicine in the development of an AE/ADR has evolved over recent decades. In general, the approach relies on a systematic review of each case report to ascertain the temporal relationship between drug intake and development of the adverse reaction, an assessment of any coexisting diseases or medications that could confound the relationship between the medicine and the AE/ADR, the clinical course after withdrawing the drug (dechallenge), and the clinical course after reintroduction of the drug (rechallenge), when applicable. Naranjo and colleagues described a method based on these general principles for estimating the likelihood that a drug caused an adverse clinical event [65]. The WHO has developed a qualitative scale for categorizing causality assessments [66].

In the development of a case series, once the individual cases are reviewed, it is important to integrate the findings across the cases to determine patterns that may point to a relationship between the drug and the AE/ADR. For example, does the AE/ADR appear at some doses but not at others? Does the AE/ADR appear after one or a few doses, or does it appear only after a more prolonged exposure? Is the spectrum of severity of the event homogeneous or heterogeneous? Are certain co-morbidities or concomitant medications more likely to be present in patients with the event? In the review of a case series, there are no prespecified answers to these questions that establish or exclude the possibility that the drug led to the AE/ADR. Rather, the characteristics of the individual cases, taken together with the patterns observed in the case series itself, can lead the analyst to determine if the medication has a reasonable possibility of causing the condition of interest.

Reporting Ratios

Because postmarketing safety reporting systems do not capture all cases of an event of interest, it is not possible to calculate an incidence rate for

a particular drug–event pair. However, analysis of AEs/ADRs based simply on numbers of reports, even after thorough analysis of these reports, does not in itself put these reports into the context of how widely a medicine is used.

To adjust for the extent of drug utilization in a population in the analysis of AE/ADR reports, a reporting ratio can be used. A reporting ratio is defined as the number of cases of a particular AE/ADR reported to a drug safety database during a specific time period divided by some measure of drug utilization in the same time period. Across drugs, the reporting ratios measure the relative frequency of the AE/ADR reports adjusting for differences in level of drug utilization. The numerator is derived from counts of AE/ADR reports associated with the drug of interest that are recorded in the postmarketing safety database during a specified time period. In the past, the denominator typically consisted of the number of dispensed prescriptions, used as a surrogate measure of drug exposure in the population over that same time period, and often estimated from proprietary drug utilization databases. The number of dispensed prescriptions was used because data on the number of unique individuals using the drug in a specified time period were generally not available.

More recently, such data have become available, and reporting ratios based on persons using the medication, and not prescriptions, are being calculated. In some cases, information is available on not only the number of persons receiving the drug or the number of prescriptions dispensed, but also on the duration of use. When such data are available, the denominator for the reporting ratio may be expressed in person-time. When using denominators based on person-time, it is important to be mindful of the assumptions of the person-time method, especially the assumption that events in the numerator occur uniformly over time. Because AEs/ADRs may not occur uniformly over time after a drug is started, this assumption does not always hold.

Because the reporting ratio (sometimes referred to as "reporting rate") is not a measure of incidence or prevalence, it must be interpreted cautiously. For AEs/ADRs that are rare in the general population (e.g., aplastic anemia), reporting ratios are sometimes compared to the background rate (incidence or prevalence) of that event in a defined population. In other situations, individual reporting ratios of a particular AE/ADR across different drugs used for a similar indication or within the same class are calculated and the magnitude of the differences in reporting ratios is compared. Interpretation of the comparison of reporting ratios across drugs must be undertaken with caution, since such comparisons are highly sensitive to variation in AE/ADR reporting and thus it is necessary to consider the differential underreporting of AEs in the postmarketing safety reporting system. The underlying assumption in estimating reporting ratios for comparison across a group of drug products is that each of the respective manufacturer's reporting practices for the drug of interest is similar over the reporting period. However, this assumption may not hold true in some cases, and a comparison of reporting ratios across drugs may not be valid.

Strengths

Signal Detection

The principal strength – and, arguably, the principal purpose – of a postmarketing safety reporting system is that it allows for signal detection, the further exploration of drug safety hypotheses, and appropriate regulatory decision making and action when necessary. As noted earlier in this chapter, signals can be detected by data mining methods, review of individual case reports, or assessment of case series. In many instances, further work is needed to determine with more certainty the relationship of the drug to the AE/ADR. The

capability for timely and effective signal detection is a key strength of a postmarketing pharmacovigilance reporting system.

Another key strength of a well-designed and effectively utilized postmarketing pharmacovigilance reporting system is that, in certain cases, the relationship of a drug to an AE/ADR can be established with sufficient confidence, usually by a case series, that necessary regulatory action can be taken. AEs/ADRs for which the relationship to a drug can be established with reasonable certainty are generally those that have a strong temporal association with drug administration, a low or near absent frequency in the underlying population, are not part of the underlying illness being treated, are generally the result of exposure to a drug or other toxin, and have no other likely explanation. Aplastic anemia, agranulocytosis, acute liver failure, rhabdomyolysis, certain arrhythmias such as torsades de pointes, and serious skin reactions such as Stevens–Johnson syndrome are examples of adverse events whose relationship to a drug can often be established by case series [67,68,69]. However, relative to all signals detected in a postmarketing safety reporting system, those about which a reasonably firm conclusion can be made on the basis of AE/ADR reports alone are few in number.

Opportunity for the Public to Report AEs/ADRs

Postmarketing safety reporting systems allow healthcare professionals to report suspected AEs/ADRs to national pharmacovigilance centers, drug regulatory authorities, and/or manufacturers. Such systems allow for direct engagement of healthcare professionals in the drug safety monitoring system. The advantage of this involvement is that it allows for careful clinical observations, made at the point of care, to inform drug safety surveillance. Clinicians can provide succinct but detailed accounts of relevant symptoms, signs, diagnostic test results, past medical history, concomitant medications, and clinical course of an AE/ADR, including information on dechallenge and rechallenge. Such a synthesis of clinical information is generally not available from automated data sources. For those AEs/ADRs that are serious, rare, and often the result of a medication exposure, the ability to obtain detailed information directly from the point of care is an essential feature of postmarketing pharmacovigilance reporting systems.

Postmarketing safety reporting systems also can accept reports from consumers and patients, though this practice is not a feature of all reporting systems. In the US, where consumers and patients can report either to the manufacturer or directly to the FDA, the percentage of reports in 2016 that originated from consumers was about 50% [7]. When consumer- and patient-generated reports do not contain sufficient medical detail for meaningful review, subsequent follow-up with health professionals may be possible in potentially important cases, so that more complete clinical information (e.g., hospital discharge summary) can be obtained.

Scope

The scope of a postmarketing safety reporting system is quite broad. The system can cover all medicines used in the population, and it can receive reports of AEs/ADRs occurring in any member of the population. Because it need not restrict the reports it receives, it can receive AE/ADR reports throughout a medicine's marketed life cycle. Thus, AEs/ADRs recognized late in a product's life cycle, such as those resulting from prolonged exposure to a medicine, can, in theory, be ascertained. In practice, such ascertainment is difficult to achieve, because healthcare professionals may be less likely to ascribe an AE/ADR not known to be associated with a medicine that has been marketed for several years. In addition, patients who take a medicine for several years may also receive other treatments during that

time, making it difficult to conclude that there is an association between the medicine and the AE/ADR.

Despite this broad scope, a postmarketing spontaneous reporting system can be relatively inexpensive. Most of these pharmacovigilance systems rely on voluntary reporting, and those who report AEs/ADRs are generally not paid. Thus, information collection is not expensive from the perspective of effective pharmacovigilance, given that the system has the capacity to handle all medicines and all outcomes. This is in contrast to other data used to study drug safety questions, such as data from clinical trials, registries, and electronic healthcare data, each of which is relatively expensive to operate.

Limitations

Quality of Reports

Perhaps the major potential limitation of a spontaneous postmarketing safety reporting system is that it depends quite heavily on the quality of individual reports. Although data mining and other informatics methods can detect signals using coded bioinformatics terms in safety databases, each individual case report must still be carefully reviewed by a clinical analyst to determine if there is a plausible relationship between the medicine and development of the AE/ADR. The quality of the report, as described earlier in this chapter, is critical for an informative and meaningful review. Report quality depends on the care, effort, and judgment of the person submitting the report, as well as the diligence of the person receiving and/or transmitting it to the health authority. Reports without sufficient information for an independent determination of the relationship between the medicine and the AE/ADR are problematic for drug safety surveillance. However, with successful follow-up, sometimes even such deficient reports can yield useful information.

Underreporting

Another well-recognized limitation of spontaneous postmarketing reporting systems is underreporting. Because most systems are voluntary, not all AEs/ADRs are reported. A consequence of underreporting is that population-based rates of AEs/ADRs cannot be calculated, because all such occurrences in the population are not reported and the extent of underreporting for any individual AE/ADR is not known. Reporting ratios, discussed earlier in this chapter, allow the reported number of AEs/ADRs to be put into the context of drug utilization, though this measure is not an incidence rate.

Nonuniform Temporal Trends in Reporting

Another limitation of spontaneous reporting systems is that temporal trends in the number of AE/ADR reports for a drug–event combination may not reflect actual population-based trends for that combination. This is because multiple factors can affect the number of AE/ADR reports received for a given drug–event pair.

First, the number of reports for a medicine is thought to peak in the second year after approval and decline thereafter, even though the drug may be used more widely. This phenomenon, known as the Weber effect, was originally described in relation to nonsteroidal antiinflammatory medicines [70]. A more recent analysis of reporting patterns for the angiotensin II receptor blocker class of medicines revealed no discernible trend when the number of reports over time was examined [71]. Specifically, this analysis did not confirm that the number of reports increased toward the end of the second year and declined thereafter. Rather, it indicated that additional factors, such as the approval of additional indications and modifications of the firms' reporting requirements, affected the total number of reports received. However, when the

number of reports in a year was adjusted for the number of prescriptions dispensed in that period, it was found that the adjusted number of reports was highest in the first years after approval and declined thereafter. The frequency of AE/ADR reports per estimated unit of drug utilization may not be constant over time, although a recent analysis of FAERS data for 62 drugs did not confirm a reporting pattern over time as described by Weber [72].

Second, publicity about an important new AE/ADR often gives rise to a large number of reports shortly after the publicity, with a decline in the number of reports shortly thereafter. This phenomenon is known as stimulated reporting and was observed, for example, in the reporting pattern of statin-induced hospitalized rhabdomyolysis after publicity of this risk. For these reasons, changes in the number of AE/ADR reports for a given drug–event pair cannot reliably be interpreted as a change in the population-based frequency of the AE/ADR.

Another limitation of a postmarketing reporting system is that it is usually not well suited to ascertaining the relationship of a medicine to an AE/ADR that is common in the treated population, especially if the condition is a manifestation of the underlying illness. In such cases, the combined effect of confounding of patient factors and indication makes causality assessment of individual cases difficult.

Finally, duplicate reports of the same AE/ADR may be received by drug manufacturers and health authorities and if undetected as duplicates, may be entered into the database as multiple occurrences of the same event. Algorithms have been developed and various methods can be used to identify such reports; nonetheless, this issue is a potential source of bias and limits the utility of data mining or other calculations which rely on "crude" case counts which have not been "deduplicated."

Particular Applications

Fingolimod

Fingolimod, a sphingosine-1-phosphate receptor modulator that reduces the number of lymphocytes in peripheral blood, is used to reduce the frequency of clinical exacerbations and delay the accumulation of physical disability in patients with relapsing forms of multiple sclerosis. When the product was initially approved in the US in September 2010, the product label noted a dose-dependent reduction in peripheral lymphocyte count of 20–30% of baseline values and warned of the risk of serious infections. Based on experience in premarketing clinical trials, the label described the specific risk of fatal herpetic infections in two patients who received a dose higher than the recommended dose for multiple sclerosis. The label also noted that while the overall rates of infections and serious infections were similar in fingolimod-treated and placebo-treated patients in clinical trials, bronchitis and pneumonia were more common in fingolimod-treated patients.

Approximately three years after approval in the US, a patient in Europe was reported to have developed progressive multifocal leukoencephalopathy (PML), a demyelinating central nervous system disease caused by the JC virus. PML is a rare disease; when it occurs, it is usually in the setting of immunosuppression. Because the patient in whom PML was reported had received prior immunosuppressants, the PML could not be conclusively linked to fingolimod. At the time this case was reported, approximately 71 000 patients worldwide had received fingolimod, according to the manufacturer.

Two years after the initial case report of PML, the US FDA announced that it had received two case reports of fingolimod-treated patients with no prior immunosuppressant treatment [73]. In the first case, a 49-year-old patient with a five-year history of multiple sclerosis was suspected to have PML when results of a routine magnetic

resonance imaging test (MRI) showed lesions, not present at the time fingolimod treatment was initiated, that were atypical for multiple sclerosis and more consistent with PML. The patient had prior treatment with interferon beta-1a and intermittent corticosteroids. Cerebrospinal fluid analysis was positive for JC virus DNA. Based on the MRI findings and cerebrospinal fluid analysis, a diagnosis of probable PML was made, in accordance with the diagnostic criteria of the American Academy of Neurology consensus statement [74].

The second case concerned a 54-year-old patient with a 14-year history of multiple sclerosis who had been taking fingolimod for 2.5 years when PML was diagnosed. The patient had previously been treated with interferon beta-1a for 11 years, and was then switched to treatment with fingolimod. At the time of the PML diagnosis, the patient had been receiving treatment with mesalazine for ulcerative colitis for four years. After 2.5 years of treatment with fingolimod, the patient developed walking instability, clumsiness, inattention, and somnolence. A brain MRI was suggestive of PML, and cerebrospinal fluid analysis was positive for JC virus DNA. Based on the symptoms, MRI findings, and cerebrospinal fluid analysis, a diagnosis of definite PML was made, in accordance with the American Academy of Neurology diagnostic criteria. On the basis of these two cases, the product label for fingolimod in the US was updated to include a warning for progressive multifocal leukoencephalopathy.

This example illustrates some important features of the analysis of individual case safety reports. First, individual reports can be used to establish a causal relationship between a drug and an adverse event when the adverse event is rare in the population. In this example, PML is extremely rare, and when it occurs, it is usually in the setting of immunosuppression due to treatment with certain medicines or certain malignancies. If PML occurred spontaneously (i.e., in the absence of these particular conditions) in the general population or in patients with multiple sclerosis, it would be quite difficult to establish a causal relationship between PML and fingolimod therapy. Second, detailed, though not necessarily lengthy, case reports are important for robust case analysis, and especially for causality assessment. The two case reports in this example included detailed information about prior and concomitant medications (none of which is known to cause PML). Without information on prior and concomitant medications, the uncertainty about exposure to immunosuppressants would have limited the conclusions that could be made from the case reports. Third, the inclusion of relevant clinical information used to establish the diagnosis of the adverse event allows reviewers of the case report to come to an independent conclusion about the diagnosis. In this case, the details of the diagnosis were applied to the published consensus-driven diagnostic criteria set forth by a professional society. While use of such criteria is ideal, formal, established diagnostic criteria are not available for all adverse outcomes of interest, and reviewers of individual case safety reports should establish their own criteria.

Finally, this example is unusual in that a causal relationship between a drug and a serious AE was established based on two individual case reports. Because establishing a diagnosis and evaluating causality are difficult with individual case safety reports, a higher number is usually needed.

Dabigatran

Dabigatran is an oral direct thrombin inhibitor approved in the US in October 2010 to reduce the risk of stroke and systemic embolism in patients with nonvalvular atrial fibrillation. It was the first oral anticoagulant approved for this indication since warfarin had been approved for a similar indication. In the clinical trial that supported dabigatran's approval, 6076 patients were randomized to dabigatran 150 mg twice daily, and 6022 were randomized to warfarin

treatment. The rates of major bleeding were 3.3 per 100 person-years in dabigatran-treated patients and 3.6 per 100 person-years in warfarin-treated patients (hazard ratio 0.93, 95% confidence interval (CI) 0.81–1.07). The corresponding rates for life-threatening bleeds were 1.5 per 100 person-years and 1.9 per 100 person-years in the dabigatran and warfarin groups, respectively (hazard ratio 0.80, 95% confidence interval 0.66–0.98). Gastrointestinal bleeding was more common in dabigatran-treated than in warfarin-treated patients (1.6% vs 1.1%, hazard ratio 1.5, 95% confidence interval 1.2–1.9). In the first 14 months after dabigatran's approval, the US FDA received 2347 case reports of bleeding with dabigatran (348 with a fatal outcome), compared to 647 case reports of bleeding with warfarin (46 with a fatal outcome) [75].

On its face, this disparity in report numbers between the two agents suggested that dabigatran might be responsible for more bleeding in actual practice, a finding that was contrary to the preapproval observations. These numbers also raised the possibility of increased mortality with dabigatran relative to warfarin. A population-based analysis using administrative claims data, however, found that the rates of bleeding associated with dabigatran use were no higher than those associated with warfarin use [76]. A subsequent study using data from the US Medicare system found that, in actual practice settings, dabigatran was associated with a lower risk of ischemic stroke, intracranial hemorrhage and death and a higher risk of major gastrointestinal bleeding, relative to warfarin – findings that were consistent with those of the preapproval clinical trial data [77].

This example illustrates some important limitations concerning use of aggregate spontaneous report data to estimate population-based risk or relative risk of an adverse event between two drugs. A comparison of raw numbers of adverse event reports generally cannot be used to estimate the relative frequency of the adverse event in a population between two drugs. Population-based rates of an adverse event generally cannot be estimated from spontaneous reporting data because of underreporting and lack of a reliable measure of population exposure. Importantly, there often is a differential extent of underreporting of adverse events across a product's marketed life. Studies of adverse event reporting patterns of angiotensin receptor blockers and antiepileptic drugs have shown that, after adjustment for drug utilization, there were more adverse event reports in the first year after approval compared to subsequent years [71,78].Thus, even though a newly approved drug may not be widely used, there may be more spontaneous adverse event reports received for the newer drug compared to an older, widely used drug, even if there is no true difference in risk between them.

Peginesatide

Peginesatide, a novel synthetic peptide which was considered to be an important breakthrough for treatment of anemia in patients with dialysis-dependent chronic kidney disease, was withdrawn from marketing in 2012, within months of becoming commercially available, when the manufacturer received an unexpected number of case reports of fatal anaphylaxis [79]. Subsequent analyses suggested that the root cause of the reactions may have been a preservative present in the commercially available multiple-use vials but not in the single-use formulation that had been used exclusively in clinical trials [80,81].

Anaphylaxis, whether mediated by immunologic or nonimmunologic mechanisms, is a rare, unpredictable adverse reaction that can occur within minutes of exposure to an offending agent. Such reactions can alter the benefit–risk balance of newly approved drugs or biologics. Because fatal anaphylaxis is a rare occurrence with a strong temporal relationship between a triggering exposure and the onset of severe

symptoms, it represents a good example of the type of adverse drug reaction for which postmarketing spontaneous reporting systems are the primary means of timely signal detection. Although the decision to withdraw peginesatide from marketing was relatively swift, the results of subsequent nonclinical analyses suggesting an unexpected root cause illustrate the role of multiple data streams [82].

Drugs to Treat Attention-Deficit/ Hyperactivity Disorder

In other examples of postmarketing pharmacovigilance issues, spontaneous reports have provided actionable information about the clinical spectrum of adverse drug effects that may not have been well recognized in more restrictive clinical trial settings. An FDA safety evaluator became aware of several spontaneous reports describing psychiatric adverse events in otherwise normal children who were being treated with an extended-release formulation of methylphenidate for attention-deficit/ hyperactivity disorder (ADHD), and presented her findings at a Pediatric Advisory Committee meeting in June 2005. Committee members expressed concern, and a comprehensive evaluation of psychiatric adverse effects with drug treatments of ADHD was undertaken with the full cooperation of the drug's manufacturers. The results of the analysis were presented at a subsequent Pediatric Advisory Committee meeting in March 2006 and were also later published in a peer-reviewed journal [83]. Data were analyzed from 49 randomized controlled clinical trials. Results showed a total of 11 psychosis/mania adverse events which occurred during 743 person-years of double-blind treatment with the drugs of interest, compared to no similar adverse events during 420 person-years of placebo exposure in the same trials. Analysis of postmarketing spontaneous data yielded a total of 865 unique reports of psychosis or mania-type adverse events associated with these drugs. These findings were the basis for a MedWatch Alert in 2007, and for the addition of new warnings and medication guides for all of the ADHD drug treatments which were studied [84].

Medication Errors

The detection of medication errors is now an established area of pharmacovigilance [85,86]. An analysis of the EudraVigilance database revealed that between 2002 and 2015, a total of 147 824 cases of medication errors had been reported, with the annual number of such reports increasing throughout that period. Between 2010 and 2015, case reports of medication errors accounted for 1–2% of all reports in EudraVigilance [87].

For the purposes of pharmacovigilance, there is not an internationally accepted definition of a medication error. In the US, the National Coordinating Council for Medication Error and Reporting defines a medication error as "any preventable event that may cause or lead to inappropriate medication use or patient harm while the medication is in the control of the health care professional, patient, or consumer" [88]. In the European Union, the Good Practice Guidance defines a medication error as "an unintended failure in the drug treatment process that leads to, or has the potential to lead to harm to the patient." Regardless of the specific definition used, preventability is a key concept underlying the detection of medication errors. Careful analysis of case reports of medication errors can lead to changes in the design of a product, changes to its instructions for use, changes to carton or container labeling, or other changes aimed at reducing the frequency of preventable errors.

Because a medication error can occur at many points in the drug use process, attentive healthcare professionals, patients, and others can detect the error (such as a wrong drug or wrong dose) before it reaches the patient – a so-called "near miss." Thus, unlike case reports of adverse

events, which describe an adverse outcome associated with use of a medicine, a case report of a medication error describes a medication error along any point in the medication use process, whether or not the patient receives the medication or experiences harm. Analysis of case reports of medication errors focuses on the product(s) involved, the sequence of events leading up to the error, the work environment in which the error occurred, the personnel involved (healthcare professionals, patient, family, and others), the type(s) of errors that occurred, and other contributing factors. For these reasons, case reports of medication errors should include detailed information on these factors [34]. The Medical Dictionary for Regulatory Activities (MedDRA) [50] contains terminology for medication errors, which allows for both broad and narrow searches of reports of medication errors in pharmacovigilance databases.

For example, the antidepressant vortioxetine was approved in the US in September 2013 and carried the proprietary name Brintellix®. By June 2015, the US FDA had received 50 case reports describing medication errors in which the name Brintellix was mistaken for Brilinta®, the proprietary name of the antiplatelet agent ticagrelor. Review of the case reports indicated that the wrong medication was dispensed in at least 12 cases, though there were no reports of ingestion of the wrong medicine. The case reports also indicated that this medication error occurred both when prescribing the medication and when dispensing it. Based on analyses of the two proprietary names, the confusion was likely due to the drugs' having the same first three letters, being presented near each other in a computerized order entry system, lack of pharmacist familiarity with the recently approved medication Brintellix, and the drug names looking and sounding similar to each other.

Between the analysis of these cases and a subsequent regulatory action, the FDA received an additional five case reports of Brintellix being confused with Brilinta. In one case, the medical record of a patient undergoing a lung biopsy indicated that the patient was taking Brilinta but the medical staff confused it for Brintellix. Not aware that the patient was taking an antiplatelet agent at the time of the lung biopsy, the medical staff did not take the necessary precautions and the patient experienced bleeding and a collapsed lung. In May 2016, the FDA approved a change in the proprietary name from Brintellix to Trintellix [89].

Data Mining Signals

According to the UMC glossary of pharmacovigilance terms, a signal is "a hypothesis of a risk with a medicine, with various levels of evidence and arguments to support it" [8]. Signals are identified by UMC analysts from the WHO Global Individual Case Safety Report (ICSR) database (VigiBase) by applying a predefined triage algorithm (data mining). The disproportionality measure used by the UMC is the information component (IC), originally introduced through the BCPNN, which is a logarithmic measure of the disproportionality between the observed and expected reporting of a drug–event pair. A positive IC value means that a particular drug–event pair is reported more often than expected, based on all the reports in the database. Signals from VigiBase are reported quarterly in the Signal document, which is circulated in restricted fashion to national pharmacovigilance centers for the purpose of communicating the results of UMC evaluations of potential data mining signals from the WHO database. A recent analysis found that of 43 UMC signals disseminated between 2007 and 2010 for products with approved labeling, 15 (35%) were labeled, and eight of the labeled signals were subsequently updated after the signal communication, supporting the relevance of routine data mining [90].

Below is an example of a WHO program signal identified by data mining applied to the WHO Global Individual Case Safety Report Database, VigiBase.

Topiramate and Glaucoma

Topiramate was approved in the US in 1996 as an anticonvulsant drug [91]. In the second quarter of 2000, reports of topiramate and glaucoma in VigiBase reached the threshold of an "association" (i.e., the lower limit of a 95% Bayesian confidence interval for the IC exceeded zero). When potential signals are identified, the available information is reviewed by the UMC staff and an expert review panel. At the time, there were six cases reported to VigiBase. After review, a summary of the findings were circulated in the Signal document in April 2001 to all national pharmacovigilance centers in the WHO program. On September 26 the same year, the Market Authorization Holder issued a Dear Healthcare Professional letter warning about "an ocular syndrome that has occurred in patients receiving topiramate. This syndrome is characterized by acute myopia and secondary angle closure glaucoma." By August 17, there were 23 reported cases according to the company. The FDA issued a warning in the revised labeling on October 1, 2001 [91].

Signals from Developing Countries

At the annual meetings of the WHO program members, country representatives are invited to share problems of current interest in their countries. Below are two examples illustrating the kind of issues that have been investigated in developing countries, presented at the 2017 meeting in Uganda [92].

Blindness and Retinal Disorder Associated with Clomifene Citrate: Case Series Assessment

A case of retinal detachment with the use of clomifene citrate that caused irreversible blindness triggered an assessment by the Eritrean Pharmacovigilance Centre. A search of VigiBase identified 24 cases of blindness and retinal disorder. All cases were evaluated using Austin Bradford Hill considerations to assess the causal relation. In all cases, clomifene was reported as the sole suspected drug and in all but three cases, no concomitant drugs were reported. There were two cases of blindness in which the reaction abated with sequelae following withdrawal of clomifene. The conclusion was that the findings support a causal relationship and warrant further investigation to substantiate the signal [93].

Signal of Alpha-Chymotrypsin and Anaphylaxis

Alpha-chymotrypsin is a biological product commonly used in Vietnam for numerous conditions. The efficacy of the oral product was questioned because this product is a large molecule product and the potential for safety issues of the injectable form warranted an investigation. From the national spontaneous reporting database, significant signals related to hypersensitivity, including anaphylactic reactions (reporting odds ratio [ROR] 2.12; 95% CI 1.46–3.07). Since 2010, 249 reports were received nationwide, of which 65 cases were related to anaphylactic reactions, and this is approximately equal to all spontaneous reports related to alpha-chymotrypsin obtained from VigiBase. The National Centre sent an official letter to the Drug Administration of Vietnam, Ministry of Health to advocate a safety effectiveness revision for this product [92].

Deployment of Pharmacovigilance During Mass Drug Administration in Sierra Leone

The specific challenges for pharmacovigilance in a developing country during a public health emergency were illustrated by Wiltshire Johnson, Registrar and CEO of the Pharmacy Board of Sierra Leone during the May 2016 Uppsala Forum conference [94]. Pharmacovigilance during the Ebola crisis in 2014 meant not only the safety surveillance of experimental treatments, but also of products such as disinfectants, rubber gloves, and other equipment. Treatment of malaria, as well as pneumonia and diarrhea, became difficult due to the reluctance to seek medical help; many feared that the similarity of symptoms with Ebola would prevent them from returning home. The surveillance of the antimalarial mass drug administration

of over 5 million doses of artesunate-amodiaquine that needed to be rolled out during the peak of the Ebola outbreak stretched all capacity, but became a success story. In collaboration with the National Malaria Control Programme, the Pharmacy Board's National Pharmacovigilance Centre actively participated in real-time pharmacovigilance by going into the communities and searching for, identifying, and managing adverse events. The data analysis led to changing first-line treatment of malaria from artesunate-amodiaquine to artemether-lumefantrine [94].

The Future

Spontaneous AE/ADR reporting is an important component of drug safety surveillance. The widespread availability of electronic healthcare data may, at first, seem to undermine the importance of AE/ADR reporting. This is not likely to be the case. Because careful observation at the point of care is an essential component of pharmacovigilance, electronic systems may be able to facilitate AE/ADR reporting in the future but will not replace it. It is technologically and administratively feasible for carefully designed systems to allow clinicians to report AEs/ADRs directly from electronic medical record systems. If designed properly, these systems could allow for the accurate, complete, and efficient inclusion of laboratory, radiologic, and other diagnostic test results, information which is often incomplete in current AE/ADR reports. The challenge of such a system will be to encourage reporters to routinely provide a clinically meaningful narrative that explains concisely the clinical course of the AE/ADR and its relationship to medication usage.

There is also interest in using modern informatics techniques to facilitate review of adverse event reports, especially in large AE databases. For example, the use of natural language processing techniques is being explored to determine if they can identify individual case safety reports that warrant further evaluation, or individual case reports that suggest a causal association between a medicine and an adverse event. Postmarketing safety reporting systems depend on the involvement of healthcare professionals and, in some areas, consumers and patients as well, for high-quality AE/ADR reports.

As new medicines become available, it will be increasingly necessary to monitor postmarketing safety. Postmarketing safety reporting systems will continue to be the cornerstone of this effort, because of their unique advantages. As social media, active surveillance, and the use of large healthcare databases begin to play a role in drug safety surveillance, demonstrate their utility, and realize their potential, they could become valuable adjuncts to existing pharmacovigilance reporting systems worldwide.

Electronic Data Systems

11

Overview of Electronic Databases in Pharmacoepidemiology

Brian L. Strom

Rutgers Biomedical and Health Sciences, Newark, NJ, USA

Once hypotheses about drug-induced adverse effects are generated, usually from spontaneous reporting systems (see Chapter 10), techniques are needed to test these hypotheses. Usually between 500 and 3000 patients are exposed to the drug during Phase III testing, even if drug efficacy can be demonstrated with much smaller numbers of patients. Studies of this size would be expected to observe a single case of outcomes with an incidence of 1 per 1000 to 6 per 1000 (see Chapter 4). Given this context, postmarketing studies of drug effects must then generally include at least 10 000 exposed persons in a cohort study, or enroll diseased patients from a population of equivalent size for a case–control study. Given a study of this size, the upper 95% confidence limit for the incidence any event that is not identified would be 3 per 10 000 (see Chapter 4). However, prospective studies this large are expensive and difficult to perform. Yet such studies often need to be conducted quickly, to address acute and serious regulatory, commercial, and/or public health crises. For all of these reasons, the past decades have seen a growing use of electronic databases containing healthcare data, sometimes called "automated databases," as potential data sources for pharmacoepidemiologic studies.

Large electronic databases can often meet the need for a cost-effective and efficient means of conducting postmarketing surveillance studies. To meet the needs of pharmacoepidemiology, the ideal database would include records from inpatient and outpatient care, emergency care, mental health care, all laboratory and radiological tests (including pharmacogenomic tests that may not have been performed as part of clinical care), functional assessments, and all prescribed and over-the-counter medications, as well as alternative therapies. The population covered by the database would be large enough to permit discovery of rare events for the drug(s) in question, and the population would be stable over its lifetime. Although it is generally preferable for the population included in the database to be representative of the general population from which it is drawn, it may sometimes be advantageous to emphasize the more disadvantaged groups that may have been absent from premarketing testing. The drug(s) under investigation must of course be present in the formulary and must be prescribed in sufficient quantity to provide adequate power for analyses.

Other requirements of an ideal database are that all parts are easily linked by means of a

Pharmacoepidemiology, Sixth Edition. Edited by Brian L. Strom, Stephen E. Kimmel and Sean Hennessy.

patient's unique identifier, that the records are updated on a regular basis, and that the records are verifiable and reliable. The ability to conduct medical chart review to confirm outcomes is also a necessity for most studies (unless validated algorithms for the study outcome already exist), as diagnoses entered into an electronic database may include rule-out diagnoses or interim diagnoses and recurrent/chronic, as opposed to acute, events. Information on potential confounders, such as smoking and alcohol consumption, may only be available through chart review or, more consistently, through patient interviews. With appropriate permissions and confidentiality safeguards in place, access to patients is sometimes possible and useful for assessing compliance with the medication regimen as well as for obtaining biosamples or information on other factors that may relate to drug effects. Information on drugs taken intermittently for symptom relief, over-the-counter drugs, and drugs not on the formulary must also be obtained directly from the patient.

These automated databases are the focus of this section of the book. Of course, no single database is ideal for all questions. In the current chapter, we will introduce these resources, presenting some of the general principles that apply to them all. In Chapters 12–14 of this book, we will present more detailed descriptions of those databases that have been used in a substantial amount of published research, along with the strengths and weaknesses of each.

Description

So-called automated databases have been used for pharmacoepidemiologic research in North America since 1980, and are primarily administrative in origin, generated by the request for payments, or claims, for clinical services and therapies. In contrast, electronic health record databases were developed for use by researchers in Europe, and similar databases have been developed in the US more recently.

Claims and other Administrative Databases

Claims data arise from billable interactions between patients and the healthcare system. When a patient goes to a pharmacy and gets a drug dispensed, the pharmacy bills the insurance carrier for the cost of that drug, and has to identify which medication was dispensed, the milligrams per tablet, number of tablets, etc. Analogously, if a patient goes to a hospital or to a physician for medical care, the providers of care bill the insurance carrier for the cost of the medical care, and have to justify the bill with a diagnosis. If there is a common patient identification number for both the pharmacy and the medical care claims, these elements could be linked and analyzed as a longitudinal medical record.

Since drug identity and the amount of drug dispensed affect reimbursement, and because the filing of an incorrect claim about drugs dispensed is fraud, claims are often closely audited, for example by Medicaid. Indeed, there have been numerous validity checks on the drug data in claims files that showed that the drug data are of extremely high quality, such as confirming that the patient was dispensed exactly what the claim showed was dispensed, according to the pharmacy record. In fact, claims data of this type provide some of the best data on drug exposure in pharmacoepidemiology (see Chapter 37).

The quality of disease data in these databases is somewhat less perfect. If a patient is admitted to a US hospital, the hospital charges for the care and justifies that charge by assigning diagnosis codes (until recently International Classification of Diseases, Ninth Revision, Clinical Modification [ICD-9-CM] codes) and a Diagnosis-Related Group (DRG). Hospital diagnosis codes are reasonably accurate diagnoses

that are used for clinical purposes, based primarily on the discharge diagnoses assigned by the patient's attending physician. (Of course, this does not guarantee that the physician's diagnosis is correct.) The amount paid by the insurer to the hospital is based on the DRG, so there is no financial incentive to provide incorrect diagnosis codes. In fact, most hospitals have mapped each set of diagnosis codes into the DRG code that generates the largest payment.

In contrast, however, outpatient diagnoses are assigned by the practitioners themselves, or by their office staff. Once again, reimbursement in the US does not usually depend on the actual diagnosis, but rather on the visit intensity during the outpatient medical encounter, and the resulting procedure codes indicate the intensity of the services provided. Thus, there is no incentive for the practitioner to provide incorrect diagnosis codes, but there is also no incentive for them to be particularly careful or complete about the diagnoses provided. For these reasons, the outpatient diagnoses are the weakest link in claims databases.

Some other databases are not made up of actual claims but derive from other administrative processes, such as data from US health maintenance organizations or other data sources. The characteristics of these data are similar in many ways to those of claims data, and they are discussed together as encounter-based databases in Chapter 12.

Electronic Health Record Databases

In contrast, electronic health record databases are a more recent development, arising out of the increasing use of computerization in medical care. Initially, computers were used in medicine primarily as a tool for literature searches. Then, they were used for billing. Now, however, there is increasing use of computers to record medical information at the point of care. In most instances, this is replacing the paper record as the primary medical record. As medical practices increasingly become electronic, this opens up a unique opportunity for pharmacoepidemiology, as larger and larger numbers of patients are available in such systems. The best-known and most widely used example of this approach is the UK Clinical Practice Research Datalink® (CPRD®), along with the newer database, The Health Improvement Network® (THIN®), both described in Chapter 13. As general practice databases, these contain primarily outpatient data. In addition, recently inpatient electronic health record databases are becoming available (Chapter 14).

Electronic health record databases have unique advantages. Important among them is that the validity of the diagnosis data in these databases is probably better than that in claims databases, as these data are being used to document medical care rather than just for billing purposes. When performing a pharmacoepidemiologic study using these databases, there is no purpose in validating the data against the actual medical record, since one is analyzing the data from the actual medical record. However, there are also unique issues one needs to be concerned about, especially the uncertain completeness of the data from other physicians and sites of care. Any given practitioner provides only a piece of the care a patient receives, and inpatient and outpatient care are unlikely to be recorded in a common medical record.

Strengths

Computerized databases have several important advantages, including their potential for providing a very large sample size. This is especially important in the field of pharmacoepidemiology, where achieving an adequate sample size is uniquely problematic. In addition, these databases are relatively inexpensive to use, especially given the available sample size, as they are by-products of existing administrative

systems. Studies using these data systems do not need to incur the considerable cost of data collection, other than for those subsets of the populations for whom medical records are abstracted and/or interviews are conducted. The data can be complete; for example, for claims databases, information is available on all medical care provided for covered services, regardless of who the provider was. As indicated above, this can be a problem for electronic health record databases, especially in the US, where primary care providers often do not serve as gatekeepers to specialty care. In addition, these databases can be population based, they can include outpatient drugs and diseases, and there is no opportunity for recall and interviewer bias, as they do not rely on patient recall or interviewers to obtain their data. Another advantage is that these databases can potentially be linked to other external electronic databases (e.g., death records, maternal-child records, police accident records), to expand the capabilities and scope of research. This requires the use of common identification elements (e.g., name and date of birth) and standardized semantics to allow communication across databases.

Weaknesses

The major weakness of such data systems is the uncertain validity of diagnosis data. This is especially true for claims databases, and for outpatient data. For these databases, access to medical record data for validation purposes is usually needed. This issue is less problematic for electronic health record databases; however, the validity of medication data from electronic health record databases in the United States is less certain than pharmacy dispensing data from claims databases. The addition of laboratory results data to these resources can assist in diagnosis validity, as well.

In addition, such databases can lack information on some potential confounding variables. For example, in claims databases there are no data on date of menopause, and diagnosis-based algorithms to identify smoking and alcohol abuse may have poor sensitivity, all of which can be of great importance to selected research questions. This argues that one either needs access to patients or physician records if these contain the data in question, or one needs to be selective about the research questions that one seeks to answer through these databases, avoiding questions that require data on variables which may be important potential confounders that must be controlled for.

Another major disadvantage of administrative data is the instability of the population due to job changes, employers' changes of health plans, and changes in coverage for specific employees and their family members. The opportunity for longitudinal analyses is thereby hindered by the continual enrollment and disenrollment of plan members. Another source of population instability is when patients transfer out of the system due to death or relocation. The effect of this is an inflated list with patients no longer seeking medical care. This will invalidate calculations of patient-time in studies of disease incidence, for example, because the denominator is inflated. The challenge for the investigator is to be creative in devising strategies to guard or correct for this incomplete information in the database (e.g., by performing sensitivity analysis censoring follow-up one or two years after the patient's last recorded entry in the database). Alternatively, strategies can be adopted for selecting stable populations within a particular database and, for example, by examining patterns of prescription refills for chronically used medications and restricting the study population to include only continuously enrolled patients. Of course, the largest such data system, US Medicare, suffers much less from this problem since it covers the elderly, so people never lose eligibility. Even there, however, patients can switch between fee-for-service plans and managed care plans, and the latter

may not record all healthcare which is provided (see Chapter 12).

Further, by definition, such databases only include illnesses severe enough to come to medical attention. In general, this is not a problem, since illnesses that are not serious enough to come to medical attention and yet are uncommon enough for one to seek to study them in such databases are generally of lower importance.

Some results from studies that utilize these databases may not be generalizable, for example on healthcare utilization. This is especially relevant for databases created by data from a population that is atypical in some way, such as US Medicaid data.

Finally, as noted briefly above, as an increasing number of electronic health record databases emerge in the US, to date all are problematic in that they do not include complete data on a defined population. In the US health system, unlike other countries, patients can, and often do, seek medical care from a variety of different healthcare providers at unaffiliated institutions with a nonlinked electronic health record systems. Thus, providers' electronic health records are inherently incomplete, and need to be linked to administrative data in order to be useful for quality research. This is different from the situation in, for example, the UK, where electronic health record databases are much more likely to be complete given the general practitioner gatekeeper paradigm and unique patient identifier for all healthcare services.

Particular Applications

Based on these characteristics, one can identify particular situations when these databases are uniquely useful or uniquely problematic for pharmacoepidemiologic research. These databases are useful in situations: (1) when looking for uncommon outcomes because of a large sample size; (2) when a denominator is needed to calculate incidence rates; (3) when one is studying short-term drug effects (especially when the effects require specific drug or surgical therapy that can be used as validation of the diagnosis); (4) when one is studying objective, laboratory-driven diagnoses; (5) when recall or interviewer bias could influence the association; (6) when time is limited; and (7) when the budget is limited.

Uniquely problematic situations include: (1) illnesses that do not reliably come to medical attention; (2) inpatient drug exposures that are not included in some of these databases; (3) outcomes that are poorly captured by the coding system, such as Stevens–Johnson syndrome; (4) descriptive studies, if the population studied is nonrepresentative; (5) delayed drug effects, wherein patients can lose eligibility in the interim; and (6) important confounders about which information cannot be obtained without accessing the patients, such as cigarette smoking, occupation, menarche, menopause, etc.

The Future

Given the frequent use of these data resources for pharmacoepidemiologic research in the recent past, we have already learned much about their appropriate role. As it appears that these uses will be increasing, we are likely to continue to gain more insight in the coming years, especially with the access in the US to Medicare data, and the advent in the US of the FDA's Sentinel system, exceeding 170 million individuals (see Chapter 25). However, care must be taken to ensure that all potential confounding factors of interest are available in the system or addressed in some other way, that diagnoses under study are chosen carefully, and that medical records can be obtained when needed to validate the diagnoses.

In this section of the book, Chapters 12–14, we will review the details of a number of these databases. The databases selected for review have been chosen because they have been the most widely used for published research. They are also good examples of the different types of data that are available. There are multiple others like each of them and undoubtedly many more will emerge over the ensuing years. Each has its advantages and disadvantages, but each has proven it can be useful in pharmacoepidemiologic studies.

Encounter databases contain electronic records of healthcare encounters for large, defined populations. They capture information on patient characteristics, prescription fills, and medical services, as part of the routine administration or reimbursement of healthcare. This is in contrast to electronic health record (EHR) databases, described in detail in Chapter 13, which are primarily intended and maintained to support patient care. Encounter data may contain records at various levels of granularity, ranging from records of individual services (fee-for-service claims) to aggregate records of care episodes (hospital discharge records). Encounter databases exist in many countries and within a number of vastly different healthcare systems. An increasing number are available for research and consequently, encounter databases have become a cornerstone of pharmacoepidemiologic research. Although they vary markedly in their specific characteristics, encounter databases share a number of defining features that warrant their discussion as a group.

While previous editions of *Pharmacoepidemiology* provided detailed information on a few select encounter databases in several dedicated chapters, this sixth edition presents this information in more general terms in a single chapter. This change in approach reflects the continued growth in the number of encounter databases used for pharmacoepidemiologic research and the often significant changes in the characteristics of individual databases over time. Rather than attempting to provide an encyclopedic description of available databases, this chapter focuses on the description of key commonalities and distinctions across encounter databases, illustrated with selected examples and supplemented by references to more comprehensive resources in the literature. The chapter now also includes a dedicated discussion of the considerations faced by researchers when evaluating the appropriateness of a specific encounter database or deciding among multiple encounter databases for their research question. The use of encounter databases for multi-database studies within distributed data networks is discussed in Chapter 25.

Pharmacoepidemiology, Sixth Edition. Edited by Brian L. Strom, Stephen E. Kimmel and Sean Hennessy.

Description

Encounter data arise as part of the routine administration of a person's interactions with various sectors of the healthcare system. When combined, these data can be used to infer a longitudinal picture of a person's medical and treatment history. The quality of that picture, that is, its usefulness for pharmacoepidemiologic and other research, depends on the completeness and validity of the information available.

The essential attribute of all encounter databases useful for pharmacoepidemiologic research is a defined population for which healthcare services are recorded regardless of the provider or location where care is received [1]. Such databases are considered *population based* (see Chapter 17). Precise definition of the database population avoids various forms of selection bias common in nonpopulation-based studies (e.g., biased control selection in hospital-based case–control studies). Complete capture of all relevant healthcare services avoids bias from incomplete and potentially differential measurement of healthcare services (e.g., incomplete ascertainment of hospitalizations occurring in a nonparticipating healthcare system). Although representativeness of a geographic region or the general population is often desirable, it is not necessary as long as the database population is accurately defined.

While encounter databases ideally capture all healthcare services, in practice specific service types may not be captured due to the nature of the data collection process (most often due to lack of reimbursement). However, accurate qualitative description of the specific service types with lack of coverage or incomplete capture is critically important to allow evaluation of the appropriateness of the database for a given research question.

Encounter databases are maintained by a number of different entities including government agencies, insurance companies, health plans, and information services companies. The primary purpose of encounter databases is often the reimbursement of fee-for-service payment claims, and such encounter data are often referred to as claims data. In some instances, for example in US health plans with staff model delivery systems or capitated payment models, the purpose is purely administrative with no processing of payments for individual services. This distinction can be important as the accuracy and validity of data correspond to the purpose of the record. For example, claims records are routinely audited to prevent fraud and thus assure high accuracy of the data in instances where the information is directly relevant to the processing of the correct payment amount (e.g., quantity and dose of medications dispensed by a community pharmacy or type of procedure performed during an outpatient physician visit). In contrast, data elements that are not directly tied to the payment, for example the specific diagnoses associated with an outpatient visit or procedure, may be recorded with lower accuracy. In purely administrative databases, data characteristics depend on the specific data collection and quality assurance processes in place for each of the data elements.

While an ideal encounter database would capture all types of healthcare services, in practice, individual databases often lack coverage of certain service types, depending on the purpose of the database and the nature of the data collection process. The completeness of information captured in a database is a function of the types of healthcare services (data domains) included, as well as of the comprehensiveness of data capture within each domain. Encounter databases useful for pharmacoepidemiologic research typically contain the following core data domains: (1) eligibility and basic demographic information, (2) outpatient pharmacy dispensations, and (3) medical services (typically including hospitalizations; commonly also including outpatient health services).

Data domains may be maintained in separate files within a single *integrated* database (e.g., US private and governmental databases), or in multiple autonomous databases that together function as a *federated* virtual database (e.g., Nordic healthcare databases), depending on whether the data are collected and maintained by a single or multiple entities. Both integrated and federated databases require reliable linkage of an individual's records over time and between data domains. Box 12.1 summarizes commonly available data elements within the core data domains. The content of the core data domains often varies across individual databases in terms of which types of healthcare services are captured. While some databases are limited to hospital discharge data, many also capture data on outpatient office-based physician visits, outpatient clinic visits, long-term care facilities, dental, and vision. Another example of incomplete data capture within a data domain is incomplete or lack of recording of over-the-counter medication fills in prescription databases. Similar variability across databases exists in terms of access to nonencounter data, such as electronic health records, laboratory test results, diagnostic examinations, provider specialty/characteristics, vital statistics, or disease registries. Lastly, profound differences also exist in data structure and coding systems.

Because the primary purpose of encounter data is administrative, any inferences about a patient's medical history made from these data have to be carefully evaluated. Validation of encounter data, ranging from the validation of individual data elements to the validation of complex encounter data-based algorithms, is critical for rigorous pharmacoepidemiologic research with encounter databases (see Chapter 37). Validation necessitates the ability to reliably link an individual's encounter data to nonencounter data sources that serve as the external gold standard, such as electronic or paper medical records, disease registries, or survey data. Furthermore, linkage with

Box 12.1 Core data domains in encounter databases

Membership	Patient identifier, sex, age/date of birth, race/ethnicity (not universally available), zip code, dates of enrollment and disenrollment, benefits package/eligibility category (if applicable)
Medical	
Outpatient services	Patient identifier, encounter date, service location (physician office, hospital outpatient, etc.), procedure codes (e.g., CPT, HCPCS), primary and secondary diagnosis codes (e.g., ICD-10-CM), provider identifier, provider profession/specialty
Inpatient services	Patient identifier, primary diagnosis, secondary diagnoses, admission and discharge dates, length of stay, patient destination, hospital identifier. Inpatient data generally do not include information on in-hospital medication use and typically represent summaries for an entire hospital stay, resulting in some lack of detail
Pharmacy	Patient identifier, unique drug identifier (e.g., US-NDC, Nordic article number) which identifies generic name, brand name, dosage form, and strength (crosswalks may be needed for some databases while others include the individual data elements coded by the unique identifier), date dispensed, quantity dispensed, prescription duration/days supply
	Typically not recorded: indication for the prescription, inpatient drug use, over-the-counter drugs

CPT, Current Procedural Terminology; HCPCS, Healthcare Common Procedure Coding System; ICD, International Classification of Diseases; NDC, National Drug Code.

complementary nonencounter data resources or *ad hoc* data collection (see Chapter 16) is also commonly implemented in order to supplement an encounter database with variables that are required to answer a specific research question but are not available in the database, such as lifestyle factors or disease severity.

Because of their size, population-based nature, comprehensive capture of the full spectrum of healthcare encounters, and ability to rapidly assemble cohorts and identify outcomes among them, encounter databases represent a tremendous resource for pharmacoepidemiologic studies. For some research questions, encounter data may be sufficient on their own, particularly when the outcome of interest has been previously validated and data on all important confounders are available within the database. In many instances, however, validation of outcomes and supplementation with external data is necessary. In these cases, the encounter databases provide the study foundation (population base and comprehensive capture of healthcare interactions) with certain data elements critical to the study question fleshed out through linkage with additional data resources.

Attributes of Encounter Databases

Although encounter databases share a basic set of defining characteristics, they differ in numerous attributes that deserve consideration when evaluating the fit of a database to address a specific research question [2,3]. Importantly, in some databases, such as US commercial insurance databases, these attributes can be heterogeneous across individual people, as availability of supplemental data (e.g., laboratory results or ability to retrieve medical records) or even core data domains (e.g., pharmacy data) may be restricted to subsets of the full database population. In these instances, suitability of the database (e.g., in terms of sample size and representativeness) should be evaluated based on the subset of the population in a given database for which the attributes required to address the question under study (i.e., key study variables) are available rather than the database population as a whole.

Population and Coverage Period

The population captured is a critically important consideration when examining the suitability of an encounter database for the study of a specific research question. The *size of the database* is typically one of the key criteria when considering an encounter database for a specific research question, in comparison to both electronic medical record databases and alternative encounter databases. A large study population is generally necessary to ensure adequate statistical power when exposures or outcomes are rare (particularly when both are rare), effect sizes are small, and when subgroup effects or treatment effect heterogeneity are of interest. In addition, some common study designs and analytic methods may further increase the size of the database necessary to achieve adequate statistical power. For example, the new-user active comparator design results in study populations that often represent only a small fraction of the total number of users of a drug of interest during the study period [4]; restriction, a common approach to reduce confounding, can substantially decrease the size of study cohorts [5]; and instrumental variable methods are statistically inefficient compared to standard regression approaches (see Chapter 44) [6].

In addition to the size of the database, the *characteristics of the database population* have to be carefully considered. As a general rule, the population covered by an encounter database is a function of the underlying healthcare system in the respective country during the study period. Knowledge of these systems is a prerequisite for informed consideration and use of databases for pharmacoepidemiologic research. Databases in countries or regions with universal single-payer coverage, such as Taiwan, South Korea, Canadian provinces (with variations in drug benefits between provinces), and the northern European countries, generally include

the entire population and do not impose eligibility restrictions. All individuals are included and membership is maintained throughout a person's life regardless of qualifying factors such as age, employment or financial situation. As such, the characteristics of the population included in these databases are stable over time and closely track the characteristics of the population of the respective country or region as a whole. In contrast, database populations in countries or regions with less complete or more fragmented coverage, first and foremost in the US, are heterogeneous and far more complicated. The fragmentation of the US healthcare system, in particular, leads to a complex landscape for encounter databases, with different databases covering distinctly different subsets of the US population (discussed in more detail below).

Furthermore, individuals may be included in different databases at different points in time based on their personal situation (e.g., employment and state of residence), resulting in short average enrollment periods (dwell times) in any specific database environment. *Dwell time* is an important consideration particularly when the research question involves studying a long-term effect of a medicine. Similarly, when dwell time is short, it becomes increasing difficult to study new users of medicines as a lag time at the start of an individual's data capture is required to differentiate incident from prevalent medication exposure.

Lastly, the *time period covered by a database* often determines its usefulness for a given study question, depending on the start of data collection and recency of the latest available data. Studies examining trends in drug utilization over time or studies on the long-term effects of drugs, such as those with cancer as an outcome, are best served by databases with long coverage periods and a stable population. Studies of newly approved medications primarily require the most current data available. The US Medicaid Analytic Extracts (MAX) data, for example, are generally not appropriate for studies of recently approved drugs, due to an approximately three-year lag in data availability. Importantly, when studying long-term utilization trends or long-term drug effects, it is important to be aware of any changes over time in health service reimbursement and administration and appreciate their impact on drug utilization.

Services Covered and Data Completeness

For obvious reasons, medication data are a prerequisite for all encounter databases used for pharmacoepidemiologic research. Generally, these data are limited to information on medications dispensed by community pharmacies. Drugs administered during hospital stays or in long-term care units, in the emergency room, or in outpatient physician office settings are typically not included. The latter, however, can in some instances be captured through drug-specific outpatient procedure codes (e.g., drug-specific procedure codes for injection administration). In-hospital databases are discussed in Chapter 14. Over-the-counter (OTC) drug use is generally not recorded, unless OTC drugs are prescribed and specifically covered by the insurance or health system [7]. In databases for which data capture depends on a reimbursement mechanism, drug dispensings may also be missing in cases where drugs are paid for entirely out of pocket (i.e., because the cash price is lower than the required co-payment) [8], or for nonreimbursable drugs (benzodiazepines, for example, were excluded from reimbursement by Medicare Part D prior to 2013) [9].

Lastly, drug formularies, stepped therapy requirements, and prior authorization programs may impose restrictions on availability and co-payments and thus have a significant impact on use rates of individual medications and medication classes. Individual formularies may apply to an entire database population or vary widely across individuals, depending on the underlying healthcare system.

Encounter databases also vary substantially in terms of which medical services are included and, importantly, what information is captured

about these services. Most widely used encounter databases capture hospital services, including emergency departments. Hospital services are generally recorded as hospital discharge data that summarize information for an entire hospital or emergency department stay rather than provide documentation of individual services. Differences, however, exist in the granularity of these data, such as number of diagnosis fields and availability of procedure codes.

Even greater variation between databases exists in the capture of outpatient services. For example, in contrast to databases in the US, Canada, Taiwan, and South Korea, the Nordic countries do not maintain a database of outpatient office-based physician visits, though visits to outpatient hospital/specialty clinics are captured. As such, Nordic database studies of outcomes that do not result in hospitalizations or require outpatient office-based diagnoses for adjustment of confounding have to rely on medication use as a proxy for outpatient office-based diagnoses [10]. Capture of other service types, such as dental, vision, or long-term care, also depends on the database and the patient's specific insurance coverage. Lastly, particularly in the US, specific benefits such as mental health or other specialty services may be excluded ("carved out") in certain benefits packages and thus are not captured for individuals covered under these plans. For many databases, it is thus important to evaluate the availability of data on specific service types not only at the level of the database but at the individual level and over time using information on each person's benefit package.

Finally, databases differ in the information available about the patient and service provider. For example, data on the patient's race and ethnicity are generally not available in US administrative claims databases but are available in US governmental databases. Similarly, databases differ in the availability of provider specialty and identity for physician medical services as well as prescriber specialty and identity for dispensing data.

Linkage to Nonencounter Data

Many pharmacoepidemiologic research questions cannot be answered with encounter data alone. Some questions will require randomized trials (see Chapter 32) or prospective primary data collection (see Chapter 16). However, linkages to complementary sources of data may help to overcome inherent limitations of encounter data. Commonly used sources for nonencounter data include electronic or paper medical records, laboratory results, cause of death registries or autopsy records, disease or immunization registries, census data, biobanks, or survey data.

Linkage of encounter data to complementary data sources serves two distinct purposes: (1) validation of encounter-based information against an external gold standard, and (2) provision of supplementary data not available in the encounter database. Linkage to an external gold standard, ideally the medical record, for a sample of cases is particularly critical in order to facilitate outcome validation and calculation of positive predictive values (PPVs) of encounter data-based algorithms. In the absence of the medical record, validation may be performed against disease registries or patient self-report/survey. The validity of pharmacoepidemiologic drug and diagnosis data as well as approaches to the conduct of validation studies are discussed in detail in Chapter 37. The ability to retrieve medical records for outcome validation varies between databases and is often a critical factor in database selection.

Linkage to nonencounter data may also be necessary to provide supplemental information on variables that are unmeasured or poorly measured in the encounter data but necessary to adjust for confounding or appropriate restriction of the study population (e.g., indication for drug prescribing, lifestyle factors, measures of disease severity). Supplemental information such as laboratory test results or autopsy records may also be required for outcome ascertainment (e.g., Hba1c level as an outcome for a study

on the comparative effectiveness of various hypoglycemic agents).

Due to privacy restrictions that prevent the sharing or use of personal identifiers, retrieval of medical records or information obtained through direct contact with physicians or patients is generally not performed by investigators, but rather facilitated through third parties (e.g., retrieval of redacted medical records for US Medicaid and Medicare) or handled internally by employees of the participating health plans (e.g., in several US commercial insurance databases). Depending on the database, encounter and nonencounter data may be available under the same umbrella organization (e.g., linkage to EHRs in many US health plans) or require linkage to outside entities (e.g., retrieval of hospital medical records for US Medicaid beneficiaries for the purpose of outcome validation), which greatly affects the feasibility, efficiency, cost, and success rates of the linkage.

Healthcare data linkages are governed by both privacy restrictions and the availability of common linkage variables in the respective databases. Privacy regulations governing the ability to link personal health information are complex and vary between countries and database owners, and over time. When these regulations do not preclude linkage, health information databases can be linked using either deterministic or probabilistic methods [11]. Briefly, in deterministic linkage, a unique identifier or a combination of several nonunique variables available in both databases must match exactly (though the match can be implemented based on transformed versions of the variables, e.g., phonetic codes instead of names to minimize the impact of spelling errors). Deterministic linkage is most useful if reliable unique identifiers are available (e.g., US social security number) but is also achievable with combinations of multiple nonunique variables (e.g., birth dates, admission dates, and names). However, use of variables with low discriminative power and errors or missingness in the matching variable(s) will lead to a high number of overlooked (false-negative) matches.

Probabilistic linkage methods can reduce the number of overlooked (false-negative) matches by allowing imperfect matches due to partially inaccurate or missing data but in turn may produce false-positive matches. Choice of matching method thus involves a trade-off between false-negative matches (i.e., missed matches) and false-positive matches (i.e., incorrectly matched records). Simulation studies have suggested that deterministic linkage is an equally valid but less computationally intensive method for databases with low rates of missingness and error in the linkage variables [12]. However, probabilistic linkage is more accurate in error-prone data. Although often challenging, validation of linkage quality is critically important as all linkage methods are susceptible to error. The Nordic prescription database networks are examples of highly reliable linkages between encounter data and disease registries with unique identifiers [13] while the Dutch PHARMO system uses probabilistic record linkage methods [14].

Access

Access regulations, costs, and feasibility considerations vary widely between encounter databases and often have a major impact on database choice. Access may, for example, be restricted to certain researchers, such as those working in academia or governmental agencies. Some encounter databases facilitate direct access to either "off-the-shelf" or customized anonymized datasets which may be physically transferred to the researcher's institution or accessed remotely (e.g., select US commercial databases, US governmental databases, or the South Korean HIRA data), while others require in-house data analyses and thus necessitate collaborative agreements with researchers employed by the database custodian or affiliated research institutes (e.g., US health plan databases or Nordic prescription databases). Some databases are directly accessible in anonymized form but

require in-house analysis performed by the database custodian when additional "custom" linkages that require personal identifiers have to be implemented (e.g., Truven MarketScan). For studies conducted through the database custodian, it is important to not only consider the attributes of the database itself, but also the data analytic capacity and track record of the in-house research collaborators. While complexity of database structure varies between databases and studies, all work with large encounter databases requires sophisticated programming skills as well as a comprehensive understanding of database-specific details. The latter consideration can be a major advantage of collaborative arrangements that include researchers or programmers from the database custodian.

Costs of data access vary across databases and often within databases, depending on the specific characteristics of the study in question. Fees often vary by size (number of individuals) and complexity (number of files/data sources) of the requested dataset as well as by funding source (e.g., federal versus commercial funding). In-house data analysis often imposes substantial additional costs.

Application processes vary widely as well. While all databases require compliance with data privacy and security restrictions, some may also impose scientific vetting of the research plan or a justification of the benefit of the research to the public. Particularly in projects that require custom linkage with identifiable patient or provider information, close collaboration with the database custodian is needed to obtain necessary approvals and maintain confidentiality. In addition, the time required for the creation of study-specific data-cuts depends on the staffing resources and experience at the database custodian and the complexity of the required dataset. As a result, the duration from the beginning of the application process until the start of the research can vary dramatically between several weeks to multiple years.

In practice, while access considerations and familiarity with a given database are often important drivers of database choice, it is vital never to lose sight of the suitability of the database for the specific research question under study.

Selected Encounter Databases

A selection of widely used encounter databases and database types with their basic characteristics is presented in Table 12.1 and discussed below. Databases will be discussed by region and include US databases, Canadian databases, European databases, and Asian databases.

Encounter Databases in the United States

US encounter databases are arguably both the largest databases available and the most fragmented. Unlike most industrialized nations, the US does not have a uniform health system or universal healthcare coverage, resulting in databases with characteristics that differ markedly from databases in the rest of the world. In 2016, 292 million people, or 91% of the US population, had health insurance coverage, with 28 million uninsured [15]. 216 million people had coverage from private plans (68%), mostly employment-based plans (179 million; 56%). 120 million people (37%) had coverage from a governmental plan; 62 million by Medicaid (19%), 53 million by Medicare (17%), and 15 million had military coverage (5%). Note that these census data-based estimates show some inconsistencies with the reporting from the Centers for Medicare and Medicaid Services (CMS) presented later in the chapter.

Broadly speaking, most employed individuals and their dependents are covered by commercial insurance, adults 65 years and older and qualifying individuals with disabilities are covered by Medicare, and the poor and other disadvantages groups are covered by Medicaid. Furthermore, insurance coverage in the US is not mutually exclusive. In 2016, 22% of the population with

Table 12.1 Database characteristics[a]

Type	Government, US	Government, US	Health System Databases, US	Commercial Insurance, US	Government, Canada	Government, Northern Europe	Government, Asia

Coding, Dx	ICD-9-CM, ICD-10-CM	ICD-9-CM, ICD-10-CM	ICD-9-CM, ICD-10-CM	ICD-9-CM, ICD-10-CM	ICD-9-CM, ICD-10-CM	ICD–8, –9 and -10	ICD-10, ICD-9
Validation	+++	+++	++++	+ to +++	++	++	++
Supplementation	+++	++	++++	+ to +++	++	+++	+++

[a] Drugs and claims only in subset.
[b] Apart from a few rare exceptions, one cannot retrieve medical charts of cases ascertained in a given study. However, can identify patients in medical records in institutions and link back to the database.

health insurance had multiple coverage types due to either switches in coverage type or to simultaneous coverage to supplement their primary insurance type.

With the exception of Medicaid programs, which generally provide prescription drug coverage for all beneficiaries, prescription drug insurance is typically provided separately from medical insurance, resulting in subgroups of patients in major databases for whom only pharmacy or medical data are available. Although pharmacy claims are recorded with high accuracy, medication dispensings can be incompletely captured in patients covered by multiple insurance programs or in instances where the co-payment is greater than the cash price of the medication [16,17]. In recent years, several large US retailers have begun to offer low-cost generic medications for as little as $4 for a monthly supply, considerably less than the average tier 1 co-payment ($11 in 2017) [8,18]. Since there is no financial incentive, pharmacies may not submit insurance claims when patients pay cash, resulting in potential underascertainment of low-cost generic medications. To date, empirical studies examining the missingness of dispensings in claims databases have reported a limited impact of such generic drug discount programs [16,17,19]. Payments rates and modalities for medical services vary widely, ranging from fee-for-service to capitated arrangements in which providers receive a fixed payment per patient per unit of time for the delivery of a specified set of services. Detailed claims data are often not available for services or patients covered by such capitated payment models as the payment amount is independent from the specific services provided.

Several large US encounter databases are available and have been widely used for pharmacoepidemiologic research [20–22]. These databases include markedly different groups of the population and often individuals with heterogeneous healthcare coverage are included within the same database. To complicate matters further, significant mobility exists between databases as changing life circumstances (loss of employment, change in employer, disability, reaching age 65/Medicare eligibility) result in changes in insurance coverage. This is often referred to as "churning" and substantially affects the average dwell time of individuals in US encounter databases [23].

US databases generally use the National Drug Code (NDC) for medication data, the Current Procedural Terminology (CPT) coding and Healthcare Common Procedure Coding System (HCPCS) for procedures, and the International Classification of Diseases, Clinical Modification (ICD-CM) system for diagnoses. The US transitioned from ICD-9-CM to ICD-10-CM on October 1, 2015 [24], which has important implications for pharmacoepidemiologic research conducted in US databases. Despite the existence of crosswalks, the performance characteristics of encounter data-based algorithms have to be demonstrated for the new coding system and studies that span the transition date will have to implement multiple coding systems in a single study. Data privacy and security of identifiable healthcare data in the US are governed by the Health Insurance Portability and Accountability Act of 1996 (HIPAA) [25].

US Private Insurance Databases

Most healthcare in the US is covered through private insurance, predominantly employer-based insurance. For-profit and not-for-profit insurance companies offer a wide range of plans that vary in characteristics such as premium, co-payment/co-insurance, deductibles, out-of-pocket limits, services covered, drug formularies, and provider choice. Payment systems and business models are complex and undergo continuing change over time. Because most private insurance plans are associated with the employer, many patients frequently change insurance plans due to changes in employment or when employers change their contracted insurance portfolio. Although there are hundreds of health insurance companies in the US, a relatively small number

of companies provide coverage for a majority of the privately insured population. The great majority of the privately insured population are covered by insurance systems that pay for the care provided by others [20]. Commercial insurance databases derived from these systems are some of the largest databases available for pharmacoepidemiologic research. A smaller group is covered by integrated, often not-for-profit, healthcare delivery systems that assume responsibility for preventive and therapeutic health services to a defined population, often employ group or staff model delivery systems, and frequently operate their own hospitals (e.g., Kaiser Permanente) [22]. Though typically smaller in size, the databases associated with these healthcare systems offer extensive data resources that combine encounter data with detailed clinical data resources, including EHRs and direct access to patients and providers.

Commercial insurance databases are longitudinal collections of billable healthcare interactions [20]. These databases are maintained by a variety of entities. This includes large insurance companies, often through health data analytics-focused subsidiaries (e.g., Optum Clinformatics/UnitedHealth Group [26]; HealthCore Integrated Research Database/Anthem, Comprehensive Health Insights Outcomes Data/Humana), as well as health information technology companies (e.g., Truven Health MarketScan [27], IQVIA PharmetricsPlus). Commercial insurance databases typically include several millions to tens of millions of individuals cross-sectionally and cumulatively often exceed 100 million unique patients over the life span of the database. Importantly, however, the extremely large sizes of these databases do not necessarily translate directly into the size of pharmacoepidemiologic study cohorts. Given the approximately 30% annual churn rate in commercial insurance coverage and the fact that prescription drug coverage is often separately administered or absent, only approximately 50%, 30%, and 15%, of beneficiaries with medical coverage have continuous medical and pharmacy coverage for 1, 2, and 4+ years, respectively [20].

Another important and often underappreciated feature of commercial insurance databases is the large within-database heterogeneity in data availability, completeness, quality, and ability to link member data to nonencounter data. Within a typical commercial database, members are covered by a variety of insurance products (often from multiple insurance companies), leading to substantial differences in services captured in the database. Drug formularies, which determine coverage and out-of-pocket costs for prescription drugs, for example, vary widely between plans. Similarly, a study that requires data on dental procedures would have to be limited to the subset of beneficiaries with a dental benefit during a specific time period. Completeness and quality of the claims data also depend on the payment model employed by the respective insurance products. As discussed earlier, completeness and accuracy with which services are captured may differ substantially depending on whether services are reimbursed through fee-for-service payments or capitated arrangements. Such capitated arrangements may apply to all medical coverage or be limited to specific services (e.g., specialist visits or mental health services).

The ability to validate or supplement the claims data is also often limited to subgroups of members included in the database. For example, for databases maintained by subsidies of insurance companies, data validation and supplementation may not be permitted for the (sometimes substantial) proportion of individuals in "self-funded" plans, where the employer assumes direct risk for payment and the insurance company only provides administrative services (ASO members). Similarly, the ability to identify patients and validate or supplement patient data depends on the contractual arrangements with the data sources (employers, health plans) and is generally restricted to a limited subset of the full database populations. Given the substantial

heterogeneity in multiple data attributes within and between commercial databases, thoughtful consideration of detailed information on members' individual benefit packages is critical to facilitate restriction of the study population to those for whom all necessary data elements and linkages are captured or available in the database.

Several models exist to enable research access to commercial insurance databases. Some databases are directly available in their entirety through licensing arrangements (e.g., MarketScan®), while others are solely accessible on a project-by-project basis via collaborative arrangements involving in-house programmers. Databases available for licensing are deidentified, with all personal identifiers removed, and as such do not support external linkages. Studies that require such linkages for validation or supplementation of the encounter data typically require collaboration with researchers employed by the database custodian. Such collaborations have the added advantage of tapping into the often substantial experience of the custodian research team. Most major commercial insurance providers also participate as data partners for the Sentinel System (see Chapter 25).

Integrated healthcare delivery system databases differ from commercial insurance databases in that they include a defined population whose entire spectrum of care is the responsibility of and provided by the integrated delivery system. Similar to commercial insurance databases, the delivery system databases include pharmacy dispensing data as well as encounter data on diagnoses and procedures from care delivered in both ambulatory and inpatient settings. However, because all care is provided by the delivery system, these databases also have access to full inpatient and outpatient electronic and paper medical records, and have the ability to interact with providers and patients. Although the latter features are also available for subsets of patients in many commercial insurance databases, the uniqueness of integrated delivery systems databases lies in the fact that these linkages cover the entire care received by the patient and are not limited to care received by specific practices or hospitals. Since many EHR systems include information on drugs prescribed, delivery system databases have often access to both prescription and dispensing data, which can be useful for a variety of research questions, such as questions of primary nonadherence [28]. In addition, several integrated healthcare delivery systems include affiliated research centers that maintain a variety of additional data resources such as registries for cancer, diabetes, or cardiovascular disease. Integrated health delivery systems have a long track record of pharmacoepidemiologic research, and many are consortium members in the Health Care System Research Network (HCSRN, formerly known as the HMO Research Network) and data partners for the Sentinel System (see Chapter 25) [22].

US Government

The US government funds healthcare services through several major programs, including Medicare and Medicaid, as well as the Department of Veterans Affairs Healthcare System (VA). In contrast to the VA, which is a large provider of healthcare services operating numerous hospitals, clinics, and nursing homes, Medicaid and Medicare function as payers. Both programs pay directly for services using fee-for-service arrangements, but a large and growing proportion of beneficiaries receives Medicaid (68% in 2016) [29] or Medicare (30% in 2016) [30] coverage administered by private insurance companies through capitated managed care plans. For beneficiaries covered by managed care plans, encounter data for individual services have only recently become available (Medicare) [31] or of mixed completeness and quality (Medicaid) [32] and thus research with Medicaid or Medicare data has historically been restricted to individuals with fee-for-service coverage.

The Centers for Medicare and Medicaid Services (CMS) administer Medicare and Medicaid data and facilitate access to research identifiable files for research purposes. Requests

for these data files require a research protocol and data use agreement, and are reviewed by CMS's Privacy Board. The application process is managed and supported by the Research Data Assistance Center (ResDAC) at the University of Minnesota, which provides technical assistance to researchers interested in CMS Medicare and Medicaid data. Data access requires payment of fees based on the requested population size as well as the number of data files requested, which can be provided through release of data files to investigators or remotely via the CMS Virtual Research Data Center (VRDC). A mechanism to obtain inpatient hospital and emergency department medical records corresponding to Medicare and Medicaid claims has been described and implemented [33,34]. Medicaid and Medicare data for select states or populations are also available from commercial entities (e.g., IBM Watson Health) [27].

Medicaid is a joint state/federal program intended to provide health coverage for low-income individuals. It is administered separately by each state and state-specific eligibility rules differ within federal regulations. Traditionally, the program has provided coverage limited to certain groups of low-income individuals, including pregnant women, low-income families with children, the chronically disabled, and the elderly. Following the passage of the Affordable Care Act in 2010, about one half of US states have expanded coverage to all individuals under certain income thresholds. In 2016, the average monthly enrollment in Medicaid was 70.9 million (5.7 million aged, 10.6 million blind/disabled, 28 million children, 26.7 million adults including 11.2 million adults eligible through Medicaid expansion) [30]. In 37 states, ≥50% of beneficiaries were covered through private managed care plans [29]. Medicaid coverage for eligible individuals is generally comprehensive although each state, within federally mandated parameters, administers its Medicaid program differently, resulting in variations in Medicaid coverage across the country.

Medicaid Analytic eXtract (MAX) data files include enrollment and claims data for all Medicaid enrollees in the 50 states and the District of Columbia as well as for the approximately 6.5 million (2016) enrollees in the Children's Health Insurance Program (CHIP) which serves uninsured children up to age 19 in families with incomes too high to qualify for Medicaid. MAX files have been produced since 1999 and are available per state per year [35]. MAX data are organized in five files: (1) person summary (demographic characteristics and enrollment information); (2) inpatient (inpatient hospital claims with one record per stay; procedure and diagnosis codes); (3) long-term care (e.g., nursing facility claims); (4) prescription drug (outpatient pharmacy data including national drug code, quantity dispensed, days supply); and (5) other services (e.g., laboratory and other diagnostic claims). MAX data are based on state-level data submitted through the Medicaid Statistical Information System (MSIS) and produced by CMS using extensive editing and quality control. There is a substantial lag of approximately 3–4 years between the end of a calendar year and MAX availability. Because the files are produced by state, some states may have MAX data available sooner than others. Once released, MAX data are final.

Importantly, the state reporting system is currently under transition from MSIS to Transformed-MSIS (T-MSIS). T-MSIS adds new file types (third-party liability, provider, and managed care plan data), new data elements, and modification of existing data elements [36]. One of the intentions of T-MSIS is to improve the capture and quality of encounter data for beneficiaries covered by managed care plans [37]. Data for these beneficiaries have historically been considered not to be up to research standards and have typically been excluded from most pharmacoepidemiologic research [21,32]. Given that a great majority of Medicaid enrollees are now covered under managed care plans, availability of research-quality data for this population (after

extensive quality checks and validation studies) would substantially increase the potential of MAX data as a resource for pharmacoepidemiologic research. Gaps in data capture due to periods of ineligibility are common as eligibility is typically determined monthly and changes with income and life circumstances. This issue affects individual eligibility groups differently, with more stable enrollment for those qualifying based on disability and less stable enrollment for low-income adults. Exclusion of beneficiaries without stable enrollment has been implemented based on eligibility files as well as through requirements for Medicaid encounters during specified periods before and after person-time under study.

Because Medicaid is administered at the state level, state-specific policies (e.g., opioid quantity limits or prior approval requirements) have to be considered in the research design. Medicaid and Medicare data for dually eligible beneficiaries can be linked. Such linkage is important in studies of dual enrollees since Medicaid or Medicare data alone fail to document the full spectrum of care provided to such dual enrollees [38]. Medicaid data for research are also available directly from individual states but access is often limited to researchers with established ties to the specific state Medicaid programs.

Medicare is the federal program that provides healthcare coverage for almost all people 65 years and over as well as for qualifying individuals with permanent disabilities [39]. Medicare coverage consists of four parts: Medicare Part A (Hospital Insurance), Medicare Part B (Medical Insurance), Medicare Part C (Medicare Advantage), and Medicare Part D (Medicare Prescription Drug Coverage). All parts of Medicare coverage require beneficiaries to pay deductibles and some stipulate cost sharing. Part A covers inpatient care in hospitals and skilled nursing facilities, as well as hospice. It is premium free for the great majority of beneficiaries. Part B covers physician and other outpatient services. It is an optional program that requires monthly premiums. Approximately 90% of Medicare beneficiaries enroll in Part B. Part C allows Medicare beneficiaries to enroll in private health plans that administer Part A and B benefits. The large majority of these so-called Medicare Advantage plans also include Part D benefits (i.e., prescription drug coverage). Part C plans are optional and require premiums. In 2016, 30% of Medicare beneficiaries received coverage through Medicare Advantage plans. Importantly, encounter data for Medicare Advantage beneficiaries have only recently become available through CMS (to date solely for service year 2015) [31].

Part D provides outpatient prescription drug coverage. Established in 2006, the program is administered by private companies that provide coverage through hundreds (782 in 2017) of prescription drug plans (PDPs) that differ in formulary coverage and cost sharing. Enrollment in Part D is voluntary and requires a monthly premium that varies between the individual PDPs. Medicare Part D imposes a coverage gap (doughnut hole) that requires beneficiaries to pay a substantial percentage of the cost of their medications (35% and 44% for brand name and generic drugs, respectively, in 2018) until they reach the out-of-pocket spending limit ($5000 in 2018). A large proportion of Medicare beneficiaries have some type of supplemental coverage (employer sponsored, Medicaid, so-called Medigap policies) to reduce out-of-pocket costs from cost-sharing requirements. In 2016, the average monthly Medicare enrollment was 57 million (48 million aged, 9 million disabled) [30]. 17 million beneficiaries were covered through Medicare Advantage and 41 million had a Part D benefit, including 16 million through Medicare Advantage plans [40].

Medicare data are available in several file types that are linkable to each other, as well as to Medicaid data for dually enrolled beneficiaries. File types include Master Beneficiary Summary Files (MBSFs), which include files on demographics and enrollment, chronic conditions, and cost and utilization; Institutional Claims,

which include files on inpatient services, skilled nursing facilities, and hospice; Noninstitutional Claims, which include outpatient physician claims (Carrier file) and claims for durable medical equipment; and the Part D event data file, which provides detailed prescription-level outpatient pharmacy claims. Supplementary files provide information on Part D plan characteristics, pharmacies, drugs (crosswalks from First DataBank), prescribers, and formularies.

Since prescription drug data for Medicare have become available after the establishment of Medicare Part D in 2006, Medicare, due to its large and stable population, has become one of the largest and most comprehensive resources for pharmacoepidemiologic research.

Encounter Databases in Canada

Canada, with its population of approximately 36 million, has a universal healthcare program covering all residents regardless of age or income. Program administration is the responsibility of each of its ten provinces. Physician visits, diagnostic tests, procedures (in- or outpatient), and hospitalizations are provided without payment by the patient at the point of care. Encounter data are transactional and consist of billings submitted by healthcare providers on a fee-for-service basis. A small number of physicians may have all or a portion of their activities covered by salary so the services they provide may not be included in the medical services databases. In contrast, public drug coverage programs differ among provinces; programs have been available for varying lengths of time and differ with respect to eligibility criteria as well as characteristics (i.e., copayments and deductibles). Some provinces, such as Saskatchewan and Manitoba, provide coverage for the entire population while in the others, public drug programs restrict coverage to specific segments of the population, such as the elderly, welfare recipients, or those who do not have access to private insurance plans through their employers.

Within each province, three encounter databases are available: (1) beneficiary, (2) medical services, and (3) prescription drugs. These databases are linkable through a unique patient identifier that remains unchanged over time. Additional linkage capacities are available to hospitalization databases, population health surveys [41] or province-specific disease registries [42]. Linkage of hospital charts or outpatient charts for validation of diagnoses or collection of data that are not present in the databases requires approval from the provincial information access commissioner and may not be feasible in all provinces. A number of validation studies of Canadian databases, primarily of diagnoses codes in the medical services databases, can be found in the literature but validation data remain far from comprehensive [43].

Each province maintains its own medical services encounter database, which includes all claims submitted by physicians regardless of setting (inpatient, outpatient, or emergency department) as long as the physician is paid on a fee-for-service basis. The nature of the information in the various provincial medical services databases is similar though differences exist in coding systems, such as the ICD version. For each medical service, the following information is recorded: service (date, description, location, diagnosis, and cost), provider (identifier and specialty). The vast majority of claims are submitted electronically, and the resulting medical services claims databases are populated in real time. In a few provinces, such as Nova Scotia, Manitoba, and British Columbia, mental health services, including psychotherapy, are recorded in a distinct database [44].

Unlike the medical services databases, hospitalization databases are intended for the creation of health statistics rather than for reimbursement purposes. The databases contain clinical data related to hospital discharges from acute or chronic care units, or rehabilitation centers, as well as day surgeries. With the exception of Quebec, which maintains its own hospital discharge database

(MED-ECHO), all provinces contribute to the Discharge Abstract Database (DAD) maintained by the Canadian Institute for Health Information (CIHI) [45]. The information is therefore homogeneous across provinces. In the hospitalization databases, diagnosis was coded with ICD-9-CM until 31 March 2006 and with ICD-10 thereafter. In the DAD database, information on mental health resources, cancer staging, and reproductive history was added in 2009–2010. Hospitalization databases are typically available six months after the end of the fiscal year (March 31).

Province-specific prescription drug databases record all prescription drugs dispensed in an outpatient setting to individuals covered by the public drug plan. Drugs obtained over the counter, in hospital, in long-term care units, not included in the formulary, or covered only by private insurance programs are not usually included in the database. One exception is PharmaNet in British Columbia that links all pharmacies to a central data system. Every prescription dispensed in the outpatient setting is recorded regardless of coverage; hence, it includes medications covered by the public drug plan and private insurance programs, as well as those acquired out of pocket. Drugs are coded according to the Canadian-specific Drug Information Number (DIN) as well as the American Hospital Formulary Service (AHFS). For each dispensing, the following information is recorded: drug (date of dispensing, drug name, dose per unit, mode of administration, prescribed duration [not recorded in Saskatchewan], cost including dispensing fees), pharmacist (identifier, pharmacy location), and prescriber (identifier, specialty). Indication for a drug prescription is not recorded in any of the dispensing databases. While data and coding systems are similar across provinces, inclusion of individual drugs in the formulary and type of listing (general or restricted) may vary. For each patient, the years of entry and exit from the drug program are available in the beneficiary database. This is important information for studies that include segments of the population whose membership in the drug program may be transitory, such as membership based on income or access to private insurance programs.

Only seven of the 10 Canadian provinces make prescription data available for pharmacoepidemiologic research. Approximately half of these databases are accessible through custodians located in a university setting while the other half are accessible through provincial government agencies. In addition to the drug databases, custodians also act as a repository for other provincial databases and are responsible for their linkage.

Database access varies across provinces. Some provinces (Saskatchewan, Quebec, Nova Scotia) provide raw anonymized datasets to researchers (from academic or industry settings) while others (Ontario, BC) require data to be analyzed in-house by specific research organizations. To maintain confidentiality of the data, no patient, healthcare provider (including pharmacist), or institution identifiers are transmitted to researchers. Additional restrictions are in place in individual provinces. For example, in Quebec only a random sample of approximately 75% of the population eligible for a given study (capped at a maximum of 125 000 eligible patients) may be obtained, and no birthdates are transmitted. Exceptions can be granted through a request to the Provincial Access to Information Commission, which substantially increases the delay in data extraction.

Although Canadian encounter databases are much smaller than US encounter databases, their greatest advantage is that they include a stable population, thereby allowing longer follow-up periods. This is, for example, illustrated through a study on benzodiazepines and Alzheimer's disease, in which a 10-year follow-up was available [46]. The time required for database extraction varies across provinces, ranging from 10–20 weeks to one year, more if a request to the Provincial Access to Information Commission is required.

Encounter Databases in Europe

Nordic Prescription Databases

The Nordic countries (Denmark, Iceland, Norway, Sweden, and Finland) have tax-supported universal health coverage. All citizens (a combined population of over 25 million people ranging from ~300 000 in Iceland to more than 9 million in Sweden) are provided with unrestricted access to health services including partial or complete reimbursement of medications.

Pharmacies electronically submit information on dispensed prescriptions to national databases without a requirement for informed consent by the patient (available since 1994 in Finland and Denmark, 2004 in Norway, 2005 in Sweden, and 2006 in Iceland) [47]. Unique civil registration codes facilitate unambiguous linkage to various national databases using a central patient router file. Linkable national databases include but are not limited to hospital discharge databases, laboratory data including results, pathology databases, medical birth databases, cancer registries, and cause of death databases, as well as census data, health surveys, biobanks, and patient records. Together, these databases create a federated database network that provides exposure information from the prescription database as well as patient and clinical outcome data from the patient router file and multiple linked autonomous databases.

The prescription databases largely include similar data elements with slight variations between countries. Besides a patient identifier (which also encodes birth year and sex), data include drug data (dispensing date, Nordic article number, a unique identifier similar to the NDC code used in the US, ATC classification, quantity dispensed in defined daily doses), a prescriber identifier (which can be linked to prescriber data such as basic demographics, profession, specialty, practice site), and pharmacy data (name and location). OTC drugs are not included unless they are obtained via prescription. Importantly, some drugs that are also available OTC are used primarily via prescription, to ensure reimbursement [7]. Besides the difference in the age of the databases, the most noticeable difference is the fact that nonreimbursed drugs are not covered by the Finnish database.

Outcome data are primarily based on national hospital discharge databases (registries). While comparable, some differences exist in the age of the patient databases, with the Finnish database dating back to 1969 [48], followed by the Danish (1977) [49], Swedish (1987) [50], and Norwegian registry (2008) [51]. Numerous other databases including cancer, birth, and death, together with pathology and laboratory results, further complement the dataset. Importantly, no large-scale data are available that provide details regarding general practice visits or other nonhospital health services. This is often referred to as a lack of "outpatient" data. However, this term can lead to misunderstandings in the context of the Nordic healthcare model. All hospital databases cover activities within hospital outpatient clinics, and as such all specialized care is covered. However, in all Nordic countries, general practice physicians serve as gatekeepers to specialized care (including both hospital and private practicing specialists). Detailed data, such as diagnoses or laboratory data, are not available. However, data on contacts (without specification for the reason for such contacts) can be obtained.

Rules governing data access vary between the Nordic countries, but generally require collaboration with local researchers. Access to Danish prescription data is particularly restrictive. Consequently, data from the Danish National Prescription Registry [52] cannot leave the data havens provided by Danish authorities. For multinational studies involving Danish individual-level prescription data, pooled analyses require data to be transferred to, for example, Statistics Denmark [53] or metaanalysis techniques to be applied to obtain pooled estimates [54]. Other sources of Danish prescription data are not restricted in the same way, but either only offer local coverage [55,56] or only provide

data on reimbursed prescriptions and only cover more recent years [57].

Other European Encounter Databases

Pharmacy-based federated database networks also exist in The Netherlands (PHARMO) [14] and Scotland (Tayside MEMO) [58]. These networks are limited to specific regions of their respective countries and have the ability to link to a number of databases that provide outcome and confounder information similar to those in the Nordic countries. In addition, integrated encounter databases are available in France [59] and some regions of Italy (Lombardy, Tuscany) [60]. The French national claims database, SNIIRAM, captures data for more than 66 million individuals (~98% of the French population) regardless of socioeconomic or employment status. It captures encounter data on outpatient visits, dispensed medication, procedures, chronic conditions, hospital admission diagnoses and procedures, and date of death. Data access, however, is complex.

Encounter Databases in Asia

There are many encounter databases available across the Asia-Pacific region. Many of these are population-wide databases due to the prominence of nationwide healthcare coverage in these countries. For example, South Korea and Taiwan both have single-payer, universal government-run health insurance systems that predominantly operate on a fee-for-service basis and have established national research databases. The National Health Insurance Databases of South Korea and Taiwan are the most well-established and widely used Asian encounter databases. Similar to encounter databases in the US, Canada, and Europe, they capture patient demographic information, medical (in- and outpatient) services and prescription and dispensing data. Encounter databases also exist in Australia and Japan [61]. In Australia, the commonwealth government maintains a dataset of dispensing of subsidized medicines under the Pharmaceutical Benefits Scheme (PBS) and medical services under the Medicare Benefits Schedule (MBS) [62]. A 10% sample of these data, linked longitudinally, is available and has been used for research [63,64]. Additionally, an encounter database of services provided to Australian veterans is maintained by the Australian Department of Veterans Affairs (DVA). These data include all prescriptions dispensed, medical services claimed and hospital visits attended by the veterans, their dependents, and spouses. The DVA data have been used widely for research [65,66].

One of the advantages of databases across the Asia-Pacific region is the consistency of coding systems. For example, encounter databases in South Korea, Taiwan, and Australia all use ATC codes to identify individual medicines and all but Taiwan use ICD-10 codes to identify diagnoses. This allows for comparisons of similar products across different countries without the need to map individual country-specific codes. This has allowed cross-national studies to be conducted using a distributed network approach through the Asian Pharmacoepidemiology Network (AsPEN) [67]. Pharmacoepidemiologic studies using Asian databases have historically been limited due to restrictions in the accessibility of these data. One study found that of 54 encounter databases across the Asia-Pacific region, very few allowed access to raw data [68]. Databases in Australia, Taiwan, and Japan, for example, were considered as having a high level of data accessibility, while South Korea had a medium level and Thailand, China, Malaysia, and Singapore had a low level of accessibility. The level of accessibility can differ for individual databases within the same country; some databases may require a local researcher to access data while others do not provide raw data with only summary-level data available for researchers.

Taiwanese National Health Insurance Research Database

Established in 1995, the National Health Insurance (NHI) program of Taiwan covers approximately

23 million individuals, more than 99% of the country's population [69]. The NHI maintains the National Health Insurance Research Database (NHIRD), which is accessible for research. The NHIRD includes but is not limited to patient demographics, prescription and dispensing data, outpatient visits, hospitalizations, and dental care. Data are updated biannually. The NHIRD can be linked to a number of external national databases through a unique and universal personal identification number. Databases available for linkage include numerous registries (birth, death, immunization, cancer, reportable infectious diseases, suicide), population-based screening programs (various cancers, myopia, urine, newborns) as well as regular examinations in school children. Strict procedures for data access and human subject review are in place to assure protection of confidentiality and data security.

South Korean Health Insurance Review and Assessment Data

South Korea has provided universal health coverage since 1989. In 2000, all health insurance systems were integrated into a single national system, creating the National Health Insurance Service (NHIS) and the Health Insurance Review and Assessment Service (HIRA). All healthcare providers are covered under the NHIS and are, with a few exceptions, reimbursed on a fee-for-service basis. Claims are electronically submitted by providers to the HIRA for reimbursement and form the basis for the HIRA database, which contains healthcare utilization and prescribed medications for approximately 50 million individuals [70]. Use of the database was initially limited until it became publicly available for research in 2009.

The HIRA research data include beneficiary ID, basic demographics, procedures, diagnostic tests, all diagnosis received by the beneficiary (coded in KCD6, the Korean Standard Classification of Disease Version 6, which is closely based on the ICD-10 system), in- and outpatient prescriptions (including brand name, generic name, prescription and dispensing date, duration, dose, and route of administration), as well as provider ID and characteristics. Validity of diagnosis data in the HIRA database has been shown to vary according to the severity of the condition (with greater validity for more severe conditions) and the care setting (with higher validity for inpatient than outpatient diagnoses) [71]. HIRA data are available to researchers in academia and government agencies and for those in the private sector such as pharmaceutical companies and medical device companies but access requires in-person consultation at the HIRA and submission of a study proposal. Once approval is given, tailored data extracts with encrypted ID information for protection of privacy are uploaded in a remote access system accessible only by the individual researcher for the study. Importantly, HIRA data are currently available only for a five-year period beginning from the current year although plans exist to expand this period to 10 years.

Strengths

Encounter databases have a number of strengths in comparison to other data sources for pharmacoepidemiologic research, which explain their broad representation in the literature.

First, automated healthcare databases facilitate the rapid and cost-efficient assembly of extremely large cohorts of patients and provide data on drug exposures, health outcomes, and potential confounding factors. Encounter databases, in particular, are the largest available population-based healthcare databases. Several of the databases discussed in this chapter cumulatively include more than 100 million individuals and provide the ability to rapidly assemble cohorts that are substantially larger than analogous cohorts from EHR databases or *ad hoc* data collection.

Encounter databases thus are uniquely able to address research questions that require the largest possible study sizes. The following example

illustrates the differences in cohort sizes for the same study in selected encounter and EHR databases. Filion and colleagues examined proton pump inhibitors and the risk of hospitalization for community-acquired pneumonia among new users of NSAIDs, aged ≥40 years in multiple databases within the Canadian Network for Observational Drug Effect Studies (CNODES) [72]. The respective sizes of study cohorts assembled using a common protocol and allowing multiple cohort entry dates for a single patient were approximately 2.2 million for MarketScan, 1.5 million for the combined Canadian provincial databases, and 0.6 million for the UK GPRD, the largest population-based EHR database. The MarketScan cohort was more than 3.5 times larger than the GRPD cohort, despite not including data on ≥65 year olds who made up around 35% of the total study population.

Second, because encounter databases are population based and provide a comprehensive capture of covered healthcare encounters regardless of the provider, they can support the full range of epidemiologic study designs including cohort, nested case–control, and self-controlled designs. While this strength is shared by a number of other population-based automated databases, it is a critical limitation to nonpopulation-based data sources such as EHR databases of individual institutions or health systems.

Third, many encounter databases facilitate systematic or *ad hoc* linkage to nonencounter data resources, including electronic or paper medical records, disease registries, laboratory results, or patient and provider surveys. Such linkages can support validation of study outcomes and allow supplementation of encounter data with variables such as laboratory results or lifestyle data. In ideal circumstances, such linkages thus provide the ability to take advantage of the size and population-based nature of encounter data, while also accruing the advantages of higher data quality and greater clinical detail available from data sources such as EHRs, disease registries, or patient and provider surveys. Importantly, however, linkage ability and quality vary substantially between individual encounter databases and have to be carefully considered for each study question.

Fourth, many large encounter databases are broadly representative of nations, regions, or particular health systems. As such, they can often serve an important role in facilitating health services and health policy research. Many include very stable populations that facilitate assessment of long-term safety effects and long-term trends in treatment practice and quality. Further, encounter databases from countries or regions with universal health coverage – by definition – are free from selection bias as inclusion in the database is universal.

Fifth, for encounter data generated from fee-for-service payment claims, data elements that directly pertain to the payment amount are subject to auditing and considered highly accurate. This is true for procedure claims (type of procedure performed) [73] as well as for pharmacy claims (date, drug, and quantity dispensed) [74]. Importantly however, the accuracy of procedure data primarily relates to the occurrence of the procedure billed while the accuracy of the clinical indication associated with the procedure may be substantially lower. For example, a validation study that used specific surgical procedure codes in Medicaid data as part of an algorithm to identify cases of hip fracture found in medical record review that while all of the procedures billed for were actually performed, some of the procedures were used to correct orthopedic conditions other than hip fracture [75]. A further advantage of pharmacy data compared to prescription data recorded in EHR databases (see Chapter 13) is the fact that prescription dispensings are one step closer to ingestion than what was prescribed and thus are subject to a lesser degree of exposure misclassification [76]. The accuracy of encounter data generated by administrative processes not

related to payment is less well established and likely to vary depending on the existence and rigor of quality assurance processes.

Sixth and last, data capture processes in encounter data are automated and independent of the study question and hypothesis, greatly diminishing the likelihood of recall or assessment biases.

Limitations

Encounter databases are primarily intended and maintained for payment or other administrative purposes, and therefore are subject to important limitations when used for research.

First, one of the greatest concerns when using encounter databases for pharmacoepidemiologic research is the uncertain validity of diagnostic information (see Chapters 11 and 37) [49]. While these concerns apply to all diagnostic encounter data, they are amplified for diagnoses recorded in the outpatient setting where diagnosis is typically not directly linked to a particular level of payment. It is thus critically important for all encounter-based research to validate diagnostic data (for both outcomes and important confounders) against external gold standards such as the medical record or disease registries. These gold standards, of course, may not be correct either when compared to research-grade diagnoses as employed by randomized controlled trials.

Second, encounter data lack clinical detail such as markers of disease severity (e.g., blood pressure, ejection fraction) and lifestyle factors (tobacco and alcohol use, body mass index, physical activity). Oftentimes, data elements are available (e.g., diagnostic codes for obesity or smoking status) but of extremely low sensitivity. For example, a study using data from the National Health and Nutrition Examination Survey to validate diagnosis of obesity in Medicare claims found that claims-based diagnostics codes fail to identify a great majority of patients with obesity (sensitivity of 18%) [77]. Though still far from perfect, clinical details such as disease severity and lifestyle factors are generally better captured by paper or electronic medical records. Because such clinical detail is often critical for confounding adjustment, methods that minimize unmeasured or residual confounding (self-controlled designs, active comparator new-user designs, instrumental variable analyses, propensity score calibration) are of great importance to encounter-based pharmacoepidemiologic research (see Chapter 43).

Third, while limitations of encounter databases can often be overcome by facilitating linkage to nonencounter data such as EHRs, disease registries, or laboratory results, such linkages are typically time-consuming and costly and, in many cases, only available to subsets of the database population. Further, when compared to population-based EHR databases, the resulting linked/enriched encounter data typically remain less comprehensive, and validation is often restricted to small samples often with poor response/retrieval rates.

Fourth, in certain situations, medication dispensing information may not capture data for specific drugs or drug classes. This may include drugs excluded from reimbursement, drugs that are primarily obtained over the counter, as well as low-cost generic drugs that are paid for out of pocket because the cash price is lower than the required co-payment. This may result in misclassification of exposure, such that some patients will appear not to be exposed to a medicine when in fact they were. Nonreimbursable drugs as well as low-cost generics are often better captured in EHR databases, which contain information on all prescriptions written. However, the disadvantage of prescription information is that not all prescriptions will be dispensed and will result in misclassification of exposure, such that some patients will appear to be exposed to a medicine when in fact they were not.

Fifth and last, due to the fragmentation of the US healthcare system, many large US encounter databases lack representativeness of the general population and feature significant turnover and short dwell times (e.g., US private insurance databases, MAX) [20,21,78].

Particular Applications

Encounter databases have been used in thousands of pharmacoepidemiologic publications, many of which have shaped clinical medicine or regulatory decision making. These databases have supported work across a wide spectrum of areas including drug safety, comparative effectiveness, drug utilization and health services research, methods and validation, as well as pharmacoeconomics. Descriptions of numerous specific applications of individual databases can be found in the 5th edition of *Pharmacoepidemiology* [14,20–22,45].This section outlines some typical activities involved in encounter database studies and presents some of the considerations in choosing the optimal encounter database when multiple options are available or assessing the suitability of a specific database for a given research question.

Typical Activities Involved in Studies Using Encounter Databases

Although encounter databases vary in data structure, coding schemes, and numerous other specifics, a number of activities are typical across all such databases [20]. Virtually all pharmacoepidemiologic studies of encounter databases require *linkage of records between data files and over time*. Records from different data domains, such as membership, outpatient services, inpatient services, and pharmacy, are linked so that an individual's entire set of encounters over the study period can be available for analysis. Another ubiquitous step in the conduct of pharmacoepidemiologic studies involves the *aggregation of drug, diagnosis, and procedure codes into meaningful study variables*. Exposures, outcomes, potential confounders, and inclusion/exclusion criteria for study are defined via code lists using drug, diagnosis, and procedure codes, or combinations thereof. These code lists are typically study and database specific using the coding schemes utilized by the respective database and drugs approved and available for the study population during the study period. It is often desirable to use previously validated algorithms for the definition of study outcomes and important confounding variables. Such algorithms often combine diagnostic codes, drug codes, and procedure codes for more accurate measures of disease (see Chapter 37).

Together with demographic information, these study-specific variables (e.g., drug classes, disease states) facilitate the *creation of the study population*. Study populations often consist of (new) users of specific drugs or drug classes within individuals who meet specific inclusion and exclusion criteria based on their encounter-derived medical history. Once the study population is identified in the dataset, analytic plans often specify the construction of longitudinal histories. Exposure, occurrence of outcome events, and presence of confounding factors are measured over time, typically in temporal relation to the study's index date. This facilitates the assessment of exposure periods and person-time at risk, and allows calculation of incidence rates and measures of association. If additional data not available in the encounter database are required, complementary information may be gathered through linkage to electronic medical records, data obtained directly from patients or their physicians from surveys, retrieval of paper medical records, or data routinely collected in disease, immunization, or national vital registries.

Deciding Between Individual Encounter Databases

Database choice or evaluation of suitability of a single database should involve consideration of all database attributes relevant to the research question under study [3]. Some of the key attributes that differentiate individual encounter databases are shown in Table 12.1 and discussed below.

Target Population

The database should capture a large and representative sample of the target population (e.g., patients exposed to a particular drug) to adequately address the study question. For example, Stroup and colleagues aimed to examine the effectiveness of initiating treatment with either clozapine or a standard antipsychotic among adults with evidence of treatment-resistant schizophrenia using national US Medicaid data [79]. On first glance, this might not be an obvious choice as the adult Medicaid population is highly selective and often transient. However, Medicaid covers approximately two-thirds of all US adults with schizophrenia because most patients with severe schizophrenia qualify for disability [80]. In addition, because these individuals qualify for Medicaid because of disability rather than because of their economic condition, they are typically stably enrolled without breaks in coverage. While non-US encounter databases might have provided similarly large numbers of stably enrolled patients with schizophrenia, the authors sought a US database because of the pronounced differences in psychiatric treatment practice between US and most other countries. The study was conducted as a 1:1 propensity score matched cohort study and found that clozapine-treated patients compared to patients treated with a standard antipsychotic had a decreased risk of psychiatric hospital admission (hazard ratio 0.78, 95% confidence interval (CI) 0.69–0.88) but an increased risk of diabetes mellitus (hazard ratio 1.63, 95% CI 0.98–2.70).

Database Size

The database should be large enough to provide sufficient power to answer the research question, that is, to detect a meaningful difference between treatment groups (should a difference truly exist). This assessment should be based not on the size of the overall database but rather the size of the actual study cohort, that is, the cohort after exclusion of individuals for whom required data elements are unavailable (e.g., after exclusion of individuals under capitated payment plans), and after application of inclusion and exclusion criteria (e.g., sufficient uninterrupted baseline period).

A study by Shin et al. aimed to determine the risk of cardiovascular conditions in children and adolescents with ADHD associated with use of methylphenidate [81]. As the outcome was rare, the South Korean HIRA database of over 50 million participants was used. From this large population database, 144 258 patients aged less than 18 with a diagnosis of ADHD were retrieved. Of these, 114 657 were new users of methylphenidate and 1224 had an incident cardiovascular event. Due to the rare outcome, a self-controlled case series design was used which, compared to other designs, has the advantage of requiring fewer patients for similar power (see Chapter 43).

Ability to Validate Outcomes

Because encounter data are primarily collected for administrative purposes, the ability to validate or adjudicate outcome definitions derived from these data is essential for pharmacoepidemiologic studies. Outcome validation should generally be performed as part of any encounter-based study unless the outcome measures have previously been validated for the database. However, the ability to validate outcomes, through reliable linkage to external gold standards such as the medical record or disease registries, varies markedly between databases and is often a major consideration for database selection.

Lo Re and colleagues, for example, conducted a series of postauthorization safety studies to examine the safety (hospitalization for major adverse cardiovascular events, acute kidney injury, acute liver failure, infections, and severe hypersensitivity events) of saxagliptin compared to other oral antidiabetic drugs in patients with type 2 diabetes [82,83]. The studies were conducted separately in two EHR databases (Clinical Practice Research Datalink, The Health Improvement Network) and two encounter databases (Medicare, HealthCore Integrated Research Database). One of the requirements for the choice of encounter databases in this study was the ability to obtain inpatient medical records for outcome adjudication. Using a new-user active comparator cohort design, the study found no evidence of increased risk of any of the outcome events within any of the four databases.

Other outcomes are notoriously undercoded in encounter data and require development of custom algorithms. For example, using data from Quebec, Moride et al. developed and validated a case detection algorithm for suicide attempts in youth through a review of medical charts [84]. The following algorithm was used: diagnostic code of injury or intoxication with a location of service in the ED, followed by a psychiatric consult or a psychiatric diagnosis (psychiatric diagnoses consisting of depression, eating disorder, schizophrenia, ADHD, substance abuse, others) within two days of the ED visit. This algorithm had a sensitivity of 70% and a specificity of 97.6%.

Availability of Nonstandard Encounter Data

While all encounter databases provide information on medical services and prescription drugs, studies often require encounter data on services that are not universally available in all databases. For example, Gupta and colleagues examined opioid prescribing practices among US dentists from 2010 to 2015 using the MarketScan database [85]. Because dental services are not captured for all individuals in the database, the study population was appropriately restricted to those with simultaneous enrollment in a medical and a dental plan.

Ability to supplement with non-encounter data: Studies using encounter data may require clinical detail not available from encounter data often for the purpose of confounding adjustment or to supplement outcome identification. The ability to perform linkages that allow enrichment of the dataset with non-encounter data is thus vital and often a decisive consideration in choosing a study database. For example, Huybrechts and colleagues examined the comparative mortality risk of individual antipsychotics in elderly nursing home residents using data for US nursing home residents dually eligible for Medicaid and Medicare [86]. Clinical variables such as cognitive function or behavioral symptoms of dementia are important potential confounders but poorly measured in encounter databases. Linkage to the Minimum Data Set (MDS, available from CMS), a federally mandated health assessment tool used in nursing homes that captures information on physical, psychological, and psychosocial functioning, active clinical diagnoses, health conditions, treatments, and services, allowed the inclusion of these important covariates into the study. Using a propensity score-adjusted new-user cohort design, the authors showed that compared to initiators of risperidone, initiators of haloperidol had an increased mortality risk and initiators of quetiapine had a decreased mortality risk.

As another example, a Swedish-Danish study investigated the risks associated with being admitted to an emergency department with suspected poisoning, most often psychotropics or analgesics. Leveraging the ability to link data on admissions and prescription fills to a dataset including detailed ECGs on those admitted to the hospital, they could estimate not only the occurrence of QTc prolongation within the population but also to what extent QTc prolongation as a marker was associated with 30-day mortality [87].

The Future

Pharmacoepidemiologic research with encounter databases has become more and more widely used and involves an increasing number of databases in a growing number of regions of the world. This trend is expected to continue, particularly as encounter databases become available in regions for which currently no data are available. In addition, the following three major factors are likely to shape the future of encounter databases: (1) advances in information technology (IT), (2) privacy regulations, and (3) changing healthcare systems. Advances in IT will continue to expand the boundaries of data storage and processing, and increasingly facilitate linkages with new and more complex sources of data, including biomarkers, social media, web searches, and around-the-clock biometric information from wearables. In addition, automated tools for data visualization and analysis of health data are becoming more accessible.

The potential for rapid development of progressively complex, detailed, and complete data resources is likely to be counteracted by increasingly strict regulations governing data privacy. These regulations will vary substantially between countries and are likely subject to rapid change.

Last, and maybe most importantly, encounter-based data are a secondary byproduct of administrative systems, created to support the local healthcare system; research applications are secondary uses. As such, encounter-based healthcare data will continue to be subject to changes in the healthcare systems that generate the data. Again, these changes are likely to vary drastically between countries and over time.

For example, the US healthcare environment is undergoing enormous transformation. Historically, healthcare providers in the US have been paid using a fee-for-service approach, where providers bill health insurance companies for the cost of the services they provide, generally justifying those bills with diagnoses. These paid claims represent the core of these encounter databases. However, the net result of this approach is that the more providers do, the more they are paid, which may result in overservicing and wasted resources. The result has been a large incentive to increase utilization, and rapidly increasing costs in the US for providing healthcare, made worse by an aging population. Under this model, the levels of expenditure are unsustainable. This has led to a shift from a fee-for-service model to a "per patient per month" payment system, so-called "population health", which of course switches the incentive to providing less care. In order to attempt to address that, incentives are being put in place to ensure that people are not receiving *too little* care, referred to as "value health". The US is in the middle of this transition now, varying greatly in different parts of the country. However, in response, there has been a remarkable consolidation of physician practices, hospitals, etc., in order to achieve sufficient scale to create the needed extensive and costly data infrastructure, and to assume the large risk associated with population health. Many other initiatives are under way as well, to limit the increasing costs of medical care. The results will likely be large changes over the next few years in the data as part of US encounter databases.

Encounter-based data are an important resource for pharmacoepidemiologic research. These data are comprehensive and often have a high level of quality as they are collected for payment purposes. As these data are generated for purposes other than research, consideration of their applicability, completeness, and generalizability needs to be carefully weighed against their convenience. As with any data source, careful consideration should be given to the issues of bias and confounding (see Chapter 3) which are not problems diminished by the increased size of the database.

Databases that contain health information can be divided into two broad categories: those that collect information for administrative purposes, such as filing claims for payment (administrative claims databases), and those that serve as the patient's medical record (electronic health record [EHR] databases), which physicians use to track health information about their patients. Administrative claims databases are maintained for billing or administrative purposes rather than for the actual provision of patient care. In contrast, data from EHR databases are thought more likely to be clinically accurate because they are collected for patient care, recorded by clinicians (versus coders), and reflect information that may not relate to billing. Unlike administrative databases, EHR databases are more likely to capture important health information about patients, such as symptoms of illness, historical data, family history, smoking and alcohol use, vital signs (e.g., body mass index [BMI]), and laboratory data [1]. Of note, we use the term *electronic health record* databases to encompass their use in the provision of clinical care (that is, as medical records) as well as the interoperability of these electronic systems across broad healthcare networks, serving various nonclinical functions, such as administration, billing, and research [2].

Despite their many advantages, EHR databases have certain limitations. Some EHR databases, like that of the Veterans Affairs (VA) and other US EHRs, may not capture diagnoses and treatments from out-of-system care. Other EHR databases, particularly European primary care databases, lack information from secondary care settings (e.g., hospitals and specialists), and linkage to secondary care datasets is not available for some databases. While EHR databases are thought to have greater clinical accuracy in recorded diagnoses, one cannot presume the validity of diagnostic codes without formal validation. EHR databases usually contain data on prescribed outpatient drugs, but many databases lack information on drug dispensing or inpatient medications. In addition, there may be a high proportion of

Pharmacoepidemiology, Sixth Edition. Edited by Brian L. Strom, Stephen E. Kimmel and Sean Hennessy.

Table 13.1 Overview of EHR databases.

	Arianna	BIFAP	CPRD	LPD Italy	IPCI
Country or countries (and region)	Italy (Caserta)	Spain	United Kingdom	Italy	Netherlands

Table 13.1 (Continued)

	Arianna	BIFAP	CPRD	LPD Italy	IPCI
Software used	SANI.A.R.P.	Various, mainly OMI-AP [37]	Vision and EMIS	Millewin	Various
Quality checks, standards, and feedback to clinicians	Arianna conducts periodic data checks. GPs whose recorded data do not meet preestablished standards are excluded from research [34]	BIFAP performs extensive quality and validity checks of raw data from individual autonomous regions, including physician- and patient-level data. Patient data that are inconsistent or fail quality checks are excluded. BIFAP provides feedback to participating GPs and pediatricians by comparing their patients' registrations, disease characteristics, and prescribing indicators with those of other clinicians within BIFAP	CPRD performs permanent, ongoing quality checks of data from all practices. Patients with noncontiguous follow-up or poor data recording are excluded. Remaining patients are flagged as acceptable for use in research. See text for description of Up-to-Standard dates	IQVIA performs periodic quality checks based on coding accuracy, concordance between GP-specific and national prevalence of selected diseases, and mortality rates [168]. Data from GPs that do not meet set standards are excluded [25]	IPCI evaluates each GP practice for data quality based on several indicators. Data from practices below a preestablished quality threshold are excluded from research. GPs are not permitted to keep paper-based records to improve data quality [172]
Data access and approval	Arianna is available through collaboration with either the Local Health Unit of Caserta or academic institutions with data access, such as the University of Campania or the University of Messina. Researchers must first notify their local ethics committee before using the data. Full ethics committee evaluation is not needed (anonymized data, no direct patient interaction)	BIFAP is available to affiliated and other noncommercial researchers. Investigators must receive approval from the BIFAP scientific committee	CPRD (www.cprd.com) licenses online access to the database. Researchers can download CPRD data using a secure file transfer protocol. CPRD receives annual regulatory ethics approval to supply anonymized linked data for public health research. All research requests to access data held by CPRD are reviewed by the Independent Scientific Advisory Committee	Within Italy, LPD Italy (www.healthsearch.it/?lang=en) is available through collaboration with the Italian College of General Practitioners or with IQVIA (www.iqvia.com)	Access to IPCI (www.ipci.nl/Framework/Framework.php) is provided through collaboration with the Erasmus Medical Centre. Protocols for studies using IPCI data must be approved by the IPCI ethics committee [174]

IQVIA DA	**Pedianet**	**SIDIAP**	**THIN**	**VA**
Various	Junior Bit	e-CAPTM	Vision	Various
IQVIA checks all data for quality standards and plausibility. IQVIA gives all physicians monthly feedback reports showing their prescription patterns and those of colleagues within the IQVIA panel and within their specialty group. Data from DA Germany are also checked annually by the German Medical Association	Data quality in Pedianet is evaluated for every study conducted, either by a central database unit or by researchers. Quality checks include validation of ICD-9-based diagnoses in the clinical chart and free text	SIDIAP performs systematic quality checks to harmonize data and identify duplicate patients, logical errors, and implausible values and inconsistent units within laboratory data. SIDIAP initially used the Registry Quality Standard score to assess data quality [173], but this has been discontinued	IQVIA performs ongoing consistency and integrity checks on all THIN data. See text for description of Acceptable Mortality Reporting	All VA data are updated regularly and checked for quality. Drug data are updated daily with quality checks
IQVIA (www.iqvia.com) administers DA France or Germany with various options: researchers can buy the software and data with monthly updates, preprocessed datasets, or data analyzed directly by IQVIA. Approval for IQVIA DA France and Germany requires only local IRB approval	Pedianet data (pedianet.it/en/about) can be obtained by collaboration with Pedianet-affiliated epidemiologists	Researchers must pay a fee and sign an agreement to obtain data from SIDIAP. Commercial organizations may not use SIDIAP data directly but can contract the core SIDIAP research team to conduct studies with input from the scientific and ethical committee	IQVIA (www.iqvia.com) makes THIN data available in a few forms: a sublicense for the whole research-formatted dataset, a data subset, or a preprocessed dataset with some data manipulation. THIN studies require approval by the Scientific Review Committee of independent researchers. If additional information will be collected, ethics approval is required from the NHS Multi-Centre Research Ethics Committee	Access to VA data is limited to researchers employed by the VA or with VA appointments, and their collaborators. Approval by the local or central VA IRB is required

ATC, Anatomical Therapeutic Chemical; CPT, Current Procedural Terminology; GPs, general practitioners; HES, Hospital Episode Statistics; ICD, International Classification of Diseases; ICPC, Classification of Primary Care; M, million; NDC, National Drug Code; NHS, National Health Service; PCP, primary care professional.

Table 13.2 Selected variables in EHR databases available for epidemiologic research.

	Arianna	BIFAP	CPRD	LPD Italy	IPCI
Healthcare professional demographics	Arianna provides physicians' age, sex, years since graduation	BIFAP provides geographic area of GP but not GPs' demographic data. One cannot determine whether nurse or doctor entered data	CPRD reports if nurse or doctor entered data	One can identify GPs' geographic region but not demographics	GPs' demographics are not available
Types of physicians	GPs	Mainly GPs but also other members of the primary care team, such as pediatricians and nurses	GPs	GPs	GPs
Practice and patient demographics	Practice: Location Patient: DOB, sex, healthcare exemption (based on salary and disability)	Practice: Number of patients registered with GP; number of persons registered in practice available upon request Patient: DOB, sex	Practice: Region, practice size, practice-level SES (Index of Multiple Deprivation and Townsend scores, ~60%), date of last registration, Up-to-Standard date (see text) Patient: YOB for adults, month and YOB for children; sex, ethnicity (~25% recorded; also available via census data), census-based socioeconomic class; patient status (active, died, transferred out)	Practice: Location Patient: DOB, sex healthcare exemption (based on salary and disability)	Practice: Number of employees may be available for some practices Patient: DOB, sex
Vital signs and social history	Height, weight, BMI, smoking, alcohol use available for 25% persons aged ≥65 (2013–present); BP available for some patients (2016–present)	Weight, BMI, BP, smoking, and alcohol consumption	Height, weight, BP, and BMI recorded but may be biased towards patients with a more relevant need for these measurements; smoking (83–93%) [175,176], obesity (61–79%) [175–177], alcohol (~80%) [175,178]	BMI [179], BP [172], smoking, alcohol intake [180]	BP, weight, BMI, and smoking [181] available but recorded only when GPs consider them relevant

IQVIA DA	Pedianet	SIDIAP	THIN	VA
IQVIA DA provides physicians' age, sex, and years in practice	Pedianet provides pediatricians' age, sex, and city of clinic. More detailed information (e.g., years since graduation) is available by request	SIDIAP provides age, sex, type of primary care professional, and performance indicators (quality of care, quality of prescriptions, and quality of diagnosis)	THIN reports if nurse or doctor entered data	One can identify the doctor, nurse, or pharmacist who entered prescription data
Mainly GPs; IQVIA DA Germany and France also include specialists (e.g., cardiologists, dermatologists)	Family pediatricians	Health professionals working in primary care: GPs, pediatricians, dentists, nurses, midwives	GPs	Mainly PCPs but also physician specialists (e.g., cardiologists) and other clinicians (e.g., nurse practitioners, clinical pharmacy specialists)
Practice: Region, community size, patients per practice, number of doctors, number of employees, type (e.g., GP vs specialty) Patient: Age, sex, health insurance status (e.g., private, statutory), medical insurance company, region, town size (>100 000 vs <100 000)	Practice: Region, patients per practice Patient: YOB, age, sex, region of residence, nationality, information about parents (e.g., nationality, habits, blood group, mother's educational level, socioeconomic level)	Practice: Location, urban/rural, number of patients, deprivation index (MEDEA) Patient: DOB, sex, country of origin	Practice Region, number of patients, computerization date, Vision date, Acceptable Mortality Reporting (see text) Patient: YOB for adults, month and YOB for children; patient-level, location-based socioeconomic status (Townsend deprivation scores, 95% recording), region, ethnicity, (20% recording), patient status (active, died, transferred out)	Practice: Region, facility, type of facility (medical center clinics vs community-based outpatient clinics), facility's level of complexity Patient: DOB, sex, race, ethnicity, zip code
BMI (~40% [182]); smoking and alcohol recording unknown	Gestational age, birth weight, birth height, neonatal jaundice; growth measurements (e.g., height, weight); parental smoking	BP, BMI, smoking, alcohol intake, Framingham score. Pediatric screening data (height, weight, head circumference, pubertal development)	Height, weight, BP, and BMI recorded but may be biased towards patients with a more relevant need for these measurements; smoking (86–94%) [86,183–185], obesity (73–83%) [185], alcohol intake (75–85%) [185]	BP, HR, height, weight, SES, education, marital status, smoking history (>90%)

(*Continued*)

Table 13.2 (Continued)

	Arianna	BIFAP	CPRD	LPD Italy	IPCI
Referrals, procedures, results of investigations	Laboratory test results for ~25%; linkage to hospital discharge data, referral data, and orders for diagnostic tests	PCPs' referrals to specialists and hospitals; results from referrals may be recorded in coded fields or as free text; self-referrals (less common) not available	Detailed information on referrals, procedures, and laboratory tests available for approximately 75% of all patients through linkage to HES	Referral data and orders for diagnostic tests available for all patients	Often not available; letters from hospitals to GPs with test results may be available for some practices; test results may be manually recorded in free-text notes
Type of drug data	Drugs prescribed in community setting; drug dispensing by linkage to claims	Drugs prescribed and dispensed in community setting; vaccine data available	Drugs prescribed in primary care; some OTC drug data available (see text); vaccine data available	Drugs prescribed in community setting; vaccine data available	Drugs prescribed in community setting; vaccine data available
Available drug information	Drug ATC code, NDC (with brand, formulation, units), indication for use	Drug name, active substance, number of prescribed packages, duration, prescribed daily dose, strength, indication for use	Drug name, route, strength, frequency, duration; immunizations including batch; cost of therapy upon request	Drug name, route, dose, frequency, duration, cost of therapy	Drug name, quantity, strength, dose [187]
Health care utilization	GP visits; hospital discharge letters, referrals to specialists, admission to ED available by linking with claims data	GP visits; referrals by GP to secondary care and ED; hospital admissions available if patients referred to GPs after discharge	GP visits, hospitalizations, and consultant visits; links to HES provide detailed ward-level resource utilization (England only)	GP visits, hospital discharge letters, referrals to specialists	GP visits; other data generally not available unless hospital discharge letters sent to GP
Identification of pregnancy and families	ICD-9 codes for pregnancy or birth by linkage to claims data; cannot identify families	ICD-9/ICPC codes for pregnancy; cannot identify families	Pregnancy and pregnancy outcomes, family/ household identification number; mother–baby link via family/ household number and algorithm	Not available	Some birth-related data available through hospital discharge letters; cannot identify families

IQVIA DA	Pedianet	SIDIAP	THIN	VA
HbA1c, blood glucose, cholesterol, LDL, HDL available; other test results variably available but can be requested from paper files	Apgar scores, laboratory and imaging tests ordered and reasons for request; test results not always available	Laboratory tests (date, results), diagnostic and imaging referrals; spirometry; referrals for therapeutic procedures; referrals to secondary and tertiary care [186] (date, reason of referral [ICD-10], specialty referred)	Electronic referrals available; older referrals may be in paper files; most outpatient laboratory results available	Provider referrals for specialists available; all laboratory results available but must be standardized
Drugs prescribed	Drugs prescribed and dispensed in community setting, including drugs not covered by healthcare system; inpatient drug data available if reported to pediatrician; noncompulsory vaccine data available, remaining vaccine data identified via linked claims	Drugs prescribed and dispensed in community setting for drugs covered by the national healthcare system; vaccine data available	Drugs prescribed in primary care; vaccine data available	Drugs prescribed and dispensed in outpatient and inpatient settings; vaccine data available
Drug name, route, dose, frequency, duration, cost of therapy	Drug name, ATC code, indication for use, Italian MINSAN code, NDC (with brand, formulation, units), number of prescribed packages, dose (not available for 30%)	ATC code, NDC, indication for use, profession of prescriber; prescribing data only: start and end date, drug units per day; dispensing data only: units per package, number of packages per month, month of drug dispensation	Drug name, route, strength, frequency, duration; immunizations including batch; linkage available to cost of therapy	Drug name, route, strength, dose, frequency, quantity, duration; cost of therapy
GP visits, hospitalizations, sick leave	Pediatrician visits, ED or hospital admission if referred by pediatrician	PCP visits, referrals to secondary and tertiary care, sick leave (date, length, ICD-10), hospital discharge	GP visits, hospitalizations entered by GP, sick leave (if issued by GP); links to HES provides detailed ward-level resource utilization (England only)	Outpatient visits, ED visits, hospitalization (including medical surgical, and intensive care units), community living center (VA nursing home)
Pregnancy variable, gynecologist records; family data incomplete	May identify siblings	Pregnancy and pregnancy outcomes; mother–baby link available	Pregnancy and pregnancy outcomes; mother–baby link via family/household number and algorithm	ICD-9/ICD-10 codes for pregnancy

(*Continued*)

Table 13.2 (Continued)

	Arianna	BIFAP	CPRD	LPD Italy	IPCI
Identification of death and cause of death	Date of death by linkage to claim data	Date of death; cause of death not available consistently	Date and cause of death available via CPRD data and linkage to Office for National Statistics	Date of death	Date of death; cause of death available via free text
Additional data, such as consult records, free text, or paper files	No free text or letters available	Anonymized free-text notes by GPs are available	Hospital discharge summaries, consultant letters; no free text available	No free text or letters available	Free text available on request
Questionnaires and investigator-initiated outcome validation	Not possible to administer questionnaires	Questionnaires can be given to GPs	Questionnaires can be given to GPs and patients; response rates from three recent studies were ~90% [188] (and CPRD internal data)	Not possible to administer questionnaires	Possible to administer questionnaires but response rates usually low
Settings and types of missing data	Inpatient data (except via discharge forms with main diagnoses), laboratory results for 75%, OTC drugs, vaccines	Inpatient data, OTC drugs (few OTC drugs in Spanish national healthcare system)	Prescriptions in secondary care, OTC drugs (exceptions in text), drug dispensing, adherence	Inpatient data, OTC drugs, drug dispensing, pediatric clinical and prescribing data (any setting)	Inpatient and specialist data, OTC drugs, drug dispensing; linkage available to Dutch PHARMO database with dispensing data

IQVIA DA	Pedianet	SIDIAP	THIN	VA
Date and cause of death seldom recorded	Date and cause of death	Date of death	Death date, sometimes cause of death; death certificates may be accessed for a fee if ethics approval is obtained	Date of death
No free text available	Free text available on request	Hospital discharge for 30% of the SIDIAP patients; other data available by request	Hospital discharge summaries, consultant letters; no free text available	Additional data including consult records and free text available by chart review
Questionnaires available upon request	Patients and families can be contacted for structured or unstructured interviews by phone calls from participating pediatricians	Questionnaires can be given to sample of GPs	Questionnaires can be given to GPs and patients; response rates to paper questionnaires ~90% [51] (and THIN internal data)	Charts may be reviewed for validation
Secondary care records, vaccine data, linkage between patients seen in both primary care and specialty clinics	Inpatient data not available for 60%; OTC drug data (unless reported to pediatrician); adult health data	Inpatient data not available except admission/discharge data for hospitals of the Catalan Health Institute; OTC drugs, indication for drug use, drugs not covered by national health system	Prescriptions in secondary care, OTC drugs (exceptions in text), drug dispensing, adherence	Encounter and drug data from healthcare facilities outside VHA, including for patients taken to nearby hospitals for acute events (e.g., stroke); some inpatient medications housed in floor stock for acute care

BP, blood pressure; DOB, date of birth; ED, emergency department; GPs, general practitioners; HES, Hospital Episode Statistics; ICD, International Classification of Diseases; ICPC, International Classification of Primary Care; NDC, National Drug Code; OTC, over the counter; PCP, primary care professional; SES, socioeconomic status; VHA, Veterans Health Administration; YOB, year of birth.

missing data for some variables of interest, such as disease severity, smoking history, body mass index, and patients' race or occupation.

In this chapter, we focus on selected primary care EHR databases from Europe and a national EHR database for veterans from the United States. Several European databases are available for licensing by investigators in government, academia, and industry, while access to certain European databases and to VA data requires collaboration with affiliated researchers. These databases have been used by epidemiologists, and in particular pharmacoepidemiologists, resulting in thousands of published studies. While there are many similarities among the databases, there are also important differences, which we describe in more detail below (see also Tables 13.1 and 13.2). Of note, we do not discuss other outpatient EHR databases that may have been used in pharmacoepidemiologic research but are less widely utilized or less representative of broader source populations. Claims databases from various countries are covered in Chapter 12, and inpatient EHR databases will be discussed at length in Chapter 14.

Description

Europe and the United Kingdom

Overview of Healthcare Systems and Populations

France, Italy [3], Spain [4], and the UK have universal, government-funded healthcare systems. Germany and the Netherlands require all persons to have medical insurance to cover healthcare [5]. In several of these and other European countries, general practitioners (GPs) act as gatekeepers for medical care. In Italy and Spain, family pediatricians function similarly as gatekeepers of most children's healthcare. Except in certain European countries (e.g., France, Germany), practically the entire population have primary care professionals (GPs or family pediatricians), and the vast majority of these clinicians have EHRs. Where GPs and pediatricians act as gatekeepers of the health system, they not only provide general (primary) medical care but are also involved in or informed of nearly all medical events involving their patients, including referrals to specialists, admission to emergency departments or hospitals, and prescribing of medicines recommended by consulting specialists. Thus, European primary care-based EHR databases capture most of their patients' health information.

Of note, the Italian and Spanish healthcare systems are strongly decentralized [6]. Healthcare services in these countries are managed and provided at the regional level, and their respective EHR databases reflect this regionalization. Notably, while both France and Germany have universal healthcare systems, patients often have additional private insurance, and GPs have less of a gatekeeper role than in other countries. These more open healthcare systems, therefore, make the French and German EHR databases less complete records of patients' health information [7–10].

Overview of Databases

The UK was the setting of the first European EHR database, Clinical Practice Research Datalink® (CPRD®), (previously known as Value Added Medical Products [VAMP] database and then the General Practice Research Database® [GPRD®]). CPRD was established in 1987 as a tool for conducting public health research. The Dutch IPCI database followed shortly thereafter in 1989. Since then, multiple other European health record databases were developed and used for research purposes (see below and Table 13.1).

Clinical Practice Research Datalink is a research service of the UK government, supported by the Medicines and Healthcare products Regulatory Agency (MHRA) and National Institute of Health Research. The Health Improvement Network® (THIN®) was set up in 2002 as a collaboration between software and database companies (respectively, Cegedim and

Epic Database Research Company Ltd, now part of IQVIA; THIN is a Cegedim database). CPRD and THIN collect similar health information from approximately 3–5 million individuals per year seen by GPs in the UK, representing 5–8% of the population [11–19]. The same practices may contribute to both CPRD and THIN, but the proportion of overlap changes over time as new practices join or leave each database.

In a study validating well-established drug–outcome associations from the literature, findings were similar in CPRD practices and non-CPRD practices within THIN [16]. As an example of the overlap of these two databases, one study identified over 60% of individuals initiating a particular drug in both THIN and CPRD [20]. Increasingly, pharmacoepidemiologists are combining information from both databases to increase sample size and improve statistical power and generalizability. Because CPRD and THIN are not mutually exclusive, merging data requires identification and singular inclusion of practices contributing to both databases in a given year. Investigators have developed an algorithm for identifying overlapping practices while maintaining anonymity based on total numbers of patients per practice stratified by gender and birth year [21].

The IQVIA Disease Analyzer databases (DA, previously known as Mediplus®) were set up in France, Germany, and the UK. Because the DA UK database is no longer available, it will not be discussed in detail, but additional information may be found in Tables 13.1 and 13.2. The IQVIA DA databases include anonymized patient records from primary care practices as well as some office-based specialists, including cardiologists, dermatologists, diabetes specialists, gynecologists, neurologists, orthopedists, otolaryngologists, pediatricians, psychiatrists, and urologists [22,23]. Patients who see both general practitioners and specialists have different identity codes in the databases to preserve patient confidentiality, making it challenging to track patients across different settings of care. With nearly 30 million patients (5–7% of the total population), DA Germany is larger than DA France, which has over 10 million patients (16% of the total population).

In Italy, the Health Search Longitudinal Patient Database (LPD Italy from IQVIA) contains data on 1.6 million people from GPs across the nation (2.6% of the population), making it the country's largest EHR database [24–29]. Founded in 1998 by the Italian College of General Practitioners, LPD Italy is now owned by IQVIA. The Arianna database contains EHR data on approximately 600 000 people (60% of inhabitants) in a region of southern Italy [30–34]. The Arianna database is the only Italian EHR database that systematically links to several administrative claims databases and includes drug dispensing and hospital discharge data (see Chapter 12 for other data sources combining claims and EHR data). Of note, Arianna data may be linked to comprehensive geriatric assessments (systematic, multidimensional evaluations of health status covering cognitive and physical function, mobility, disability, social support, etc.) for almost three-quarters of the local elderly population (90 000 since 2014), making it a valuable resource for geriatric research [35]. On the other side of the age spectrum, Pedianet contains data on over 400 000 children throughout Italy since 2000, over half of whom are being actively followed (see Chapter 22 for other data resources for pediatric pharmacoepidemiologic research).

In Spain, Base de Datos para la Investigación Farmacoepidemiológica en Atención Primaria (BIFAP) and Sistema de Información para el Desarrollo de la Investigación en Atención Primaria (SIDIAP) are primary care EHR databases that differ in catchment area. Founded in 2000 by the Spanish Agency on Medicines and Medical Devices, BIFAP contains data on 7.9 million individuals from nine of 17 autonomous communities (17% of the Spanish population) [36,37]. SIDIAP was founded in 2006 by the Catalan Institute of Health and the Primary Care Research Institute Jordi Gol. SIDIAP contains data on almost 5.6 million persons from a single

autonomous community, Catalonia (85% of the Catalonian population).

General practitioners across the Netherlands contribute data to Integrated Primary Care Information (IPCI, previously known as Interdisciplinary Processing of Clinical Information). As of 2018, 2.4 million individuals (14% of the Dutch population) are registered in IPCI.

Data Collection and Structure

Practitioners use electronic health records to document a wide range of clinical information about their patients. These data are then electronically extracted for research purposes by specialized software (see Table 13.1), examined for completeness and accuracy by database administrators, and uploaded in anonymized form into the database. The frequency of data extraction and transmission varies among databases. Some EHR databases receive frequent data updates (e.g., real-time contributions in Pedianet, daily in CPRD, three times per week in THIN, monthly in Arianna). Other databases receive new clinical data just 1–2 times per year (e.g., BIFAP, IPCI, LPD Italy). Nonetheless, all of these databases continue to accrue new information over time, adding data on new patients entering the healthcare system and updating data on existing patients who are followed longitudinally. There is substantial heterogeneity in how information is extracted for research across databases, and sometimes within databases, reflecting the diversity of software and healthcare systems. For example, in Spain, some autonomous regions send data to BIFAP directly, whereas other regions use local software programs for data extraction.

Primary care EHR databases generally contain a minimum set of clinical information, including data on patient demographics, medical diagnoses, and drug prescriptions. Table 13.2 contains detailed lists of data collected in each database and highlights differences among them.

European EHR databases use a variety of standardized coding systems to record diagnoses: Read codes (THIN and CPRD); International Classification of Diseases, 9th edition (ICD-9) (Arianna, one autonomous region in BIFAP, LPD Italy, and Pedianet); ICD-10 (IQVIA DA, SIDIAP, part of Pedianet, Hospital Episode Statistics [HES] data linked with CPRD and THIN); and the International Classification of Primary Care (ICPC) (IPCI, most autonomous regions in BIFAP).

The European EHR databases also vary in the ways they record drug data. CPRD and THIN employ British National Formulary (BNF) codes through the Gemscript system. European databases outside the UK record medications using Anatomical Therapeutic Chemical (ATC) classification codes, although many countries have national drug codes contained within a governmental formulary or similar compendium. All European EHR databases discussed in this chapter contain data on prescribed medications. Arianna, BIFAP, Pedianet, and SIDIAP also contain drug dispensing data. Additionally, Arianna, BIFAP, Pedianet, and (for roughly half of drugs) DA databases specify the indications for drugs.

All the above databases are representative of their respective source populations in terms of the distribution of age and sex and the prevalence of most diseases and prescribed drugs [18,19,22]. However, because data are collected for clinical and not research purposes, the reported frequency of certain diseases may vary across databases depending on local or disease-specific patterns of clinical care [38,39]. BIFAP, CPRD, DA France and Germany, IPCI, LPD Italy, and THIN include most regions of their respective countries. However, the distribution of patients across regions in these databases may not reflect the actual populations of those regions [1,15,17,40]. Similarly, the spectrum of socioeconomic status found in the databases may differ from the country as a whole [40].

Vital signs (e.g., blood pressure, height, weight, BMI) and laboratory test results are available in Arianna, BIFAP [41], CPRD [42], DA [43], IPCI, Pedianet, SIDIAP [44–46], and THIN [47] to varying degrees (see Table 13.2). For example, in both THIN and CPRD, laboratory data from after approximately 2000 is better recorded, but some older laboratory tests may not be available electronically if they were received by GPs on paper. Furthermore, height and weight are recorded for most adults in the UK but may be missing for many children (see Incompleteness of Clinical Data). In DA Germany, HbA1c for diabetic patients is nearly complete, but many other laboratory values are not recorded. Laboratory test results are also available in Arianna (~25% of patients), BIFAP, Pedianet (with indications for testing), and SIDIAP.

Hospitalizations, referrals, and the resulting consultation letters are recorded to varying degrees in European EHR databases. In the UK, discharge summaries and other hospital and consultant letters are sent to the GP, although these identified paper documents are not directly available to researchers. Linkage of THIN and CPRD to HES data allows researchers to access additional details from hospitalizations, such as diagnosis codes on admission and discharge and length of hospital stay. Referrals to other care settings are captured in both CPRD and THIN, and data from outside consultations may be obtained by linkage to HES data. Details on available data for hospitalizations and referrals in other databases are listed in Table 13.2.

Data from social history, including smoking and alcohol usage, are available to varying extents in most EHR databases (see Data Quality: Accuracy and Completeness, and Table 13.2). Substance exposure information is less consistently recorded in DA databases and IPCI. Pedianet contains information on parental smoking habits. Certain components of social history, such as occupation, are not routinely recorded in some databases [48].

In most of the European EHR databases described, most data are entered using structured (coded) fields rather than free text [49–52]. In contrast, BIFAP and IPCI contain large volumes of unstructured data. These and other databases make information from anonymized free text entries available to researchers (see Table 13.2). These free text data can be used to identify and validate outcomes and supplement available data in structured fields. Some practitioners may still keep paper record files, which could include precomputerization records, hospital discharge paperwork, or letters from specialists. Multiple databases, including THIN and CPRD, have additional fee-based data services that will obtain and anonymize paper-based data from GPs (see Table 13.2). To maximize the quality of the electronic record, IPCI does not permit participating GPs to keep paper records, but Dutch GPs record extensive free text notes, which are available to researchers [29].

Aside from the availability of unstructured data, several databases, including BIFAP, CPRD, DA Germany, Pedianet, SIDIAP, and THIN, allow researchers to administer questionnaires to clinicians or patients [51,53–55]. Like free text data, such questionnaires can be used to validate existing data or provide additional information that is not otherwise available in the database. Moreover, unlike free text entries, such questionnaires can be tailored in their content and administration based on the specific research question and population of interest [51,56]. Researchers must pay fees to administer supplementary questionnaires, a portion of which participants receive to complete the questionnaires. Of note, investigator-initiated surveys are also permitted in IPCI, but anecdotally response rates among GPs tend to be low.

Data Quality: Accuracy and Completeness

Data quality checks are performed by the European EHR databases at regular intervals on three levels: (1) practitioner recording, (2) data

extraction, and (3) maintenance of the database (see Table 13.1 for details on database-specific measures of quality assurance). When data are uploaded or extracted from the health records, the company processing the data performs additional quality checks to make sure the data have been correctly uploaded or extracted. Subsequent updates to the databases are verified for accuracy [1,40,57]. All databases undergo routine updating of the software used to collect, check, transfer, and present data.

In the UK, national quality improvement initiatives as well as advances in software have increased overall capture and accuracy of data. The national UK initiative the Quality and Outcomes Framework (QOF), a pay-for-performance program, was instituted in 2004 to improve performance using 146 quality indicators for 10 chronic diseases [58]. The QOF measures increased GP input in the EHR, leading to more complete data recording, especially for the targeted medical conditions [59,60]. Even after certain financial incentives were removed, performance for many quality indicators persisted across UK practices [61]. However, it is unclear whether reporting also improved for other, nonspecified quality indicators or diseases [62]. Some researchers have reported that the QOF has not contributed to decreases in mortality, better care coordination, or better patient experiences in the UK [63]. In its current form, therefore, this program's future is uncertain [64].

The QOF is only one of multiple quality improvement strategies implemented in the UK since the 1990s [62,65]. In coordination with specific databases, GPs receive training in the use of their software and regular evaluation of their data recording and prescribing behavior. GPs contributing to THIN or CPRD receive feedback reports with tips on improving recording and, in some cases, a summary of their prescribing habits relative to similar practices and other GPs in the UK. Other database-directed quality measures include audits of newly added practices and comparison of acquired data to national databases (e.g., mortality, hospitalizations, cancer, and cardiovascular registries) [22,66]. Finally, as incentives to take part in research studies, GPs and practices contributing to CPRD or THIN may receive income through questionnaires or participation in interventional clinical studies.

In CPRD, only data from practices that meet quality standards (~90% of practices) are provided for research. The Up-to-Standard (UTS) date is a practice-based quality marker corresponding to when a practice in CPRD is considered to have continuous and complete recording of data [17]. The UTS date is based on two parameters: the presence of gaps in the data stream and the existence of an appropriate rate of recorded deaths at the practice. For THIN, IQVIA employs a quality measure known as acceptable mortality reporting (AMR), denoting the year in which mortality reporting was deemed complete for each practice [40,53]. Other European EHR databases have their own standards for ensuring quality and completeness (see Table 13.1 – Quality checks, standards, and feedback for details).

With regard to specific variables, completeness of data varies among databases (see Incompleteness of Clinical Data and Table 13.2). Pregnancy, family structure, mortality, and cause of death are variably recorded and may be difficult to ascertain. Family structure may require the use of coding algorithms [66–74]. CPRD offers a probabilistic mother–baby link algorithm, which identifies likely mother–baby pairs based on an anonymized family number, maternity information from the mother's primary care record, and the month of birth of newly registered babies. CPRD may also be linked to mortality records from the Office for National Statistics to improve death estimates and confirm cause of death [75–77]. Researchers may also use algorithms for data in THIN to link family members or determine cause-specific mortality [78,79]. Risk factors such as smoking

and obesity may have gaps. The introduction of QOF measures led to a substantial increase in recording of these and other variables within CPRD and THIN [80–85]. For example, recording of data on adult patients' smoking habits rose from 75% before 2004 to nearly 90% by 2007 [86]. By 2005, 99% of patients with diabetes had a reported HbA1c value in the past 15 months compared to 87% in 1998.

As with other data sources, investigators need to consider the local context when interpreting dates in European EHR databases. Dates in the medical files may reflect dates of data entry or dates on which observations were made. In the case of new registrations in general practice, dates may reflect entry of data obtained from previous practitioners or from previous recording systems.

Data Access for Researchers

Research performed using European EHR databases must first be reviewed by the home institution's institutional review board (IRB) and the ethics board for the respective database. Given researchers' inability to identify individual patients in anonymized databases, such studies often meet the criteria for IRB exemption. Investigators must usually receive approval from the ethics board of the respective database before conducting their research. Requirements for approval change over time, so investigators should check with the data vendor about approval requirements prior to starting a study. Companies may also require completion of a data use agreement before initiation of a study. See Table 13.1 (Data access and approval) for more details.

United States: Department of Veterans Affairs Healthcare

Overview of Healthcare System and Population

The Department of Veterans Affairs (VA) was established in 1930 as the Veterans Administration based on congressional approval to "consolidate and coordinate Government activities affecting war veterans" [87,88]. The VA's Veterans Health Administration (VHA) is one of the largest integrated healthcare systems in the United States, providing medical, surgical, and rehabilitative care to a diverse group of military veterans as well as active duty reservists and National Guard. In contrast to the general US population, the VA population consists of predominantly older men (87% male, 47% over age 65 as of 2017) who often have multiple chronic medical or psychiatric conditions. The female population in the VA has increased over the last several years and represents a younger cohort of veterans. In 2016, the VA healthcare system consisted of 18 regional integrated networks encompassing 145 hospitals and medical centers, over 1200 ambulatory care, mobile, independent, and community-based outpatient clinics, and 132 community living centers (VA nursing homes) [89,90].

The VHA is primarily a direct provider of healthcare services, funded by the US government. While veterans receiving healthcare are not required to pay premiums for coverage, some are charged co-payments for certain medical services and outpatient prescriptions [88]. The vast majority of medications within the VHA are prescribed by VA clinicians and dispensed by VA pharmacies. To facilitate access to care, veterans may also see and receive medications from certain authorized private providers outside the VA [91]. Prescriptions from this program (<1% of all VA prescriptions as of 2017) are similarly dispensed and recorded within the VHA. Of note, dual-care veterans with Medicare coverage (which covers virtually all US citizens age 65 years and older) may receive medications through both the VA and the Medicare Part D Plan. This arrangement may result in duplicate or excessive drug usage for some patients – a clinically important situation that might be overlooked by clinicians and researchers alike who do not jointly consider both sources of medical care [91–93]. Because the VHA is not a

closed medical system, veterans may receive out-of-network care, compromising one's ability to study certain outcomes (see Incompleteness of Clinical Data).

In 2017, approximately 6.3 million veterans (more than one-third of US veterans) were treated in the VA healthcare system, with over 5 million receiving prescriptions (see Table 13.1 for details) [89].

Overview of Database

The VA database contains demographic, clinical, and administrative data from 1997 to the present along with prescription data since 1999 and laboratory data starting in 2002. This database contains health information on 14.5 million patients; in 2017, the number of veterans in the VA database was about 2% of the US population and 32% of US veterans [89].

Data Collection and Structure

Local VA medical centers record and store clinical and administrative data within the Veterans Health Information Systems Technology and Architecture (VistA) system. The National Patient Care Database (NPCD) contains inpatient data and (through 2018) outpatient data extracted, organized, and integrated from VistA. These data include demographics, diagnoses (ICD-9 and ICD-10 codes), clinic visits, admissions, discharges, transfers, prescription orders, laboratory, surgical procedures, provider specialty, and administrative services [94,95]. The VA's Corporate Data Warehouse (CDW), a primarily operational database, contains raw clinical, medication and administrative data through VistA [96,97]. While less structured than the NPCD, the CDW contains similar information as well as additional data, including vital signs, radiology results, free text notes, consults, and health factors (e.g., smoking status). Since 2019, the CDW has been the primary source of outpatient VA data.

These data may be used for quality improvement efforts and research. The VA Vital Status File contains some demographics (birth date, gender) and death data from multiple sources [98]. Death data are cross-checked monthly with the Social Security Administration Death Master File [98]. In addition, VA has several disease-specific registries that are used for patient care and research, including cancer, diabetes, severe mental illness, amyotrophic lateral sclerosis, rheumatoid arthritis, and the human immunodeficiency virus and hepatitis C clinical case registry.

Unlike most EHR databases, the VA database contains information on both prescribing and dispensing of drugs in both outpatient and inpatient settings. Pharmacy data systems record outpatient and inpatient drug dispensing in the CDW and Pharmacy Benefit Management (PBM) databases [99,100]. The PBM database also contains information on dispensing of nonprescription medications and specific medical supplies. The majority (85%) of outpatient medications are dispensed via the VA's consolidated mail-order pharmacies. While the PBM database records the dispensing of inpatient drugs, the Bar Code Medication Administration (BCMA) database contains records of administrations of medications to inpatients [101]. The VHA also maintains its own adverse drug event reporting system (also see Chapter 10); as of 2018, this system contains over 500 000 reports related to drugs or vaccines.

Investigators may also extract data for research directly from the EHR. Such primary data collection can facilitate, for example, the validation or ascertainment of outcomes in unstructured portions of the EHR, such as reports (e.g., biopsies), text-embedded test results (e.g., cardiac ejection fraction from an echocardiogram), and free text notes. Researchers may extract data through manual chart review in the local web-based EHR portal or via natural language processing programs [102,103]. In addition to EHR data, surveys of veterans and clinicians permit access to additional information [104].

Data Quality: Accuracy and Completeness

The CDW, a nontransformed mirror of the medical record, is updated nightly. Updates of the Vital Status File occur monthly. The accuracy and completeness of data reflect the EHR and beneficiary claims they source (see Tables 13.1 and 13.2 for more details). For instance, demographic race and ethnicity data can have up to 20% missing data in certain years [105].

The PBM database undergoes daily quality assurance processes to ensure completeness and accuracy [99]. As with medications obtained through Medicaid (see Chapter 12), low or nil co-payments produce strong financial incentives for veterans to obtain outpatient prescriptions through the VA.

Data Access for Researchers

Researchers may obtain data through any of the aforementioned VA data systems (see Data Collection and Structure) following approval by the local or central VA IRB. Access to VA data is limited to VA-affiliated researchers and their collaborators.

Strengths

Population-Based Data, Sample Size, and Length of Follow-up

Population-based studies draw subjects from the greater population to produce a derived sample that reflects the source [106]. Many European EHR databases allow researchers to use population-based study designs, minimizing selection bias and improving the validity and generalizability of epidemiologic studies. Although patients can opt out of having their information used, few do so.

Population-based data sources are ideal for nested case–control studies, in which all cases (e.g., individuals with the outcome) or a representative subsample are ascertained in a precisely defined population, and unaffected controls are sampled randomly from the same source population at the time when cases develop the outcome (incidence density sampling) [107]. Similarly, population-based data allow for the design of cohort studies, given the availability of prospective data with long follow-up periods. The large numbers of patients with longitudinal follow-up (see Table 13.1) may allow for sufficient statistical power to study rare exposures, diseases, and outcomes. These large, population-representative databases are excellent settings for a wide variety of methodologic and applied studies (see Particular Applications and Table 13.3).

Given the preponderance of older, sicker men in the VA system, the VA database is distinctly not representative of the US population or even of all US veterans, a majority of whom do not receive care within the VA system. However, the VA serves a high proportion of traditionally underrepresented and vulnerable groups, including the elderly and those with multiple co-morbidities, mental illness, disabilities, and lower socioeconomic status. The large and growing size of the VA population and retention of patients in the system, often until their death, facilitate large longitudinal studies within this special population of veterans.

Validity of Clinical Information

Epidemiologic studies in any of the EHR databases involve use of lists of codes, and sometimes algorithms, for specific medical conditions, drugs or other exposures of interest, and co-variates. Methods for deriving such code lists have been described [49,108]. The validity of such code lists and algorithms has been extensively studied in many of these databases. Studies of agreement between recording in the EHR and capture of data (e.g., prescription medications and specialist referrals) have been performed for certain databases [17,22,50,66,67,109]. Numerous studies have validated outcomes within EHR databases (see Table 13.3). For unvalidated outcomes of

Table 13.3 Examples of studies using EHR databases

Type of research	Setting or subject area	Sample of publications
Validation studies	BIFAP	Community-acquired pneumonia [189], ischemic stroke [190], meningioma [191], myocardial infarction [192], Stevens–Johnson syndrome and toxic epidermal necrolysis [193], and upper gastrointestinal bleeding [194]
	CPRD [17]	Atrial fibrillation [195], autism [196], cancer [197], cataract [198], chronic obstructive pulmonary disease [199–201], familial hypercholesterolemia [202], inflammatory bowel disease [203], liver injury [204], lymphoma [205], myocardial infarction and heart disease [206,207], pregnancy outcomes [68,69], pressure ulcers [208], psoriasis [48,209,210], psychosis [211], rheumatoid arthritis and juvenile idiopathic arthritis [212], Stevens–Johnson syndrome and toxic epidermal necrolysis [213], suicide [214], and venous thromboembolism [215]
	IQVIA DA databases [22]	Venous thromboembolism [216], general validation of pharmacoepidemiologic and pharmacoeconomic studies [22]
	LPD Italy	Heart failure, ischemic heart disease, hypertension, and type 2 diabetes [3]
	THIN [16]	Quality of cancer reporting [1,217], date of death and mortality reporting [53], hepatitis C virus infection [51], myocardial infarction [50], nonmelanomatous skin cancer [54], peptic ulcer disease [50,185], psoriasis [210], and stroke [50]
	VA	Acute kidney injury [218], fatty liver disease [219], heart failure [220], hepatocellular cancer [221], inflammatory bowel disease [222], myocardial infarction and related cardiac procedures [223], posttraumatic stress disorder [224], sepsis [225], and stroke [226]
Methodologic studies	Database-specific research (CPRD or THIN)	Timing and validity of diagnoses and outcomes relative to EHR-specific administrative dates [133,227,228] and clinical coding practices [229–231]; methods to impute missing drug information [134]; potential for misclassification and resultant bias due to missing data within free text [232,233], paper records, [234] and linked hospitalization records [235]
	Generalizable research using EHR databases (various)	Sources and types of bias [236–240]; novel study designs, such as self-controlled designs [241], regression discontinuity designs [242], and prevalent new-user cohort designs [243]; various analytic approaches for causal inference, such as propensity scores [244], high-dimensional propensity scores [245], simulation [246], marginal structural models [247,248], targeted maximum likelihood estimation [249], and instrumental variable analysis [250]; handling of missing data [251–253]; handling of repeated data [254,255]; and identification of outliers [256]

Table 13.3 (Continued)

Type of research	Setting or subject area	Sample of publications
Applied studies	General epidemiologic studies	Europe: representative incidence and prevalence studies [177,195,257–266] (e.g., shoulder complaints in primary care [267], newly diagnosed heart failure [268], bullous pemphigoid [269], and pemphigus vulgaris [269]); natural history of disease (e.g., irritable bowel syndrome [270]); risk of disease-related outcomes [260,271–279] (e.g., lymphoma among inflammatory bowel disease patients [205], myocardial infarction in patients with psoriasis [274], and complications of diabetes [280]); research on associated conditions [208,281] (e.g., obesity and liver disease [282]); patterns of diseases or symptoms [199]; rates of referral (e.g., chronic pelvic pain [283,284]); impact of geography [285,286] and pollution [287–289] on disease incidence and outcomes US VA: burden of illness associated with irritable bowel syndrome [290], military sexual trauma [291], patients awaiting major joint arthroplasty [292], and mental illness among veterans [293]
	Pharmacoepidemiologic studies	Europe: studies assessing risks [113,197,214,279,294–304] and outcomes [305–311] of medication (e.g., risk of myopathy and myalgias by statins [299]); safety and tolerability of medications [14,29,33,248,298,312–319]; studies of medication exposure and pregnancy outcomes [71,320,321]; reduction of morbidity or mortality by medication [306,322,323] and vaccinations [324]; persistence of medication use [325–327] (e.g., antihypertensives [328,329], bisphosphonates [330,331], and glaucoma therapies [332]); compliance and adherence [24,25,333,334]; physician's use of guidelines in prescribing medications [335–338] (e.g., antibiotics in children [339,340], antidepressants [341]); trends in prescribing [342–351]; device utilization [352,353], effectiveness [354], and safety [355,356] US VA: risks of myocardial infarction or musculoskeletal pain associated with bisphosphonates [357], dysglycemia with fluoroquinolones [358], neuropsychiatric adverse events with smoking cessation therapy [359], gastrointestinal bleeding with selective serotonin reuptake inhibitors [360], glucocorticoid-induced osteoporosis [361], and antipsychotic-associated mortality in dementia patients [362]
	Pharmacoeconomics, health services research, and pharmacovigilance	Europe: cost-effectiveness and safety of bisphosphonates [363], comparison of cost between glaucoma therapies [332,364], use and cost-effectiveness of long-term hormonal contraception [26,365], cost-effectiveness of treatment of gastroesophageal reflux disease [366]; health insurance-related barriers in access to and compliance with medicines [367–370]; healthcare utilization in fibromyalgia [371] and diabetes [30,372–376]; prescribing trends and their financial impact [377,378]; comparison of care of the elderly and nonelderly regarding symptoms concerning for ovarian cancer [379]; research on disparities and health outcomes [285,380–384]; variability in resource utilization and prescribing [385,386]; vaccination uptake and distribution [387–389]; impact of risk minimization measures [27,31] US VA: costs of erythropoietin therapy [390,391], treatment for metastatic prostate cancer [392], atrial fibrillation and stroke prevention [393], and healthcare costs of a collaborative intervention for chronic pain [394]; impact of clinical practice guidelines on quality of care [395] and adherence to the diabetes guidelines [396]

interest, one should strongly consider validating outcomes before or during a study to ensure that the specified diagnostic codes or algorithms reflect patients' true conditions. Codes or diagnoses that have not been validated may lead to spurious results and compromise a study's validity [50,51] (see also Chapter 37).

Accuracy of Drug Information

Electronic health record databases contain information on the name, strength, and quantity of prescribed drugs, which can be used to estimate their expected end date. In the UK, unlike in other countries, the prescription is the payment document. Although information is usually lacking on whether a prescribed drug has been dispensed from a UK pharmacy or taken by the patient, new prescriptions are generated and recorded when the current refills have been used and the patient requests a refill. A prespecified number of repeat prescriptions can be issued upon request of patients, after which a repeat clinical evaluation is required to ensure the prescribed therapy is still appropriate. The number of prespecified refills depends on factors such as patients' medical history and the drug in question.

Arianna, BIFAP, Pedianet, SIDIAP, and the VA databases contain information on outpatient drug dispensing in addition to the prescription data. VA databases also include detailed data on inpatient drug dispensing and administration. Of note, research using THIN has shown a high correspondence between issued and dispensed prescriptions except for a few selected drug classes; antipsychotics, drugs for malignancy, and immunosuppressants had lower redemption rates while anesthesia and vaccines were underreported as prescribed [110].

Ability to Access Original Health Records

Electronic health record databases contain information from patients' actual health records, which gives researchers insights into medical and social histories that are not possible with other types of databases (e.g., claims). For instance, researchers can access information about antecedent symptoms, prior medical conditions, family history, vital signs, physical exam finding, laboratory data, and prescribed medications, as detailed above. Particularly in closed medical systems where GPs and family pediatricians are the gatekeepers, health information in the EHR tends to be relatively comprehensive (see Europe and the United Kingdom, Overview of Healthcare Systems and Populations). Notably, some EHR databases permit access to anonymized free text data (e.g., IPCI), anonymized copies of paper records (e.g., THIN), or the entire EHR (e.g., VA), as well as access to clinicians or patients via surveys. These options allow researchers to verify information found elsewhere in a database or obtain additional supplemental data (see Data Collection and Structure). In published studies from the UK, response rates for health record requests have been greater than 80–90% [111–113].

Linkage to External Patient-Level Data

Many EHR databases may be linked to other health-related, patient-level information, thus extending the functionality and utility of EHR data. More than 75% of applications submitted to CPRD request the use of linked data (sometimes customized for a study) to augment the information available for research. The data source most commonly linked to CPRD and THIN is HES, which can provide data on hospital visits and stays, accident and emergency episodes, and tests by specialists, including imaging. The combination of data from primary care and HES facilitates research on conditions managed across multiple healthcare settings [114–117]. Linkage to official death records may improve the accuracy of mortality studies and validate data from general practice [118,119]. Researchers can link EHR data with other data sources, including disease (e.g.,

cancer) registries, mental health datasets, and socioeconomic and deprivation indices [120–124]. Furthermore, linkage of EHR data to individual patient-generated data is also possible, including patient-reported outcomes, environmental data, drug diaries, and biospecimens [125–127].

Electronic health record databases outside the UK also permit linkages to other data sources, including Arianna (e.g., claims data and registries on regional hospitalizations, national drug dispensing, and mortality), SIDIAP, and the VA (e.g., genetic information from the Million Veteran Program biobank [128] and administrative claims data from Medicare and Medicaid [92,129,130]). See Chapter 12 for information about other data sources that combine EHR and claims data.

Limitations

Incompleteness of Clinical Data

When using EHR databases for research, investigators rely on recording of patients' history and events by their clinicians and the health systems they work in. In clinical practice, human errors and omissions naturally occur, but systematic errors in recording can lead to bias. For example, in studies of the elderly, researchers can use available geriatric data to create a frailty score [131]. Notably, such data are likely to be selectively recorded for frailer patients [132]. Failure to account for such patterns of missingness could lead to bias. Although most EHR data are in electronic form, information received from outside sources (e.g., consultants or hospitals) in hard copy may not be fully captured if results are not manually reentered by clinicians. As with the above example, clinicians may be more likely to record laboratory or radiologic findings that are abnormal, but even abnormal results may not be documented reliably.

Because European EHR databases are designed to capture health information from primary care settings, they typically lack information from specialists. IQVIA DA databases record data from certain specialists, but these encounters are not linked directly to patients' primary care records. In other databases, recording of information from secondary care relies on communication between GPs and other clinicians. Researchers using THIN or CPRD may access more extensive and reliable data from other settings through linkage with HES data and other sources (see Linkage to External Patient-Level Data).

The nature of illness can affect the pattern of data recording. Unlike in administrative claims databases, codes for chronic diseases may be entered only once into EHR databases. For this reason, episodes of care involving acute events may be better recorded than chronic diseases [48,109,133]. Likewise, codes for chronic or inactive medical conditions may predate a study's follow-up or fixed baseline period. Failure to account for historical diagnoses could lead to misclassification of important study variables. Another consideration for studies using EHR data involves follow-up time and censoring: patients may transfer out of a given practice and entire practices may stop contributing patient-level data to the database. If such dropout relates both to exposure status and the outcome, bias could result.

While certain types of information can be found in EHR data and not administrative claims, some of these same variables often contain missing data. Examples include race and ethnicity, smoking and alcohol use, BMI, socioeconomic status, employment status, and occupation (see Tables 13.1 and 13.2 for database-specific details on percent recording). Unless incentives or other processes actively encourage recording (see Data Quality: Accuracy and Completeness), clinicians may more likely document these variables of interest (potential confounders) when they consider them relevant to patients' health. Of note, some databases, including CPRD, THIN, and SIDIAP, derive socioeconomic data from

patients' location of residence rather than their own finances.

Another source of missing data involves pediatric growth measurements in the UK. GPs routinely measure and record the height and weight of children in a paper record provided to families. However, GPs inconsistently document these same measurements electronically. As a result, longitudinal measures of pediatric growth are frequently incomplete in CPRD and THIN; as with other variables, recording of these measures may relate to other clinical characteristics. Recording of growth measurements in children is more comprehensive in Pedianet, although the overall size of Pedianet's pediatric population is smaller than that of either UK database.

Veterans in the VHA may receive healthcare outside the VHA either by choice (especially veterans aged 65 and older with Medicare coverage) or by necessity. For instance, veterans with urgent or emergent conditions are taken to the nearest hospital for care, as their VHA hospitals may be farther away or may lack a true emergency department. As a result, occurrences of acute conditions, such as myocardial infarction, stroke, and severe hypoglycemia, may be generally missed in inpatient data from VA hospitals, potentially resulting in missing outcome data. The frequent omission of acute outcomes of interest represents a major limitation of the VA database, making it less useful for some types of pharmacoepidemiologic studies when used as the only data source. Of note, in studies of veterans age 65 and older, one can overcome this limitation by linking VA data to Medicare claims data [91–93].

Incompleteness of Drug Data

Information on days' supply and daily dosage of prescribed medicines may not be explicitly recorded in EHR data. Methods are available for imputing days' supply [134]. Information obtained from the timing of repeat prescriptions or refills can inform the imputation of daily doses [135,136]. Additionally, algorithms have been developed to determine daily dosage and other drug data (e.g., frequency) from unstructured text [137–139]. Only a few databases (Arianna, BIFAP, Pedianet, and to some extent DA) specifically link prescribed drugs to a particular diagnosis. Without this information, one can refer to diagnoses recorded in or around encounters that correspond to prescribed drugs.

One must remember that prescribing records do not indicate which prescriptions were filled. Only a few of the EHR databases discussed (Arianna, BIFAP, Pedianet, SIDIAP, and the VA) also contain drug dispensing data, providing a more complete picture of drug utilization. Data on OTC drugs are frequently missing from EHR databases, but exceptions exist where healthcare systems pay for OTC drugs. For example, long-term use of certain OTC medications, such as aspirin and nonsteroidal antiinflammatory drugs, is recorded in UK databases [140] and Arianna [32,33]. The UK National Health Service provides free prescription items to certain segments of the population (e.g., patients over 60, children under 16, people in full-time education). Patients over age 60 also have free access to some chronically used nonprescription medications that are prescribed by GPs. These accommodations lead to more reliable usage data for OTC drugs in some UK populations. Additionally, Pedianet and SIDIAP capture prescribing and dispensing of drugs irrespective of coverage by the respective national health systems, leading to comprehensive recording of OTC medications. Notably, medication adherence is not well recorded in any setting; thus, documentation of prescribing or dispensing does not imply that patients actually take their medications (see Chapter 38 on Adherence).

In European EHR databases, data on medications restricted to specialist care,

dispensed from hospital pharmacies (e.g., biologics), and given during hospitalization or upon hospital discharge may be missing. In the UK, patients generally receive a limited quantity of medications upon hospital discharge, which in some cases may last two weeks. In the VA, certain medications are recorded in the EHR but are not accessible in the prescription databases, for example medications obtained from floor stock or administered acutely in acute care areas. The administration of other drugs may occasionally be incomplete due to work-arounds in documentation [141].

Complexity and Costs

The size and complexity of these databases require adequate computer hardware, software, and storage space as well as experienced data managers and analysts. These requirements carry costs in addition to the costs of using many databases themselves. Open-source software is available for managing and analyzing EHR data [142,143], including algorithms for use and analysis of free text [144,145].

Particular Applications

The aforementioned EHR databases have been a rich scientific setting for thousands of epidemiologic and pharmacoepidemiologic investigations. Research using these databases has included assessments of the incidence and natural history of disease; research on drug utilization, safety, and effectiveness; pharmacovigilance and signal detection; health economics research including cost-effectiveness; studies using case–control, cohort, longitudinal, self-controlled, and other designs; and a variety of methodologic studies. Examples of these studies are provided in Table 13.3. More comprehensive lists of publications using these databases may be found on their respective websites.

The Future

Electronic health records continue to evolve and expand in pursuit of delivering high-quality, high-value healthcare [146]. Interoperable EHR platforms and health information exchanges can enable broader access to and sharing of data across clinical settings. Such advances enable better coordination of care, reduce redundancy, and improve efficiency within and across healthcare systems. New technologies have improved communication not just among clinicians. Clinicians and their patients can now correspond electronically via the EHR and even interact in virtual clinical encounters through telemedicine. In some settings, patients can see their EHR data through patient-specific portals and upload their own data (e.g., patient-reported outcomes, consumer-wearable technology, "smart" digital technology) into the EHR. All these changes rely on and generate increasing volumes of data. Through advanced data analytics, healthcare systems can harness these data to learn from their patients, align and streamline processes of care, and improve patient outcomes – key objectives of learning health systems [147].

As EHR systems evolve, systems administrators, clinical informatics specialists, and end users must address important challenges. Missing data and variability in recording are common in EHRs. To optimize clinical care and maximize the potential for high-quality research, healthcare systems must implement approaches to ensure consistent and complete clinical documentation within the EHR. Future research will be needed to determine whether continuing education, financial incentive programs (e.g., QOF), targeted feedback, or other strategies can improve

patient outcomes while being cost-effective and sustainable.

In an age of ever-growing threats to data security, EHR databases require enhanced vigilance, technology, and standards to maintain individuals' privacy and confidentiality. Healthcare systems, industries, regulatory agencies, and governments must balance the potential societal benefits of broad access to and linking of health data with the personal risks to privacy and safety [148]. Contractual, practical, and technical barriers must be overcome to link and share data from disparate, proprietary EHR platforms.

The many advancements in EHR systems have important implications for the conduct of research. New technologic approaches, such as natural language processing, artificial intelligence, and other big-data analytics, have enabled researches to organize and use complex EHR data in novel ways [149–152]. Nonetheless, the clinical value of artificial intelligence-based methods to study medicines in observational settings remains unclear [153,154]. Large international research networks, such as ARITMO [29], SOS [155], and TEDDY [156] have demonstrated the capacity and power of international collaborations to use EHR databases for large-scale research on drug utilization and outcomes. Such collaborations lead to increased statistical power to study rare diseases, uncommonly used drugs, and rare outcomes; they also have greater external validity than research conducted within a single region or country. Linkage of EHRs with hospital data, administrative claims, and other data sources (e.g., patient registries) is increasingly important to maximize the advantages of each data source and minimize their respective limitations (see also Chapters 12 and 14) [92,116,157]. Furthermore, linkage of EHR data to patient-generated data and biospecimens adds to the possibilities for inquiry and discovery through population-representative, patient-centered research and molecular pharmacoepidemiology [128,158,159]. Researchers can also use the clinical networks and information infrastructure of EHR systems to conduct large pragmatic trials [160–162]. In addition, expansion of EHRs in low- and middle-income countries facilitates research and improvements in healthcare in areas of great need [163]. High-quality research conducted within EHR databases can favorably influence public policy and public health [164].

In the area of pharmacovigilance and regulation, EHR databases have an important role in postmarket evaluation. With rapid, nearly real-time analyses of recent population-based data, EHR databases are useful data sources to conduct postauthorization safety studies that monitor utilization and potential health risks of new drugs. Researchers, industries, and regulatory agencies may also use EHRs to quantify the impact of risk minimization measures, such as drug safety warnings issued by national drug agencies [165].

Through high-quality clinical and translational research and pharmacovigilance, EHR systems of the future will continue to serve as key platforms for answering important questions and improving the health of patients, communities, and populations.

Acknowledgment

The authors wish to thank the following individuals who provided information about specific databases: Arianna: Valentina Ientile; BIFAP: Miguel Gil García, Miguel Angel Maciá Martínez, Dolores Montero Corominas; HSD: Alessandro Pasqua, Iacopo Cricelli, Francesco Lapi; IPCI: Marcel de Wilde; Pedianet: Carlo Giaquinto, Luigi Cantarutti, Anna Cantarutti; SIDIAP: Bonaventura Bolíbar, Eduardo Hermosilla Pérez, Maria del Mar García Gil, Talita Duarte Salles; VA: Lucy Pandey, Kwan Hur. The authors also thank Molly E. Collins for her valuable editorial assistance.

Nationally representative nonexperimental studies evaluating the clinical effectiveness, safety, and variation in inpatient therapeutic practices were previously few in number. The dearth of these studies was primarily a function of available data sources that provide ample and accurate clinical and medication data in the inpatient setting to allow sufficiently precise and unbiased estimates of treatment effects. Furthermore, the data source needs to allow the researcher to establish temporal sequence of in-hospital exposures and events to facilitate testing of hypotheses about cause–effect relationships. Fortunately, the past two decades have seen a virtual renaissance for the development of databases containing more detailed information on inpatient medication use and clinical outcomes than has historically been captured by previous administrative data. These contemporary databases routinely incorporate, albeit to varying degrees, inpatient laboratory and radiologic test results and electronic health record (EHR) clinical data. This compilation of data from multiple institutions and across multiple settings of care (e.g., office visits, emergency room visits, inpatient hospitalizations) into comprehensive augmented administrative databases has afforded researchers the opportunity to conduct rigorous observational studies to answer important pharmacoepidemiologic research questions.

In this chapter, we first provide a general overview of how inpatient databases can be used to conduct pharmacoepidemiologic research studies. We include descriptions of a variety of existing databases that capture inpatient encounters, including Cerner Health Facts (HF), Pediatric Health Information System (PHIS), Premier Healthcare Database (PHD), and Truven MarketScan. Next, we review the common strengths and weaknesses of using these types of inpatient databases to conduct pharmacoepidemiologic research. Then, we provide illustrative examples of published

Pharmacoepidemiology, Sixth Edition. Edited by Brian L. Strom, Stephen E. Kimmel and Sean Hennessy.

pharmacoepidemiologic studies to demonstrate how these databases can be applied to particular types of research questions (temporal trends, clinical practice variation, adverse event evaluation and therapeutic monitoring, and comparative effectiveness studies). Finally, because inpatient databases continue to evolve rapidly with the inclusion of more information, we present several considerations for future research studies that utilize these valuable resources.

Description

The availability of inpatient and other databases can give pharmacoepidemiologists an opportunity to define and create datasets representing a large number of patients from a multitude of medical institutions across the United States (see also Chapters 12 and 13). In an appropriately performed study, these data can be a valuable primary or adjunctive resource in helping to define the effectiveness or safety of various medications or interventions. The availability of clinical and sometimes laboratory data elements in these databases affords the researcher versatility to answer pharmacoepidemiologic questions related to common or rare medical [1–3]. Data from medical encounters (including those recording in-hospital drug use and outcomes) for the same patient can often be linked longitudinally and the timing of a particular intervention or medication exposure can be ascertained. Formatting the data in such a way allows for the investigation of time variant medication exposures and to assess for outcomes and safety events that may be more distant in time to the actual exposure. As multiple hospitalizations for individual patients can be linked over time, these databases afford the opportunity to analyze both common and rare illnesses that may require frequent contact with the medical system (e.g., malignancy or autoimmune conditions). Furthermore, the continuous collection of data allows researchers to trend the impact of certain illnesses from year to year (e.g., methicillin-resistant *Staphylococcus aureus*). This ability to consider the chronological association of an exposure and outcome rather than just an ecological association has the potential to further strengthen the implication of such an association. Additionally, these databases often contain payment and/or insurance information that enables utilization and cost analyses to be performed. Finally, the datasets are often representative of a large geographic area (nationally or regional) and thus the data provide an opportunity to examine differences by region, including variations in treatment practices for a specific illness [4].

In the US, the common core data elements are similar between databases and the data are typically fully compliant with the Privacy Rule of the US Health Insurance Portability and Accountability Act (HIPAA). While variable names, values, and value labels may differ, each database generally contains the following subject-specific data elements:

- demographic data
- visit data (e.g., office visit, emergency room visit, or inpatient admission)
- ICD-9-CM and ICD-10-CM diagnosis and procedure codes associated with a specific instance of care
- detailed prescription data
- laboratory and radiologic imaging orders
- payment data (Table 14.1).

Each specific database may contain additional unique variables of interest.

A select set of augmented inpatient databases is summarized in alphabetical order below; some of these databases also offer data from other types of healthcare encounters, such as ambulatory or emergency department visits, which are discussed in more depth in Chapters 12 and 13. Table 14.2 provides a more granular comparison of these databases to further emphasize their particular strengths and limitations. Certainly,

Table 14.1 Examples of common data elements.

Data type	Selected data elements
Demographic	Date of birth Race Gender Admission date (or encounter date for outpatient encounters) Discharge date APR-DRG classification
Diagnoses	Discharge (or encounter) diagnosis based on ICD-9-CM or ICD-10-CM codes Order of discharge (or encounter) diagnoses
Pharmacy	Medication ordered Dose of medication Route of administration Day of administration (or date of fill for outpatients) Days supplied for outpatient encounters Pharmacy charge
Procedures	Procedures performed based on ICD-9-CM or ICD-10-CM codes Date of procedure
Supply	Supply ordered Day supply delivered Supply charge
Laboratory	Lab ordered Day lab delivered Lab charge *Availability of actual results varies by database*
Radiologic imaging	Imaging procedure ordered Utilization of contrast media Day imaging procedure was ordered *Availability of results varies by database*
Clinical	Clinical service provided Day service provided Charge associated with service

APR-DRG, all patient refined – diagnosis related groups.

this group of datasets is not exhaustive of all currently available databases containing inpatient data. However, these databases were chosen based on author familiarity and to provide the reader with a reasonable landscape of the different existing options.

Cerner Health Facts® Database

The Cerner Corporation (www.cerner.com) maintains an EHR-derived database called Health Facts (HF). HF is a nationally representative longitudinal database containing clinical, laboratory, and administrative data from more than 116 adult hospital systems across the United States that cumulatively include 84 million patients available for analysis [5]. The contributing hospitals are primarily urban teaching facilities representing a wide range of bed sizes. The database elements are populated from Cerner EHRs and include detailed laboratory results (e.g., source of specimens, timing of collection, and results with reference ranges). Hospitalized patients can be tracked longitudinally post discharge if they return for outpatient or inpatient encounters within the same health system.

Pediatric Health Information System Database

The Pediatric Health Information System (PHIS) (www.childrenshospitals.org) is a comparative pediatric administrative database containing clinical and financial data elements for over 18 million patient encounters cumulatively from 45 not-for-profit, tertiary children's hospitals in the US. The PHIS was created and is managed by the Children's Hospital Association (CHA) (formerly the Child Health Corporation of America, CHCA). CHA is owned cooperatively by free-standing, noncompeting children's hospitals within the US, most of which contribute to the PHIS database. Member hospitals represent most of the major metropolitan areas across the US. Data are updated on a quarterly basis and made available to each hospital through a web-based reporting tool. A deidentified medical record number allows a patient to be tracked across multiple admissions at a

Table 14.2 Comparison of selected inpatient databases that contain medication data.

Data source	Subject sample size (in millions)	Data setting	Underlying sample	Longitudinal patient linking	Laboratory & radiology results[a,b]	Electronic health record data[a,b]	Public insurance[a]	Disability[a]	Mortality[a]	External dataset linkage possible	HIPAA compliant	Relative cost of data	Specific comments

Truven MarketScan [34]	240	OP, ED, IP	Enrollees of employer-based insurances	Yes	Yes	Yes	Medicare Advantage Medicaid	Yes	Yes, if death occurred in medical facility	Yes	Yes	$$$	Includes retail, mail order, specialty pharmacy claims

[a] Typically available for a significantly smaller subset of the core sample, of the order of 10%.
[b] Typically limited to specific set of values, e.g., oxygen saturation, blood pressure, respiratory rate, BMI; not available at all visits by same patient.
[c] PHD does collect microbiology specific data for a select subset of participating institutions.

particular hospital. Assuming that appropriate institutional review board approval has been obtained from the respective institution, a researcher can request that the unique identifiers for patients admitted to their PHIS-affiliated institution be descrambled into the original medical record number. This allows for the possibility of performing additional chart abstraction to supplement or validate the data contained in PHIS.

Premier Healthcare Database

Premier (www.premierinc.com) is a consortium of US not-for-profit hospitals and health systems, created and owned by an alliance of more than 200 hospital and health systems. The Premier Prospective Database (PHD) originated as a merger of Premier with American Health Alliance and Sun Alliance in 1997 and continues to be managed by Premier, Inc. The PHD contains information cumulatively for 147 million patients available for analysis. Since its inception, Premier has collected and managed data from more than 700 hospitals and in so doing captures approximately 20% of all hospitalizations in the United States. Premier member hospitals are located across the US and range in size and setting from small rural to large inner-city hospitals. The PHD represents hospitals that admit both children and adults but is not typically inclusive of free-standing children's hospitals.

Truven Health MarketScan Database

The Truven Health (www.truvenhealth.com) MarketScan Research Databases contain three core databases – Commercial, Medicare Supplemental, and Medicaid – that cumulatively represent 240 million patients available for analysis. Administrative and clinical data are collected for all locations of patient care: inpatient, outpatient, outpatient pharmacy, mail order, and specialty pharmacy. For a subset of the larger database (approximately 10–15%), the claims data can be linked to additional datasets such as productivity management; health risk assessment; dental, laboratory, and medical records; and hospital data – including inpatient medication use – at the deidentified patient level. For example, the Truven MarketScan Hospital Drug Database contains inpatient drug utilization data from hospital discharge records that can be linked to the core databases at the patient level, which allows researchers to study medication utilization across both inpatient and outpatient settings [6].

Strengths

Data Quality

Many existing inpatient databases have been collecting data for over a decade. Each of the databases has data quality assurance processes in place, ensuring that the data they contain meet quality standards. For example, PHIS data audits primarily check for valid entries (e.g., valid ICD-9-CM or ICD-10-CM diagnosis codes) and reasonable patient information (e.g., birth weight). Researchers utilizing these databases and/or contributing organizations typically receive quality and benchmarking reports based on internal and external data audits, including advice on the impact of missing data elements. Finally, although studies using these databases are performed retrospectively, the actual data are collected in a prospective fashion independent of the study itself. This eliminates some of the inherent biases commonly identified for traditional retrospective studies (e.g., recall bias, interview bias or data collection biases).

Data Accessibility

These HIPAA-compliant databases are typically available either commercially (HF, Truven MarketScan) or by membership as a contributing data partner (PHD, PHIS). The cost of data

can depend on the status of the data recipient (e.g., not for profit versus for profit) and the extent of information requested for the desired dataset. Depending on the data vendor, databases can be readily accessed via a virtual network, web interface, or with assistance from the database administrators. By performing defined queries to the parent database, a researcher can "collect" necessary data from years of admissions in a matter of hours to days. Once the data are obtained, additional data cleaning and manipulation are usually necessary to establish a dataset suitable for analysis. For example, the data can be easily transformed into a time-dependent format for survival analysis.

Weaknesses

When using these databases for pharmacoepidemiologic studies, a researcher must consider several common limitations. First, the generalizability of study findings will depend on the degree to which the institutions that contribute to the dataset differ from noncontributing institutions, in terms of clinical practice or patient case mix. For example, the PHIS may accurately reflect practices within a free-standing children's hospital, but may not be generalizable to the typical community hospital. Similarly, the Truven MarketScan databases may allow researchers to ask questions that were previously impossible to answer without laboratory and radiology results, but the findings may not be generalizable because the databases are built from a large, nonrandom convenience sample of insurance claims from large employers [6].

Second, the research questions that these datasets can address may be limited by the lack of certain data elements. For example, study designs could be improved if the results of laboratory or radiographic tests performed on particular days of interest were reliably available (e.g., within 30 days prior to the index date). Even for datasets that include these types of data, laboratory and radiology results are not necessarily available for all patients or for all encounters by the same patient. Similarly, information regarding the precise day within a hospitalization on which a specific diagnosis was made, timing of onset of a complication, or documentation of a patient's condition at the time of admission or discharge are not always available. While alternative approaches can be taken to overcome certain data ascertainment challenges (e.g., creation of a severity of illness metric composed of resource utilization) this is not always possible. The existence of these metrics would enable more sophisticated analysis and allow for the researcher to draw conclusions with stronger inferences.

Finally, the validity of findings may be compromised because of some unknown degree of misclassification regarding several aspects of patient classification.

- Disease status, since the accuracy of clinical diagnoses, encoded as ICD-9-CM and ICD-10-CM codes at the time of hospital discharge, cannot be readily validated across all settings of care, and these diagnostic codes used for billing may not reflect the comprehensive set of clinical diagnoses that were made for a given patient.
- Exposure status, since drug exposure data are based on billing for dispensed drugs, which most likely but not always were administered to the patient.
- Outcome status, for the same reason mentioned above regarding disease status, as well as the possibility of the outcome occurring after hospital discharge and the patient either being readmitted to another hospital or not hospitalized.

Particular Applications

The comprehensiveness of these augmented databases makes them attractive options for testing clinically important pharmacoepidemiologic hypotheses in adult and pediatric patients,

hypotheses that were previously limited by insufficient data. Pharmacoepidemiologists have already utilized these databases to publish important findings that consider the diagnosis of less common outcomes after a pharmaceutical exposure, temporal trends of a particular disease, descriptions in variations of therapeutic practices, reports on therapeutic or drug toxicity monitoring, and comparative effectiveness studies. Examples of both pediatric and adult studies for each of these categories are discussed below.

Temporal Trends

Venous thromboembolism

Venous thromboembolism (VTE), consisting of a blood clot in the medium or large vessel venous circulation, poses several health hazards, including potential subsequent pulmonary embolism, thrombophlebitis, venous stasis, and diminished central venous access. It was hypothesized that the epidemiology of VTE was changing, due on the one hand to increasing use of intravascular venous catheters in ill patients and on the other hand to increasing prevalence of obesity and use of oral contraceptive hormones. Each of these factors, by different mechanisms, predisposes to the formation of VTEs. Data regarding the incidence of pediatric VTE, however, were sparse, consisting of two studies in Canada and The Netherlands, with only three and two years of data from the 1990s. Thus, both studies lacked sufficient precision to detect temporal trends, should they have existed. Furthermore, standard treatment for VTE includes anticoagulation, which with the advent of fractionated low molecular weight heparin in the 1990s has shifted to some degree from warfarin to enoxaparin, but the degree of this therapeutic shift had not been measured.

A study using PHIS, consisting of 41 children's hospitals that contributed data continuously from January 2001 to December 2007, identified (among 2.9 million hospitalizations) 13 449 hospital admissions of 9936 patients, with one hospitalization associated with a VTE diagnosis and 1401 patients with recurrent VTE diagnoses across several hospitalizations [7]. The annual proportion of VTE-associated admissions between 2001 and 2007 rose from 34 to 58 cases per 10 000 admissions, a 70% increase ($P<0.001$). The upward trend was observed across the age spectrum (Figure 14.1A). During the same time period, the proportion of patients diagnosed with VTE who received enoxaparin rose from 29% to 49%, while the proportion receiving warfarin declined slightly from 11% to 10% ($P<0.001$ for both trends) (Figure 14.1B). These findings helped to focus attention on improving the prevention, diagnosis, and treatment of VTE in pediatric patients.

Clinical Practices Variation

Henoch–Schönlein Purpura (HSP)

The most common pediatric vasculitis is HSP, and up to 40% of children with HSP are hospitalized to manage acute disease manifestations such as severe pain, gastrointestinal bleeding, hypertension, or glomerulonephritis [8]. There is no standard approach to diagnose and treat HSP. Clinicians use various laboratory and radiographic tests to make the diagnosis, and the subsequent treatment may include combinations of corticosteroids, antihypertensives, nonsteroidal antiinflammatory drugs (NSAIDs) and opioids, or nothing at all.

In order to describe inpatient variation in practice for HSP, researchers assessed hospitalization records from 36 children's hospitals contained in the PHIS between 2000 and 2007 [3]. Despite controversy regarding the effectiveness of corticosteroids in the treatment of HSP, 56% of patients during an initial hospitalization with HSP received this class of drug, compared to 36% who received opioids, 35% nonsteroidal antiinflammatory drugs, and 11% antihypertensive drugs. Substantial variation in the use of these medications was evident across the hospitals (Figure 14.2), and this variation persisted despite adjustment for case-mix differences

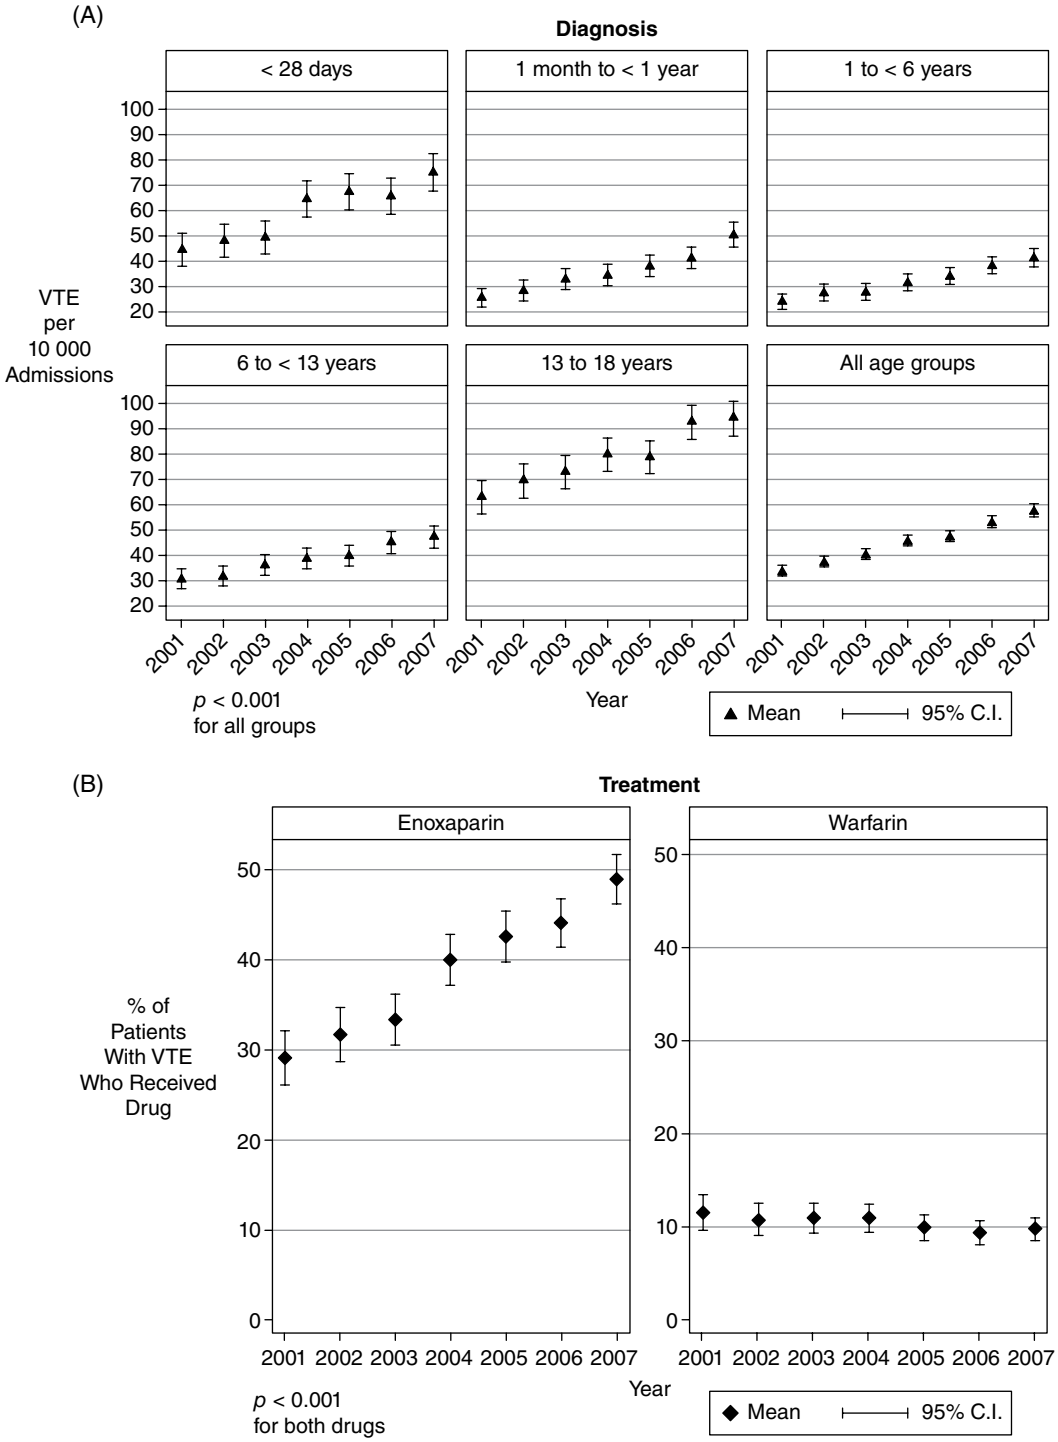

Figure 14.1 Temporal trends in (A) diagnosis and (B) treatment of VTE. *Source:* Adapted from Raffini *et al*. [7] with permission from the American Academy of Pediatrics.

among hospitals. These findings underscored the need for additional pharmacoepidemiologic research to enable the formulation of evidence-based practice guidelines.

Adverse Event Evaluation and Therapeutic Monitoring

Medication Use in Hospitalized Elderly Patients

Older adults tend to respond to certain medications differently from younger patients, with either reduced drug effectiveness or heightened susceptibility to adverse effects. Consequently, it is deemed best to avoid some drugs when treating geriatric patients. The Beers list, first developed in 1991 with multiple subsequent revisions, identifies such drugs to be avoided [9]. This list has been employed by the US Centers for Medicare and Medicaid Services and the US National Committee on Quality Assurance for regulatory and quality of care measurement purposes.

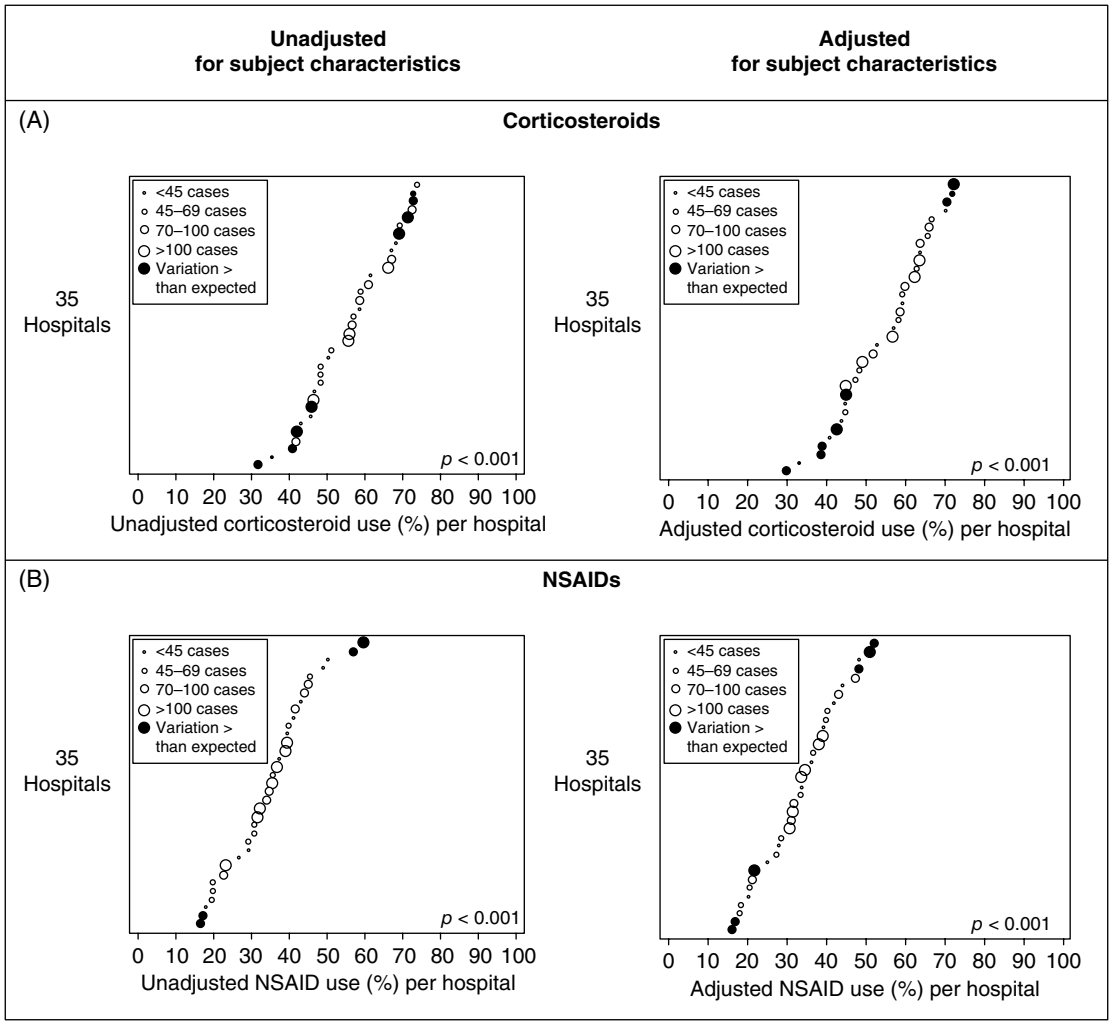

Figure 14.2 Variation in (A) corticosteroid and (B) NSAID use among hospitals in unadjusted and adjusted models. *Source:* Adapted from Weiss *et al.* [3] with permission from Elsevier.

Rothberg et al. used the PHD to identify 493 971 patients over 65 years of age (with a mean age of 78 years) cared for in 384 hospitals from 2002 to 2005 [10]. The study found that 49% of these inpatients were exposed to at least one potentially inappropriate medication (PIM, as defined by the 2002 Beers list), with 6% receiving three or more PIMs. The most commonly used PIMs were promethazine, diphenhydramine, propoxyphene, clonidine, amiodarone, and higher doses of lorazepam. Compared to internists, geriatricians were less likely to prescribe high-severity PIMs (adjusted odds ratio [AOR] 0.69; 95% confidence interval [CI] 0.61–0.78) as were hospitalists (AOR 0.90; 95% CI 0.84–0.96). However, cardiologists (AOR 1.32; 95% CI 1.28–1.36) and pulmonologists (AOR 1.10; 95% CI 1.05–1.15) were more likely to prescribe these high-severity PIMs. Of note, seven hospitals with more than 300 patients each had no PIMs dispensed to any of their elderly patients, suggesting a possible mechanism for future quality improvement efforts. Alternatively, targeted management of just three drugs (promethazine, diphenhydramine, propoxyphene) by hospital formularies or pharmacies would eliminate the use of PIMs in 24% of the geriatric patients.

This study example not only highlights the potential to identify areas for concern but also represents an opportunity to efficiently direct resources to effect a change.

Death and Cefepime Exposure

Cefepime is a fourth-generation cephalosporin antibiotic with broad-spectrum gram-positive and gram-negative activity. It is available as an intravenous formulation and is often used as empiric therapy for hospitalized patients with suspected bacteremia and sepsis. The administration of chemotherapy to children with cancer often renders them neutropenic with a high risk for bacterial infections. When a child becomes febrile during a period of neutropenia, it is recommended that they be admitted to hospital for initiation of broad-spectrum antibiotics [11]. In many instances, cefepime is the primary antibiotic utilized for these fever and neutropenia episodes. In 2007 a metaanalysis was published that questioned the safety of cefepime relative to other broad-spectrum antibiotics. The study pooled mostly adult randomized trials from various patient populations and found an increased risk of all-cause mortality in patients receiving cefepime compared to those receiving other beta-lactam antibiotics [12].

These data raised significant concern about the safety of cefepime. However, uncertainty existed regarding the true implications of the results from the metaanalysis for multiple reasons. First, the pooled studies included patient populations that were heterogeneous and included primarily adult studies; second, for each included study, mortality was not a primary endpoint, which called into question the completeness of this data point as the primary endpoint for the metaanalysis; lastly, a plausible mechanism for the increased risk for mortality secondary to cefepime was not identified. It was clear that additional data and analyses were needed to further evaluate the questioned association, especially among pediatric patients.

Therefore, using the PHIS database, a retrospective nationally representative homogeneous cohort of pediatric patients with acute myeloid leukemia (AML) was assembled. Children with AML were chosen for this analysis as they have frequent episodes of fever and neutropenia resulting in significant exposures to broad-spectrum antibiotics such as cefepime. Additionally, AML unfortunately carries a high mortality rate, thus establishing a cohort with a significant exposure to cefepime and more frequent rate of the outcome of interest (death). In total, 917 children in the PHIS database were found to have an ICD-9 code and chemotherapy receipt consistent with AML between 2002 and 2006. Table 14.3 displays the demographic characteristics of this PHIS-created cohort in comparison to the demographics of a cohort of patients with AML enrolled in a prospective chemotherapy trial sponsored by the Children's

Table 14.3 Comparison of demographic variables from a pediatric AML cohort created retrospectively in PHIS and another cohort assembled in a prospective chemotherapy trial [13,14].

	Retrospective PHIS AML cohort [21] (n=917)	Prospective AML chemotherapy trial [20] (n=492)

Oncology Group. As the table illustrates, the two cohorts have similar distributions of gender, age, and race, establishing some external validity to the cohort created retrospectively via the PHIS [13].

After extracting all admission information for each patient for up to one year from diagnosis, a survival dataset was created. After adjusting, in a Cox regression model, for potential confounding factors such as age, gender, race, severity of illness, and variation in proportional hazards, there were no identified differences in all-cause in-hospital mortality in the year after treatment between patients recently exposed to cefepime versus those exposed to ceftazidime (hazard ratio [HR] 1.29; 95% CI 0.53–3.15), an antipseudomonal penicillin (HR 1.08; 95% CI 0.44–2.66), or carbapenem (HR 1.03; 95% CI 0.45–2.33) [14].

These results had an immediate impact by giving pediatric clinicians reassurance in the continued use of cefepime in their patient population. In fact, the data from this study were shared with the US Food and Drug Administration (FDA), which at the time was performing a review of the results of the initial metaanalysis. The FDA's own review and metaanalysis did not identify an increased risk of death associated with cefepime overall, nor did an additional pediatric-specific metaanalysis and systematic review [15].

Comparative Effectiveness

Antibiotics for Chronic Obstructive Pulmonary Disease

It has been estimated that as many as 24 million US residents suffer from chronic obstructive pulmonary disease (COPD) [16]. Acute exacerbations of COPD require inpatient care, resulting in as many as 600 000 hospital admissions annually, totaling an estimated $20 billion in direct costs each year [17]. Infection is a primary contributor for such exacerbations. Prior iterations of COPD treatment guidelines supported antibiotic administration at the time of admission in those COPD exacerbations that are associated with purulent sputum, an increase in sputum production, or an increase in dyspnea [18–20]. At the time, this recommendation for antibiotics was based on limited data from relatively small randomized trials, most of which were performed close to two decades previously [21].

A retrospective cohort of patients hospitalized between January 1, 2006 and December 31, 2007 for an acute exacerbation of COPD was

assembled using the PHD. Patients were included in the analysis if they were at least 40 years old, had a principal ICD-9-CM code for an acute exacerbation of COPD and did not have other infectious diagnoses (e.g., pneumonia, cellulitis). Using this cohort, the investigators compared the effectiveness of antibiotics in the first two days of admission to no antibiotics in those first two days [16]. The primary outcome for the analysis was a composite measure of progression to mechanical ventilation, in-hospital mortality, and readmission within 30 days of admission.

The comprehensive analyses included various multivariable models which utilized propensity scores (see Chapter 43) to balance measured baseline measured confounders that may have contributed to the clinicians' choice for starting or not starting antibiotics in the first two hospital days. Additionally, a logit link generalized estimating equation excluding antibiotic status was implemented to predict the risk of treatment failure so that the impact of antibiotics could be evaluated across three strata of predicted risk of treatment failure.

The cohort consisted of 84 621 patients, 79% of whom received antibiotics in the first two hospital days. In the propensity score and covariate adjusted model, the resultant odds ratio was 0.87 (95% CI 0.82–0.92) favoring early antibiotic administration. This apparent beneficial effect of early antibiotic use was most pronounced among those patients deemed to have the highest risk for treatment failure. Importantly, the presence of increased or purulent sputum production, as reflected by a ICD-9-CM procedure code for sputum testing on hospital day 1 or 2, did not alter the point estimate; similarly, the presence of severe dyspnea, as reflected by a ICD-9-CM procedure code for arterial blood gas measurement on day 1 or 2, did not alter the point estimate. This study identified a potentially important benefit for early antibiotic administration in the setting of COPD exacerbation. Furthermore, the results suggest that in contrast to the recommendations contained in prior iterations of the guidelines, antibiotics were associated with improved outcomes in patients requiring hospitalization.

Although this study cannot be considered equivalent to a large randomized controlled trial, the importance of its results to guiding clinical care should not be underestimated. This was an efficient and relatively inexpensive approach to establish a large cohort to analyze the utility of antibiotics for acute exacerbations of COPD. The statistical analysis was thorough and the results provide clinicians with reasonable estimates of the benefits for early antibiotic initiation in this group of patients.

Activated Protein C and Sepsis

Sepsis has been and will continue to be a major cause of inpatient morbidity and mortality. It has been estimated that close to 10% of all intensive care unit admissions are sepsis related, that sepsis-associated mortality ranges from 30% to 50%, and that the estimated annual cost for sepsis approaches $17 billion per year in the United States [22–24]. Given the high mortality of sepsis, researchers and clinicians have attempted to identify effective therapies to improve outcomes. One such therapy, human recombinant activated protein C (APC), has been evaluated in various prospective trials with mixed results [25–27]. Furthermore, these trials raised a concern about hemorrhagic complications from the APC therapy. Additional randomized controlled trials were being planned but those results will be several years in the making, leaving clinicians without further guidance on their current patients.

Therefore, a retrospective study using the PHD was performed to investigate the effectiveness of APC in reducing in-hospital mortality due to sepsis and, importantly, to report the rates of hemorrhagic complications [28]. The study included a cohort of patients admitted to one of 404 hospitals between June 1, 2004 and June 30, 2006. Patients were deemed to have sepsis if they had an ICD-9-CM code consistent

with sepsis, were admitted to an intensive care unit and received antibiotics and vasopressors within the first two days of admission.

The investigators identified 33749 patients meeting the study eligibility criteria, of which 4.7% received APC in the first two hospital days. A multivariable analysis including patient and hospital characteristics was utilized to define each patient's propensity to be given APC (see Chapter 47). Subsequently, a multivariable model comparing patients treated and not treated with APC matched by propensity score was performed, suggesting a benefit of APC on mortality (oods ratio [OR] 0.87; 95% CI 080–0.95). Interestingly, the rates of gastrointestinal bleeding, intracranial hemorrhage, and major transfusions were similar between those treated with APC and those not treated. While the results from this study do not negate the importance of previous and concurrently active randomized controlled trials, this well-done nonrandomized study provided both timely and relevant data regarding the treatment of sepsis in routine clinical practice.

The Future

Inpatient databases will continue to rapidly evolve given the ever-increasing types and volume of available clinical data. The size, structure, and complexity of these data will require researchers to employ creative new approaches and cutting-edge techniques from the fields of pharmacoepidemiology, biostatistics, and data science, including advanced approaches for addressing confounding in observational studies, methods for longitudinal data analysis, procedures for exploratory data mining and machine learning, and techniques for data visualization [29,30]. As analytic capabilities advance, pharmacoepidemiologists will have unprecedented opportunities to ask and answer new and innovative research questions across broad patient populations.

Several of the database options reviewed in this chapter already include internal linkages to certain types of novel patient data; additionally, the data in many of these databases can also be combined or merged with other novel data sources, such as a data source containing patient-specific data from emergency department or ambulatory clinic encounters, or about hospitals' processes of care. For example, a study of infection control practices in children's hospitals supplemented PHIS data with data regarding each hospital's level of use of alcohol-based hand hygiene gel (gathered by a survey). The resultant dataset was used to demonstrate a reduced odds of nosocomial gastrointestinal infections (AOR 0.64; 95% CI 0.49–0.85) among children cared for in hospitals where the hand gel was present [31]. Such data linkages will continue to increase in the era of improved capture of EHR data, patient-reported outcomes data, and, perhaps not so far off in the future, the results of pharmacogenomic testing.

Additionally, improved generalizability may result from analyzing the same pharmacoepidemiologic question using each of the different available databases. Because each of the discussed databases represents different medical institutions, and thus different patient populations, such an approach would help to prove the generalizability of certain outcomes or to identify important differences in outcomes that may be attributable to variability across the types of medical institutions. For example, the data from the PHIS and PHD can be combined to provide sampling coverage of both children's hospitals (as represented in the PHIS and to a much lesser extent in the PHD) and general hospitals (as represented only in the PHD), thereby presenting a more complete and accurate representation of the entire realm of pediatric hospital care. Likewise, analyzing multiple inpatient databases that include the entire range of commercially and publicly insured subjects will ensure more generalizable results that improve pharmacotherapy and enhance drug safety for the largest possible number of patients.

Studies Involving *Ad Hoc* Data Collection

15

Event Monitoring in the UK

Vicki Osborne and Saad A.W. Shakir

Drug Safety Research Unit, Southampton, UK

Pharmacovigilance involves the detection, assessment, understanding, and prevention of adverse effects attributable to medications, in addition to any other problems related to medication use [1]. Pharmacoepidemiology is an important source of evidence for pharmacovigilance, the goals of which are to enhance patient care and safety and to provide evidence for the effective assessment of benefit–risk profiles of medications [1]. The birth of modern-day pharmacovigilance arose from the consequences of thalidomide, which was licensed in the UK in 1958 and withdrawn in 1961 [2,3]. Globally, an estimated 8000–10 000 children were born with phocomelia to mothers who took thalidomide during pregnancy for morning sickness [4]. The length of time taken to identify the safety signal and establish causality was the stimulus for establishing pharmacovigilance systems that are still in use today to monitor for suspected adverse drug reactions (ADRs).

In 1964, the Committee on Safety of Drugs (CSD) in the UK was formed (which later became the Committee on Safety of Medicines [CSM] and is now the Commission on Human Medicines [CHM]), which subsequently established a national spontaneous reporting system, known as the Yellow Card system (see Chapter 10). This was followed by the Medicines Act which was signed into law in the UK in 1968, requiring efficacy, safety, and quality to be established with all marketed medications [5]. The reasons for monitoring postmarketing drug safety were summarized in 1971 in a report of the CSD [6]:

> No drug which is pharmacologically effective is entirely without hazard. The hazard may be insignificant or may be acceptable in relation to the drug's therapeutic action. Furthermore, not all hazards can be known before a drug is marketed; neither tests in animals nor clinical trials in patients will always reveal all the possible side effects of a drug. These may only be known when the drug has been administered to large numbers of patients over considerable periods of time.

Past experience has shown that unexpected hazards can occur with older medications as well as newly licensed drugs and this evidence provides support for the concept of "postmarketing surveillance." The limitations of premarketing studies for examining safety of medications have been outlined previously (see Chapter 1) and include, but are not limited to, sample size, duration of study, and the patient selection process. Therefore, there has been general agreement for more than 50 years on the importance of postmarketing adverse

Pharmacoepidemiology, Sixth Edition. Edited by Brian L. Strom, Stephen E. Kimmel and Sean Hennessy.

event monitoring and postmarketing safety studies in providing complementary information on the clinically necessary understanding of the safety of a drug.

Study designs for postmarketing surveillance include both spontaneous reporting systems and other event monitoring methods. There are many advantages to spontaneous reporting systems, including the ability to identify rare ADRs, though limitations of such systems have been noted previously [7]. While spontaneous reporting methods are an important part of modern-day pharmacovigilance systems, nonpassive studies which actively monitor for events are also needed. Justification for active studies can be found through historical events such as in the case of practolol, which was licensed in 1970 by the CSD for the management of angina pectoris and cardiac dysrhythmias [8]. It was commercially a very successful drug but was associated with a rare condition known as oculomucocutaneous syndrome which was not detected by spontaneous reporting systems as the symptoms were not initially linked: rash, dry eyes, and sclerosing peritonitis [8,9]. The condition was eventually detected and the drug withdrawn in 1975 [8], although the five-year time period to detect this safety signal may have been avoided with the use of an active event monitoring system.

In June 1983, the CSM established a Working Party on Adverse Reactions which outlined a need for a prescription-based monitoring process to provide a method for monitoring new drugs.

The Postmarketing Drug Surveillance Research Unit was established in 1980 by Professor William Inman, to address the need for active drug monitoring [10,11]. Financial assistance for this endeavor was provided by the Office of the Chief Scientists of the Department of Health and Social Security; while it was initially formed as part of the Department of Medicine of the University of Southampton, the unit was reconstituted as a charitable trust in 1986 and the name was changed to the Drug Safety Research Unit (DSRU) which has remained to the present day. The DSRU event monitoring methodology is based on the fundamental concept of monitoring events regardless of relatedness to drug exposure, as first proposed by Finney in 1965 [10]. Over the years, this method has evolved from prescription event monitoring (PEM), to modified PEM (M-PEM) to the most recent design, specialist cohort event monitoring (SCEM). While PEM was retired by the DSRU in recent years, M-PEM and SCEM are still in use today.

The event monitoring designs used by the DSRU are the only national systems in the UK developed solely to monitor the utilization and safety of recently marketed medicines available to all primary care physicians (general practitioners [GPs]), besides the Yellow Card system. It is important to note that there are differences in the type of data collected in event monitoring compared with the Yellow Card system, the most important being that the majority of events reported with event monitoring will *not* be attributable to the drug (i.e., not adverse reactions) and should *not* be treated as spontaneous ADR reports. Nevertheless, both postapproval systems are able to generate hypotheses regarding safety signals. Event monitoring provides estimates of common to rare events while the Yellow Card scheme is able to detect signals of very rare events because of the size of the population being monitored. Thus, the Yellow Card spontaneous reporting system and event monitoring provide complementary information on hazards associated with medicines.

Description

Design and Source Data

Two different approaches are used to identify patients within M-PEM and SCEM studies, though the fundamental data collection design remains the same (see also subsection on Data Collection).

M-PEM Design and Data Source

Modified PEM is very similar to the original PEM method in that it uses an observational cohort design for active surveillance of targeted medicinal products in England. Products that are selected for study by M-PEM are usually new to the market, although established products can be monitored with specific justification; for example, a new indication or extending usage to a new population will usually require evidence from a postmarketing study to be submitted as part of the risk management plan (RMP). M-PEM utilizes the structure of the UK National Health Service (NHS), whereby all individuals are registered with a GP, who provides primary medical care and acts as a gateway to specialist and hospital care. Medical records (in paper and electronic form) are held for each individual within each general practice, are generally lifelong and are transferable among general practices when a patient moves to a new area. Medical records data include not only information obtained in primary care but information about all contacts with secondary and tertiary care, including letters from specialist clinics, hospital discharge summaries, results of laboratory and other investigations and information on GP-issued NHS prescriptions for the medicines the GP considers medically warranted.

Individuals are identified in M-PEM where they have received an NHS-issued prescription for the drug of interest. These prescriptions will be dispensed to patients at pharmacies with an NHS contract. Pharmacists are required to submit information on dispensed prescriptions for medications to a central prescription processing center within the NHS Business Services Authority (NHSBSA), formerly the Prescription Pricing Division (PPD). Reimbursement through the NHS can only be processed by following this procedure. Due to a long-standing agreement and via secure file transfer, the DSRU is provided with electronic copies of all those prescriptions issued throughout England for the drugs being monitored on a monthly basis (see also subsection on Ethics and Confidentiality). Since the NHSBSA only handles the remuneration and reimbursement to dispensing contractors across England, data are not available for Scotland, Wales, and Northern Ireland; however, where information is required from these areas, SCEM methodology can be utilized (see SCEM subsection).

The NHSBSA receives remuneration from the DSRU for providing prescription data. These data are reconciled with GP identifier records available from the NHS Organization Data Services (ODS), to obtain prescriber contact details and, with existing records on the DSRU customized database, to ascertain whether the data pertain to an existing eligible patient already within the DSRU database. It should be noted that all relevant prescriptions are collected, irrespective of whether they are a new or repeat course. Repeat prescriptions can be identified and separated from initial prescriptions for a medication for individual patients.

The DSRU arrangement with the NHSBSA operates for the necessary length of time required to collect a sufficient number of prescriptions to identify the required study sample size of patients. Since collection of dispensed prescription data usually begins immediately after the new drug has been launched, the eligible patient study population can be described either as an inception cohort (where the study drug is a new entity) or a new user cohort (where the drug under study might be a revised formulation and the patients may be regarded as "switchers" and exposed to the new formulation for the first time). In addition, as the data are sampled at national level, the cohort is representative of the population registered within the NHS in England.

SCEM Design and Data Source

To complement the already well-established technique of M-PEM, the DSRU developed

SCEM in response to the need to provide safety studies in secondary care and other specialist settings. SCEM methods allow the collection of exposure and outcome data on patients identified in other healthcare settings, such as hospitals and secondary care settings. By capturing data in specialist care through SCEM studies, safety data is collected on those who may be more complex in terms of underlying disease, co-morbidities, and concomitant medications than in the general disease population, as seen in M-PEM. SCEM methods differ from M-PEM methods in that patients are not identified via dispensed prescription data.

The DSRU works collaboratively with the UK National Institute of Health Research (NIHR) Clinical Research Networks (CRNs), which are associated with undertaking research with health service providers (trusts) at a national level. Prescribers are identified through these networks and patients are subsequently identified by these specialist prescribers and their informed consent is obtained for participation. Research personnel are used to aid with recruitment of prescribers to the study, although only prescribers have any contact with patients. As with M-PEM, data are sampled at national level and research personnel can be used to recruit in all areas of the UK, where required. In addition, the distribution of prescribers and patients is examined in further detail to ensure representativeness. Recruitment for a study continues until the desired sample size is achieved. A comparison of the M-PEM and SCEM study designs is provided in Figure 15.1.

Ethics and Confidentiality

Both M-PEM and SCEM studies are conducted according to national and international guidelines for ethical conduct of research involving human subjects [12–14]. Following the principles of good practice [15,16], a full research protocol is written for each study to monitor and research the safety of medicines. Where these protocols describe a postauthorization safety study that forms part of the EU RMP, European Medicines Agency guidelines are adhered to [17]. For M-PEM studies, under Section 251 of the NHS Act 2006, the DSRU has received support from the Ethics and Confidentiality Committee of the National Information Governance Board to gain access to and process patient identifiable information without consent for the purposes of medical research. In contrast, for SCEM studies, informed consent is obtained from each patient

	M-PEM Study	**SCEM Study**
Prescribers	Primary Care	Specialist Care
Design	Observational cohort	Observational cohort
Treatment	Naturalistic (non-interventional)	Naturalistic (non-interventional)
Period of Observation	Longer period (e.g. 12 months)	Shorter period (e.g. 12 weeks)
Ethics	No patient consent required	Patient consent required
Risk	Less likely to capture high risk patients	More likely to capture high risk patients

Figure 15.1 Comparison of M-PEM and SCEM study designs.

prior to participation in the study. A single UK-wide ethical opinion is applied for from the National Research Ethics Service and local Research and Development (R&D) approval is also required at each participating NHS trust. Considerable care is taken to preserve the confidentiality of patient data and the DSRU databases are fully protected. Patient information security is assured through strict measures guided by DSRU policies. Furthermore, highly confidential patient data (name and address) supplied by the NHSBSA for M-PEM studies are made anonymous through use of a unique study identifier code assigned by the DSRU and separately one supplied by the GP on the questionnaire at the point of return. These codes are used for any subsequent correspondence.

Data Collection

Process for M-PEM and SCEM

Relevant study data are currently collected via a manual process (as summarized in Figure 15.2).

The process for data collection in M-PEM and SCEM studies is usually the same, though in SCEM studies there is often a questionnaire sent at baseline in addition to the main study questionnaire. For both study designs, after a protocol-specified time interval (range 3–12 months) from the date of the first prescription for each eligible patient, questionnaires are sent to prescribers. For M-PEM studies, these questionnaires are sent by surface mail in monthly batches according to the chronological order of prescription issue date to those GPs who prescribed the newly marketed medicine, continuing until the target sample size is achieved. Prepaid envelopes are provided for return by surface mail. For SCEM studies, questionnaires are usually printed by the prescriber directly from the study website and returned via prepaid surface mail. However, the process is now in place for data to be entered electronically into a dedicated website by doctors in SCEM studies.

Historically, PEM questionnaires were commonly referred to as "Green Forms" because of their color. These were intended to be simple in order to expedite data collection in order to enhance surveillance and encourage response in the interest of drug safety, especially given there was no remuneration to respondents. Given that M-PEM and SCEM studies provide remuneration to prescribers, these questionnaires are more detailed than the original Green Forms and are no longer green in color. The number of M-PEM study questionnaires sent on a monthly basis to each GP is limited (maximum of four per GP), but questionnaires for patients excluded because of this rule are subsequently included in the following month. As illustrated

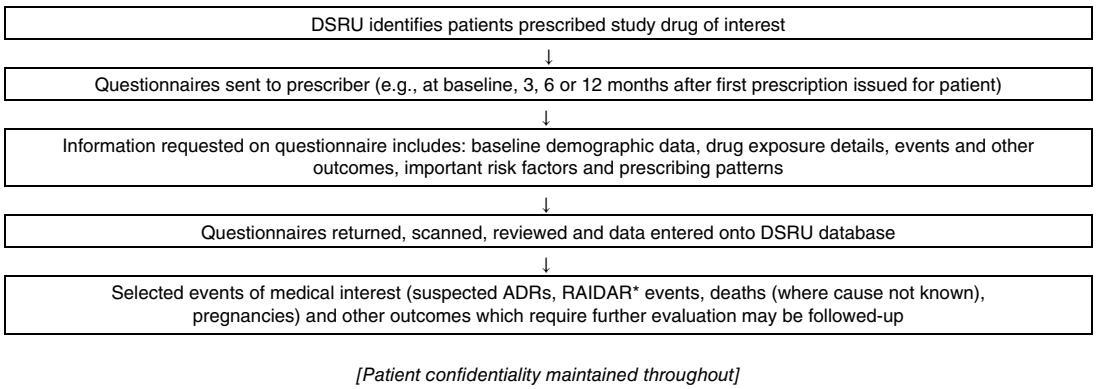

Figure 15.2 The event monitoring process. *RAIDAR, Rare and Iatrogenic Adverse Reactions.

Box 15.1 Definition of an event in event monitoring

Any new diagnosis, any reason for referral to a consultant or admission to hospital, any unexpected deterioration (or improvement) in a concurrent illness, any suspected drug reaction, any alteration of clinical importance in laboratory values, or any other complaint that was considered of sufficient importance to enter into the patient's notes.

in Figure 15.3, the standard Green Form PEM questionnaires were used to request data on patient demographics (age, gender), indication for treatment, prescribing information (dose and duration), reasons for stopping (if stopped), details of all significant events (for definition see Box 15.1) that have been recorded in patients' medical records during a specific time period after starting the PEM study drug, and cause(s) of death if applicable.

Questionnaire Design

In parallel with developments in the field of pharmacoepidemiology in general, event monitoring questionnaires have evolved over time to extend the range of data that could be collected on drug utilization patterns as well as important risk factors for selected outcomes of interest. In recent years, further expansion and modification of the nature and type of information requested on questionnaires for the whole cohort have led to the adoption of more complex forms; these are currently in use for both M-PEM and SCEM studies. Customized questionnaires have been developed to permit a wider exploration of more specific safety issues through collection of relevant information, while the underlying process remains the same.

Figure 15.4 illustrates the first page of the M-PEM questionnaire for lumiracoxib. Such customized questionnaires are designed to accommodate the increasing need for supplementary information which is relevant to a number of outcomes. Specifically, important identified and potential risks from the RMP, in addition to important missing information, can be explored. As a result, M-PEM and SCEM studies can explore a range of research questions, such as safety in special populations, drug utilization, and targeted surveillance of specific safety concerns. Because of the increased complexity of event monitoring questionnaires, prescribers receive remuneration for returning completed customized forms. Completion of these forms by prescribers remains voluntary.

Supplemental Information

During the course of any study, selected medical events (as described in Box 15.2) and other outcomes undergo preliminary evaluation for purposes of summarizing common or unusual features/manifestations, clinical course, and prognosis of conditions. Supplemental information may be sought from prescribers using targeted questionnaire(s), where such information is not provided on the main study questionnaires. For example, where a cerebrovascular accident (CVA) is reported, a specially designed questionnaire can be sent to obtain detailed information on the type of CVA, lab results, and risk factors for the event. Such questionnaires are sent within weeks of the initial review but in some cases, where an objective of a study might be to monitor events with a long latency, a lag period may be introduced, for example 12 months from the date of first occurrence of the event of interest, such as androgenic manifestations with testosterone use in women. However, the lag period can be increased significantly for studying delayed outcomes, such as reports of cancer. Remuneration is paid to physicians in appreciation of the time taken to complete these supplementary questionnaires.

Box 15.3 lists the medically serious events that have been associated with the use of medicines, as compiled by the DSRU. Cases of these events routinely undergo further evaluation (see

We collect EVENT data

An EVENT is any new diagnosis, any reason for referral to a consultant or admission to hospital, any unexpected deterioration (or improvement) in a concurrent illness, any suspected drug reaction, any alteration of clinical importance in laboratory values or any other complaint which was considered of sufficient importance to enter in the patient's notes.
Example: A broken leg is an EVENT.

Please indicate if you suspect an EVENT to be an adverse reaction to a drug.

These studies are conducted in accordance with the results of authorative discussions and the International Ethical Guidelines for Biomedical Research Involving Human Subjects prepared by the Council for International Organizations of Medical Sciences (CIOMS) in collaboration with the World Health Organization (WHO), Geneva 1993. The method of study also complies with the Guidelines on the practice of Ethics Committees in Medical Research Involving Human Subjects, as issued by the Royal College of Physicians of London (August 1996)

➧ *Or Died?* **Yes** ☐ ➧ *Please complete questionnaire if possible and provide details of death -* ***Question 13*** *overleaf*

3. Please specify the clinical prescribing indication(s) for lumiracoxib (tick all that apply)

Osteoarthritis (OA): OA Knee ☐ OA Hip ☐ OA Other ☐
Acute pain relief from surgery: Orthopaedic ☐ Dental ☐
Primary Dysmenorrhoea ☐

Other: please specify.....

4. Please indicate the reason for prescribing lumiracoxib for the above indications: (tick all that apply)

Prescriber decision ☐ Patient preference ☐
Initiated in secondary care ☐ Prescribing formulary ☐
Non-response to previous NSAID:
COX-2 selective inhibitor ☐ Other NSAID ☐
Intolerance to previous NSAID:
COX-2 selective inhibitor ☐ Other NSAID ☐

Other: please specify.....
.....

5. Please provide the following data regarding stopping treatment with lumiracoxib

Has treatment stopped? Yes ☐ No ☐ DK ☐
if Yes please provide:
a) Stop date ___/___/___ and/or last prescription date ___/___/___

Reason for stopping:.....
.....

PATIENT DATA

6. Please specify your patient's ethnicity, if known:

Caucasian ☐ Asian (Indian sub-cont) ☐ Hispanic ☐
Black ☐ Asian (China/Japan) ☐

Other.....

7. At the time of starting lumiracoxib, please specify this patient's status regarding general health:

Body Mass Index.....kg/m² DK ☐
Smoking status: Current ☐ Past (ex) ☐ Never ☐ DK ☐
Alcohol consumption: Occasional ☐ Excessive* ☐ Never ☐ DK ☐
*Male > 21 units/week; Female > 14 units/week

8. Prior to starting lumiracoxib did the patient have a history of the following: (tick all that apply)

	Yes	No	DK
Hypersensitivity reactions (e.g. angio-oedema/urticaria)	☐	☐	☐
Serious skin reactions (e.g. erythema multiforme)	☐	☐	☐
Excessive* alcohol use	☐	☐	☐

*Male > 21 units/week; Female > 14 units/week

9. At the time of starting lumiracoxib did the patient have any of the following: (tick all that apply)

	Yes	No	DK
Dyspeptic or other upper gastrointestinal conditions	☐	☐	☐
Cardiovascular disease (e.g. hypertension)	☐	☐	☐
Coronary disease (e.g. arrhythmia/infarct/cardiac failure)	☐	☐	☐
Cerebrovascular disease (e.g. CVA/TIA)	☐	☐	☐
Abnormal renal function/renal disease	☐	☐	☐
Diabetes	☐	☐	☐
Rheumatoid arthritis	☐	☐	☐
Abnormal liver function/hepatic disease*	☐	☐	☐

*Because of recent prescribing restrictions for lumiracoxib, we are collecting additional information on liver function tests and relevant risk factors **(see q14 and 15)***

10. Was this patient taking any of the following medications in the periods indicated: (tick all that apply)

	In 3 months prior to starting			During treatment		
	Yes	No	DK	Yes	No	DK
Antacids	☐	☐	☐	☐	☐	☐
Histamine $_2$ Antagonists / PPIs	☐	☐	☐	☐	☐	☐

EVENT DATA

An EVENT is any new diagnosis, any reason for referral to a consultant or admission to hospital, any unexpected deterioration (or improvement) in a concurrent illness, any suspected drug reaction, any alteration of clinical importance in laboratory values or any other complaint which was considered of sufficient importance to enter in the patient's notes. Example: a broken leg is an EVENT.

IMPORTANT: please indicate any events reported to Commission on Human Medicines (CHM) [previously known as Committee on Safety of Medicines (CSM)]or manufacturer

11. Please list any events after starting treatment with lumiracoxib?

None ☐

Event date	Dose (mg/ day)	Event

12. Please list any events within 3 months after stopping lumiracoxib?

None ☐

Event date	Event

13. If your patient has died please provide:

Date of death:
Cause of death as recorded on death certificate:
1a
1b
2

LIVER FUNCTION

14. On starting lumiracoxib, please specify if this patient had any specific risk factors for abnormal liver function/hepatic abnormality?

	Yes	No	DK
Medical conditions			
Malignancy	☐	☐	☐
Autoimmune Disease	☐	☐	☐
Chronic Viral Infection (e.g Hepatitis B/C, EBV)	☐	☐	☐
Iron or copper overload	☐	☐	☐
Other conditions:	☐	☐	☐

If Yes to Other conditions, please specify:.....

.....

.....

.....

Concomitant medications

Paracetamol	☐	☐	☐
DMARDS (e.g methotrexate)	☐	☐	☐
Biologics (e.g beta-interferon)	☐	☐	☐
Other medications (prescribed, OTC, herbal products:	☐	☐	☐

If Yes to Other medications, please specify:.....

.....

.....

.....

15. Please provide liver function lab test values in the table below / send copies of reports as applicable on starting lumiracoxib and during treatment.

***NB** Please include **normal ranges** as they are vital for interpretation.*

	At start*	During treatment			After stopping	Normal range (Units)
		(1)	(2)	(3)**		
Date						
Bilirubin						
AST						
ALT						
GGT						
Alk Phos						
Albumin						

**nearest to the lumiracoxib start date*

*** If test results reported on more than three occasions during treatment please provide on a separate sheet as appropriate*

Thank you for your co-operation.
Your time and effort is greatly appreciated.

Please return in the FREEPOST envelope provided.

Figure 15.4 (Continued)

section on Qualitative Evaluation of Important and Medically Important Adverse Events). All pregnancies reported during treatment or within three months of stopping the drug are followed up using a supplementary questionnaire to determine the outcome of the pregnancy. All reported deaths for which no cause is specified are also followed up to try to establish the cause of death.

Data Processing

Each event monitoring questionnaire returned for each patient is scanned onto the database and electronic copies are reviewed by the DSRU research fellow monitoring the study. This initial review aims to identify possible serious ADRs or events requiring action, such as external communications or expedited follow-up. In accordance with DSRU procedures, any events of interest or deaths reported on questionnaires require further review by a clinical research fellow who will determine if supplementary information is required. It should be noted that event monitoring is designed to capture all events, regardless of attribution, unlike spontaneous reporting systems which collect events for which there is often an inherent assumption of a causal relationship with the treatment in the mind of the reporter. These events may be expected or unexpected and may be either serious or nonserious.

For each patient, trained coding staff prepare a computerized, longitudinal, chronological record of demographic, exposure, and outcome data associated with starting the study drug. All events reported on questionnaires are coded onto a DSRU database using MedDRA® [18]. This hierarchical dictionary, which is arranged by system-organ class, groups associated lowest level terms (terminology used by the prescribing physician) under preferred terms; similarly, related preferred terms are grouped under further broader terms (high-level term and higher level group term) [18]. Selected attributes can be linked to selected data; for example, an event can be flagged as a suspected ADR if the GP specified that the event was attributable to a drug (either the study drug or another drug taken during the study observation period). Other examples include if the event had a fatal outcome or if the event was a reason for stopping.

Good clinical data management is a high priority. The DSRU has a set of rules and processes associated with the conduct of all studies which undergo regular review. Data quality is assured through a number of methods based on error prevention, data monitoring, data cleaning, and documentation. For example, data cleaning is undertaken to screen for errors, missing values, or extreme values and to diagnose their cause.

Sample Size and Duration

As summarized in Chapter 4, the ability to detect an adverse event in a cohort study is dependent on the expected incidence rate of the adverse event in those exposed to the drug, the background rate in those not exposed to the drug, and the total number of patients. In original PEM studies, the sample size of 10 000 exposed patients was driven by PEM's original objective to bridge the gap between randomized trials and spontaneous reporting regarding sensitivity to rare and uncommon events that can be achieved by including a larger sample size than premarketing studies. Based on the general 'rule of 3' (see Chapter 4), it follows that the larger the sample size, the rarer the event that can be detected. A sample size of 10 000 patients allows one to be 95% certain that any events not observed occur less often than 1 in 3333 cases (incidence <0.0003) (see Chapter 4).

A sample size of 10 000 should allow for the detection of at least three cases of an adverse event, with 85% power, if the event occurs at a rate of at least one in 2000 patients (assuming the background rate is zero) [19]. If the background rate is known and there is an *a priori*

Box 15.2 Categories of events and outcomes which undergo further evaluation

Medically important[a] adverse events:
- Reported during premarketing development
- Reported during postmarketing in other countries (for products launched elsewhere before the UK)
- For the therapeutic class
- Previous undocumented medically important events considered to be possibly associated with the study drug during the study

Rare and Iatrogenic Adverse Reactions (RAIDAR) events (see Box 15.3)

Any other adverse events deemed to be of medical importance by the DSRU during the study

Specific outcomes associated with the study aims and objectives, for example aspects of prescribing, preexisting medical conditions or use of other medications immediately prior to or concurrently with the study drug which may be contraindicated, or which requires special warnings or precautions for use

[a] Defined as "events that may not be immediately life threatening or result in death or hospitalization, but may jeopardize the patient or require medical intervention to prevent serious sequelae."

Box 15.3 Rare serious adverse events that have been associated with the use of medicines

- Agranulocytosis
- Alveolitis
- Anemia, aplastic
- Anaphylaxis
- Angioneurotic edema
- Arrhythmia
- Bone marrow, abnormal
- Congenital abnormality
- Dermatitis, exfoliative
- Disseminated intravascular coagulation
- Erythema multiforme
- Erythroderma
- Guillain–Barré syndrome
- Hepatic failure
- Hepatitis
- Jaundice
- Leukopenia
- Multiorgan failure
- Nephritis
- Nephrotic syndrome
- Neuroleptic malignant syndrome
- Neutropenia
- Pancreatitis
- Pancytopenia
- Pseudomembranous colitis
- Renal failure, acute
- Retroperitoneal fibrosis
- Rhabdomyolysis
- Stevens–Johnson syndrome
- Sudden unexpected death
- Thrombocytopenia
- Torsade de pointes
- Toxic epidermal necrolysis
- Any event for which there is a positive rechallenge

This list is based on a similar list used by the Medicines and Healthcare products Regulatory Agency (MHRA), UK.

hypothesis of the effect size, then it is possible to analyze the statistical power of a study given a fixed sample size. For example, assuming 5% (two-sided test) significance, the power of a study based on 10 000 subjects to detect as statistically significant an increase in incidence from 0.1% to 0.2% would be 80% [20].

Because of the customized nature of M-PEM and SCEM studies, a specific sample size is calculated depending on the research question of interest, for which the outcomes are chosen and defined through internal DSRU scientific discussion as those which best reflect the research question. For example, if the study has been designed to test an increase in risk of an event between two study periods, then the sample size will depend on the background rate of the event, the estimated effect size of the adverse drug

event, the level of significance used (the fixed probability of wrongly rejecting the null hypothesis when no real difference exists; most commonly set at 5% – the type I error or false-positive result) and the desired power (the probability that the test will reject a null hypothesis that is false, i.e., that it will not make a type II error, usually taken to be 80%, which means a 20% chance of a type II error or false-negative result). The background rate and the expected adverse effect size are estimated from the published literature and clinical study data. For the majority of M-PEM and SCEM studies that have been undertaken to date, the sample size has been smaller than the 10 000 required for original PEM studies.

The duration of any study is dependent on the level of prescribing of the study drug by physicians in the UK; if the desired sample size has not been reached by a prespecified date then the study may either be extended or finalized, dependent on discussions with the marketing authorization holder and regulatory agencies. Interim analyses are usually undertaken at prespecified milestones (e.g., annually) or defined sample sizes (e.g., 2500 patients) and contacts are, whenever possible, maintained with the marketing authorization holder, so that the pharmaceutical companies (although the study is independent of them) can comply with the drug safety reporting procedures of the regulatory authorities.

The DSRU has completed 111 PEM studies to date with a median cohort size of 11 541 patients (interquartile range 8482–13 643). In addition, 13 M-PEM studies have been completed with a median cohort size of 4624 patients (interquartile range 1666–12 135). Two SCEM studies have also been completed to date and other M-PEM and SCEM studies are currently ongoing. A wide range of drugs have been studied using event monitoring, including agents to treat hypertension, angina, asthma and chronic obstructive pulmonary disease (COPD), diabetes, epilepsy, depression, schizophrenia, erectile dysfunction, and urinary incontinence. In addition, a number of nonsteroidal antiinflammatory drugs (including selective COX-2 inhibitors), several antibiotics, and antiviral agents have been studied.

Data Analysis

The primary objective of pharmacovigilance is signal detection and evaluation. Several methods are applied for signal detection in event monitoring, both qualitative and quantitative, not only to look for new unexpected adverse reactions but also for further information regarding expected drug–adverse event associations of interest that might affect the benefit–risk balance of a drug.

Qualitative Evaluation of Important and Medically Important Adverse Events

As described earlier, each questionnaire is evaluated for adverse events that may possibly be related to drug exposure. This qualitative evaluation by the DRSU research fellow takes into consideration a number of points (see Box 15.4). An example of a safety signal generated in event monitoring as a result of careful clinical evaluation is the visual field defects in patients receiving long-term treatment with the antiepileptic drug vigabatrin [21].

Because of the epidemiologic nature of the design of event monitoring studies, any inferences on drug-relatedness will be made on an aggregate basis at study milestones, such as when the interim and final reports are written. Such aggregate analyses can help formulate possible hypotheses, which then require further analytic study. Event monitoring is dynamic in nature and the types and nature of events evaluated may evolve during the course of the study, for example, following publications of case reports or regulatory concerns. An example is that of serious skin reactions and selective COX-2 inhibitors [22].

Quantitative Analysis of Events

All event monitoring studies provide a numerator (the number of reports of an event) and denominator in terms of the number of patients

Box 15.4 Points for consideration in evaluation of reported events

- The temporal relationship (time to onset)
- The clinical and pathologic characteristics of the event
- The pharmacologic plausibility based on previous knowledge of the drug and the therapeutic class, if appropriate
- Whether the event was previously reported as an adverse reaction in clinical trials or post-marketing in the UK or in other countries
- Any possible role of concomitant medications or medications taken prior to the event
- The role of the underlying or concurrent illnesses
- The effect of dechallenge or dose reduction
- The effect of rechallenge or dose increase
- Patient's characteristics, including previous medical history, such as history of drug allergies, presence of renal or hepatic impairment, etc.
- The possibility of drug interactions

and the number of patient-months of exposure to the drug; all are collected within a known time frame. This allows for event profiles over time to be examined through application of various statistical methods; such analyses are performed using "high-level" event terms from MedDRA (or historically, higher level terms from the DSRU dictionary). The trend of reports after starting treatment can be very informative: pharmacologically related side effects tend to occur early in the study (although this period may also be affected by carryover effects from previous medication), or the number of reports may rise as time passes (as with long latency adverse reactions).

Analysis by Event Counts (Incidence)

One simple but effective descriptive method is to examine the incidence of events for the whole cohort by month, by system-organ-class (SOC). Such tables can generate signals; for example, the incidence of an event in the first month or subsequent months may be unusually high (in contrast to that expected from the Summary of Product Characteristics [SPC]). An example of such a signal is gynecomastia with finasteride (Case example 15.1) [23].

Analysis by Event Rates (Incidence Densities)

Event monitoring takes advantage of the information on duration of exposure that is provided on the questionnaire and, for M-PEM, from the NHSBSA. Rates (incidence densities [IDs]) can be calculated for a given fixed time period (t) – ID_t –for all events reported in patients for a given time period and are expressed in units of first event reports per 1000 patient-months of treatment (the time between treatment start and stop dates) or observation (the time between start date and end of survey date) if pattern of drug use is continuous or intermittent, respectively.

Thus:

$$ID_t \text{ per } 1000 \text{ patient-months of treatment } (or\ observation) = \frac{N_t}{D_t} \times 1000$$

where N_t = number of 1st reports of an event during treatment (*or observation*) for period t, and

$$D_t = \frac{\text{Number of patient-days of treatment } (or\ observation) \text{ for period t}}{30}$$

where 30 defines a 30-day month.

Incident densities can be calculated for each individual month for the relevant study period, as well as combinations of months (this being dependent on the study question – see later) and all months combined (ID_A). Ideally, the exposure time would be censored at the time of the first event. However, since there are a large number of health outcomes of interest and the

Case example 15.1 Finasteride and gynecomastia

Background

- Indicated for the treatment and control of benign prostatic hyperplasia (BPH).
- Finasteride is an inhibitor of 5-alpha-reductase, which catalyzes the conversion of testosterone to dihydrotestosterone (DHT).
- Company literature at time of marketing indicated that the most frequent AEs were related to sexual function and that there were feminizing effects; gynecomastia was not included in the data sheet when the product was launched.

Question

- How did PEM help in identifying this signal?

Approach

- Quantitative methods included constructing a list of events, by system–organ class and according to treatment status, with denominators of number of male patients still in the study, by month. Data were then compared across other drugs within the PEM base.
- Qualitative methods involved further evaluation and characterization of the event.

Results

- The PEM cohort comprised 14 767 males (mean age 69 years).
- Reports of impotence/ejaculatory failure and decreased libido were received in relation to the first and all subsequent months of treatment, but reports of gynecomastia were only rarely received before the fifth month of therapy (Figure 15.5).
- To assess whether gynecomastia was an adverse event with finasteride, the data for 41 completed PEM studies were examined for reports of this event; only 17 of these 41 studies had gynecomastia. There were 42 reports (39 on drug) for finasteride (incidence rate 0.26 per 1000 patient-months of treatment) compared to 75 (56 on drug) for the other 17 studies combined (incidence range 0.03–0.23 per 1000 patient-months of treatment). These results strengthened the signal further.
- Follow-up of these cases of gynecomastia and 12 "potential" cases (with signs and symptoms of the condition based on other events) reported that the gynecomastia resolved on dechallenge in 15 of the 31 men in whom

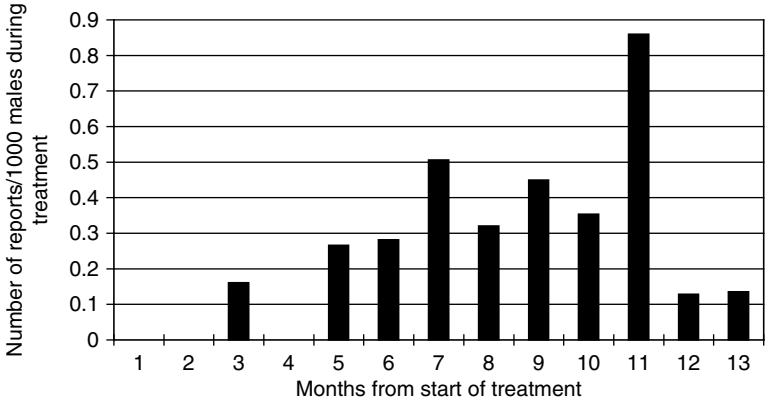

Figure 15.5 Reports of gynecomastia during treatment with finasteride.

finasteride was given in the absence of other relevant concomitant therapy.

Strengths

- This shows the complementary and essential nature of qualitative and quantitative methods in assessing risk.

Limitations

- The incidence rate calculated was a crude measure, and there was no ability to control for confounding.
- Follow-up was not systematic for all reports in the database, so only additional data were obtain for the cases exposed to finasteride.

Key points

- This postmarketing surveillance study generated a signal that was not identified in premarketing clinical trials of finasteride.
- While the incidence measure may have been subject to bias, the outcome was that the data sheet was amended.

censoring would be different for each outcome, the denominator for the crude ID does not initially account for censoring. Any subsequent analysis of particular signals would use appropriately censored denominator data. One of the many different evaluations possible is to rank these data in descending order of the estimate of ID_1 (ID in month 1) and to examine the frequency of clinical events unlikely to be confounded by indication. See Case example 15.2 which describes the PEM study of drospirenone/ethinyl estradiol [24].

Comparisons of Event Rates (Incidence Densities)

Calculating measures of impact (ID rate differences) or measures of effect (rate ratios) are other quantitative evaluations that can be used to identify events that occur significantly more frequently soon after starting the study drug. The null hypothesis is that the incidence rates are constant between the two time periods in a fixed cohort, that is, the events are not related to treatment in any way; the alternative hypothesis is that the incidence rates are different between the two time periods in a fixed cohort. In rejecting the null hypothesis where substantial differences are observed, this could be explained by a number of factors, including drug treatment. Most frequently, for each reported event, the difference or ratio between the IDs in the first month after starting treatment and the IDs for months two to six ($ID_1 - ID_{2\text{-}6}$) is calculated to allow the examination of the null hypothesis that the rate for the event is not increasing or decreasing between these two time periods.

A confidence interval (CI) (99% or 95%) is applied to the difference or ratio in the rates between months as specified above; these are computed based on the Normal approximation. Thus, where the $ID_1 - ID_{2\text{-}6}$ value for an event is positive, or $ID_1/ID_{2\text{-}6}$ is above one and the confidence limits around the point estimate exclude the null value (zero or one respectively), the rate of events in month 1 is significantly greater than the rate of events in month 2–6 combined. This result can be considered a signal for an event associated with starting treatment with the study drug.

In comparing these two time periods, the assumption is made that, given an event, its reporting is equivalent in both periods in a fixed cohort. It is recognized that there are a number of limitations to this method of examining the data – these will be discussed subsequently. Similarly, ID differences or ratios can be used to identify events that have a delayed onset, for example where the $ID_1 - ID_{2\text{-}6}$ value for an event is negative, or the $ID_1/ID_{2\text{-}6}$ is less than one and the confidence limits around the point estimate exclude the null value (0 or 1 respectively).

Case example 15.2 Yasmin®

Background
- Yasmin is a combined oral contraceptive (COC) containing ethinyl estradiol and a new progestogen, drospirenone; it was launched in the UK in May 2002.
- While the association between estrogen-containing oral contraceptives and venous thromboembolism (VTE) is well established, VTE is a rare event in young women and the risk associated with a new COC cannot generally be determined from clinical trials.
- The initial prescribing information for Yasmin stated that "It is not yet known how Yasmin influences the risk of VTE compared with other oral contraceptives."

Question
- How can prescription event monitoring help to evaluate the risk of this new drug?

Approach:
- Obtain prescriptions for all new users in England, which avoids the selection bias inherent in premarketing clinical trials.
- Obtain outcomes, which are events, regardless of causality, reported by the patients' doctors (who have access to the patients' health information in both primary care and hospital contact).
- Apply qualitative and quantitative methods to generate and test hypotheses.

Results
- The PEM study for Yasmin identified 13 cases (deep vein thrombosis 5; pulmonary embolism 8) in 15 645 females using Yasmin, with a crude incidence rate of 13.7 cases per 10 000 woman-years (95% CI 7.3–23.4).
- Each of the cases had one or more possible risk factors for VTE.

Strengths
- The PEM allowed for a rapid assessment of risk; to our knowledge, this was the first description of cases of DVT and PE in users of Yasmin in the primary care setting in England.

Limitations
- Although an incidence rate has been calculated, there was no control group and no ability to account for confounding.
- Cases all had risk factors for VTE and therefore the events may not have been related to the drug.

Key points
- While premarketing clinical trials identified many aspects of the safety of Yasmin, apparently no cases of VTE were reported.
- An association between COCs and VTE has been recognized for more than 40 years so it is important to know whether a new COC is associated with VTE and to what extent.
- The lack of selection bias and large numbers of women studied led to identification of women who developed VTE while taking Yasmin, all of whom had risk factors for VTE. The PEM study raised the need for special consideration before women with risk factors for VTE take Yasmin.
- While the incidence of VTE in the PEM study may have been subject to bias, it is the first computed incidence for this condition with Yasmin. Nonetheless, it needs to examined by other studies.

In such settings, the rate of events in months 2–6 combined is considered to be significantly greater than during month 1 and this result is considered to be a signal for a delayed-onset event. These signals then require confirmation or refutation by further study. Table 15.1 shows a summary of such data from a typical PEM study of a drug (oxcarbazepine) for which

Table 15.1 Incidence densities (ID per 1000 patient-months) for standard PEM study for oxcarbazepine ranked in order of ID_1 for all events during treatment (between date of starting and stopping) where $ID_1 \geq 3$. Events associated with starting treatment are in ***bold italic.***

(*Continued*)

Table 15.1 (Continued)

Higher term	N_1	$N_{2–6}$	ID_1	$ID_{2–6}$	ID_1-$ID_{2–6}$	99% CI	N_A (%)	ID_A	RFS	ADR
Patient request	6	8	3.11	0.99	2.12	–1.28, 5.51	22 (1.0)	1.21	22	-
Pruritus	6	10	3.11	1.24	1.87	–1.55, 5.29	20 (0.8)	1.10	8	1
Tremor	6	2	3.11	0.25	2.86	–0.44, 6.16	11 (0.5)	0.61	5	2

N_1 = Total number of reports of each event during the first month of treatment.
$N_{2–6}$ = Total number of reports of each event during treatment in months 2–6.
ID_1 = Incidence density for each event during the first month of treatment (where D_1 = 1930).
$ID_{2–6}$ = Incidence density for each event during treatment months 2–6 (where $D_{2–6}$ = 8054).
ID_1–$ID_{2–6}$ = Arithmetic difference between ID_1 and $ID_{2–6}$.
99% CI = 99% confidence intervals for ID_1–$ID_{2–6}$.
N_A (%) = Total number of reports of each event (% incidence in total cohort) during total treatment period.
ID_A = Incidence density for each event for the total treatment period (where D_A = 18170).
RFS = Reason for stopping oxcarbazepine (total no. reports = 932 in 698 patients (31.1% of cohort).
ADR = Adverse drug reaction (total no. reports = 158 in 105 patients – 4.7% of cohort).

pattern of use is considered continuous; it is restricted to events reported during treatment (between start date and stop date) and with corresponding denominator of patient-months of treatment. Events associated with starting treatment are in bold.

For drugs where pattern of use is intermittent and/or short term, such summaries are also produced, but there are several differences. First, the numerator is based on total incident counts irrespective of treatment status (whether recorded during or after treatment or whether "unknown") and the denominator takes into account the observation period (between start date and end of survey date). Second, the comparator (reference) period may be restricted. Table 15.2 shows a summary of such data from a PEM study of a drug (levocetirizine) intended for short-term (<30 days) intermittent use, where the second month was considered most appropriate as the reference period.

Time to Onset

It is acknowledged that the generalized approach to segregation of time periods may not be appropriate for all events with respect to their most relevant time periods of excess. It is possible to explore the time taken for an event of interest to occur by using time-to-event analysis, thus providing an additional tool for signal generation purposes. One example is the incidence rate of venous thromboembolism (VTE) as reported in the PEM study of strontium [25].

Plotting a hazard function in a fixed cohort for events of interest is another useful method to determine whether the hazard (instantaneous risk) of the event increases or decreases with time. A constant hazard over time may be consistent with a background (i.e., not caused by the drug) event rate, whereas a nonconstant hazard over time may be an indicator of a drug–event relationship. Since it is desirable to understand the shape of the underlying survival function, parametric time-to-event models can estimate the baseline hazard function and the instantaneous change in hazard over time, and the goodness-of-fit can be assessed. An example is the examination of hazard rates of neuropsychiatric events as reported in the M-PEM study of varenicline [26].

Reasons for Stopping the Drug

All event monitoring questionnaires ask the prescriber to record the reason why the drug was stopped, where treatment cessation occurred. This is informative because it includes possible adverse reactions which the physician and/or the patient considered serious or sufficiently troublesome to stop the medication. Clinical and nonclinical reasons for stopping a drug are presented in two ways: by system-organ class by month, and also ranked by total count. The ranked reasons for discontinuation can be compared with the ranked incidence density estimates and this comparison can also generate signals. There is usually a good correlation in terms of the most frequently reported events (see examples in Tables 15.1 and 15.2).

Outcomes of Pregnancy

All pregnancies reported during event monitoring studies are followed up in order to determine the outcome in those babies exposed *in utero* to the drugs being monitored. There is interest in determining the proportion and nature of congenital anomalies in babies born to women exposed to newly marketed drugs during pregnancy, in particular in the first trimester. PEM studies have shown that from 831 such pregnancies, 557 infants were born, of whom 14 (2.5%) had congenital anomalies [27]. It is important that studying pregnancy outcomes continues in order to exclude, to the greatest extent possible, teratogenic effects of medicines (see Chapter 22).

Drug Utilization

In recent years, the focus on drug utilization has become more important in terms of safety, especially in relation to use in special populations

Table 15.2 Incidence densities (ID per 1000 patient-months) for standard PEM study for levocetirizine ranked in order of ID_1 for all events during observation (between date of starting and end of observation) in the first two months after starting treatment (where $IDobs_{m1}$ >1).

Higher term[a]	N_1	N_2	$IDobs_{m1}$	$IDobs_{m2}$	$IDobs_{m1/m2}$ (95% CI)	ADR	Reason for stopping[b]
Condition improved	1470	434	118.90	35.15	3.38 (3.04, 3.77)	NA	**1896**
No further request	640	59	51.77	4.78	10.83 (8.29, 14.40)	NA	699
Not effective	460	133	37.21	10.77	3.45 (2.84, 4.22)	NA	588

Nonformulary product	13	8	1.05	0.65	1.62 (0.62, 4.52)	NA	21

[a] Clinical events associated with starting treatment are highlighted in bold.
[b] 3732 reasons for stopping during months 1 and 2 of observation, of 5509 (for whole study period).
ADR, events recorded as adverse drug reactions (25 reports [in months 1 and 2 of observation] of 31 [for whole study observation period]); ID, incidence densities; $IDobs_{m1}$, incidence density for each event during observation month 1; $IDobs_{m2}$, incidence density for each event during observation month 2; $IDobs_{m1/m2}$, relative difference between $IDobs_1$ and $IDobs_2$; N_1, total number of first reports of each event during observation in month 1; N_2, total number of first reports of each event during observation in month 2; NA, not applicable.

and off-label use. There is interest in determining the prevalence of use in such populations, in addition to adverse event profiles. For example, an M-PEM study on extended-release quetiapine found that the prevalence of off-label prescribing in terms of indication and high doses was common, as was use in special populations such as the very elderly [28].

Strengths

Representativeness and Size

Event monitoring uses a noninterventional cohort design; it does not interfere with the decision to prescribe a medication and information is collected *after* the prescribing decision has been made and implemented. This means that in event monitoring, data are collected on patients who have received the study drug because the doctor considered it the most appropriate treatment for that patient, as in everyday real-world clinical practice the patient would have been prescribed the drug regardless of whether they were included in the event monitoring study. In contrast to clinical trials, there are no predefined selection criteria in terms of prescribers or patients based on specific characteristics. These study characteristics make it likely that the event monitoring cohort is representative of all patients who have started the study drug under similar circumstances on a national scale in England. As a result, generalizability is ensured, unlike in many clinical trials.

In terms of size, event monitoring has been shown to be successful in collecting information on very large cohorts of patients exposed to new treatments in the UK. Cohorts of 10 000 patients were regularly established during original PEM studies and current M-PEM and SCEM studies have gathered appropriate sample sizes based on the objectives of the study.

Variable Direction of Investigation

Event monitoring consists of both prospective data collection and retrospective collection where required. Patient medical history can be studied, in addition to prospective data collection on specific events or conditions of interest.

Exposure Data

It is important for drug safety that exposure windows are appropriately calculated to minimize biased estimates of association (ID differences) or estimates of effects (ID ratios) where internal *a priori* comparisons are undertaken. In M-PEM, exposure data are derived from dispensed prescriptions, with validation from prescribers through confirmation of such data on the questionnaires. Considering the large proportion of patients who are prescribed a medication but do not get the prescription filled [29], this is an advantage in that M-PEM exposure data are more accurate than those derived from records of physician-issued prescriptions (which are not always dispensed), as held in some pharmacoepidemiologic databases. In SCEM studies, exposure data are not based on dispensed prescriptions; however, since patients are under specialist care in such studies, they are likely to be more closely monitored in terms of medication use and adherence. Many patients will also visit their specialist at frequent intervals, unlike in the primary care setting.

Outcome Data

In event monitoring, the study design collects information on events regardless of causality. Therefore, event monitoring is able to identify signals of adverse reactions or syndromes which none of the participating physicians suspect to have been due to an ADR [30]. If the physician suspects an event is due to the use of a drug, then they can specify this on the questionnaire. In addition, the nonpassive design

prompts the physician to fill in the questionnaire regardless of any events experienced and does not rely on them taking the initiative to report. This "prompting" effect of event monitoring is critical because ADR reporting is enhanced in event monitoring compared to the passive Yellow Card spontaneous ADR reporting system in the UK [31].

Signal Strengthening

Event monitoring can be used to identify patients with potential ADRs who can be studied further. Case series can be used to examine clinical characteristics of particular adverse events within patients at aggregate level. In addition, comparisons within the DSRU database are also possible and can be conducted to refine signals [32,33]. These comparisons are appropriate because the database is composed of new drug user populations with exposure in the immediate postmarketing period since introduction of each product. It is also possible to conduct external comparisons using demographic data of the population as a whole, such as standardized mortality ratio [34]. However, in contrast to event monitoring data, some medical record databases (such as the Clinical Practice Research Datalink or The Health Improvement Network, see Chapter 13) have limited data on recently introduced products, which precludes reliable comparisons being made because of small sizes of the population exposed.

Definitive Answers

Event monitoring can also confirm or refute drug safety signals. Various approaches can be used, such as nesting a case–control study within an event monitoring cohort. This method overcomes some of the disadvantages associated with nonnested case–control studies while incorporating some of the advantages of a cohort study [35]. As a pharmacoepidemiologic tool for risk management plans, the design potentially offers impressive reductions in costs and efforts of data collection and analysis compared with the full cohort approach, with relatively minor loss in statistical efficiency. Event monitoring cohorts provide opportunities to conduct such nested case–control studies, for example, for patients who develop selected ADRs and matched patients who receive the same drug without developing ADRs. One example is the possible association between the use of an atypical antipsychotic and extrapyramidal symptoms. Other approaches include comparisons between event monitoring cohorts, such as comparing the risk of drowsiness and sedation between two antihistamines [32].

Use of Reference (Contextual) Cohorts

Event monitoring studies can use reference (contextual) cohorts when it is considered inappropriate to use counterfactual comparative cohorts. The objective of such contextual cohorts is to examine differences in characteristics between patients who receive a new medicine and those who are on standard therapy. This is undertaken when it is expected that there are substantial differences in the characteristics of the two cohorts which will impact on comparative safety and where this cannot be adequately addressed by methods usually used in pharmacoepidemiology to handle such imbalances [36].

Participation in Research

For physicians in the UK, research and academic medical practice are considered noncore activities and therefore receive no payment from the NHS. Although GPs have a duty of care to report ADRs and cooperate with requests for information from organizations monitoring public health, those GPs who participate in event monitoring studies do so on behalf of research and not for monetary interest – the remuneration received for completion of forms barely covers administration costs for

M-PEM, while for SCEM studies remuneration is paid to the NHS trust and not to the physician. This is also the case for other pharmacovigilance activities such as the Yellow Card spontaneous reporting scheme, where no money is received for participation.

Since the early 1980s, close contact has been fostered between the research staff in the DSRU and the reporting doctors; focus groups and advisory committees are used to ensure maximum response and maintain good relationships with physicians. This facilitates the gathering of supplementary information on important events, pregnancies, deaths, etc. (see Table 15.1 and Box 15.1), which allows for the maximal clinical understanding of biases, the natural history of ADRs, and other important risk factors (which could be potential confounders for prespecified internal comparisons).

Limitations

Single-Group Cohort Design

As highlighted earlier, event monitoring uses a simple single-group cohort design where subjects have been assembled based on a common exposure (the particular medication under surveillance). Compared to the "classic" cohort design with an explicit comparator, it is more efficient in terms of resources. In event monitoring studies with absence of data on an unexposed comparator, calculating measures of effect (relative risks) is restricted to internal comparisons between subgroups defined by particular characteristics, or external comparisons to carefully selected data sources. Moreover, as stated above, in recent years, the DSRU has modified the event monitoring design to include a contextual comparator within certain studies; for example, a warfarin cohort was also recruited for the Rivaroxaban Observational Safety Evaluation (ROSE) SCEM study. This comparator was chosen to inform on the adoption of rivaroxaban into clinical practice and variation in determinants of treatment choices though it was not used to calculate differences in risk between treatment groups.

Bias

Validity in observational studies is an important consideration and selection bias can be introduced if a nonrepresentative sample of the population is recruited [37]. Such error cannot be adjusted for. How an event monitoring cohort differs to all other patients with the same indication receiving other healthcare in the UK cannot be assessed since, as mentioned previously, event monitoring does not always monitor an unexposed cohort concurrently. Channeling of new drugs can also introduce selection bias through preferential prescribing. Patterns of adoption of a new drug cannot be predicted, and while it may be examined in event monitoring, it cannot be controlled.

Nonresponse bias is another form of selection bias which is possible since not all M-PEM questionnaires are returned. The response rates for M-PEM studies are usually over 50%, which is comparable to response rates reported elsewhere for GP postal surveys [38] and higher than the reporting rates of suspected ADRs in the Yellow Card scheme [31,39]. In M-PEM, it is not known whether the prescribers who do not respond (and their patients) differ from those prescribers (and their patients) who do participate.

Underreporting, including underreporting of serious and fatal adverse events, is possible in event monitoring since it depends on reporting by physicians. Information bias in terms of misclassification of outcome and exposure is also possible since the data depend on the accuracy and thoroughness of the physicians in diagnosis, record keeping, and reporting.

In event monitoring, exposure misclassification may be introduced through inaccurate calculation of exposure (time on treatment).

It is important because inappropriately calculated exposure windows can result in a biased estimate of effect, particularly if unnecessarily long because relative differences get diluted as the time window widens and a potential signal may be lost. In M-PEM, exposure is calculated from dispensed prescriptions, which means that exposure data used for M-PEM are more accurate than exposure data based on physician-issued prescriptions alone. In SCEM, exposure data are based on the prescription date from specialist care, which is likely to be closely monitored by the specialist and in some cases event administered within a hospital setting. Nevertheless, patients may not take all the dispensed medication. In this regard, the misclassification of exposure is likely to be non-differential, being the same across the new drug cohorts, and the effect estimate (ID rate difference/ratio) biased towards the null. As for observational studies in general, assumptions are made regarding compliance and for drugs used for chronic conditions, the assumption is made that individual patients take the medication up to the end of treatment (or stop date) unless otherwise indicated. However, for drugs taken over long periods of time, repeat dispensing is not an absolute proof of good compliance but is a usually a good marker of compliance.

Confounding

Event monitoring is affected by a limitation common to all observational studies – the inability to control for factors that might differ between groups being compared [37]. Hypotheses generated by event monitoring may be further explored using traditional hypothesis-testing techniques, such as case–control methods. However, it is important to acknowledge that the range of data that can be collected on important co-variates for *all* possible outcomes may be limited. In such cases, when examining relationships between exposure and outcomes within a case series, or when conducting comparisons between subgroup populations within a drug or between drugs to strengthen or refine signals, data may be incomplete or missing and residual confounding is likely. Nevertheless, M-PEM and SCEM provide considerable opportunities to enhance collection of supplementary data on important risk factors.

Limited Statistical Power and Sample Size

It is possible to calculate power and sample size for a single cohort study, provided one has a hypothesis about the effect size and the background rate involved. However, the detection of rare ADRs is not always possible, even with cohorts of 10 000–15 000 patients. Due consideration should also be given to the nature of event monitoring statistical analysis which involves running routine multiple comparisons whereby event ID difference or ratio statistics are generated to examine the null hypothesis that event rates are constant between two time periods. A minimum 95% confidence interval has routinely been used in event monitoring to aid decision making, but in terms of signal generation for safety surveillance, there is still the chance of a type II error, that is, of missing a difference that really is there.

Particular Applications

Signal Strengthening

Signal Strengthening through Quantitative Evaluation

Once a signal has been recognized, supplementary analysis is required to further characterize important attributes. As highlighted previously, PEM provides the opportunity for further collection of detailed information on reported events and allows systematic review of individual case reports and aggregate data.

One important example of follow-up exploration in relation to a long-latency adverse event concerned visual field defects in patients receiving long-term treatment with vigabatrin [21]. The initial PEM study showed three cases of bilateral, irreversible peripheral field defects, whereas no similar reports occurred with other antiepileptic drugs or in any of the other drugs already monitored by PEM. A follow-up exploration with a repeat questionnaire, sent to the doctors whose patients had received vigabatrin for over six months, showed that the incidence of this serious event was much higher and that many of the relevant patients had objective evidence of visual field defects. Another example of signal follow-up is given in Case study 15.1 in relation to gynecomastia and finasteride [23].

Signal Strengthening and Hypothesis Testing

Comparison of Event Rates and Risks

Comparisons can be used to give estimates of relative measures of associations (e.g., relative risk) and are often associated with hypothesis testing. However, such pharmacoepidemiologic methods can be used to explore or strengthen signals as an extension of postmarketing safety surveillance. In event monitoring, a variety of targeted comparisons of event rates and risks occurring between different patient populations are conducted to explore apparent associations. These can be segregated into two sorts: using internal comparators such as subsets of patients within the same drug cohort or between drugs within the same therapeutic class; or using an external comparator. The research question being asked (usually) determines which pharmacoepidemiologic design for these comparisons should be used and the most appropriate statistical analyses required.

Various methods are applied to enable nested internal comparisons between subgroups defined by particular characteristics. Such comparisons can be conducted using event monitoring data, including simple stratification, "before and after" matched analyses, multivariate modeling, and standardization.

Simple stratification

Through simple stratification, event profiles in subgroups of patients can be examined, and rates of preselected events compared between these subgroups by calculating crude relative risks or rate ratios. The assumption is that all other characteristics are constant because the subgroups are nested within the new user cohort, although residual confounding is likely (as discussed above).

One example, for which the aim was to look for evidence of channeling a new drug to problem patients, was to examine and compare the frequency of gastrointestinal events reported in a PEM study of the COX-2 selective inhibitor celecoxib in those patients with gastrointestinal (GI) risk factors (past history of GI conditions, gastroirritant drugs, use of concomitant gastroprotective agents) to those without [40]. In this example the null hypothesis was that risk was the same in both subgroups. In this study, significantly higher rates of GI events were observed in patients with risk factors, which supports the possibility of channeling bias.

In another example, a M-PEM study examined the frequency of major and minor depressive episodes with rimonabant (an obesity treatment) after starting treatment. This was a safety concern identified at the time of marketing approval and so patients with a previous history of psychiatric illness were examined separately to those without a previous history. In patients without a previous history of psychiatric illness, there were more major and minor depressive episodes in the six months after starting treatment compared with the six months before starting treatment with rimonabant (relative risk [RR] 1.7; 95% CI 1.2–2.3 and RR 1.33; 95% CI 1.20–1.48, respectively). The same was not found for those who had a previous history of psychiatric illness [41]. Marketing authorization for rimonabant was withdrawn in

October 2008, mainly because the psychiatric adverse effects could not be addressed by further risk minimization [41].

Before and After Studies

"Before and after" studies compare the rate of particular outcomes during a defined period of exposure (or observation) after starting the study drug with those rates in the same individuals during a defined period of observation before starting, using a matched pair analysis. The null hypothesis is that event rates are the same before and after starting treatment.

One example was the examination of rates of respiratory events with the introduction of a new chlorofluorocarbon (CFC)-free formulation of an anticholinergic (ipratropium) metered-dose inhaler (MDI) in populations who were "switchers" from the original MDI and those naïve to ipratropium treatment [42]. The analyses suggested that characteristics of these two subpopulations differed such that naïve patients were more likely to be children, have an indication of asthma, and have milder disease severity, while switchers were more likely to be adults, have an indication of COPD, and have more severe disease. Such differences have an important impact on ongoing evaluation of benefit/risk balance of the new formulation. Common respiratory events occurred at higher rates after starting treatment than before for switchers, for example lower respiratory tract infection (LRTI) (RR 1.45; 99% CI 1.17–1.81) and worsening asthma (RR 1.58; 99% CI 1.00–2.51). Of these events, only LRTI was significant for naïve patients (RR 1.42; 99% CI 1.04–1.95).

Modeling

Multivariable modeling examines the potential effect of one variable on the outcome of interest while controlling for many other variables. An example of multivariable conditional logistic regression modeling was a within-PEM study comparison to examine the risk of pioglitazone treatment combinations (with insulin or other antidiabetic agents) on risk of hypoglycemia [43]. The null hypothesis was that the risk of this outcome was the same regardless of treatment. Pioglitazone may be used alone or in combination with a sulfonylurea, metformin, or insulin as an adjunct to diet and exercise for the management of type 2 (noninsulin-dependent) diabetes mellitus (NIDDM). The summary of product characteristics states that hypoglycemia is common when pioglitazone is administrated in combination with insulin and very common during the triple combination treatment with metformin and sulfonylurea [43]. Patients taking combination therapy with sulfonylurea or insulin were estimated to have approximately three and four times the hazard of having an event compared with those who were not taking these adjunctive therapies (hazard ratio [HR] 3.11; 95% CI 1.64–5.88; HR 4.15; 95% CI 1.74–9.91, respectively). Patients treated with adjunctive metformin were 25% less likely to experience hypoglycemia than those who did not take concomitant metformin (HR 0.75; 95% CI 0.44–1.27). This suggests that patients taking pioglitazone with insulin or sulfonylurea had higher risks than those on pioglitazone monotherapy [43].

An example of the application of Poisson regression modeling (which takes different exposure durations into account) was to examine whether there was a difference in incidence rates for thromboembolic (TE; cardiovascular, cerebrovascular, and peripheral venous) events reported for patients dispensed rofecoxib and meloxicam, because of the unexpected association shown in a clinical trial [44]. The null hypothesis was that event rates were the same regardless of drug. This study reported a relative increase in the rate of cerebrovascular TE events (RR 1.68; 95%CI 1.15–2.46) and a relative reduction in peripheral venous thrombotic events (RR 0.29; 95% CI 0.11–0.78) for rofecoxib compared to meloxicam, after adjusting for age and sex. There was no difference in the rate of

cardiovascular thrombotic events. This particular example shows how the DSRU event monitoring database provides a resource to evaluate signals and hypotheses generated by other sources. Another example is the comparison of mortality and rates of cardiac arrhythmias with atypical antipsychotic drugs [45].

Standardization

Where appropriate, comparisons are made between patients identified within an event monitoring study and an external reference group, if a suitable internal reference cohort cannot be found and the research question requires the result to be contextual. For instance, calculation of standardized mortality ratio (SMR) is an indirect method of adjusting a mortality rate to that the observed death rate can be compared to that expected if the study cohort has the same characteristics of the reference cohort. Thus, the SMR is the ratio of observed deaths to expected deaths. Hence through using this indirect method of standardization, the expected deaths in an event monitoring cohort can be calculated using information on the general population age-specific rates.

Following concerns about cardiovascular safety with sildenafil, the mortality from ischemic heart disease in users of sildenafil in a PEM study was compared with external epidemiologic data for men in England [34]. The SMR for deaths reported to have been caused by ischemic heart disease (IHD) in the sildenafil PEM cohort was 31.41 (95% CI 18.29–50.29, based on Poisson error factors), indicating that the point estimate mortality in the cohort was 68.6% lower than that for males in England in 1998. However, the 95% CI is wide and there is no evidence to suggest a higher incidence of fatal IHD among men in England taking sildenafil. Similarly, death from ischemic heart disease in the bupropion PEM (when used for smoking cessation) was compared with external data and showed no difference in the SMR [46]. Obviously, there is higher potential for bias when using external comparators than comparisons undertaken between event monitoring studies, principally due to differences in study design and data collection methods; results of external comparisons must therefore be interpreted very carefully.

Automated Signal Generation

The DSRU has previously explored the use of data-mining disproportionality methods that are commonly used in pharmacovigilance (see Chapters 10 and 27) as a possible additional quantitative tool in event monitoring for signal generation, because of the large number of drug–event combinations held in the DSRU database. Feasibility studies have employed proportional reporting ratios (PRRs) [47] to quantify the ratio of observed-to-expected PEM event reports to explore historical signals – for example, Stevens–Johnson syndrome with the antiepileptic drug lamotrigine [48,49]. An extension to this method which integrates available PEM data on exposure to calculate the incidence rate ratio (IRR) has also been examined and applied to investigating new signals such as exacerbation of colitis with rofecoxib [50].

There are a number of methodologic issues which may influence whether a signal is generated; these include selection of comparator(s), signal threshold, variation in duration of study observation period, handling small event counts, and the level of dictionary terms used, such as higher- or lower-level terms. However, with refinement, automated signal generation can be a useful tool to support signal generation for event monitoring through other quantitative methods as described above.

Drug Utilization

Drug utilization research (see Chapter 18) is an essential part of pharmacoepidemiology, as it describes the extent, nature, and determinants of drug exposure at the patient level.

Data from event monitoring studies can inform about prescriber adoption of new drugs. The demographic and clinical characteristics of new users can be described and examined in relation to signals of off-label use, for example, indications, dose, and conditions or other factors that are contraindicated or special warnings for use.

An example is the PEM study of testosterone patch indicated for hypoactive sexual desire disorder in surgically menopausal women receiving concomitant estrogen therapy. Given the narrow prescribing indication, only 20.9% of the cohort were being prescribed the patch according to the manufacturer's recommendations [51].

In addition, PEM studies can examine aspects of adherence to prescribing guidelines. For example, in both PEM studies of rofecoxib and celecoxib, not only were high proportions of new users recorded as NSAID naïve (approximately 50%), but also a significant proportion (38% and 46%, respectively) had no prior history of gastrointestinal conditions (i.e., were at low risk) [40,52]. These observations were discordant with national NSAID prescribing practice during the time these drugs were first marketed, and agree with findings from elsewhere [53]. In addition, in the M-PEM study of extended-release quetiapine, off-label prescribing in terms of indication and high doses was common, as was use in special populations such as the very elderly [28].

Monitoring Drug Safety in Children

The safety of medication use in children is of major public and regulatory interest. However, there is a significant lack of safety data when a new drug is launched because of the limited number of clinical trials in this population. Furthermore, postmarketing pharmacovigilance systems for this population face significant challenges, particularly in regard to data capture of "off-label" use. European regulations have been issued that oblige pharmaceutical companies to submit a Pediatric Investigation Plan (PIP) for all new compounds, indications, and formulations. Pediatric pharmacovigilance activities have to be included in the benefit/risk management plan (see Chapter 24) and other pharmacovigilance activities. Therefore, pharmacovigilance tools may need to be adapted to examine specific issues associated with this special population.

Given that event monitoring studies capture drug usage under "real-life" conditions in general practice, including off-label prescribing to the pediatric population, it is possible to explore differences in risk profiles between children and adults using these studies. An example is a study which compared the adverse event profiles of children and adults taking lamotrigine, using modified signal detection methods [54]. Data were stratified by age and IDs were examined between two time periods after starting treatment (month 1 and months 2–6 combined). Proportional reporting ratios (PRR) and incidence rate ratios compared the risk of adverse events between adults (n=7379) and children (n=2457). Rash (PRR 1.2) and Stevens–Johnson syndrome (PRR 4.5) were more commonly reported in children, and confusion more frequently in adults (PRR 6.3). In children, 33% of events suspected to be ADRs (15/46) were reported to the regulatory authority compared with 44% (56/128 reports) in adults. In another PEM study of the oral iron chelating agent deferasirox, reported events were stratified by pediatric age groups relevant to the licensed indications for use, allowing examination of the safety profile within these specific groups [55].

Quantifying ADR Reporting

The characteristics of ADR reporting have been examined previously within the DSRU database. Two studies conducted on different PEM studies and over different periods of time compared events that were considered as ADRs by doctors

reported in PEM, with spontaneous reports sent by the same doctors to the regulatory authority [31,39]. The first study showed that 275 of 3045 suspected ADRs reported on the questionnaires of 10 PEM studies (9%) (95% CI 8.00–10.00) were spontaneously reported to the UK regulatory authority [39]. The estimate was similar in the second study conducted in 2001, based on 15 other completed PEM studies. In that study, 376 of 4211 ADRs (9%) (95% CI 8–9.8) reported on the PEM questionnaires were reported on Yellow Cards to the CSM [49]. This represents an underreporting rate of 91% in both studies. It is of interest that a higher proportion of serious than nonserious reactions were reported to the regulatory authority by doctors in both studies (53.0% vs 8.4% and 22.8% vs 8.3%, respectively), which suggests that doctors use the spontaneous adverse reaction reporting system more energetically when reporting those serious reactions that concern them most.

It is possible to use event monitoring to study general patterns of ADRs. Our studies in this area have also shown that, in general practice in England, suspected ADRs to newly marketed drugs are recorded more often in adults aged between 30 and 59 years and are 60% more common in women than in men [56]. Possible explanations for these observations include increased frequency of consulting rates for women compared to men, pharmacologic differences between men and women in distribution of medication in the body, and increased rates of recording of clinical events with age. Another important factor is prescriber type – whether they routinely participate in postmarketing studies or not.

Supporting Pharmacovigilance Risk Management Plans

The management of risk of medicines requires identification, measurement, and assessment of risk, followed by benefit/risk evaluation, then taking actions to eliminate or reduce the risk, followed by methods to monitor that the actions taken achieve their objectives. Event monitoring not only contributes to the identification and measurement of risks of medicines but, with some additions, can examine how the risks of medicines are being managed in real-world clinical settings.

An example of such a study was conducted to monitor the introduction of carvedilol for the treatment of cardiac failure [57]. The product (a combined alpha- and beta-adrenergic blocker) has been used for the treatment of angina and hypertension for some time, but there was concern about its appropriate use for cardiac failure in the community. The aim of the M-PEM study was to monitor how the product was being managed in the community; for example, what clinical investigations were undertaken prior to starting the drug, who supervised the dose titration (GP or specialist), was the drug given to patients with the appropriate severity of heart failure, etc. The design included sending an eligibility questionnaire followed by up to three detailed questionnaires for a period of up to two years. Overall, regulatory guidelines for the use and risk management of carvedilol were mostly adhered to [55].

Since risk management of medicines became a regulatory requirement in Europe in 2005, a number of event monitoring studies have been undertaken to address specific questions related to detailed examination of particular adverse events and studying drug utilization patterns (Table 15.3). Such studies support the construction of risk management plans by providing opportunities for a number of additional research applications which can be used to generate signals of potential ADRs and to further evaluate safety concerns identified by other pharmacovigilance methods or arising from regulatory concerns. Their customized sample size is advantageous in terms of study conduct, limiting costs and providing timely information to the dynamic risk management process. Thus, they should be considered a valuable tool when

Table 15.3 Design and applications of event monitoring methods.

Type	Method	Applications	Examples of completed or ongoing M-PEM studies
Special populations	Patients identified according to prespecified criteria (age, sex, indication) through use of eligibility questionnaire	• New indications • License extensions • Reclassifications • New formulations • Switching • Regulatory intervention • Hospital initiations • Health outcomes management	Carvedilol [57] – Licensed for angina and hypertension with extension in 1998 to treat mild to moderate chronic heart failure. M-PEM monitored compliance with UK regulatory authority's request for monitoring the use and safety of carvedilol in heart failure in clinical practice, and assessed clinical risk management of patients within the new indication Travoprost – Eye drops initially approved for second-line use in the treatment of ocular hypertension in open-angle glaucoma; license extension to first-line use was granted in 2003. M-PEM monitored long-term development of discoloration of the iris CFC-free MDIs (Flixotide Evohaler® and Seretide Evohaler®) [60,61] – EMA produced guidelines for the conduct of postmarketing surveillance studies to assess the introduction of CFC-free inhalers. M-PEMs collected data 3 months before and after exposure to allow event comparison before and after starting
Drug utilization	Collection of data on extent, nature, and determinants of drug use and prescribing over time	• Adherence to prescribing recommendations/ clinical guidelines • Exploration of off-label use • Characterization of real-life populations	Atomoxetine [62] –Licensed in the UK in May 2004 for the treatment of attention-deficit/hyperactivity disorder in children (6+ years) and adolescents. M-PEM monitored drug utilization with targeted data capture on psychiatric events, convulsions, abnormal liver function, and selected cardiovascular events Ivabradine – Licensed in the UK in 2006; indicated for the treatment of chronic stable angina pectoris in patients with normal sinus rhythm, with a contraindication or intolerance for beta-blockers. M-PEM investigated its use in relation to diseases/conditions that are contraindicated or warnings for use
Targeted event surveillance	Collection of data on relevant risk factors	• Hypothesis strengthening/testing	Quetiapine extended-release formulation [28] – First marketed in the UK in September 2008; indicated for the treatment of schizophrenia and manic episodes associated with bipolar disorder with license extension for add-on therapy for major depressive disorder. M-PEM included prospective nested matched case–control study to explore relationship between dose and events of somnolence and EPS. SCEM study examined safety and use in the specialist care setting Rivaroxaban – First marketed in the UK in December 2011 for the new indication of prevention of stroke and systemic embolism in adult patients with nonvalvular atrial fibrillation and the treatment of deep vein thrombosis (DVT) and pulmonary embolism (PE), and prevention of recurrent DVT and PE in adults. Complementary M-PEM and SCEM studies conducted to examine safety in both the primary care setting and the specialist care setting

CFC, chlorofluorocarbon; MDI, metered-dose inhaler.

developing a risk management plan for the evaluation of the safety of a new medicine.

The DSRU is registered within the European Network of Centres for Pharmacoepidemiology and Pharmacovigilance (ENCePP) Database of Research resources, which serves as a central resource for both researchers and study sponsors seeking to identify organizations and datasets for conducting specific pharmacoepidemiologic and pharmacovigilance studies in Europe. The protocols for many of the individual studies conducted by the DSRU are also registered with the ENCePP.

The Future

In the future, event monitoring aims to utilize improvements in information technology, by collecting data electronically through tools such as online surveys. Additionally, plans are under way to complement the information obtained through event monitoring studies with data from across Europe, through collaborative networks spanning multiple countries.

Electronic Data Capture

Historically, all event monitoring studies at the DSRU have captured data through paper surveys; however, advances in information technology now allow data capture through a variety of methods, such as online surveys, text messaging, mobile applications, and email.

Several recent studies at the DSRU have tested these methods; a pilot study on the safety of the intranasal quadrivalent live attenuated influenza vaccine (QLAIV) was conducted. The primary objective of the study was to estimate the crude incidence rate of adverse events of interest (AEIs) following vaccination with the nasal QLAIV early in the 2014–2015 influenza season in children and adolescents in England. Participant outcomes, validated by a healthcare professional (general practitioner) where appropriate, were captured through questionnaires sent by the participant's method of choice: surface mail, telephone or web survey with email reminders. In total, 53.8% of those who consented to participate chose to complete questionnaires online [58]. The results of this pilot study indicate that offering electronic data capture is important in new studies and may help to improve response rate.

Another study examined the feasibility of rapidly monitoring safety with the new swine flu vaccines in the UK. Email and text messaging were two forms of data capture offered in this study. The methodology and use of modern technologies to collect safety data from large numbers of patients were considered successful and indicated that these could be used again for future studies [59] The questionnaire format of event monitoring studies is highly compatible with electronic data capture and the success of previous studies utilizing these techniques indicates that these are appropriate for the future of event monitoring.

Multicountry Network Studies

The 2012 EU pharmacovigilance legislation made it necessary in some cases to conduct a postauthorization safety study (PASS) in several European countries. The EMA's pharmacovigilance committee, PRAC, and Member State rapporteurs expect some risk management and risk minimization studies to be conducted in such a way. The DSRU has extensive experience designing and implementing event monitoring studies in the UK, but can also work as the coordinating center for PASS studies in a network of several European countries.

The "network of studies" is established by initially identifying research units in multiple European countries that have data sources capable of answering the research question and that can work together. The analysis of the network studies depends on the nature of the study and the expected results. Depending on the characteristics of the data and their analysis,

a metaanalysis or pooling of the results is undertaken. The advantages of these European network studies are many and include conducting PASS studies in several EU countries with their different healthcare systems, increasing the sample size and providing assurance that risk management and risk minimization are working in a number of member states. Such EU network studies provide a way forward to integrating pharmacovigilance across the EU, while complementing the information provided from event monitoring studies within the UK.

Conclusion

Event monitoring contributes to the better understanding of medicines safety. Both signals generated by event monitoring itself and those generated in other systems and studied further by event monitoring have been useful to inform the debates on the safety of medicines, including supporting public health and regulatory decisions.

Like all scientific approaches, event monitoring is evolving, aiming to reduce its weaknesses and enhance its strengths. The most significant development of event monitoring in the last few years has been the introduction of M-PEM and SCEM studies which obtain more information about background history and baseline details of clinical information as well as more details about specific events. M-PEM and SCEM also provide opportunities for comparisons of event rates of different drugs. New methodologic modifications and additions include more effective utilization of information technology, as well as collaborative studies across multiple countries.

Pharmacovigilance and pharmacoepidemiology are emerging and exciting disciplines with evolving study methods. Event monitoring continues to contribute to the progress of these important scientific and public health disciplines.

Acknowledgment from the Director

Event monitoring is a team effort; we are only two members of a large team. The DSRU is most grateful to the thousands of doctors across England who provide the Unit with the safety information which makes its public health work possible. The Unit is equally grateful to the NHSBSA; event monitoring would not be possible without their immense support. We are most grateful to previous and current staff of the DSRU; this chapter is based on their work! Special gratitude goes to Ron Mann for allowing the use of material from the previous editions and to Georgina Spragg who helped in locating research material.

[2] *QuintilesIMS, Madrid, Spain*

Introduction

Primary data collection refers to data that are collected specifically for a given research study or program, while secondary data are data that were collected to meet needs other than the research for which they are being used. Primary data collection can be used in all types of pharmacoepidemiologic study designs, both interventional and noninterventional, cohort, and case–control studies, as well as patient registries, which are conceptually a data collection structure for disease- or product-related studies, and in practice may closely resemble observational cohort study designs. These studies generally address effectiveness and safety of various medical treatments, and also are used to characterize diseases including progression over time.

Research Questions That Require Primary Data

The nature of the research question(s) and accompanying study design determine the need for collection of primary data from clinicians, patients, and/or others to address the study's aims, and are generally weighed against the sufficiency of availability of the required information in existing data sources (see Chapter 17). Some studies may combine existing data with limited supplementary primary data collection in order to collect critical aspects of the patient or healthcare provider experience; in those situations, accurate linkage is required between primary data collection and existing data (see section on "Hybrid or Enriched Designs" later in this chapter).

Research questions that may require primary data include the following.

Designs Involving Randomization

Pragmatic and explanatory randomized clinical trial designs (see Chapter 32) generally necessitate at least minimal site and/or patient contact for screening to determine eligibility and consent to participate in the trial. Pragmatic randomized trials are particularly useful for studying products that may not be widely used, either because they are newly approved or because they are not covered by health insurance plans or their costs are only covered to a small extent. Assignment of treatment through a randomization schedule assures that the product will be

Pharmacoepidemiology, Sixth Edition. Edited by Brian L. Strom, Stephen E. Kimmel and Sean Hennessy.

used in the target population of interest, and in the doses, sequence, and/or combinations of interest. Treatment may or may not be blinded, depending on whether the outcome can be measured objectively. Blinding (or masking) treatment is particularly important for outcomes that may be heavily influenced by the patient's or clinician's estimation of the benefit of the study treatment [1]. Placebos are used in drug development but in pragmatic randomized trials (see Chapter 26), the comparators are more frequently either a single product or whatever is being used in the locale of interest as treatment for the condition of interest, often called the "standard of care."

While randomized studies frequently involve extensive primary data collection to meet the trial objectives, these considerations overlap with those of observational designs and will be addressed further in that context.

Endpoint Assessment/Adjudication

Studies may require collection of detailed primary data for endpoint assessment and/or for endpoint adjudication. Collection of primary data for endpoint assessment becomes important when study endpoints are not consistently recorded in available medical records systems, or are not recorded with the reliability, timing or frequency needed to meet study aims. Additional primary data may also be collected to validate or confirm endpoints collected through secondary data or patient self-reports.

Endpoint validation can be particularly important for studies that use the patient as the primary reporter, since patients report as consumers, and clinical validation may be needed to confirm the endpoint of interest. For example, in the European PROTECT (Pharmacoepidemiological Research on Outcomes of Therapeutics) Consortium, funded by the Innovative Medicines Initiative, data were collected directly from pregnant women recruited online from the UK, Denmark, The Netherlands, and Poland [2]. Researchers learned that women could accurately report serious birth defects, but there were many reports of potential abnormalities that were difficult to classify without more clinical information [3].

Some observational as well as interventional studies, especially those designed to meet postmarketing requirements with safety or effectiveness endpoints that require an additional level of rigor, may include a full or modified approach to clinical endpoint review or adjudication by a central committee over and above the reporting by individual study sites. Reasons for this additional adjudication include concerns regarding investigator bias, if they hold strong opinions as to the benefit or harm associated with a treatment under study, the need to apply consistent standard definitions given variability in diagnostic criteria in usual practice, and lack of detail or inconsistent use of standard coding practices in accessible secondary data sources [4].

Clinical Assessments Not Consistently Captured in Secondary Data

Even as the collection of medical data from routine care is increasingly recorded and available from electronic as well as paper medical records, substantial variability in performing assessments on the part of healthcare providers according to individual and local practice, magnified by patients' variability in coming in for recommended routine visits, limits the extent to which clinical data from secondary sources can be used to address some research questions. See section on "Clinician- or Site-Reported Outcomes" later in this chapter.

Commonly, prospective studies, including planned analysis of laboratory data or imaging studies over time, may incorporate primary data collection to ensure complete collection of assessments and that timing of assessments is aligned with the study follow-up period. Additionally, use of a central lab to reduce variability in laboratory measures may be

considered to further increase the validity of study results. The PROVALID study (PROspective cohort study in patients with type 2 diabetes mellitus for VALIDation of biomarkers), launched in five EU countries (Austria, Hungary, The Netherlands, Poland, and Scotland), will obtain laboratory measurements on 4000 enrolled patients with type 2 diabetes treated in the primary care setting to examine the impact of medication and predict the clinical course of disease, including renal and cardiovascular events. PROVALID requires collection of a minimum set of clinical data parameters, with the option to collect many additional laboratory and medical history characteristics on enrolled patients [5].

Characterization of Patient-Reported Outcomes Not Captured in Secondary Data

It is often important to evaluate the burden of disease on patients and how that burden is affected by various treatments. For example, the symptom burden on work-related abilities was evaluated in patients being treated for locally recurrent or metastatic breast cancer. Information on the ability to perform work was ascertained directly from patients [6]. More information on patient engagement and direct-to-patient designs can be found in an electronic book on 21st Century Patient Registries [7] and in the section on "Patient-Reported Outcomes and Other Patient-Reported Measures" later in this chapter.

Studies of Rare Populations

When it is necessary to assemble as large and representative a sample as possible from a rare population, one or more existing data sources may not capture enough of the patient population of interest to address study aims.

Rare disease registries and pregnancy exposure registries commonly face the challenge of a small number of patients with the condition or exposure of interest, distributed over many countries, for which no single existing data source likely includes enough patients to address research aims.

The lysosomal storage disorders (LSDs) are a group of genetic conditions characterized by enzyme deficiencies that leave cells unable to clear waste products, which accumulate with a range of harmful physical effects if not successfully treated. A number of global registries developed to study the natural history, treatment patterns, and effectiveness of existing treatments for LSDs, including Fabry, Gaucher, hereditary angioedema, mucopolysaccharidosis I (MPS 1) and 2 (MPS 2, Hunter syndrome), and Pompe disease have been sponsored by manufacturers of enzyme replacement therapies and other treatments, and by patient associations [8–12]. In the case of such rare conditions, where small numbers of patients and the providers who treat them are scattered across the globe, a registry serves multiple purposes of linking individual patients with each other and with a treatment community, as well as potentially drawing upon a large and representative population available for research. The validity of conclusions that may be drawn from analyses of this kind of registry data depends on the degree to which subjects in the registry are not selectively included because of their treatment outcomes, and that follow-up is relatively complete.

Vaccine Safety

Some adverse events (AEs) of interest may not be routinely captured in existing data sources (see Chapter 20).

Beginning in 2014, the European Medicines Agency (EMA) has required annual enhanced safety surveillance (ESS) for all seasonal influenza vaccines. The interim guidance from the Pharmacovigilance Risk Assessment Committee (PRAC) included the requirement to collect data that would support the identification of any significant change in frequency or severity of reactogenicity in comparison with previous

years' experience with the same vaccine composition [13]. Reactogenicity AEs of interest as specified in the guidance include vaccination site reactions, headache, malaise, myalgia, shivering, rash, vomiting, nausea, arthralgia, decreased appetite, irritability, and crying (in pediatric vaccinees less than 5 years of age). Such symptoms, especially when mild or moderate in severity, are not commonly reported to healthcare providers and thus medical records are not a useful source of data to study these outcomes following vaccination. Instead, studies and surveillance activities to implement the requirements for ESS have incorporated patient (and proxy for pediatric patients) self-report of occurrence of symptoms to obtain this information in a systematic manner, for example through distribution of Safety Report Cards allowing patients to report these symptoms by telephone or mail [14].

Studies of Medical Devices

Device studies may require information on batch and manufacture location that are not often available in existing data sources (see Chapter 21). Additional information on the "operator" or healthcare provider implanting or administering the device may also help to provide a full characterization of product safety and effectiveness.

For example, the National Cardiovascular Data Registry compares the effectiveness of drug-eluting and bare metal stents in reducing risk of death or myocardial infarction [15]. Studies of the Björk–Shiley heart valve showed the importance of manufacturing site as a risk factor for valve failure [16].

Special Requirements, Controlled Distribution Products

Some products are approved by regulatory authorities with special requirements for reporting mainly related to safety concerns. Often such requirements necessitate data collection specific to the product to ensure robust monitoring of safety concerns.

Several active mandated safety registries and an example of a multisponsor pediatric safety registry were described in the Pink Sheet in 2009, "Registries Rising: FDA Looking at TNF Inhibitors; AHRQ Updates Standards" [17]. These examples included a pregnancy registry for the same product (ClinicalTrials.gov identifier NCT01026077), a pregnancy registry as part of a restricted distribution program for eltrombopag (ClinicalTrials.gov identifier NCT01064336), a thrombopoietin receptor agonist for treatment of idiopathic thrombocytopenia purpura (ITP) sponsored by GlaxoSmithKline, and a safety registry for teriparatide, an anabolic treatment for osteoporosis and an expanded indication of glucocorticoid-induced osteoporosis sponsored by Eli Lilly.

Hybrid or Enriched Designs

Some studies may not rely on primary or secondary data alone. The terms "hybrid" or "enriched" are frequently used to describe study designs that draw upon both primary and secondary data, with some data collected *de novo* specifically for the purposes of the study and other study-specific data collected via probabilistic or deterministic linkage with other data sources, such as electronic health records, administrative claims and billing data, vital records, and genetic information.

The DISCOVER study is an example of an enriched study. The study objective is to characterize and describe the management of patients initiating second-line therapy for type 2 diabetes; data are being collected from patients at sites in 38 countries, with linkage of electronic health records where feasible. Information is collected about diabetes management including patients' health-related quality of life [18]. For more information see www.discoverdiabetes.com/.

Description

Clinician- or Site-Reported Outcomes

The traditional approach to primary data collection has been to recruit healthcare providers (HCPs) for study and then for those HCPs to recruit patients following agreed-upon inclusion and exclusion criteria as described in the protocol. When HCPs can form accurate assessments after observation of a patient's health condition, those clinician-reported outcomes (ClinROs) can become the measurement on which a study endpoint is based. Traditionally, data collection was performed on paper, but now most such data collection is electronic through case report forms (CRFs) designed specifically for study purposes. This model requires institutional board review (ethical review) and site contracts with each investigator. Generally, investigators expect some payment for data collection, and such payments must be proportional to time spent and fair market value.

Patient-Reported Outcomes and Other Patient-Reported Measures

There is a growing interest in collecting data from patients on exposures and outcomes. These data can be collected directly from patients without the intervention of HCPs or can be collected from patients during a study visit or electronically in between study visits.

Recent research has established the validity of patient-reported prescription medication use, laying a foundation for its reliability as well as demonstrating the rich additional information that can be obtained, such as nonprescription medication use, recreational drug use, smoking, and alcohol intake [3]. There are a large number of validated patient-reported outcome (PRO) measures that can provide important insights into the patient experience, including treatment satisfaction, quality of life, ability to care for oneself, work, etc., and new tools are constantly in development. If patients will be contacted for any study data, supplementary information can often be obtained at a small marginal cost, especially if data collection is as brief as possible.

Despite good motivations, the more data that are sought from patients, the less likely it is that they will complete the questions or continue to participate in the study. Also, clinical input may be needed to accurately and fully report patients' medical histories and serious health events of special interest. Clinical validation is often obtained for patient-reported clinical events of special interest.

Objective measures of patients' physical activity are of interest in numerous therapeutic areas for pharmacoepidemiologic research, including chronic obstructive pulmonary disease, cardiovascular disease, and depression. Quantification of the validity and reliability of wearable sensors that collect information about physical activity and various other clinically useful data will encourage greater use in longitudinal observational studies and pragmatic trials. At the time of this chapter, mainly smaller or cross-sectional observational studies and a few randomized clinical trials have incorporated accelerometry measurement of physical activity as a study exposure, covariate of interest, or endpoint [19,20].

Registries as Means of Data Collection

As previously mentioned, registries may be established to fill a need for data collection that may support multiple research and/or public health surveillance objectives.

Population-based state, regional, and national cancer registries have played a major role in cancer surveillance, by quantifying cancer incidence and mortality, and trends over time throughout the world, and in pharmacoepidemiology, by providing data on prognostic factors, treatment, and outcomes for analysis within single or across linked databases. In the United States, the Surveillance, Epidemiology,

and End Results (SEER) program of the National Cancer Institute works from a network of 18 cancer registries in 14 states that actively collect information on all reported cancers diagnosed in their coverage areas [21].

Pharmacoepidemiologic studies using cancer registries have included case–control studies such as the Cancer and Steroid Hormone (CASH) study of oral contraceptive use and breast [22], ovarian [23], and endometrial [24] cancer, and patterns of care studies of the dissemination of advanced cancer treatment modalities throughout different population groups and into community practice [25–27]. With approval, researchers may be granted access to the SEER-Medicare linked data files, which include Medicare claims before, during, and following cancer diagnosis and treatment [28]. Topics studied include influences of treatment, facility, and provider characteristics and interventions on survival and cost outcomes [29–31], as well as disparities in care [32].

Biobanks/Specimen Banks

Clinical data are increasingly being linked with biorepository data to guide researchers in the identification of biomarkers that are predictive of clinical outcomes and support the development of targeted therapies, for example by identifying patients whose tumors harbor a genomic variant that can potentially be targeted by a new drug. Some biobanks are being set up internationally, such as the EuroBioBank network, which was created to support research on rare diseases [33]. The UK Biobank is also a good example of an international long-term registry accessible for research, which is following around 500 000 volunteers for at least 25 years to investigate the contributions of genetic predisposition and environmental exposure (including nutrition and lifestyle) to disease development, and gain valuable insights to support the development of new medicines [34].

Guidelines on the Quality of Data Collection

There are a variety of recent guidelines that broadly speak to studies that use primary data collection, such as the Guidelines for Good Pharmacoepidemiologic Practice developed by the International Society for Pharmacoepidemiology [35], the checklist for study protocols developed by the European Network of Centers for Pharmacoepidemiology and Pharmacovigilance [36], and principles of good epidemiologic methods and practice (see Chapter 3) [37]. Also, the GRACE (Good Research for Comparative Effectiveness) Principles for conducting and evaluating observational studies of comparative effectiveness are applicable to studies that use primary data collection and may help guide the study design [38,39]. More detail about operational aspects of primary data collection can be found in the Registries for Evaluating Patient Outcomes: A User's Guide [40]. In that guide, the chapter on assessing quality provides a detailed listing of various aspects of primary data collection relating to research quality and evidence quality, describing both the basic elements of good practice and potential enhancements [41].

Strengths

A notable strength of primary data collection is that it can address research objectives that require information that is not otherwise accessible or not consistently recorded in available secondary data sources. This type of information can be particularly meaningful to clinicians, patients, regulators, payers, and those involved in drug development, and is often more directly useful than inferences derived from billing data and often cryptic and spotty electronic health data.

Studies that use data collection directly from patients also provide the opportunity to follow

patients over long periods of time and to evaluate a variety of outcomes. For chronic diseases, patients may be followed for years by their treating physicians, regardless of whether a patient's health insurance program changes – an important limitation of health insurance claims data. Patients may also be followed directly for self-reported outcomes, both for clinical outcomes (which may be confirmed with medical records or by physicians, as needed) and quality-of-life measures. It is often the patient's relationship with the physician, and the physician's relationship with the research program, that is particularly effective for long-term retention. For example, the VIRGO study followed patients with metastatic breast cancer in collaboration with their treating physicians to understand the impact of treatment on quality of life as the disease progressed [42].

Limitations

Primary data collection requires cooperation of data contributors, often over long periods of time (follow-up). While it would seem that altruism should be a sufficient motivation, experience has shown that successful primary data collection requires an infrastructure supporting patient and/or physician enrollment and retention, as well as an active program of data curation to assure that the data collected are accurate and reliable. Further, one must be mindful about the use of patient-centered endpoints, especially pertaining to general and disease-specific quality of life assessments and to detailed information on past exposures, such as in case–control studies where the study outcome is known to the patients at the time of the assessment [43]. Like all data, the contribution to be made by patients in recall of past medical diagnoses and exposures of interest to pharmacoepidemiologic studies must be considered carefully in view of their strengths and limitations [44–46].

It is also important to keep in mind that consumers are likely to report serious AEs quite differently from clinicians, and such reports may require clinical validation for use for research purposes. For example, the PROTECT study examined medication use during pregnancy using biweekly or monthly questionnaires administered via the internet, with the frequency of follow-up determined according to the participants' choosing [47]. Respondents were able to clearly describe serious but rare birth defects, but used common terms that were difficult to code for less serious conditions that might not meet the clinician threshold for being considered a birth defect, for example the eyes were too small or the nose appeared to be off-center.

In addition to data quality, the two major challenges in primary data collection relate to enrollment and retention. It is often difficult to find and recruit clinicians who treat patients of interest, or patients who have the exposures or conditions of interest, no matter how important the research question. For example, Pfizer made great fanfare over the launch of its first "virtual trial" called REMOTE, that focused on overactive bladder treatment. The study was halted less than a year after launch because of poor recruitment, with a spokesman from the sponsoring organization commenting that social media was a great way to spread awareness of the trial but did not build enough trust for patients to actually sign up [48].

"Sufficient" retention (regardless of the target) can be difficult to achieve when using primary data collection. Retention rates are often higher for studies that are (1) responsive to the needs of patients and physicians. so they are motivated to continue participating (a special concern for pregnancy registries and other vulnerable populations), and (2) parsimonious in their data collection [49]. Operational challenges relate to the need to deploy primary data collection systems that are easy to use, and simple enough to encourage steady reporting but

which do not result in reporting fatigue. Multiple methods of data entry such as internet, text messaging, and/or mail can be an advantage, considering the demographics of the target population, although many researchers believe that there is a positive impact on retention from consistent personal interactions between study staff and clinical investigators and/or patients, a technique often deployed in pregnancy registries.

While there is some optimism that newer technologies and the nearly universal adoption of smartphones would support the use of text messaging and internet-based patient surveys, results from the PROTECT study raised a cautionary note [47]. Researchers noted that internet-based recruitment of pregnant women was surprisingly difficult and study retention was low, speculating that although it was relatively easy to send questionnaires frequently, participants appeared to tire quickly of responding to the same questions over time.

Enrollment logs that record some information about those who are eligible to participate but decline or later drop out can be used to evaluate selection bias and the impact of loss to follow-up. For example, studies that collect some basic personal identifiers such as name (first, last, and middle initial) and date of birth can be linked with the National Death Index in the United States to search for deaths and obtain information on cause of death.

Particular Applications

To provide further illustration of some of the applications of primary data collection in modern pharmacoepidemiologic research, several examples are described in further detail in this section. These include a prospective comparative effectiveness research (CER) study incorporating collection of clinical endpoints and PROs, a novel hybrid study intended to provide data in support of a label expansion with FDA, use of large registry data as a framework for conduct of multiple observational studies, and incorporation of measures of physical activity through accelerometry as part of the UK Biobank effort.

The Registry in Glaucoma Outcomes Research (RiGOR) study, funded by the US Agency for Healthcare Research and Quality, was a prospective observational study that used primary data collection to address which treatment strategy for open-angle glaucoma was associated with the greatest improvement in patient outcomes [50]. The study found that patients treated with incisional surgery after failing at least one course of medication were twice as likely as patients treated with additional medication to achieve a 15% reduction in intraocular pressure (IOP) at 12 months, while patients treated with laser surgery had similar results to those who were treated with additional medication [51]. While IOP is routinely recorded when glaucoma patients see their ophthalmologists, in order to ensure complete assessment of IOP at around six and 12 months of follow-up, it was a required element in the study's CRF, along with a vast array of other detailed clinical information. The RiGOR study also included several validated PROs assessments as secondary endpoints, which further required patients to complete these questionnaires at the time of a study visit or at home through mail or electronic means [52].

The Bioventus Exogen® device registry is a novel example of a hybrid or enriched design involving both primary and secondary data. This study was planned following extensive discussions with the US Food and Drug Administration Center for Drug Evaluation and Research (FDA CDER) regarding this novel design for a label expansion. The study utilizes a prospective direct-to-patient product registry linked with a propensity score matched comparator group from a commercial claims database for study of a device used to treat bone fracture nonunion, currently used broadly outside of labeled indications to treat fracture [53].

Two European cancer registries provide examples of registry infrastructure being built to address innumerable current and future research questions pertaining to cancer incidence and survival. The EUROCARE (European Cancer Registry Based Study on Survival and Care of Cancer Patients) registry is a very large collaborative research project on cancer survival [54]. The registry started in 1989, aiming to provide updated descriptions of cancer survival time trends and differences across European countries, to measure cancer prevalence, and study patterns of care of cancer patients. Its fifth and current edition, EUROCARE-5, includes data on more than 21 million cancer diagnoses provided by 116 cancer registries in 30 European countries [55]. At least 165 publications have been generated from EUROCARE-1–5, covering trends in survival across a very broad range of cancer types as well as patterns of care and predictors of survival and other outcomes [56]. The European Cancer Observatory (ECO) is another important project developed at the International Agency for Research on Cancer (IARC) in partnership with the European Network of Cancer Registries (ENCR) in the framework of the EUROCOURSE project which is supported by the European Commission. It presents national estimates of cancer incidence, mortality, and prevalence for 24 major cancer types in 40 European countries for 2012. This registry also allows for the exploration of geographical patterns and temporal trends [57]. Access to cancer datasets is possible on a user registration and permission request basis [58].

An additional area of data collection for the UK Biobank to support the inclusion of objective measures of physical activity in large-scale observational studies has been to obtain measures of physical activity from accelerometers from over 100 000 participants [59]. Forty-five percent of those invited to wear accelerometers for seven days accepted the invitations; from these, over 93% provided sufficient valid data for analysis.

The Future

Newer methods of collecting data directly from patients and from doctors, including internet-based data collection, integrated voice response systems with auto-coding features, and use of wearable sensors, will facilitate rapid accumulation of data; however, the validity, accuracy, and usefulness of these new methods need to be evaluated. Factors that affect recruitment and retention also must be considered. Just because it may be relatively easy to contribute data does not mean that patients will continue to do so over a long period of time. In focus groups used in the PROTECT study, pregnant women reported that some reimbursement for their time for each survey completed, even something nominal, would increase their interest in staying in a study since it would show that researchers value their input [60].

An exciting new direction is the potential for enriched studies to be conducted on a more routine basis. For example, there is growing interest in expanding patient registry data collection to allow patients to authorize linkage with other of their healthcare data on an ongoing basis. In these situations and where local law allows, the Informed Consent document is likely to require inclusion of general information described below.

- I have read the contents of this form and I understand, agree, and allow my Health Plan, The REGISTRY Coordinating Center at XXXX, and my healthcare provider to use and release information about me as described above. I also understand that signing this form is of my own free will and will in no way affect the medical care that I receive.
- If I choose not to participate in this linkage to claims information, I understand that my Health Plan will not base decisions regarding my treatment, eligibility for benefits, enrollment in a Health Plan, or payment of claims on my decision regarding study participation.

- If I choose not to participate in this linkage it will not impact my participation in the main REGISTRY. Additionally, I can choose to withdraw from the linkage at any time and remain in the main REGISTRY if I choose.
- I have the right to withdraw this approval at any time by giving written notice of my withdrawal to the REGISTRY. I understand that my withdrawing this approval will not affect any action taken before I do so. I also understand that once my information is shared outside the REGISTRY, it will not be traceable to me. However, the information from my records will still be protected by other privacy rules and agreements.
- At my request, I will be given a copy of this form either when I sign it or while the study is ongoing.

In summary, despite the growing availability of large amounts of data on treatments and patients' clinical experience, it is unlikely that such data will ever contain all information needed for every study purpose; thus, the need for primary data collection will remain. Traditionally, HCPs have been the primary reporters/recorders of data for studies that use primary data collection, although there is growing interest in collecting data directly from patients either exclusively or in combination with wearable devices and/or clinician-reported data, and/or to enrich existing data. While the methods for such data collection can and will change over time, it is likely that researchers will always need to invest time in data curation to assure that the data are accurately represented and to check for critical data that are systematically missing. Primary data collection will continue to be a mainstay of pharmacoepidemiologic research, either as the sole method of data collection or as a key component of research that uses many modes of data collection.

Choosing a Data Source

17

Choosing among the Available Data Sources for Pharmacoepidemiology Research

Brian L. Strom

Rutgers Biomedical and Health Sciences, Newark, NJ, USA

As discussed in previous chapters, pharmacoepidemiologic studies apply the techniques of epidemiology to the content area of clinical pharmacology. Between 500 and 3000 individuals are usually studied prior to drug marketing. Most postmarketing pharmacoepidemiologic studies need to include at least 10 000 subjects, or draw from an equivalent population for a case–control study, in order to contribute sufficient new information to be worth their cost and effort (see Chapter 4). This large sample size raises logistical challenges. Chapters 10–16 presented many of the different data collection approaches and data resources that have been developed to perform pharmacoepidemiologic studies efficiently, meeting the need for these very large sample sizes. This chapter is intended to synthesize this material, to assist the reader in choosing among the available approaches.

Choosing among the Available Approaches to Pharmacoepidemiologic Studies

Once one has decided to perform a pharmacoepidemiologic study, one needs to decide which of the data collection approaches or data resources described in the earlier chapters of this book should be used. Although to some degree the choice may too often be based upon a researcher's familiarity with given data resources and/or the investigators who have been using them, it is very important to tailor the choice of pharmacoepidemiologic resource to the question to be addressed. One frequently may want to use more than one data collection strategy or resource, in parallel or in combination. If no single resource is optimal for addressing a question, it can be useful to use a number of approaches that complement each other. Indeed, this is probably the preferable approach for addressing important questions. Regardless, investigators are often left with a difficult and complex choice.

In order to explain how to choose among the available pharmacoepidemiologic data resources, it is useful to synthesize the information from the previous chapters on the relative strengths and weaknesses of each of the available pharmacoepidemiologic approaches, examining the comparative characteristics of each (see Table 17.1). One can then examine the characteristics of the research question at hand, in order to choose the pharmacoepidemiologic

Note: See the chapter text for descriptions of the column headings, and previous chapters for descriptions of the data resources. N/A, not applicable.

approach best suited to addressing that question (see Table 17.2). The assessment and weights provided in this discussion and in the accompanying tables are arbitrary. They are not being represented as a consensus of the pharmacoepidemiologic community, but represent the judgment of this author alone, based on the material presented in earlier chapters of this book. Nevertheless, I think that most would agree with the general principles described, and even many of the relative ratings. My hope is that this synthesis of information, despite some of the arbitrary ratings inherent in it, will make it easier for the reader to synthesize the large amount of information presented in prior chapters.

Note that there are a number of other data sources not discussed here, some of which have been, or in the future may be, of importance to pharmacoepidemiologic research. Examples include the old Boston Collaborative Drug Surveillance data [1], MEMO [2], Pharmetrics® [3], Aetna [4], Humana [5], and many others, many reviewed in prior editions of this book. Given the wonderful proliferation of pharmacoepidemiologic data resources, we are making no attempt to include them all. Instead, we will discuss them in categories of types of data, as we did in the chapters themselves.

Comparative Characteristics of Pharmacoepidemiologic Data Resources

Table 17.1 lists each of the different pharmacoepidemiologic data resources that were described in earlier chapters, along with some of their characteristics.

The *relative size* of the database refers to the population it covers. Only spontaneous reporting systems, US Medicare, some of the pharmacy-based medical record linkage systems, and Prescription Event Monitoring in the UK cover entire countries or large fractions thereof. Of course, population databases differ considerably in size, based on the size of their underlying populations. Aggregations of Medicaid databases are the next largest, with the commercial databases approaching that. The UK electronic health record databases would be next in size, as would the health maintenance organizations (HMOs), depending on how many are included. The Canadian provincial databases again could be equivalently large, depending in part on how many are included in a study. The other data resources are generally smaller. Case–control surveillance, as formerly conducted by the Slone Epidemiology Unit, can cover a variable population, depending on the number of hospitals and metropolitan areas included in the network for a given study. The population base of registry-based case–control studies depends on the registries used for case finding. *Ad hoc* studies can be whatever size the researcher desires and can marshal resources for.

As to *relative cost*, studies that collect new data are most expensive, especially randomized trials and cohort studies, for which sample sizes generally need to be large and follow-up may need to be prolonged. In the case of randomized trials, there are additional logistical complexities. Studies that use existing data are least expensive, although their cost increases when they gather primary medical records for validation. Studies that use existing data resources to identify subjects but then collect new data about those subjects are intermediate in cost.

With regard to the *relative speed* of study completion, studies that collect new data take longer, especially randomized trials and cohort studies. Studies that use existing data are able to answer a question most quickly, although considerable additional time may be needed to obtain primary medical records for validation. Studies that use existing data resources to identify subjects but then collect new data about those subjects are intermediate in speed.

Representativeness refers to how well the subjects in the data resource represent the population at large or a more specific population of

Table 17.2 Characteristics of research questions and their impact on the choice of pharmacoepidemiologic data resources.

Notes: See the text of the chapter for descriptions of the column headings, and previous chapters for descriptions of the data resources.
[a] Hypothesis-generating studies are designed to raise new questions about possible unexpected drug effects, whether adverse or beneficial.
[b] Hypothesis-strengthening studies are designed to provide support for, although not definitive evidence for, existing hypotheses.
[c] Hypothesis-testing studies are designed to evaluate in detail hypotheses raised elsewhere.

interest. US Medicare, Prescription Event Monitoring in the UK, the provincial health databases in Canada, and the pharmacy-based medical record linkage systems include entire countries, provinces, or states, and so are typical populations. Spontaneous reporting systems are drawn from entire populations, but of course the selective nature of their reporting could lead to less certain representativeness. Medicaid programs are limited to the disadvantaged, and so include a population that is least representative of a general population. Analogously, randomized trials include populations limited by the various selection criteria plus their willingness to volunteer for the study. The Clinical Practice Research Datalink® (CPRD®) and The Health Improvement Network® (THIN®) use a nonrandom large subset of the total UK population, and so may be representative of the overall UK population. Health plans and commercial databases are closer to representative populations than a Medicaid population would be, although they include a largely working population and, so, include few patients of low socioeconomic status and fewer than normal elderly. Some of the remaining data collection approaches or resources are characterized in Table 17.1 as "variable," meaning their representativeness depends on which hospitals are recruited into the study. *Ad hoc* studies are listed in Table 17.1 "as desired," because they can be designed to be representative or not, as the investigator wishes.

Whether a database is *population based* refers to whether there is an identifiable population (which is not necessarily based on geography), all of whose medical care would be included in that database, regardless of the provider. This allows one to measure incidence rates of diseases, as well as being more certain that one knows of all the medical care that any given patient receives. As an example, assuming little or no out-of-plan care, the Kaiser programs are population based. One can use Kaiser data, therefore, to study medical care received in and out of the hospital, as well as diseases that may result in repeat hospitalizations. For example, one could study the impact of the treatment initially received for venous thromboembolism on the risk of subsequent disease recurrence. In contrast, hospital-based case–control studies conducted outside a closed network like Kaiser are not population based: they include only the specific hospitals that belong to the system and do not capture all healthcare services a patient may receive. Thus, a patient diagnosed with and treated for venous thromboembolism in a participating hospital could be readmitted to a different, nonparticipating hospital if the disease recurred. This recurrence would not be detected in a study using such a system. The data resources that are population based are those that use data from organized healthcare delivery or payment systems. Registry-based and *ad hoc* case–control studies can occasionally be conducted as population-based studies, if all cases in a defined geographic area are recruited into the study [6], but this is unusual (see also Chapters 3 and 16).

Whether cohort studies are possible within a particular data resource would depend upon whether individuals can be identified by whether or not they were exposed to a drug of interest. This would be true in any of the population-based systems, as well as any of the systems designed to perform cohort studies.

Whether case–control studies are possible within a given data resource depends upon whether patients can be identified by whether or not they suffered from a disease of interest. This would be true in any of the population-based systems. Data from spontaneous reporting systems can be used for case finding for case–control studies, although this has been done infrequently [7].

The *validity of the exposure data* is most certain in hospital-based settings, where one can be reasonably certain of both the identity of a drug and that the patient actually ingested it. Exposure data in spontaneous reporting systems come mostly from healthcare providers

and so are probably valid. However, one cannot be certain of patient adherence in spontaneous reporting data. Exposure data from claims data and from pharmacy-based medical record linkage systems are unbiased data recorded by pharmacies, often for billing purposes, a process that is closely audited as it impacts reimbursement. These data are likely to be accurate with regard to medication possession, although, again, one cannot assure adherence. Refill adherence, though, has been found to correlate closely with adherence measured using microchips embedded in medication bottles (see Chapter 38). However, there are drugs that may fall beneath a patient's deductibles or co-payments, or not be on formularies, so dispensed by the pharmacy but paid for in cash. In claims databases, these scenarios may result in misclassification of true medication exposure, as the patient would falsely appear unexposed. Also, since drug benefits vary depending upon the plan, pharmacy files may not capture all prescribed drugs if beneficiaries reach the drug benefit limit or pay for the prescription out of pocket. In the UK medical record systems, drugs prescribed by physicians other than the general practitioner could be missed, although continued prescribing by the general practitioner would be detected. *Ad hoc* case–control studies generally rely on patient histories for exposure data. These may be very inaccurate, as patients often do not recall correctly the medications they are taking [8]. However, this would be expected to vary, depending upon the condition studied, type of drug taken, questioning technique used, and so on [8–16] (see Chapter 37).

The *validity of the outcome data* is also most certain in hospital-based settings, in which the patient is subjected to intensive medical surveillance (see Chapter 14). It is least certain in outpatient data from organized systems of medical care. There are, however, methods of improving the accuracy of these data, such as using drugs, laboratory data, and procedures as markers of the disease and obtaining primary medical records (see Chapter 37). The outcome data from automated databases are listed as variable, therefore, depending upon exactly which data are being used and how. The UK medical record systems analyze the actual medical record, rather than claims, and can access additional questionnaire data from the general practitioner as well. Thus, their outcome data may be more accurate.

Control of confounding refers to the ability to control for confounding variables. As discussed in Chapter 3, randomization is the most convincing way of controlling for unknown, unmeasured, or unmeasurable confounding variables. Approaches that collect sufficient information to control for known and measurable variables are next most effective. These include health plans, the UK medical record systems, case–control surveillance, *ad hoc* case–control studies, and *ad hoc* cohort studies. Users of health databases in Canada, commercial databases, and Medicaid (sometimes) can obtain primary medical records, but not all information necessary is always available in those records. They generally are unable to contact patients directly to obtain supplementary information that might not be in a medical record. Finally, spontaneous reporting systems do not provide enough systematically collected information for control of confounding.

Relatively few of the data systems have data on *inpatient drug use*. The exceptions include spontaneous reporting systems, in-hospital databases (see Chapter 14), and some *ad hoc* studies if designed to collect such.

Only a few of the data resources have sufficient *data on outpatient diagnoses* available without special effort to be able to study them as outcome variables. *Ad hoc* studies can be designed to be able to collect such information. In the case of *ad hoc* randomized clinical trials, this data collection effort could even include tailored laboratory and physical examination measurements. In some of the resources, the

outpatient outcome data are collected observationally, but directly via the physician, and so are more likely to be accurate. Included are spontaneous reporting systems, the UK medical record systems, HMOs, Prescription Event Monitoring, and some *ad hoc* cohort studies. Other outpatient data come via physician claims for medical care, including Medicaid databases, commercial databases, and the provincial health databases in Canada. Finally, other data resources can access outpatient diagnoses only via the patient, so they are less likely to be complete; although the diagnosis can often be validated using medical records, it generally needs to be identified by the patient. These include most *ad hoc* case–control studies.

The degree of *loss to follow-up* differs substantially among the different resources. They are specified in Table 17.1.

Characteristics of Research Questions and Their Impact on the Choice of Pharmacoepidemiologic Data Resources

Once one is familiar with the characteristics of the pharmacoepidemiologic resources available, one must then examine more closely the research question, to determine which resources can best be used to answer it (see Table 17.2).

Pharmacoepidemiologic studies can be undertaken to generate hypotheses about drug effects, to strengthen hypotheses, and/or to test *a priori* hypotheses about drug effects. *Hypothesis-generating studies* are studies designed to raise new questions about possible unexpected drug effects, whether adverse or beneficial. Virtually all studies can and do raise such questions, through incidental findings in studies performed for other reasons. In addition, virtually any case–control study could be used, in principle, to screen for possible drug causes of a disease under study, and virtually any cohort study could be used to screen for unexpected outcomes from a drug exposure under study. In practice, however, the only settings in which this has been attempted systematically have been health plans, case–control surveillance, Prescription Event Monitoring, and Medicaid databases. To date, the most productive source of new hypotheses about drug effects has been spontaneous reporting. However, this is the goal of Sentinel, a Congressionally mandated data system of over 100 million US lives, initially built primarily for hypothesis strengthening as "Mini-Sentinel," although now being used for hypothesis generation as well, in addition to the traditional approach of using such data for hypothesis testing (see Chapter 25). In the future, new approaches using the internet (e.g., health websites with consumer posting boards and other social media) could potentially be used for hypothesis generation of events, including those not coming to medical attention.

Hypothesis-strengthening studies are designed to provide support for, although not definitive evidence for, existing hypotheses. The objective of these studies is to provide sufficient support for, or evidence against, a hypothesis to permit a decision about whether a subsequent, more definitive study should be undertaken. As such, hypothesis-strengthening studies need to be conducted rapidly and inexpensively. They can include crude analyses conducted using almost any dataset, evaluating a hypothesis which arose elsewhere. Because not all potentially confounding variables would be controlled, the findings could not be considered definitive. Examples would be the modular studies conducted within Sentinel (see Chapter 25). Alternatively, hypothesis-strengthening studies can be more detailed, controlling for confounding, conducted using the same data resource that raised the hypothesis. In this case, because the study is not specifically undertaken to test an *a priori* hypothesis, the hypothesis-testing type of study can only serve to strengthen, not test, the hypothesis. Spontaneous reporting systems are useful for raising hypotheses, but are

not very useful for providing additional support for those hypotheses. Conversely, randomized trials can certainly strengthen hypotheses, but are generally too costly and logistically too complex to be used for this purpose. (*Post-hoc* analyses of randomized trials can obviously be reanalyzed, for the purposes of generating or strengthening hypotheses, but then they are really being analyzed as cohort studies.) Of the remaining approaches, those that can quickly access, in computerized form, both exposure data and outcome data are most useful. Those that can rapidly access only one of these data types, only exposure or only outcome data, are next most useful, while those that need to gather both data types are least useful, because of the time and expense that would be entailed.

Hypothesis-testing studies are designed to evaluate in detail hypotheses raised elsewhere. Such studies must be able to have simultaneous comparison groups and must be able to control for most known potential confounding variables. For these reasons, spontaneous reporting systems cannot be used for this purpose, as they cannot be used to conduct studies with simultaneous controls (with rare exceptions, see [2]). The most powerful approach, of course, is a randomized clinical trial, as it is the only way to control for unknown or unmeasurable confounding variables. Instrumental variable analyses can approximate a randomized clinical trial, but only in the circumstances, to date limited, that all the underlying assumptions are met. (On the other hand, studies of dose response, duration response, drug–drug interactions, determinants of response, etc. are more readily done in nonrandomized than randomized studies; see Chapter 3.) Techniques which allow access to patients and their medical records are the next most powerful, as one can gather information on potential confounders that might only be reliably obtained from one of those sources or the other. Techniques which allow access to primary records but not the patient are next most useful.

The research implications of questions about the *beneficial effects* of drugs are different, depending upon whether the beneficial effects of interest are expected or unexpected. Studies of *unexpected beneficial effects* are exactly analogous to studies of unexpected adverse effects, in terms of their implications for one's choice of approach; in both situations one is studying side effects. Studies of *expected beneficial effects*, or drug efficacy, raise the special methodologic problem of confounding by the indication: patients who receive a drug are different from those who do not in a way which usually is related to the outcome under investigation in the study. This issue is discussed in detail in Chapter 33. As described there, it *is* sometimes possible to address these questions using nonexperimental study designs. Generally, however, the randomized clinical trial is far preferable, when feasible.

In order to address questions about the *incidence of a disease* in those exposed to a drug, one must be able to quantify how many people received the drug. This information can be obtained using any resource that can perform a cohort study. Techniques that need to gather the outcome data *de novo* may miss some of the outcomes if there is incomplete participation and/or reporting of outcomes, such as with Prescription Event Monitoring, *ad hoc* cohort studies, and outpatient pharmacy-based cohort studies. On the other hand, *ad hoc* data collection is the only way of systematically collecting information about outcomes that need not come to medical attention (see below). The only approaches that are free from either of these problems are hospital-based approaches. Registry-based case–control studies and *ad hoc* case–control studies can occasionally be used to estimate incidence rates, if one obtains a complete collection of cases from a defined geographic area. The other approaches listed cannot be used to calculate incidence rates.

To address a question about a *low incidence outcome*, one needs to study a large population

(see Chapter 4). This can best be done using spontaneous reporting, US Medicare, Prescription Event Monitoring, or the pharmacy-based medical record linkage systems, which can or do cover entire countries. Alternatively, one could use commercial databases, health plans, or aggregates of Medicaid databases, which cover a large proportion of the US, or the medical record systems in the UK. Canadian provincial databases can also be fairly large, and one can perform a study in multiple such databases. *Ad hoc* cohort studies could potentially be expanded to cover equivalent populations. Case–control studies, either *ad hoc* studies, studies using registries, or studies using case–control surveillance, can also be expanded to cover large populations, although not as large as the previously mentioned approaches. Because case–control studies recruit study subjects on the basis of the patients suffering from a disease, they are more efficient than attempting to perform such studies using analogous cohort studies. Finally, randomized trials could, in principle, be expanded to achieve very large sample sizes, especially large simple trials (see Chapter 32), but this can be extremely difficult and costly.

To address a question about a *low prevalence exposure*, one also needs to study a large population (see Chapter 4). Again, this can best be done using spontaneous reporting, US Medicare, the pharmacy-based medical record linkage systems, or Prescription Event Monitoring, which cover entire countries. Alternatively, one could use commercial databases, large health plans, or aggregates of Medicaid databases, which cover a large proportion of the US, or the medical record databases in the UK. *Ad hoc* cohort studies could also be used to recruit exposed patients from a large population. Analogously, randomized trials, which specify exposure, could assure an adequate number of exposed individuals. Case–control studies, either *ad hoc* studies, studies using registries, or studies using case–control surveillance, could theoretically be expanded to cover a large enough population, but this would be difficult and expensive.

When there are *important confounders* that need to be taken into account in order to answer the question at hand, then one needs to be certain that sufficient and accurate information is available on those confounders. Spontaneous reporting systems cannot be used for this purpose. The most powerful approach is a randomized trial, as it is the most convincing way to control for unknown or unmeasurable confounding variables. Techniques which allow access to patients and their medical records are the next most powerful, as one can gather information on potential confounders that might only be reliably obtained from one of those sources or the other. Techniques which allow access to primary records but not the patient are the next most useful.

If the research question involves *inpatient* drug use, then the data resource must obviously be capable of collecting data on inpatient drug exposures. The number of approaches that have this capability are limited, and include spontaneous reporting systems and inpatient database systems. *Ad hoc* studies could also, of course, be designed to collect such information in the hospital.

When the *outcome under study does not result in hospitalization, but does result in medical attention*, the best approaches are randomized trials and *ad hoc* studies, which can be specifically designed to be sure this information can be collected. Prescription Event Monitoring and the UK medical record systems, which collect their data from general practitioners, are excellent sources of data for this type of question. Reports of such outcomes are likely to come to spontaneous reporting systems as well. Medicaid databases and commercial databases can also be used, as they include outpatient data, although one must be cautious about the validity of the diagnosis information in outpatient claims. Canadian provincial databases are

similar, as are health plans. Finally, registry-based case–control studies could theoretically be performed, if they included outpatient cases of the disease under study.

When the *outcome under study does not result in medical attention at all*, the approaches available are much more limited. Only randomized trials and prospective cohort studies can be specifically designed to be certain this information is collected. Finally, occasionally one could collect information on such an outcome in a spontaneous reporting system, if the report came from a patient or from a healthcare provider who became aware of the problem while the patient was visiting for medical care for some other problem. In the future, as already noted, new approaches using the internet (e.g., health websites with consumer posting boards) could potentially be used for hypothesis generation of events not coming to medical attention.

When the *outcome under study is a delayed drug effect*, then one obviously needs approaches capable of tracking individuals over a long period of time. The best approach for this are some of the provincial health databases in Canada. Drug data are available in some of these for more than 25 years, and there is little turnover in the population covered. Thus, this is an ideal system within which to perform such long-term studies. Some health plans have even longer follow-up time available. However, as health plans they suffer from substantial turnover, albeit more modest after the first few years of enrollment. Commercial databases are similar. Any of the methods of conducting case–control studies can address such questions, although one would have to be especially careful about the validity of exposure information collected many years after the exposure. Medicaid databases have been available since 1973. However, the large turnover in Medicaid programs, due to changes in eligibility with changes in family and employment status, makes studies of long-term drug effects problematic. Similarly, one could conceivably perform studies of long-term drug effects using Prescription Event Monitoring, the pharmacy-based medical record linkage systems, *ad hoc* cohort studies, or randomized clinical trials, but these approaches are not as well suited to this type of question as the previously discussed techniques. Theoretically, one also could identify long-term drug effects in a spontaneous reporting system. This is improbably, however, as a physician is unlikely to link a current medical event with a drug exposure long ago.

When *the exposure under study is a new drug*, then one is, of course, limited to data sources that collect data on recent exposures, and preferably those that can collect a significant number of such exposures quickly. *Ad hoc* cohort studies or a randomized clinical trial are ideal for this, as they recruit patients into the study on the basis of their exposure. Spontaneous reporting is similarly a good approach, as new drugs are automatically and immediately covered, and in fact reports are much more common in the first three years after a drug is marketed. The major databases are next most useful, especially the commercial ones, as their large population base will allow one to accumulate a sufficient number of exposed individuals rapidly, so one can perform a study sooner. In some cases, there is a delay until the drug is available on the program's formulary; however, that especially can be an issue with HMOs. The US government claims databases (Medicare and Medicaid) have a delay in availability of their data, which makes them less useful for the newest drugs. *Ad hoc* case–control studies, by whatever approach, must wait until sufficient drug exposure has occurred that it can affect the outcome variable being studied.

Finally, if *one needs an answer to a question urgently*, potentially the fastest approach, if the needed data are included, is a spontaneous reporting system; drugs are included in these systems immediately, and an extremely large population base is covered. Of course, one cannot rely on any adverse reaction being detected

in a spontaneous reporting system. The computerized databases are also useful for these purposes, depending on the speed with which the exposures accumulate in them; of course, if the drug is not on the formulary in question, it cannot be studied. Modular analyses in Sentinel were designed for exactly this purpose (see Chapter 25). The remaining approaches are of limited use, as they take too long to address a question. One exception to this is Prescription Event Monitoring, if the drug in question happens to have been a subject of one of its studies. The other, and more likely, exception is case–control surveillance, if the disease under study is available in adequate numbers in its database, either because it was the topic of a prior study or because there was a sufficient number of individuals with the disease collected to be included in control groups for prior studies.

Examples

As an example, one might want to explore whether nonsteroidal anti-inflammatory drugs (NSAIDs) cause upper gastrointestinal bleeding and, if so, how often. One could examine the manufacturer's premarketing data from clinical trials, but the number of patients included is not likely to be large enough to study clinical bleeding, and the setting is very artificial. Alternatively, one could examine premarketing studies using more sensitive outcome measures, such as endoscopy. However, these are even more artificial. Instead, one could use any of the databases to address the question quickly, as they have data on drug exposures that preceded the hospital admission. Some databases could only be used to investigate gastrointestinal bleeding resulting in hospitalization (e.g., Kaiser Permanente, except via chart review). Others could be used to explore inpatient or outpatient bleeding (e.g., Medicare, Medicaid, Canadian provincial databases). Because of confounding by cigarette smoking, alcohol, and so on, which would not be well measured in these databases, one also might want to address this question using case–control or cohort studies, whether conducted *ad hoc* or using any of the special approaches available, for example case–control surveillance or Prescription Event Monitoring. If one wanted to be able to calculate incidence rates, one would need to restrict these studies to cohort studies, rather than case–control studies. One would be unlikely to be able to use registries, as there are no registries, known to this author at least, which record patients with upper gastrointestinal bleeding. One would not be able to perform analyses of secular trends, as upper gastrointestinal bleeding would not appear in vital statistics data, except as a cause of hospitalization or death. Studying death from upper gastrointestinal bleeding is problematic, as it is a disease from which patients usually do not die. Rather than studying determinants of upper gastrointestinal bleeding, one would really be studying determinants of complications from upper gastrointestinal bleeding, diseases for which upper gastrointestinal bleeding is a complication, or determinants of physicians' decisions to withhold supportive transfusion therapy from patients with upper gastrointestinal bleeding, for example age, terminal illnesses, and so on.

Alternatively, one might want to address a comparable question about nausea and vomiting caused by NSAIDs. Although this question is very similar, one's options in addressing it would be much more limited, as nausea and vomiting often do not come to medical attention. Other than a randomized clinical trial, for a drug that is largely used on an outpatient basis one is limited to systems which request information from patients, or *ad hoc* cohort studies.

As another example, one might want to follow up on a signal generated by the spontaneous reporting system, designing a study to investigate whether a drug which has been on the market for, say, five years is a cause of a relatively rare condition, such as allergic hypersensitivity

reactions. Because of the infrequency of the disease, one would need to draw on a very large population. The best alternatives would be Medicare or Medicaid databases, health plans, commercial databases, case–control studies, or Prescription Event Monitoring. To expedite this hypothesis-testing study and limit costs, it would be desirable if it could be performed using existing data. Prescription Event Monitoring and case–control surveillance would be excellent ways of addressing this, but only if the drug or disease in question, respectively, had been the subject of a prior study. Other methods of conducting case–control studies require gathering exposure data *de novo*.

As a last example, one might want to follow up on a signal generated by a spontaneous reporting system, designing a study to investigate whether a drug which has been on the market for, say, three years is a cause of an extremely rare but serious illness, such as aplastic anemia. One's considerations would be similar to those just described, but even Medicare or Medicaid databases would not be sufficiently large to include enough cases, given the delay in the availability of their data. One would have to gather data *de novo*. Assuming the drug in question is used mostly by outpatients, one could consider using Prescription Event Monitoring or a case–control study.

Conclusion

Once one has decided to perform a pharmacoepidemiologic study, one needs to decide which of the resources described in the earlier chapters of this book should be used. By considering the characteristics of the pharmacoepidemiologic resources available as well as the characteristics of the question to be addressed, one should be able to choose those resources that are best suited to addressing the question at hand.

Historical Background

Interest in drug utilization studies began on both sides of the Atlantic in the early 1960s. There was recognition of the virtual explosion in the marketing of new drugs, the wide variations in the patterns of drug prescribing and consumption, growing concern about delayed adverse effects, and increasing concern about drug expenditure, as reflected in the increase in both the monetary sales and the volume of drug prescriptions [1,2]. However, the development of pharmacoepidemiologic methods can be characterized by two different lines of work (drug utilization studies as performed in Europe versus pharmacoepidemiology as performed in the US), approaching each other from opposite directions, strongly influenced by variations in availability and accessibility of data sources.

Drug utilization studies at the national and international levels have been more developed in Europe, and pioneered by the Nordic countries, Scotland, the Czech Republic, and Northern Ireland. Under the auspices of the World Health Organization (WHO) Regional Office for Europe, a Drug Utilization Research Group was established in the 1970s to stimulate interest in studies comparing drug utilization between countries using a common methodology [1]. Factors that contributed greatly to this line of development, primarily in the countries of Northern Europe, have been the relatively small size of the populations involved, the limited number of pharmaceutical products on the market (2000–3000 in Norway and Sweden), and the availability of centralized statistics on wholesaler sales or dispensed prescriptions [1]. The early drug utilization studies were conducted during a time when data were not computerized and when there was no uniform classification system for medicines. However, with the growth of registers and computer technology, the size of the population is less of an issue and studies can be conducted on large populations. During the last decades, national databases with patient-level data on prescription medicines have been established in most European countries, but there is still a lack of comprehensive databases on medicines used in inpatient care [3,4].

Pharmacoepidemiology, Sixth Edition. Edited by Brian L. Strom, Stephen E. Kimmel and Sean Hennessy.

Drug utilization studies in Europe were originally predominantly quantitative, describing and comparing patterns of utilization of specific groups of drugs according to geographic regions and time. For example, international comparative studies have documented wide variations in the utilization of antidiabetic [1,5], psychotropic [6], nonsteroidal anti-inflammatory drugs (NSAIDs) [7,8], antihypertensive [1,6], antibiotic [9], and lipid-lowering drugs [10] in European and other countries. Longitudinal studies on the utilization of antidiabetic and antihypertensive drugs in some of these countries indicate that the differences cannot be explained only by differences in the prevalence of disease [11,12], and studies on, for instance, lipid-lowering agents have shown that the large increases in statin utilization were not associated with a subsequent decrease in coronary heart disease (CHD) mortality [13]. This illustrates that drug utilization patterns are complex and dependent on a range of factors. Furthermore, there is substantial room for improvement in the quality of medicines use; that is, how patients use medicines.

National studies have also revealed striking variations in drug utilization between regions and communities within the same country [1,6]. However, most of these studies have been descriptive and only a few of them have addressed the relation between variations in drug sales and treatment outcomes [14]. Since many of the studies have an ecologic design, examining associations between exposure and outcome in populations rather than individuals, they cannot directly be interpreted as associations at the level of the individual.

In Canada and the US, drug utilization research developed on a smaller scale, primarily at institutional or local health program levels. Factors that have hindered studies at a national level were originally the size of the population, the number of pharmaceutical products on the market (20 000–30 000), and the lack of an all-encompassing pharmaceutical data collection system [15]. Data on drug use are more readily available from health plans, health delivery institutions, and public healthcare programs. For example, early studies of physician prescribing showed that prescribing patterns varied greatly among physicians, according to their place and type of practice and the community in which they prescribed [16]. North American drug utilization research placed greater emphasis on studying the quality of physician prescribing practices, in particular with respect to antibiotics, in both hospital and outpatient settings [17–19]. This was followed by studies that targeted medications for cardiovascular diseases [20–23]. Studies describing national patterns of drug utilization and expenditures in the US are scarce [15], while those addressing the use of various types of medications, including herbal and other natural products, in adults and children are performed more often [24–27].

Drug utilization research has also developed in Latin America, Australia, Asia, and Africa. In Latin America, a drug utilization research group (the Latin American Group for Drug Utilization, DURG-LA) was founded in 1991 [28]. Over the years Latin American drug utilization researchers have conducted a wide range of studies on rational use of medicines, often using primary data collection in people's homes, in pharmacies, or in health facilities. Secondary data on drug utilization have traditionally been fragmented and difficult to access in Latin America [29]. There has been a rapid development of drug utilization research in low- and middle-income countries. In the early 1990s, the WHO and the International Network for the Rational Use of Drugs (INRUD) published a simple sampling method and a standard set of indicators to describe core aspects of prescribing and dispensing [30]. The first International Conference on Improving the Use of Medicines (ICIUM), held in Chiang Mai, Thailand, in 1997, systematically reviewed interventions to promote rational drug use in developing countries [30]. Substantial problems of irrational use of

medicines were identified and some key areas were highlighted for future research, such as interventions to improve the use of antibiotics and antimalarial drugs, methods to assess the impact of Drugs and Therapeutic Committees, and the impact of financial incentives on drug utilization patterns. During the last decade, we have witnessed a rapid growth of large prescription databases in Asia [31]. It is likely that these will further contribute to the globalization of drug utilization research.

Definitions

Drug utilization research can be defined as "an eclectic collection of descriptive and analytical methods for the quantification, the understanding and the evaluation of the processes of prescribing, dispensing and consumption of medicines and for the testing of interventions to enhance the quality of these processes" [32]. This definition includes both quantitative and qualitative research methods.

The WHO defined drug utilization as the "marketing, distribution, prescription and use of drugs in a society, with special emphasis on the resulting medical, social, and economic consequences" [33]. Some authors have suggested that the development of drugs relative to health priorities should also be included in studies of drug utilization [34]. This broad definition differs from the narrower one that appeared in the North American literature, "the prescribing, dispensing and ingesting of drugs" [35,36].

In the US, drug utilization review (DUR), or drug use evaluation (DUE), refers to an authorized, structured, ongoing review of prescribing, dispensing, and use of medication (see Chapter 19). It involves a comprehensive review of patients' prescription and medication data before, during, and/or after dispensing to ensure appropriate medication decision making and positive patient outcomes. As such, DUR is a quality assurance measure [37].

In all of these definitions, recognition is granted, explicitly or implicitly, of the nonclinical (e.g., socio-anthropological, behavioral, and economic) factors influencing drug utilization. Studies of the process of drug utilization focus on the factors influencing and events involved in the prescribing, dispensing, administration, and taking of medication. However, the broader definitions of the WHO, the Academy of Managed Care Pharmacy (AMCP), and the European Drug Utilization Group go beyond the "process" of drug utilization, which is the movement of drugs along the therapeutic drug chain, to include consideration of the various outcomes, such as use of drugs of doubtful or no clinical efficacy, and the quality of drug use [38]; that is, the degree to which it adheres to established norms. According to these definitions, studies of drug utilization include not only studies of the medical and nonmedical factors influencing drug utilization, but also the effects of drug utilization at all levels, from the individual patient to the society. Studies of how drug utilization relates to the effects of drug use, beneficial or adverse, are usually labeled analytic pharmacoepidemiologic research. These two aspects of the study of drug utilization have developed along parallel lines, but may now be regarded as interrelated and part of a continuum of interests and methods.

As stated by Lunde and Baksaas [39], the general objectives of drug utilization studies are:

> problem identification and problem analysis in relation to importance, causes, and consequences; establishment of a weighted basis for decisions on problem solution; assessment of the effects of the action taken. These objectives are relevant to problems and decision making throughout the drug and health chain. The approaches may vary according to the purpose and the needs of the users. Those include the health authorities, the drug manufacturers, the academic and

clinical health professionals, social scientists, and economists as well as the media and the consumers.

Since many drug utilization studies have a strong focus on health policy, the discipline may be seen as the bridge between pharmacoepidemiology and health services research. It is also closely connected to clinical pharmacology, with the principal aim of drug utilization research being to facilitate the safe and effective use of medicines in populations [40].

This chapter focuses on the current status of descriptive epidemiologic approaches to the study of the processes of drug utilization and analytic studies on factors associated with drug utilization patterns. The epidemiologic approaches to the study of the beneficial and harmful effects of drug utilization are covered elsewhere in this book.

Clinical Problems to Be Addressed by Pharmacoepidemiologic Research

In order for a drug to be marketed, it must be shown that it can effectively modify the natural course of disease or alleviate symptoms when used appropriately, for the right patient, with the right disease, in the proper dosage and intervals, and for the appropriate length of time. Used inappropriately, however, drugs often fail to live up to their potential, with consequent morbidity and mortality and waste of resources.

Drug utilization research describes the extent and pattern, quality, determinants, and outcomes of drug exposure. Pattern of use covers the extent, profiles, and trends in drug use and costs over time. It gives answers and helps understand how drugs are used in terms of incidence, prevalence, and trends over time. Quality of use is determined using audits to compare actual use to national prescription guidelines or local drug formularies. Indicators of quality of drug use may include the choice of drug (adherence with the guideline or formulary), drug cost (compliance with budgetary recommendations), drug dosage (awareness of interindividual variations in dose requirements and age dependence), awareness of drug interactions and adverse drug reactions, and the proportion of patients who are aware of or unaware of the costs and benefits of the treatment.

Drug utilization research may generate hypotheses for further investigation by comparing drug utilization patterns and costs between different regions or time periods and by comparing observed patterns of drug use with current recommendations and guidelines for the treatment of a certain disease. These considerations should include both underuse and overuse of drugs. Determinants of use include user characteristics (e.g., sociodemographic parameters and attitudes towards drugs), prescriber characteristics (e.g., specialty, education, and factors influencing therapeutic decisions), and drug characteristics (e.g., therapeutic properties and cost).

A number of studies have addressed the factors that influence prescribing decision making, including education, advertising, colleagues, working circumstances, personality, control and regulatory measures, demands from society and patients, and cultural factors [41–43]. Some controversy exists concerning the relative impact of the various sources of influence on prescribing behavior, particularly the influence of pharmaceutical advertising. In studies of hospital practice the following factors have been stated to contribute to inappropriate prescribing: simple errors of omission; physician ignorance of cost issues in prescribing; failure to review medication orders frequently and critically; inability to keep up to date with developments in pharmacology and therapeutics; insulation of physicians and patients from cost considerations because of third-party coverage; and lack of communication between physicians and pharmacists [44].

Cultural factors are known to play a role in illness behavior and drug prescribing/consumption. A popular model describing cultural differences that may also influence drug prescribing is Hofstede's model of cultural dimensions. Five cultural dimensions are defined by which countries may be scored: power distance, individualism, masculinity, uncertainty avoidance, and long-term orientation. Power distance refers to the degree of hierarchy in a country and the extent to which the less powerful members of organizations and institutions accept and expect that power is distributed unequally. Individualism refers to the prevalence of the interests of an individual versus the group and the degree to which individuals are integrated into groups. Masculinity refers to a culture in which the emotional roles of the two genders are clearly separated. The assertive, competitive pole has been called "masculine" and the modest, caring pole "feminine." Uncertainty avoidance deals with a societal tolerance for uncertainty and ambiguity. It indicates to what extent a culture programs its members to feel either uncomfortable or comfortable in unstructured situations. Long-term orientation values are thrift and perseverance, while short-term orientation values are respect for tradition, fulfilling social obligations, protecting one's "face" [45]. It has been found that power distance and uncertainty avoidance are cultural dimensions associated with higher antibiotic use, suggesting that hierarchical societies use more antibiotics (difficulties dealing with authority), whereas more egalitarian societies use fewer, and in societies that tend to avoid uncertainty antibiotics have a defensive function (as the prescriber and the patient aim for certainty) [46,47].

Drug utilization research enables assessment of whether interventions to improve drug use had the desired impact, as well as the extent to which other factors influenced the pattern of use, including regulatory changes, reimbursement policy, pharmaceutical industry promotional activities, and others.

Intervention strategies aimed at improving prescribing behavior in hospital as well as primary care settings have been critically reviewed [48–51]. These are discussed in Chapter 19 and include dissemination of printed educational materials alone; multimedia warning campaigns; drug utilization audit followed by mailed or interactive feedback of aggregated results; group education through lectures or rounds; use of computerized reminder systems; use of opinion leaders to informally endorse or support specific behavior change interventions; one-to-one education initiated by a drug utilization expert; required consultation or justification prior to the use of specific drugs; and use of clinical guidelines.

Drug utilization research addresses the medical, social, and economic aspects of drug use [32,52]. Even when used appropriately, drugs have the potential to cause harm. However, a large proportion of their adverse effects is predictable and preventable [53,54]. Adverse drug reactions and drug nonadherence are important causes of hospital admissions in both adult and pediatric patients [54–56] (see also Chapter 38). Studies in the US have estimated that adverse drug events account for up to 28% of emergency department visits and 25% of ambulatory care encounters; up to 70% of these visits are deemed preventable [57]. Similar figures are also found in the UK and Sweden [54,58,59].

Many of these drug-related admissions may be preventable through the application of existing principles and data [60,61]. The situations that may lead to preventable adverse drug reactions and drug-induced illness include the use of a drug for the wrong indication; the use of a potentially toxic drug when one with less risk of toxicity would be just as effective; the concurrent administration of an excessive number of drugs, thereby increasing the possibility of drug–drug interactions (see Chapter 40); the use of excessive doses, especially for pediatric or geriatric patients; and continued use of a drug after evidence becomes

available concerning important toxic effects. Many contributory causes have been proposed: excessive prescribing by the physician; failure to define therapeutic endpoints for drug use; the increased availability of potent prescription and nonprescription drugs; increased public exposure to drugs used or produced industrially that enter the environment; the availability of illicit preparations; and prescribers' lack of knowledge of the pharmacology and pharmacokinetics of prescribed drugs [53]. Increased morbidity or mortality due to medication error [62] (see Chapter 41), poor patient adherence [63] (see Chapter 38), discontinuation of therapy [64–66], and problems in communication resulting from modern-day fragmentation of patient care are also to be considered (see Chapter 39).

Medication underdosing and underprescribing are often overlooked and can result in poor patient outcomes. The failure of physicians to prescribe an effective drug or effective doses for a treatable disease is a significant concern. For example, in a geographic area of Sweden with a higher suicide rate than average for the country, sales of antidepressant drugs were about half of those in other areas [67]. In the US, the underuse of beta-blockers in elderly patients with myocardial infarction was associated with an increased risk of death [20]. Other studies have documented significant underuse of antithrombotic drugs [21,68,69], lipid-lowering therapy [66,70–72], beta-blockers [22], aspirin [73], and thrombolytics [23] in patients with appropriate indications, but where outcomes were not assessed. In addition, underuse of beneficial medications may have other reasons, such as lack of access due to economic reasons or geographic access to the pharmacy and availability of prescription drugs [74–76].

Therapeutic practice, as recommended by relevant professional bodies, academic researchers, and opinion leaders, is initially based predominantly on data from premarketing clinical trials. However, the comparative effectiveness (i.e., the effectiveness of one medication compared to another medication in the real-world setting; see Chapter 26) and safety of new agents cannot be known with certainty until a drug has been on the market for many years or been extensively used. Complementary data from clinical experience and studies in the postmarketing period may result in changes in indication (e.g., a specific antibiotic no longer being a choice due to antimicrobial resistance), treatment duration (e.g., short-course antibiotic treatment of community-acquired pneumonia in children under 5 years of age), regimen (e.g., changes due to tolerance to oral hypoglycemic agents), precautions and contraindications (e.g., gastrointestinal bleeding with NSAIDs), and safety-based withdrawals [77,78]. For instance, when serious adverse reactions or special problems occur, particularly those that may lead to death or serious injury, a prominently displayed boxed warning, the so-called black box, is added to the US Food and Drug Administration (FDA) labeling of drugs or drug products. As therapy recommendations are updated through guidelines and other approaches, drug utilization studies must address the relationship between therapeutic practice as recommended and actual clinical practice [79].

Methodologic Problems to Be Solved by Pharmacoepidemiologic Research

There are several methodologic issues in drug utilization research. Most of them are the same as for other pharmacoepidemiologic studies and are well described in other parts of the book. In this section, some specific issues of importance related to the different study designs in drug utilization are described, along with an overview of the available data sources.

Study Designs

There are many types of drug utilization studies. Research methods in drug utilization can be either *quantitative* or *qualitative*. Quantitative research deals with quantities; data are presented in numeric figures in categories or rank order and measured in various units. Quantitative research usually starts with a predefined hypothesis or theory, followed by data collection to provide an answer to the research questions formulated. Associations between variables and differences between different categories may be studied by using different statistical methods. Qualitative research, on the other hand, refers to the examination, analysis, and interpretation of observations for the purpose of discovering underlying meanings and patterns of relationships [80]. Qualitative studies include information that is not in numeric form collected through focus group discussions, open-ended questionnaires, in-depth interviews, and observations. Such studies may be used to explore the views of prescribers, dispensers, and patients in dealing with medicines. Consequently, they are important to gain a deeper understanding of various phenomena in drug utilization. Qualitative drug utilization studies are not further described in this chapter. For further reading on qualitative studies, there is a separate chapter on qualitative methods in drug utilization research in the handbook on drug utilization research [81].

The simplest quantitative drug utilization studies are descriptive. Such studies identify patterns or trends in drug utilization, without any attempt to draw conclusions about factors influencing drug use. Objectives of descriptive studies may be to quantify the present state, developmental trends, and time course of drug usage at various levels of the healthcare system, whether national, regional, local, or institutional. Routinely compiled drug statistics or drug utilization data that are the result of such studies can be used to estimate drug utilization in populations by age, sex, social class, morbidity, and other characteristics, and to identify areas of possible over- or underutilization. They also can be used as denominator data for calculating rates of *reported* adverse drug reactions in the context of spontaneous reporting systems (see Chapter 10); to monitor the utilization of specific therapeutic categories where particular problems can be anticipated (e.g., narcotic analgesics, hypnotics and sedatives, and other psychotropic drugs); or as markers for very crude estimates of disease prevalence (e.g., antiparkinsonian drugs for Parkinson's disease); to plan for drug importation, production, and distribution; and to estimate drug expenditures [34].

Descriptive drug utilization studies may also address quality of drug prescribing, dispensing, or use. In these studies, explicit predetermined criteria are created against which aspects of the quality, medical necessity, and appropriateness of drug prescribing may be compared. Drug use criteria may be based on such parameters as indications for use, daily dose, or length of therapy. Other possible criteria for poor drug prescribing include the failure to select a more effective or less hazardous drug if available, the use of a fixed combination drug when only one of its components is justified, or the use of a costly drug when a less costly equivalent drug is available [82]. In North America, these studies are known as *drug utilization review* (DUR) studies. For example, a large number of studies in North America have documented the extent of inappropriate prescribing of drugs, in particular antibiotics, and the associated adverse clinical, ecologic, and economic consequences [17–19].

Analytic drug utilization studies aim to gain a deeper understanding of the explanatory factors behind utilization patterns. The most robust analytic study designs are cohort studies or case–control studies. In traditional pharmacoepidemiology, such studies are used to assess the effectiveness or safety of drug therapy, where drug utilization is the exposure and clinical events constitute the outcome. In analytic drug utilization studies, drug exposure is the outcome

and the explanatory factors behind drug use constitute the exposure. The same methods for matching or confounder adjustment could thus be applied as for cohort and case–control studies used to assess safety or effectiveness. These methods are well described in other chapters of this book (see Chapter 43). Some examples of cohort studies in drug utilization include persistence studies, where discontinuation is the outcome to drug treatment [83–85]. Theoretically, case–control studies may also be conducted, selecting subjects on the basis of whether they have (or had) been prescribed or dispensed the drug of interest or not. An investigation of previous exposure to a factor might reveal whether there is an association between the drug utilization and previous exposure. Such studies are scarce in the literature, however.

In the absence of individual-level data to link drug utilization to other factors, ecologic studies could be conducted. In these studies, group-level data on dispensed or prescribed drugs are compared with other datasets, either for different geographic areas or population groups at a certain point in time or for the same population at different times. Some examples of ecologic studies in drug utilization research include the associations between antidepressant use and suicide [86]; respiratory medication prescribing, air pollution, and deprivation [87]; coronary heart mortality and statin use [88]; and unemployment rates and prescription drug utilization patterns [89]. Ecologic studies are simple to conduct, but they have limited value since no individual linkage has been conducted between exposure and outcome. Consequently, the correlations found in these studies cannot be interpreted as associations at the individual patient level.

Types of Data on Drug Utilization

A considerable amount of drug use data may be obtainable or is already available, the usefulness of which depends on the question at hand. All the data have certain limitations in their direct clinical relevance [90]. For quantitative studies, the ideal is a count of the number of patients in a defined population who ingest a drug of interest during a particular time frame, with a certain diagnosis or indication. The data available are only approximations of this for reasons that are described shortly, and thereby raise many questions about their presentation and interpretation.

Since most statistics on drug consumption were compiled for administrative or commercial reasons, the data were usually aggregated and expressed in terms of volumes or expenditure. First, data on drug utilization can be available as total costs or unit cost, such as cost per package, tablet, dose, or treatment course. Although such data may be useful for measuring and comparing the economic impact of drug use, these units do not provide information on drug exposure in the population. Moreover, data on expenditure are influenced by price fluctuations over time, distribution channels, inflation, exchange rate fluctuations, price control measures, and so on [91].

Volume data may be available from manufacturers, importers, or distributors as the overall weight of the drug that is sold or the unit volume sold; that is, the number of tablets, capsules, or doses sold. However, tablet sizes vary, making it difficult to translate weight into even the number of tablets. Prescription quantities also vary, so it is difficult to translate number of tablets into the number of exposed patients.

The number of prescriptions (either written or dispensed) has traditionally been one of the most frequently used measures in drug utilization studies. This measure may have some relevance in studies of medicines given for short treatment courses, such as antibiotics. For medicines used for chronic treatment the value is limited, since different patients receive a different number of prescriptions in any given time interval, and the amount allowed to prescribe or dispense on a prescription may vary substantially between countries. To translate

the number of prescriptions into the number of patients, one must divide by the average number of prescriptions per patient, or else distinctions must be made between first prescriptions and refill prescriptions. The former is better for studies of new drug therapy, but will omit individuals who are receiving chronic drug therapy. Additional problems may be posed by differences in the number of distinct drugs written in each prescription. Finally, it should be noted that these aggregate measures of prescribed or dispensed volumes represent approximate estimates of true consumption. The latter is ultimately modified further by the patients' actual drug intake; that is, their degree of adherence.

In the context of DUR, drug utilization data may be presented in the form of prescribing profiles for individual physicians or practices according to the number, monetary value, and even type of prescription ordered during a given time period. Pharmacies may also be ranked according to the number, cost, and type of prescription dispensed for similar intervals. However, these gross measures of prescription activity and drug use are limited in their capacity to reflect the wide spectrum of specific problems in prescribing. For example, they ignore problems such as the wrong drug for the indication, the wrong drug for the patient, the wrong dose, the wrong dosing interval, and the wrong duration of therapy. Also, one's deviation from the practices of the mean practitioner is not a good measure of one's "appropriateness" as a provider. Purely quantitative data characterizing prescribers as "high" or "low" may be driven, for example, by the number of patients seen by the physician and the type and severity of the patients' diseases. Data presented by pharmacy are even less informative, since patients may be dispensed prescriptions from an unknown range of different healthcare providers. However, for studies of medicine use in hospitals and studies of over-the-counter (OTC) products, pharmacy sales data may provide important information. Finally, it is important to emphasize that data on expenditures are not necessarily indicative of appropriateness, whether high or low relative to the mean.

In recent years, large patient-level prescription databases have become increasingly available [3]. They may contain all dispensed prescription drugs regardless of the reimbursement status and irrespective of who the prescriber is. These data are also closer to estimating actual drug exposure compared to prescribing data from electronic health records. However, there may be problems of poor sensitivity, with patients having other ways of receiving medications (e.g., drugs purchased abroad, OTC medicines, or drugs "borrowed" from relatives), or poor specificity, with patients not taking the drugs they have purchased. There are many useful methods available for studying drug utilization using individual data on dispensed prescriptions. Based on experiences from Denmark, Hallas and Støvring discussed three nonspecific analytic templates that could be applied to individual-level data on dispensed prescriptions [92]. Such methods include the ratio of prevalence odds to incidence rate to estimate the average duration for drug use, the Lorenz curve, and the waiting time distribution. The Lorenz curve expresses skewness in drug use. It shows the proportion of drug use that is accounted for by percentiles of drug users, ranked according to their volume of drug intake. It may express the extent of heavy users as well as sporadic small-volume users and may, for example, be used to screen for an unsuspected abuse potential of a drug. Figure 18.1 illustrates the use of insulin in a defined population: 50% of the users used 76% of the volume [92].

The waiting time distribution is a frequency distribution of first occurrences of drug use within a time window (Figure 18.2). It forms the basis for estimates of prevalence and incidence rate. Furthermore, it displays visual correlates of epidemiologic prescribing parameters such as

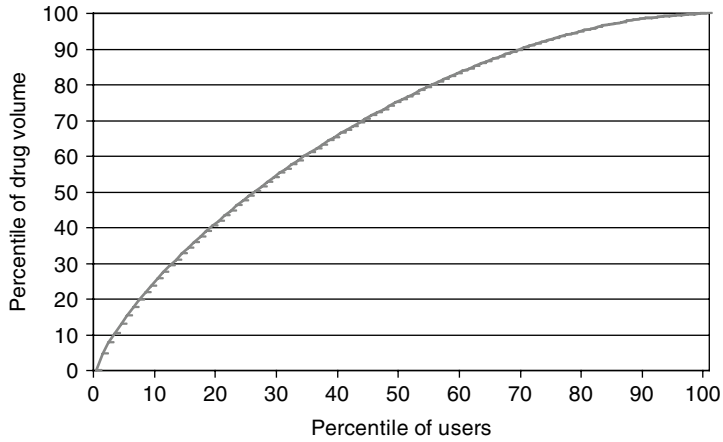

Figure 18.1 Lorenz curve for insulin use. The graph shows the proportion of insulin use that is accounted for by percentiles of insulin users, ranked according to their annual insulin consumption. period prevalence, point prevalence, incidence rate, duration, prescription renewal rate, relapse of treatment, and seasonality.

From a quality-of-care perspective, to interpret drug utilization data appropriately, there is a need to relate the data to the reasons for the drug usage. Data on morbidity and mortality may be obtained from national registries (general or specialized); national samples where medical service reimbursement schemes operate; *ad hoc* surveys and special studies; hospital records; physician records; and patient or household surveys. "Appropriateness" of use must be assessed relative to indication for treatment, patient characteristics (age-related physiologic status, sex, habits), drug dosage (over- or underdosage), concomitant diseases (which might contraindicate or interfere with the chosen therapy), and the use of other drugs (interactions). However, no single source is generally available for obtaining all of this information. Moreover, because of incompleteness, the medical record may not be a very useful source of drug use data [93,94].

Generally agreed standards or criteria for appropriateness, based on currently available knowledge, are essential elements of the DUR process. These criteria must be based on scientifically established evidence; updated regularly according to new scientific evidence; explicitly

stated (to ensure consistency in evaluations); and applicable to a given setting. The development and standardization of these criteria are major undertakings. Finally, for DUR programs, even the strategy to be used to optimize one's intervention is still unclear.

Data Sources

A large variety of data sources can be used for drug utilization research. They may provide either primary or secondary data [95]. Primary data sources refer to original data collected by the investigator conducting the research for a specific purpose [96]. Secondary data sources include already collected data; that is, data which have not been usually generated for a specific research purpose but can be adapted to the analysis of a new research question [95].

Drug utilization studies have been conducted using a large variety of secondary data sources, including sales registries, procurement records, reimbursement/claims databases, medical records, pharmacy dispensing records, pharmacy stock records, disease-based registries, and population health surveys. The availability of such data varies substantially between countries, but there has been a large growth in access to them over time everywhere. The ongoing digitalization of healthcare brings further opportunities to access large amounts of clinical data for DUR. Some of these data may be unstructured and tricky to analyze, but new techniques and methods have been developed to address these challenges.

In the earlier editions of this book, we listed some diagnosis-linked and non-diagnosis-linked computer databases for drug utilization studies, as well as providing an overview of historical databases important for the development of pharmacoepidemiology and drug utilization research. In this edition, electronic databases are discussed in separate chapters (Chapters 11–14) and here we briefly give an overview of some types of sources that may be used. A more comprehensive overview of secondary data sources may be found in a recent textbook on drug utilization research [97].

Drug utilization data may be collected at any point in the pharmaceutical supply chain, starting with the manufacturer, passing through wholesalers and pharmacies, and ending with patients. Aggregate level sales data (from manufacturer/wholesaler/pharmacy) or purchases (from purchaser/payer, e.g., hospitals or community pharmacies) are regularly collected in most countries. Such data do not contain any information on number of patients, or any clinical data. Consequently, these data have limited value in analytic studies on the effectiveness and safety of medicine use. Still, they may be valuable in studies assessing quality of medicine use or to assess the effect on interventions in health systems. They may also be used in ecological studies comparing utilization patterns with other data, generating hypotheses to be studied with more robust study designs. At pharmacies, drug dispensing data may be recorded at an individual patient level. These data may subsequently be collected by insurers or reimbursement agencies. Such patient-level databases provide valuable sources for drug utilization, with and without linkage to other clinical information. Finally, healthcare providers are another important source of data on drug utilization studies, with information on drugs prescribed to patients available in their health records. Healthcare providers may also report information on selected drugs to disease-based patient registries.

Aggregated sales data have been used in drug utilization research for decades. Today, most countries keep some records of drug sales, at a regional or national level. These data can be obtained from health authorities [4,5] as well as from private companies such as IQVIA, a well-known commercial source of drug utilization data. An overview of European databases performed by Pharmacoepidemiological Research on Outcomes of Therapeutics by a European ConsorTium (PROTECT) indicates

that aggregate sales data are widely collected across Europe [3,4]. In the US, the IQVIA National Sales Perspective database documents sales data for prescription drugs, OTC products, and some self-administered diagnostic products. Data collected include volume of dollars and quantities moving from manufacturers in various outlets within all states. In Canada, the IQVIA CompuScript database contains data on prescriptions sold from about two-thirds of Canadian retail pharmacies. Sales data collected by authorities or by companies such as IQVIA may be the only secondary source available to studies conducted in regions where other databases are not yet established or not accessible.

Dispensing data containing unique identifiers of patients are regularly collected at pharmacies. Since patients visit a pharmacy to fill their prescriptions, such data provide a more appropriate estimation on actual drug exposure than prescribing data from electronic health records. However, it is important to acknowledge that patients may also have other ways of obtaining medications (e.g., purchasing abroad, receiving in inpatient care, or "borrowing" from relatives), Furthermore, even though the patient claimed the prescription, it is uncertain whether the patient has taken the medicine as indicated by the prescriber. In Europe, the first patient-level research databases were established in the late 1960s to early 1970s [76]. These databases were based on prescriptions dispensed at the pharmacies and primarily used to study drug utilization. They were too small for drug safety studies. In the 1980s and 1990s larger databases were created, also based on administrative data, such as prescriptions dispensed at pharmacies, in Scotland [40], Denmark [98], Italy [99], and the Netherlands. An example of such a dispensing database is the Swedish Prescribed Drug Register, established in 2005, containing data with unique patient identifiers for the entire population of 10 million inhabitants for all dispensed prescriptions in ambulatory care [100]. This registry includes data on the patient (age, sex, personal identification number, place of residence), dispensed drug (Anatomic Therapeutic Chemical [ATC] classification code, defined daily dose [defined shortly] number, prescribed dose, package, reimbursement, date of prescribing and dispensing), prescriber (profession, specialty, workplace), and pharmacy (identifier, location). It can be linked to many other registers including outcome data and many quality registers with clinical data for different diseases. A recent review summarized the scientific output from the register after the first decade [101].

In many countries, third-party payers (public or private) collect medication data from pharmacies for billing purposes. Drug reimbursement/claims databases typically contain unique patient identifier, prescriber (either individual prescriber and/or clinic/practice), pharmacy dispensing the drug, drug name and ATC code, strength, dosage form, quantity dispensed, date of prescription and dispensation, days' supply, as well as patient co-payment and total drug expenditure. In some countries reimbursement data also include information on diagnosis, as an International Classification of Diseases (ICD) code is written on prescriptions. Reimbursement databases are commonly used in DUR. A limitation, though, is that they may only contain those drugs that are reimbursed. Furthermore, they are sensitive to changes in co-payment over time. There are also differences between health systems in regulations and reimbursement and, consequently, the amount of information documented in these databases varies. In some countries, prescription drugs are funded only for selected groups of the population (e.g., the elderly) [102,103], and various other public and private prescription plans may be used for other population groups.

In countries with many different insurers (e.g., in the US), it may be difficult to follow people over time, since patients move in and out as their insurance eligibility changes [104]. In the

US, Medicaid medical and pharmaceutical billing data have been available for drug utilization studies for many years. With the disadvantaged and disabled population included in Medicaid, however, the generalizability of the results is a potential concern, especially for such descriptive studies. In contrast, in many European and some Asian countries with national health systems, insurance coverage can be close to 100% of the population, thus providing a complete picture of medicine use in these countries [4,105].

Large databases are also derived from electronic health records. The key advantage of these databases is that they contain clinical data such as diagnoses. One example is the General Practice Research Database® (GPRD®) in the UK (see Chapter 14), which is based on medical records from general practitioners (GPs). Hundreds of GPs contribute anonymized patient information to a central database, that now contains millions of patients. Included are prescriptions issued by the GP but with no information from the pharmacy (compliance/adherence). All these databases were primarily used for drug safety studies, but have also been used to study drug utilization [96,106].

Another example is the Integrated Primary Care Information (IPCI) database, established at Erasmus University in the Netherlands. It consists of the computer-based patient records of 150 general practitioners. To date the database has accumulated data on approximately 500 000 patients. The records are coded to ensure the anonymity of patients; data include patient demographics, symptoms (in free text), diagnoses (based on the International Classification for Primary Care and free text), clinical examination findings, referrals, laboratory test results, hospitalizations, and physician-linked drug prescriptions and dosage regimen (but no information from the pharmacy on compliance/adherence).

The National Disease and Therapeutic Index (NDTI), by IQVIA, is an ongoing study of physician prescribing that is conducted mainly for use by pharmaceutical companies for marketing [107]. This study employs a rotating sample of office-based physicians, who record all patient encounters and corresponding "drug mentions" for two-day periods four times a year. A special prescription form is used to collect information on the drug (specific product, dosage form, new vs. continuing therapy), patient characteristics (sex), prescriber (specialty, location, region), type of consultation (first versus subsequent), concomitant drugs and diagnoses, and the desired pharmacologic action [15]. Data have been made available to academic researchers (for a fee) and the FDA [15]. Although useful for studies of prescribing, longitudinal patient-specific studies are not possible with this database.

Currently Available Solutions

DUR studies are activities aimed at the detection and quantification of problems. They should be distinguished from DUR *programs*. DUR studies are usually one-time projects, not routinely conducted. They provide only minimal feedback to the involved prescribers and, most importantly, do not include any follow-up measures to ascertain whether any changes in drug therapy have occurred. A DUR program, on the other hand, is an intervention in the form of an authorized, structured, and *ongoing system* for improving the quality of drug use within a given healthcare institution. The quality of drug prescribing is evaluated by employing predetermined standards for initiating administrative or educational interventions to modify patterns of drug use that are not consistent with these standards. The measurement of the effectiveness of these interventions is ideally an integral part of the program [108,109].

In the US, DUR programs (commonly known in hospitals as DUE programs) are part of the quality assurance activities required by

Medicaid–Medicare regulations, the Joint Commission, the former Professional Standards Review Organizations (PSRO), and Section 4401 of the Omnibus Budget Reconciliation Act of 1990 [109]. In Europe, DUR programs have been proposed as periodic "therapeutic audits" performed at various levels (patient, prescriber, hospital, county, municipality, country, and groups of countries), assessing not only the clinical consequences of drug utilization, but also the social and economic consequences. These studies are to be followed by whatever feedback is felt to be necessary and appropriate to effect changes in therapeutic practices [6,110,111]. Most commonly, these therapeutic audits have been based on aggregate data analysis of medicines consumption at a national level and interventions, usually regulatory or informational and educational, and are aimed accordingly at whole populations or subgroups, rather than specific individuals. Despite their widespread implementation in the US, the effectiveness of DUR programs in reducing prescribing errors and improving patient outcomes remains to be established (as discussed later).

Units of Measurement

The defined daily dose (DDD) method was developed in response to the need to convert and standardize readily available volume data from sales statistics or pharmacy inventory data (quantity of packages, tablets, or other dosage forms) into medically meaningful units, to make crude estimates of the number of persons exposed to a particular medicine or class of medicines [112].

The DDD method is useful for working with readily available gross drug statistics; allows comparisons between drugs in the same therapeutic class and between different healthcare settings or geographic areas, and evaluations of trends over time; and is relatively easy and inexpensive to use. The method is firmly established in Europe and is increasingly used by researchers in other regions [113–118]. A WHO manual on drug utilization research provides an overview of the method [119]. Guidelines for classifying medicines and their assigned DDDs are updated annually by the WHO Collaborating Centre for Drug Statistics Methodology (www.whocc.no).

The DDD is a technical statistical unit defined as the assumed average daily maintenance dose for a drug for its main indication in adults. It is only a measurement unit and does not necessarily reflect the prescribed or recommended dose. To enable comparison of drug use in DDDs the information has to be presented with an adequate denominator; that is, the population that was exposed to a drug. Ambulatory drug use is commonly expressed as DDDs per 1000 inhabitants per day. For chronically used drugs, it can be interpreted as the proportion of the population that receives treatment with a particular medicine on any given day. For example, if the use of a drug is measured as 30 DDDs/1000 inhabitants/day in a given country, this indicates that around 3% of the country's population receives that drug daily. Sometimes better estimates can be given by adjusting the denominator for a target population (e.g., for oral contraceptives the denominator is females below 45 years of age). For use in hospital settings, the unit is expressed as DDDs per 100 bed-days (adjusted for occupancy rate); it suggests the proportion or percentage of inpatients that receive a DDD in a day. For example, 30 DDDs/100 bed-days indicates that 30% of patients in a day receive a certain drug. For medicines that are used in the outpatient setting for short-term periods, such as antimicrobials, the unit is expressed as DDDs per inhabitant per year; this provides an estimate of the number of days for which each person is treated with a particular medication in a year. For example 8 DDDs/inhabitant/year indicates that every inhabitant is on average treated with that drug for 8 days in a year.

The DDD method has been useful in describing and comparing patterns of drug utilization [1,2,111], providing denominator data to estimate reported adverse drug reaction rates [120], performing epidemiologic screening for problems in drug utilization [111], and monitoring the effects of informational and regulatory activities [113,121]. It has also been used to study variations in antimicrobial utilization [9,122,123], as well as antimicrobial utilization and its correlation with antimicrobial resistance in outpatient [123,124] and inpatient settings in Europe [125], and to report on sustained reduction of antibiotic use and low bacterial resistance with implementation of a multidisciplinary, coordinated national antimicrobial and rational use program [126].

The European Surveillance of Antimicrobial Consumption Network, ESAC-Net (formerly ESAC), collects and analyzes data on antimicrobial consumption from European Union (EU) and European Economic Area/European Free Trade Association (EEA/EFTA) countries, using the DDD methodology. The data on community and hospital antimicrobial consumption are publicly available from ESAC-Net [127].

The DDD method should be used and interpreted with caution. The DDD is not a recommended or a prescribed dose, but a technical unit of comparison; it is usually the result of literature review and available information on use in various countries. Thus, the DDDs may be high or low relative to actual prescribed doses. Moreover, the DDDs refer to use in adults. Since children's doses are substantially lower than the established DDDs, if unadjusted this situation will lead to an underestimation of population exposures, which may be significant in countries with a large pediatric population. Although pediatric DDDs have also been proposed [128], the concept and its applicability have not been incorporated into the WHO method [119]. Finally, DDDs do not take into account variations in adherence.

The prescribed daily dose (PDD) is another unit, developed as a means to validate the DDD. The PDD is the average daily dose prescribed, as obtained from a representative sample of prescriptions [129]. Problems may arise in calculating the PDD because of a lack of clear and exact dosage indication in the prescription, as is often the case with the prescribing of insulin. Prescriptions for chronic therapy, as in the case of insulin, may be refilled many times and the dosage may be altered verbally between prescribing events [130]. For certain groups of drugs, such as oral antidiabetics, the mean PDD may be lower than the corresponding DDD. Up to twofold variations in the mean PDD have been documented in international comparisons [129]. Higher PDDs have been observed in the US relative to Sweden for commonly prescribed drugs, such as hydrochlorothiazide, diazepam, and oxazepam [131]. In studies assessing whether antidepressants increase the risk of suicide, a refined person-year of use estimate was obtained from adjusting the DDD by the average PDD for individual antidepressants [132]. Although the DDD and the PDD may be used to estimate population drug exposure "therapeutic intensity," the method is not useful to estimate incidence and prevalence of drug use, or to quantify or identify patients who receive doses lower or higher than those considered effective and safe.

The Infectious Diseases Society of America and the Society for Healthcare Epidemiology of America (IDSA/SHEA) have recommended days of therapy (DOT) for expressing antimicrobial drug use [133]. DOT is the number of days when at least one dose of a medication was administered irrespective of dose or route of administration. They are not impacted by dose adjustments and can be used in both adult and pediatric populations. Similar to PDDs, expressing drug use in the number of DOTs requires patient-level use data, which may not be feasible at every facility.

Drug and Disease Classification Systems

The Anatomic Therapeutic Chemical classification system is generally used in conjunction with the DDD method [112,119]. It was originally

developed by the Norwegian Medicinal Depot, which became a WHO Collaborating Centre for Drug Statistics Methodology; the center is now located at the Norwegian Institute of Public Health (www.whocc.no). The ATC system is based on the main principles of the Anatomical Classification system developed by the European Pharmaceutical Market Research Association (EPhMRA) and the International Pharmaceutical Market Research Group (IPMRG).

The ATC system consists of five hierarchical levels: a main anatomical group, two therapeutic subgroups, a chemical-therapeutic subgroup, and a chemical substance subgroup. The coding of furosemide preparations is used to illustrate the ATC classification structure in Table 18.1. The first three levels are modifications of the three-level EPhMRA and IPMRG classification system. The fourth and fifth levels are extensions that are developed and updated by the WHO Collaborating Centre for Drug Statistics Methodology. Ongoing discussions aim to identify differences in the two classification systems and harmonize the first three levels. Statistics reported with the ATC system should not be directly compared with figures prepared with the EPhMRA system.

Medicinal products are classified according to the main therapeutic indication for the principal active ingredient. Most products are assigned only one ATC code. However, some active medicinal substances may have more than one ATC code, if the drug has different uses at different strengths (acetylsalicylic acid as a platelet aggregation inhibitor and as an analgesic–antipyretic), dosage forms (timolol to treat hypertension and to treat glaucoma), or both (medroxyprogesterone for cancer therapy and as a sex hormone). Prednisolone is an example of a drug that has six different codes. Fixed-dose combination products pose classification difficulties. For example, a combination product that contains an analgesic and a tranquilizer is classified as an analgesic, even though it also contains a psychotropic substance. Because the ATC codes and DDDs may change over time with regular revisions, researchers must carefully document which version of the classification and DDD assignment is used, so that the resulting drug statistics may be adequately interpreted [134].

The European Drug Utilization Research Group (EuroDURG), formerly the WHO Drug Utilization Research Group and currently an association of European national Drug Utilization Research Groups, and the International Society of Pharmacoepidemiology Special Interest Group in Drug Utilization Research (ISPE SIG DUR) recommend the use of the ATC classification system for reporting drug consumption statistics and conducting comparative drug utilization research [130]. The WHO International Drug Monitoring Program uses the system for drug coding in adverse drug reaction monitoring (www.who-umc.org). Some developing countries also use the ATC system to classify their essential drugs [135,136]; this may eventually lead to the preparation of annual drug utilization statistics [137].

In the US, the Iowa Drug Information System (IDIS) is a hierarchical drug coding system that is based on the three therapeutic categories of the American Hospital Formulary Society (AHFS), to which a fourth level was added to code individual drug ingredients [138]. The IDIS code has eight numeric digits, two digits per level (see Table 18.1). This coding system was used in the Established Populations for Epidemiologic Studies of the Elderly survey [138]. Other coding systems such as the National Drug Code and the Veterans' Administration Classification [139] do not provide unique codes for drug ingredients.

In the UK, British National Formulary (BNF) codes are widely used for drug utilization studies. The BNF provides monographs for drugs available in the UK. The numbering system is produced by NHS Prescription Services, part of the NHS Business Services Authority in England [140].

Table 18.1 Anatomic Therapeutic Chemical (ATC) and Iowa Drug Information System (IDIS) classification and coding structures for furosemide.

ATC Classification (C03CA01)					
C	Cardiovascular System (First level, main anatomical group)				
	03	Diuretics (Second level, main therapeutic group)			
		C	High-ceiling diuretics (Third level, therapeutic subgroup)		
			A	Sulfonamides, plain (Fourth level, chemical therapeutic subgroup)	
				01	Furosemide (Fifth level, chemical substance)
IDIS Classification (40280401)					
40	Electrolyte Solutions (First level, main therapeutic group)				
	28	Diuretics (Second level, therapeutic subcategory)			
		04	Loop-diuretics (Third level, therapeutic subcategory)		
			01	Furosemide (Fourth level, chemical substance)	

The International Classification of Diseases is a system of diagnostic codes for classifying diseases and other health problems. The ICD is published by the WHO and used worldwide in morbidity and mortality statistics, drug reimbursement systems, and automated decision support in healthcare. The system includes categories relating to medicinal substances, but in the context of adverse outcomes, and often in quite broad terms. It does not include codes suitable for recording and classifying drug utilization [141].

The Systematized Nomenclature of Medicine (SNOMED) provides a core general terminology for use in various medical fields. SNOMED clinical terms (CT) contain more than 311 000 active concepts in clinical settings, organized in different hierarchies. An individual number represents each concept, and several concepts can be used in combination to describe a complex condition. Clinical finding/disorder and procedure/intervention are examples of the main levels in SNOMED CT. Substance and pharmaceutical/biologic product are also in the main levels. The pharmaceutical/biologic product hierarchy was introduced as a top-level hierarchy in order to distinguish drug products from their chemical constituents (substances). It contains multiple levels of granularity, used to support a variety of purposes, including electronic prescribing and formulary management (www.ihtsdo.org).

Quality Indicators

Drug utilization studies assessing the quality of drug prescribing involve the use of various types of quality indicators [142]. These may be defined as "A measurable element of prescribing performance for which there is evidence or consensus that it can be used to assess quality, and hence in changing the quality of care provided." Quality indicators for drug utilization may be classified based on the amount of clinical information incorporated in the indicator. *Drug-oriented indicators* focus solely on the drugs prescribed, dispensed, or consumed. The simplest approaches only require aggregate data on the volume and expenditure of prescribed or dispensed drugs. Such data could be presented as time trends or top-ten lists and used as a catalyst to stimulate discussion around areas for improvement in drug therapy. Simple drug-oriented indicators can be constructed to compare practices, clinics, or regions. Such drug-oriented indicators are based on drug data alone and can be used irrespective of the indication for which the drug is prescribed. The most commonly used drug-oriented indicator is the ratio between different drugs. Some examples include the ratio of COX-2 inhibitors to all NSAIDs measured in DDDs, the ratio of simvastatin to statins, and the ratio of angiotensin-converting enzyme (ACE) inhibitors to all renin-angiotensin drugs [143–146]. Other types of drug-oriented indicators have been focused on inappropriate drugs in children and the elderly [147–150].

Another approach analyzed the number of drugs that accounted for 90% of drug utilization (DU90%) and the percentage of these drugs that were included in evidence-based guidelines [151]. The first studies on the DU90% method used the guidelines on rational drug use issued by the regional Drug & Therapeutics Committee in Stockholm, Sweden [152]. (See Figures 18.3 and 18.4.) These guidelines consist of approximately 200 medicines recommended as first-line choices for the treatment of common diseases. The 90% level was arbitrarily selected to focus on the bulk of prescribing, yet allow some degree of individual variation. The number of different products in the DU90% segment varied between 117 and 194 among 38 primary healthcare centers in Stockholm; adherence to the guideline varied at between 56% and 74%. The Swedish Medical Quality Council has recommended the DU90% method for assessing quality in drug prescribing. Using this method, researchers in the Netherlands did not find any

	SUBSTANCE	(DDD)	DDD	% TOT	Rx	COST	COST/DDD
1	**Acetylsalicylic acid**	1 tablet	39,894,782	4.9%	650,808	22,995,814	0.58
2	**Simvastatin**	30 mg	29,455,125	3.6%	438,802	26,731,380	0.91

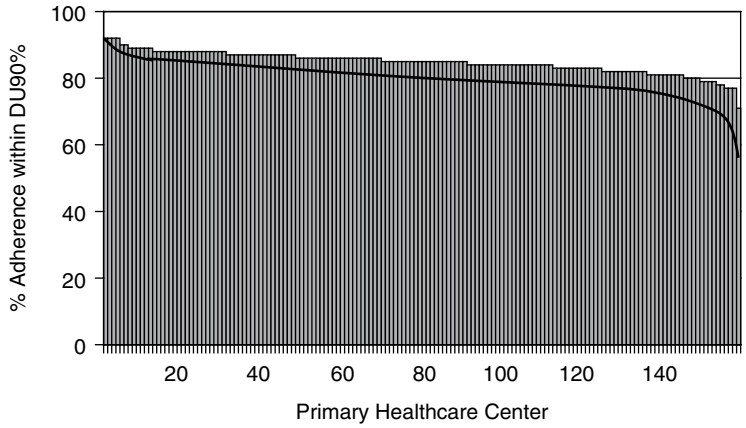

Figure 18.4 Adherence to "Wise List" recommendations for 156 primary healthcare centers for prescriptions dispensed in 2009. The thick black line equals the adherence range for the same practices in 2003. Observe that the order of the practices may differ between the two years. *Source:* Gustafsson LL, Wettermark B, Godman B, *et al*. The "Wise List": a comprehensive concept to select, communicate and achieve adherence to recommendations of essential drugs in ambulatory care in Stockholm. *Basic Clin Pharmacol Toxicol* 2011; **108**(4): 224–33, Figure 5. Reproduced with permission of John Wiley & Sons.

association between different levels of performance in pharmacotherapy audit meetings and quality of prescribing for seven drug classes. They suggested that for certain drug classes, such as antidepressants, duration of treatment may be more relevant for quality prescribing than using the drug of first choice in the guidelines; for diabetes, co-medication with statins may be more important than the number of different oral antidiabetics; and for obstructive airway diseases, concomitant use of corticosteroids may be more a more appropriate criterion than choices within the guidelines [153].

DU90% has also been used, for example, to compare NSAIDs prescribing in Denmark, Italy, Croatia, and Sweden [7,8], antibiotics in Denmark and Italy 199], and general intensive care unit antibiotic prescribing and cost patterns in Israel [154], and to assess the effect of financial incentives linked to self-assessment of prescribing patterns in Swedish primary care [155]. In Stockholm, the DU90% profile was useful in following up adherence to recommendations of essential drugs in ambulatory care for 15 years [152,156]. Furthermore, integrating resistance to the antibiotic DU90% profiles showed striking figures on the use of antibiotics that were cheap but resistant rather than effective and more expensive [157]. (See Figure 18.5.)

Access to patient-level data enables the construction of more clinically relevant drug-oriented indicators linking different drugs to each other or over time. Some examples of approaches include the identification of inappropriate or interacting drugs (questionable combinations) prescribed to individual patients [60,61,150,158,159] or co-prescribing of beta-adrenoreceptor antagonists and agonists [160]. They may also be used to identify in which order drugs are initiated to patients, for instance the proportion of patients initiated on angiotensin receptor blockers previously dispensed ACE-inhibitors [161].

Disease-oriented indicators include information on drugs linked to the diagnosis or healthcare problem. They may either indicate to what extent patients are being treated with the recommended drugs for a certain condition, or to what extent drugs are avoided for patients with conditions for which the drugs should not be used.

	SUBSTANCE	(DDD)	DDD	% TOT	DDD/100 BED-DAYS	COST/DDD (rubles)	% RESIST

Patient-oriented indicators include information on drugs linked to individual clinical characteristics of the patient, such as the severity of the disease and whether a certain treatment is suitable for a specific patient [160].

Although the use of health insurance databases has been reported in countries outside North America, Europe, and Asia [31,162–164], medical and pharmaceutical databases are generally not available in most low and middle income countries. An approach based on the use of standardized criteria (indicators) to measure changes in medicines prescribing, dispensing, and patient care was developed in the

Table 18.2 World Health Organization/International Network for the Rational Use of Drugs drug use indicators.

Core indicators
Prescribing indicators
Average number of drugs per encounter
Percentage of drugs prescribed by generic name
Percentage of encounters with an antibiotic prescribed
Percentage of encounters with an injection prescribed
Percentage of drugs prescribed from essential drugs list or formulary
Patient care indicators
Average consultation time
Average dispensing time
Percentage of drugs actually dispensed
Percentage of drugs adequately labelled
Patient's knowledge of correct dosage
Facility indicators
Availability of copy of essential drugs list or formulary
Availability of key drugs
Complementary indicators
Percentage of patients treated without drugs
Average drug cost per encounter
Percentage of drug costs spent on antibiotics
Percentage of drug costs spent on injections
Prescription in accordance with treatment guidelines
Percentage of patients satisfied with care they received
Percentage of health facilities with access to impartial drug information

Source: How to Investigate Drug Use in Health Facilities: Selected Drug Use Indicators. EDM Research Series No. 007. Reproduced with permission of WHO.

early 1990s by INRUD and the WHO [165]. The approach has facilitated the study of drug utilization in developing countries. It includes recommendations on minimum sample sizes, sampling methods, and data collection techniques, depending on study objectives. The method recommends 12 core indicators and 7 complementary indicators to study drug use in health facilities (Table 18.2). These indicators can be used to describe prescribing practice [166], for conduct monitoring and supervision [167], and to assess the impact of interventions [168–170]. The WHO has compiled indicator results and other findings reported in studies conducted in 97 developing and transitional countries between 1990 and 2006 [171].

INRUD has also developed simple low-cost indicators to measure adherence to antiretroviral (ARV) treatment in resource-poor settings. Adherence measures derived from dispensing data in pharmacy records, self-report data in medical records, and attendance logs predicted key clinical outcome related to individual patient treatment success, and were feasible to collect [172]. The four indicators were percentage of patients with self-reported full adherence, percentage of days covered by ARVs dispensed, percentage of records with a 30-day gap in ARVs dispensed, and percentage of patients who attended within 3 days of the scheduled appointment. These indicators allow assessment and comparison of programs and facilities, and monitoring and evaluation of interventions.

Intervention Strategies Based on Drug Utilization Data

Numerous studies have described interventions aimed at improving prescribing by the use of drug utilization data obtained from drug utilization studies, and are discussed further in Chapter 19. Two intervention strategies may illustrate different approaches to the use of drug utilization data available from computer databases of office practice.

In a randomized clinical trial, Avorn and Soumerai [173] used Medicaid data to identify physicians who were prescribing drugs that were assessed as inappropriate (based on considerations of documented efficacy, relative efficacy, and relative cost). These physicians were targeted for educational or information activities, as either face-to-face contacts or written drug information. Schaffner *et al.* [174] and Ray *et al.* [175] used a similar approach in another controlled intervention study, comparing different strategies aimed at modifying physician prescribing behavior: written drug information versus personal visits by pharmacists versus personal visits by physician educators. These two studies demonstrated the efficacy of face-to-face methods in improving drug prescribing.

The second approach uses claims data to perform computerized screening for patients who may be at increased risk for drug-induced illness, using patient-specific medical and drug histories [176–178]. Health professionals then evaluate profiles of patients with possibly inappropriate drug use. If drug use is indeed considered inappropriate, a letter is sent to the prescriber providing a profile of the patient's relevant computerized claims record and a warning of the potential for drug-induced disease. Often the problem is a concomitant drug or diagnosis of which the prescriber was unaware. This approach is obviously much less expensive than the face-to-face approach. Using before-and-after comparisons, a significant reduction in drug-induced hospitalizations has been noted [177]. However, the interpretation of these results is hampered by the use of a nonexperimental design. Other authors have found no effect on measures of prescribing or on patient outcomes [179]. A simultaneously controlled trial is needed to adequately assess the value of this approach.

Many other studies have described intervention strategies based on providing drug utilization data feedback, alone or in combination with printed material and/or other "educational strategies," for example group discussions, lectures, seminars, or personal visits by "experts." The results from these studies are conflicting. Some suggest that methods that involve only feedback of drug utilization data or audit results are ineffective. Others suggest a transient effectiveness for those that combine the use of drug utilization review data with group discussions, lectures, and visits by experts. However, these are difficult to interpret because of limitations in their research designs [180].

Conceptually, DUR programs are aimed at the improvement of medical care and cost containment. However, in practice traditional approaches have focused on control of the abuse or overuse of drugs, polypharmacy, or patients obtaining prescriptions from many different prescribers. Moreover, most DUR studies have emphasized process measures of quality of care, for example the use of clinical laboratory tests to monitor for adverse effects during chloramphenicol or aminoglycoside therapy. The approach described by Strom *et al.* [176], Lee Morse *et al.* [177], and Groves [178] was a significant advance in DUR programs, as it was primarily aimed at improving measurable patient outcomes. Also, it does not impose arbitrary restrictions on drug use, potentially impairing patient care, but seeks to reduce costs by improving patient care. In seeking to reduce the financial impact of drug use, it does not focus on the drug costs themselves, but on the effects of the drugs. By reducing the need for medical care through the beneficial effects of drugs, or by increasing the need for remedial medical care because of drug toxicity, pharmaceuticals can have a financial impact on the healthcare system that is much larger than the cost of the drugs themselves. (This is discussed more in Chapter 35.)

Despite their appeal, the effectiveness of DUR programs remains to be established. A study of six Medicaid programs failed to identify an effect of retrospective DUR on the rate of potential prescribing errors and rate of all-cause or specific-cause hospitalizations [179]. Another study did not find effects of two state prospective DUR interventions on the frequency of drug problems, utilization of prescription drugs and other health services, and clinical outcomes [181].

The Future

Opportunities

Drug utilization research is rapidly expanding in all countries across the globe, from the early descriptive studies to advanced studies combining different data sources to further understand medicine use in the population. In the early days, drug utilization studies were suggested to focus on the medical, social, and economic

aspects of drug utilization [2]. Medical aspects included potential inappropriate prescribing in different groups such as children and the elderly. Social aspects included attitudes to medicines and health, drug abuse and dependence, and their causes and trends, as well as socioeconomic inequities. Economic aspects included drug prices and expenditure for generics and brands, as well as allocation of resources (money, personnel, facilities) to drugs and other aspects of healthcare. All these aims are still relevant for future drug utilization research. However, the types of drugs in focus will differ, with 42% of the substances in drug development being biologics, compared to 8% on the market today [182]. The growing pressures on all healthcare systems with aging populations, rising patient expectations, stricter clinical targets, and expensive new medicines will further increase the need for drug utilization studies to monitor that resources are used wisely and that new medicines are prescribed to those who may benefit most from them.

From a public health perspective, the observed differences in national and international patterns of drug utilization require much further study. The medical consequences as well as the explanations for such differences are still not well documented. The increasing availability of patient-level databases on dispensed medicines will facilitate studies of the incidence and prevalence of medicine use, as well as more sophisticated studies on patterns of use, including drug combinations, dosing regimens, and persistence to drug therapy. These databases contain or may be linked to diagnoses and other clinical data that facilitate drug utilization studies, where drug utilization can be understood in its clinical context. The ongoing digitalization of healthcare will further increase access to large amounts of data for drug utilization research. Considerable amounts of healthcare data are generated every day, some of it from data sources to a large extent unexplored or unused in drug utilization research, such as clinical records systems, mail traffic, social media, and various devices.

Numerous studies have addressed the factors influencing drug prescribing. However, the relative importance of the many determinants of appropriate prescribing is still to be adequately elucidated. Further research is needed to better define to what degree and which determinants of inappropriate prescribing are susceptible to modification, and what might be an appropriate mix of interventions to achieve optimal impact. Although regulation is effective, it is not possible to regulate all aspects of the clinical decision-making process to ensure optimal drug prescribing [183]. Other approaches in addition to educational and informational measures are being explored. It is also important to emphasize the growing role of the patient in drug utilization research, both as a source of information to understand how drugs are used in reality, and also as a partner in designing and conducting research.

There is a need too for many more intervention studies targeted at the various stakeholders involved in the process of prescribing, dispensing, and consumption of medicines. Many strategies aimed at modifying prescribing behavior have been proposed and adopted. The evidence to date indicates that mailed educational materials alone are not sufficient to modify prescribing behavior [173,180]. Early studies conducted in Australia [184] and Denmark [185] concluded that mailed, unsolicited, centralized, government-sponsored feedback, one based on aggregate prescribing data and the other with a clinical guideline, had no impact on physician prescribing. For interventions that have been shown to be effective in improving drug prescribing (discussed in Chapter 38), there is a need to further define their relative efficacy and proper role in a comprehensive strategy for optimizing drug utilization. Questions yet to be addressed through a proper methodology deal with the role of printed drug information such as drug bulletins; the duration

of effect of educational interventions such as group discussions, lectures, and seminars, each in both the outpatient as well as the inpatient settings; and the generalizability of face-to-face methods, as described by Avorn and Soumerai [173], Schaffner *et al.* [174], and Ray *et al.* [175]. There is also a need for more research on whether the benefits and savings achieved with intervention strategies outweighed the costs of performing the intervention.

More clinically applicable approaches to DUR programs, such as the computerized screening of patient-specific drug histories in outpatient care to prevent drug-induced hospitalizations, still require further development and assessment. Although numerous studies have described the results of these and other novel programs [177,178,186,187], adequate documentation of their efficacy in improving quality of care is an important subject for future work. Patient outcome measures as well as process measures of quality of drug utilization have to be included in such studies. To be effective and efficient, healthcare policy options should be based on sound scientific evidence [188].

Challenges

The use of computerized databases has greatly facilitated studies of drug utilization. Although useful, most of these databases are far from ideal, as they have been set up mainly for administrative purposes, such as reimbursement, and drug utilization data are obtained as "spin-off" information. The model information system that will suit both medical and administrative needs [189] is still unavailable, although there is increasing use of electronic medical records for routine practice in countries such as the Netherlands, Australia, the UK, and the US. There is also a general lack of patient-level databases on medicine use in inpatient care [190]. Existing medical and pharmaceutical databases, with all their described limitations, will continue to be the main resources for these drug utilization studies. There is, however, a rapid growth of data coming from other sources. Even though new computer techniques and machine learning have been developed, many challenges remain, such as how to deal with missing data, unstructured data, poor data validity, and interoperability.

We have been fortunate to live in an era when large amounts of drug utilization data have become available for research. It is important to recognize, however, that the increasing amounts of digitalized personal data may add fuel to the debate on confidentiality. Confidentiality of patient data has so far been successfully handled and procedures have been implemented in most countries that are consistent with the guidelines for good practice in data privacy, medical record confidentiality, and research developed by the International Society for Pharmacoepidemiology (ISPE). Still, it is important to acknowledge the ongoing debate. In the EU, a new data protection framework is being implemented in all member states. Similar initiatives are being taken in other countries. Hopefully, this will not prevent opportunities for conducting research.

Even though drug utilization analyses today are conducted routinely in most health systems, this does not imply that drug utilization research is awarded high priority. The recruitment and training of researchers may be hampered by limitations in funding, as well as limitations in career opportunities. These two problems impose constraints on the future development of studies in drug utilization. However, despite this, the search continues for simple and relatively inexpensive methods to conduct descriptive studies of drug utilization, and effective intervention strategies that may contribute to the optimization of drug therapy. Fortunately, the increasing commitment to drug utilization research is reflected in the development and growth of international groups such as ISPE (www.pharmacoepi.org) [191], the International Clinical Epidemiology Network (INCLEN; www.inclentrust.org) [192], EuroDURG (www.

eurodurg.com) [193], DURG-LA [28], and INRUD (www.msh.org/INRUD) [194,195].

In summary, the study of drug utilization continues to evolve. The development of computerized databases is allowing the linkage of drug utilization data to clinical data and much other information to get a better understanding of drug utilization. The WHO/INRUD indicator-based approach to drug utilization studies is facilitating the development of drug utilization research in developing and transitional countries. Many strategies have already been proposed, tested, and implemented to improve the quality of drug prescribing in developed [196] and developing countries [197]. DUR programs, particularly approaches that take into primary consideration patient outcome measures, merit further rigorous study and improvement. Opportunities for the study of drug utilization are still underexplored, but the political issue regarding the confidentiality of medical records, as well as limitations in funding and personnel, may limit the growth of drug utilization research.

Evaluating and Improving Physician Prescribing

Christine Y. Lu[1], the late Sumit R. Majumdar[2], Helene Lipton[3], and Stephen B. Soumerai[1]

> Research and clinical practice may be on parallel tracks headed in the same direction, but in contact only through rotting ties. [1]

The broad purposes of pharmacoepidemiology are to advance our knowledge of the risks and benefits of medication use in real-world populations, and to foster improved prescribing and patient health outcomes. If, however, physicians and other health practitioners fail to update their knowledge and practice in response to new and clinically important evidence on the outcomes of specific prescribing patterns, then the "fruits" of pharmacoepidemiologic research may have little impact on clinical practice.

It is for these reasons that a new discipline in the fields of health services research and clinical decision making has grown rapidly in importance – the science of assessing and improving clinical practices. The rapid growth of this new field (sometimes referred to as T-2 translational research or knowledge translation research) is based on the recognition that passive knowledge dissemination (e.g., publishing articles, distributing practice guidelines) is generally insufficient to improve clinical practices without supplemental behavioral change interventions based on relevant theories of diffusion of innovations, persuasive communications, and adult learning or social cognitive theory [1–10].

This chapter reviews some of these developments as they relate to medication use, defines several types of drug prescribing problems, discusses several thorny methodologic problems in this literature, reviews existing pharmacoepidemiologic and other evidence on the effectiveness of common interventions to improve prescribing, and concludes with a discussion of future research needs. For a more detailed and comprehensive examination of the literature on prescribing education, the role of the pharmacist as a change agent, disease management strategies for use in various settings, and the use of financial incentives and penalties, the reader is advised to consult several previous works

We dedicate this chapter to our colleague and friend Dr. Sumit Majumdar, whose untimely death occurred shortly after this chapter was written. We thank Caitlin Lupton MSc, of Harvard Pilgrim Health Care Institute for research assistance and administrative support.

Pharmacoepidemiology, Sixth Edition. Edited by Brian L. Strom, Stephen E. Kimmel and Sean Hennessy.

published elsewhere [11–33]. Portions of this chapter are derived from this body of work; in addition, we conducted computerized literature searches for papers published through early 2017, hand-searched our personal files and the cited references, and extensively consulted the Cochrane Effective Practice and Organisation of Care (EPOC) Group, a rigorous and continuously updated registry and synthesis of available evidence on studies of interventions to change physician behaviors [33].

Clinical Problems to Be Addressed by Pharmacoepidemiologic Research

There is little doubt that the importance of suboptimal prescribing practice (both underuse and overuse) vastly outweighs the costs of medications themselves [33–37] (see also Chapter 38). Drug therapies are the most common treatments in medical practice and more than three-quarters of all visits to a physician terminate with the writing of a prescription [15]; the potential for drug therapies for both alleviating and causing illness is illustrated throughout this book. As suggested by Lee [37], in this chapter we take a broad view of the concept of prescribing errors, and consider issues related to underuse, overuse, and misuse, since all contribute to the suboptimal utilization of pharmaceutical therapies. For example, we would consider as prescribing "errors" the following:

- Use of toxic or addictive drugs when safer and clinically appropriate agents are available (e.g., opioids instead of nonsteroidal anti-inflammatory drugs for pain [38,39]).
- Use of drug therapy when no therapy is required (e.g., antibiotics for viral respiratory infections).
- Use of an ineffective drug for a given indication (e.g., hormone therapy for prevention of cardiovascular disease in postmenopausal women).
- Use of a costly drug when a less expensive preparation would be just as effective (e.g., newer angiotensin-receptor blockers, instead of effective and inexpensive angiotensin-converting enzyme inhibitors or thiazide diuretics, for uncomplicated hypertension).
- Misuse of effective agents (e.g., too low doses of narcotic analgesics or too high dosages of benzodiazepines, when indicated, for the elderly).
- Failure to discontinue therapy when the drug is no longer needed (e.g., use of proton pump inhibitors for months to years in patients without documented gastroesophageal reflux disease).
- Failure to introduce new and effective drugs into practice (e.g., failure to use inhaled corticosteroids for asthma or spironolactone for heart failure).
- Failure to prescribe necessary drug therapies (e.g., failure to use beta-blockers following acute myocardial infarction or bisphosphonates after an osteoporotic fracture).
- Failure to achieve recommended therapeutic goals (e.g., failure to achieve systolic blood pressure levels below 130 mmHg or LDL cholesterol levels below 70 mg/dL for the secondary prevention of myocardial infarction).

Specific illustrations of these problem categories are ubiquitous in the literature. In the outpatient setting, numerous studies have documented that as much as 50% of antibiotic use is potentially inappropriate, with the unintended consequence that overuse of antibiotics may lead to the emergence of resistant pathogens [40]. A group at particular risk of iatrogenic injuries as a result of inappropriate medication exposure appears to be the frail elderly, whether they reside in the community or in nursing homes [34,41,42].

Because of the absence of diagnostic data in most published drug utilization research, and

because of the emphasis on cost containment within drug utilization review (DUR) programs (see subsequent definition), the existing literature may *underemphasize* the clinically important problem of underuse of highly effective medications. For example, Berlowitz *et al*. found that nearly 40% of patients with documented hypertension in the Veterans Administration (VA) healthcare system had uncontrolled hypertension (>160/90 mmHg), despite adequate healthcare and prescription drug coverage and more than six hypertension-related primary care visits each year [43]. Indeed, this demonstrates profound clinical inertia, as changes in antihypertensive therapy occurred in less than 10% of all of these visits [43]. In another study of 623 outpatients treated for acute myocardial infarction at the Yale-New Haven Hospital, researchers found that one-third of patients meeting strict randomized controlled trial (RCT) eligibility criteria for use of beta-blockers did not even receive a trial of therapy – contrary to existing guidelines. These patients experienced a 20–40% higher mortality rate postmyocardial infarction than may have been necessary [44]. There are many other examples of underuse and resultant unnecessary morbidity and mortality throughout the pharmacoepidemiologic literature.

Why do these problems occur? Can a comprehensive theory of behavioral change or knowledge translation provide the basis for programs designed to improve prescribing? Such an ideal model must be complex given the diversity of economic, organizational, educational, psychological, social, informational, and technological influences on daily prescribing practices [1–10,45–52]. Some of the factors responsible for suboptimal prescribing include the following:

- The failure of clinicians to keep abreast of important new findings on the risks and benefits of medications [6–8,45,52].
- Excessive promotion of some drugs through pharmaceutical company advertising, sales representatives, or other marketing strategies [45,52].
- Lack of promotion of highly effective but nonprofitable medications (e.g., spironolactone for heart failure) [45,52].
- Simple errors of omission [8,23,25,48,52].
- Negative attitudes toward issues of cost effectiveness of medications.
- Direct-to-consumer marketing strategies and other competing influences [49].
- Patient and family demand for a particular agent, even when it is not scientifically substantiated [49,50,52].
- Physician overreliance on clinical experience in opposition to scientific data [50,51].
- Skepticism toward, and distrust of, the literature and academia among some community-based physicians [51].
- Clinical inertia [52].
- The need to take some definitive therapeutic action even when "watchful waiting" may be the most justifiable action [50,52].
- Concerns related to medicolegal liability and the perceived need to practice defensive medicine [37,50,51].
- Influence from clinical opinion leaders or other health practitioners [50–52].

These diverse influences suggest the need for tailoring multifaceted intervention strategies to the key factors influencing a given clinical behavior, based on models of behavioral change and knowledge translation.

Methodologic Problems to Be Addressed by Pharmacoepidemiologic Research

Research on the impact of educational and administrative interventions to improve drug prescribing presents numerous methodologic challenges. This section will review several of the most important methodologic problems,

such as internal validity, regression toward the mean, unit of analysis errors, logistical issues, ethical and legal problems, and the detection of effects on patient outcomes.

Internal Validity

As early as 1975, Gilbert *et al*. established that poorly controlled studies produce misleading estimates of the effects of a variety of social programs [53]. Many nonintervention factors can affect medication use over time, such as marketing campaigns, mass media, state or federal regulatory policies, seasonal effects, changing staff of healthcare organizations, other "competing" interventions, changes in eligibility for insurance programs, shifting demographics, and so on. Because RCTs are sometimes not feasible (e.g., contamination of controls within a single institution) or ethical (e.g., withholding quality assurance programs from controls), other strong quasi-experimental designs (e.g., interrupted time series with or without comparison series, pre–post with concurrent comparison group studies) should be used instead of weak one-group post-only or pre–post designs that do not generally permit causal inferences. In fact, the Cochrane Collaboration's EPOC Group considers rigorously conducted time-series studies and pre–post studies with a concurrent comparison group (and several baseline observations to control for secular trends) to be sufficiently valid to merit inclusion within its systematic reviews [54].

Interrupted time-series designs include multiple observations (often eight or more) of study populations before and after intervention. Such designs often permit investigators to control for preintervention secular changes in study outcomes, and to estimate the size and statistical significance of sudden changes in the level or slope of the time series occurring at initiation of the treatment. The availability of a comparison series collected from a similar, but unexposed, comparison group can further increase causal interpretability if no simultaneous change in trend is observed for this group [18,55].

Another popular design that may lead to valid results is the *pre–post with comparison group design*. Ideally, this design includes several observations before and at least one observation after treatment in a nonrandomly selected group exposed to a treatment (e.g., physicians receiving feedback on specific prescribing practices) [54], as well as simultaneous before-and-after observations of a similar (comparison) group not receiving treatment. Although this design controls for many threats to the validity of causal inferences (e.g., due to the effects of testing or maturation), it sometimes cannot control for unknown factors (e.g., a regulatory policy), which might result in preintervention differences in trends between study and comparison groups, and it is thus not as rigorous as a controlled interrupted time-series design [53,55].

The weakest, and not uncommon, design is the *one-group, post-only design*, which consists of making only one observation on a single group that has already been exposed to a treatment. The *one-group pre–post design* merely adds a single preintervention observation to the previous design. Such weak designs are unlikely to produce valid or reliable estimates of the effects of interventions, so much so that they are routinely excluded from careful reviews of the literature [18–24,54]. Furthermore, many (if not most) studies of newer technology-based approaches to improving prescribing, such as computerized physician order entry and other types of computerized decision support, have used the post-only or one-group pre–post designs to evaluate their efficacy and effectiveness [56–58].

Inadequately controlled studies may exaggerate the effectiveness of many interventions to improve prescribing. For example, inadequately controlled studies of the dissemination of print-only materials used alone have all reported positive effects on behavior, while well-controlled

studies of such strategies all reported small or nonexistent changes in behavior [59]. The "success" of uncontrolled studies is often due to the attribution of preexisting trends in practice patterns to the studied intervention.

There are many examples of the potential bias involved in failing to account for prior trends. In one study, the naturally occurring trends in the use of 23 categories of medication were examined in a four-year study of 390 000 enrollees in the New Jersey Medicaid program [60]. The results indicated that 50% of the estimated one-year percentage changes in prescriptions per 1000 enrollees exceeded +20.3% or −10.8% of baseline levels. Effect sizes reported in the prescribing intervention literature are similar to these natural fluctuations [61], suggesting that changes in drug use attributed to such interventions could merely reflect these underlying secular trends. This is particularly noteworthy, because the effect sizes reported for valid intervention studies tend to be modest at best, with improvements in the quality of prescribing (as variously defined by investigators) usually reported on the order of a 10–20% absolute improvement over controls.

Recently the Institute for Health Improvement (IHI) in the US failed to control for baseline trends before its nationwide hospital safety program, the "100,000 Lives Program," and falsely stated that the program saved 130 000 lives until a reanalysis including a long baseline showed already occurring mortality changes before the policy (Figure 19.1) [62].

These examples provide further support for more widespread application of RCTs or, when RCTs are not feasible, time-series and other valid comparison series designs to evaluate

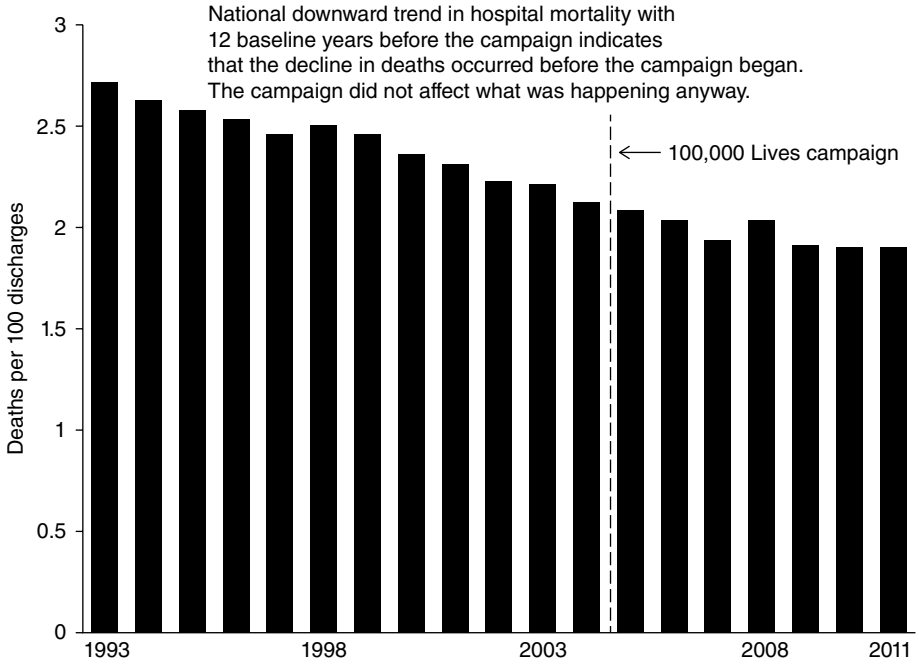

Figure 19.1 Example of a strong time-series design that controlled for history bias in the Institute for Healthcare Improvement's 100,000 Lives Campaign. Figure is based on data from the Agency for Healthcare Research and Quality.

whether suddenly introduced interventions are associated with corresponding changes in the level or slope of the utilization series, after controlling for prior trends. If the collection of time-series data is not feasible, investigators may consider using pre–post with comparison group designs (ideally incorporating several baseline points), which also control to some degree for temporal changes and unforeseen co-interventions that may concurrently affect prescribing or utilization, as described in respected texts on intervention research design [53,55].

Regression toward the Mean

Regression toward the mean – the tendency for observations on populations selected on the basis of exceeding a predetermined threshold level to approach the mean on subsequent observations – is a common and insidious problem in much of the drug utilization literature. For example, the most common Medicaid DUR programs typically screen prescribing data and eligibility files for possible co-occurrences of two interacting medications, or higher than recommended dosages for individual drugs. After case-by-case review by expert committees, letters (or email equivalents) are written to responsible physicians questioning the practice and asking for written responses. However, methodologic papers on this topic indicate that published research evaluating DUR used poorly controlled designs that were unable to control for regression to the mean [14,17,18]. For example, in one often-cited DUR study [61], 50% of prescribing problems were absent several months after letters were sent, suggesting to the noncritical reader that the program was effective. However, it is equally plausible that the offending medications were withdrawn because the patients' conditions improved or because the physicians detected the error on their own.

The likelihood that all screening algorithms employed in DUR programs are subject to regression toward the mean argues strongly for the need to conduct RCTs and well-controlled quasi-experiments (e.g., pre–post with comparison group design) to justify the efficiency and effectiveness of these interventions *before* they become a routine part of private and public quality improvement programs [14,17,18]. If regression effects are unavoidable – for example, due to selection of at-risk populations – investigators may consider including a "wash-out" period after selection and before pre- and postintervention observations [18,46].

Unit of Analysis

A common methodologic problem in studies of physician behavior is the incorrect use of the patient as the unit of analysis [63–66]. Such a practice violates basic statistical assumptions of independence, because prescribing behaviors and outcomes for individual patients are likely to be correlated within each physician's practice. To some degree, the prescribing practices of physicians within a group practice may also not be statistically independent of each other [64–66]. These forms of hierarchical "nesting" or statistical "clustering" often lead to accurate point estimates of effect but inappropriately low P values and narrow confidence intervals, when the unit of analysis is assumed to be a statistically independent patient and the analytic framework does not account for correlation among patients treated by the same physician, or groups of physicians within a practice or hospital [64–66]. As a result, interventions may appear to lead to statistically significant improvements in prescribing practices because of mistakenly inflated sample sizes. For example, one review of articles on physicians' patient care behavior found that 70% of 54 articles incorrectly analyzed the data using the patient as the unit of analysis without accounting for statistical clustering; among 19 reviewed studies of medication prescribing, 58% used the incorrect unit of analysis [66].

The simplest, although overly conservative, solution to the problem of incorrect unit of analysis is to analyze data by facility or physician. Fortunately, more statistically efficient methods for analyzing clustered data are becoming increasingly available; such models can simultaneously account for clustering of observations at the patient, physician, and facility levels [65–70]. Such models allow aggregation at the patient level by accounting for correlation between patients cared for by the same provider or facility. The resulting P values for differences in prescribing rates between study and control groups are almost always more conservative (and confidence intervals wider) than assuming no intraclass correlation, but are still greater (narrower confidence intervals) than the most conservative methods of analyzing at the provider or facility level. Much methodologic work remains to be done in terms of understanding what the appropriate unit of allocation and analysis is for various studies, how to best estimate power and sample sizes, and whether sensitivity analyses regarding unit of analysis need to be conducted or presented in the results of such studies.

Logistical Issues

While continuity of care is a goal in most healthcare settings, many patients, particularly those treated within academic medical centers, see multiple primary providers over time. For example, patients treated by residents may be reassigned to other residents at the end of the academic year. Providers may go on extended leave and transfer cases to other clinicians. Patients themselves may choose another primary care provider. In addition, many patients develop ongoing relationships with specialists as particular problems develop and are resolved.

While these changes may or may not affect patients' care, they almost always complicate and sometimes weaken research conducted in a clinical setting. Particularly in settings where providers may be assigned to both "intervention" and "control" patients, contamination problems are difficult to avoid. Even when interventions can be focused effectively on the intended patients or providers, informal communication among providers can lead to contaminated effects, thereby decreasing the likelihood of detecting significant changes.

Fortunately, some solutions to these problems exist. First, investigators should identify, through baseline interviews and organizational records, the extent to which patients are cared for by multiple providers, and the patterns of consultations and referrals between caregivers within and between facilities. If randomization of clinicians is likely to lead to contamination of controls, or if patient–provider pairs are frequently broken, then randomization of facilities should be used, such that an entire facility or subunit cluster (e.g., the "firm" within an academic teaching hospital or the "primary care practice" in the community) is assigned to the same study group. For instance, a quality improvement intervention cluster randomized 37 hospitals in one state to intervention or control status [69]. However, when this strategy is not feasible, because it results in a small sample of facilities and inadequate statistical power, investigators are encouraged to collect data during multiple observation periods both before and after the intervention, and to use time-series regression methods that can often detect modest changes in utilization levels after as few as 6–12 months.

Ethical and Legal Problems Hindering the Implementation of Randomized Clinical Trials

Adequate control groups are essential for rigorous evaluation of results. Yet it has been argued that there are ethical and legal problems related to withholding interventions designed to improve drug prescribing practices. This argument explicitly assumes that the proposed

interventions are known to be beneficial. In fact, the efficacy and effectiveness of many programs to improve drug use is the very question that should be under investigation. Some commentators have argued, quite reasonably, that mandating such programs or interventions without adequate and valid proof of benefit is in fact unethical. For example, many researchers and policymakers have stated that computerized physician order entry (CPOE) does not need to be studied, and the Leapfrog advocacy group has gone so far as to state that not having CPOE compromises patient safety and quality of care [71]. What is important is to demonstrate that such interventions are safe, efficacious, and cost-effective *before* widespread adoption. Later studies have, in fact, found that health information technology can cause unintended patient harms or deaths [72,73]. Even a safe and nonefficacious intervention is associated with opportunity costs and unknown harms; if this given intervention is widely adopted or legislatively mandated, many resources will have been diverted away from other parts of the healthcare delivery system. In those very rare instances in which the intervention has shown unusual promise in similar populations, the application of RCTs may be inappropriate, but alternative research designs should still be considered to better define the absolute risks, benefits, and costs of the intervention. Feasible design alternatives are quasi-experimental designs such as interrupted time-series analysis or staged implementation, in which the control population (or regions) receives the intervention after comparative data have been collected [29,55,65,70,74,75].

Detecting Effects on Patient Outcomes

While a number of studies have demonstrated beneficial effects of various interventions on prescribing practices, few large well-controlled studies have linked such changes in the processes of care to improved patient outcomes. A notable exception was a randomized trial of computerized alerts to improve venous thromboprophylaxis for hospitalized patients in a teaching hospital of over 700 beds [75]. Kucher *et al*. allocated about 2500 patients and their physicians to either usual care or exposure to a computerized alerting system that automatically generated a clinical risk of deep venous thrombosis score, and alerted physicians to the need for prophylaxis using either drugs or devices. Unlike most studies, this trial was designed to detect a difference in clinical events, namely objectively diagnosed life-threatening deep venous thrombosis or pulmonary embolism [75]. The computerized system more than doubled rates of appropriate prophylaxis (34% vs. 14% for controls), although there was still room for improvement. More importantly, it led to a clinically important (41% decrease) and statistically significant ($P = 0.001$) reduction in adverse clinical events. There are only a limited number of studies suggesting a tight link between improvements in processes of care and patient-related outcomes. Under most circumstances, it is profoundly difficult to demonstrate statistically significant changes in patient outcomes in response to intervention. Explanations for the far more commonly observed dissociation between improvements in prescribing and better patient outcomes include that (i) easily available clinical measures (e.g., mortality, unplanned hospital admission) may not be sensitive to the kinds of patient-related outcomes that might be affected by introduction or withdrawal of medications; (ii) changes in physician prescribing may lead to little or no change in patients' health status if patients do not adhere to the recommended regimens; and (iii) many medical therapies require months to years of continued persistence before clinical benefits become apparent.

Because of these problems, sample sizes may need to be enormous to detect even very modest changes in patient outcomes (see Chapter 4

for a discussion of methods for determining statistical power). These problems are much less severe in drug trials (especially placebo-controlled studies) because of experimenter control over the major independent variable – exposure to medications (see Chapter 36). However, process outcomes (e.g., use of recommended medications for acute myocardial infarction from evidence-based practice guidelines) are often sensitive, clinically reasonable, and appropriate measures of the quality of care [74–76], and improvements in process should not be dismissed outright as surrogate outcomes. They may be important in and of themselves, as long as the processes are a measure of evidence-based and proven effective therapy [74–76].

Conceptual Framework for Changing Clinical Behaviors

A useful starting point for designing an intervention to improve prescribing is to develop a framework for organizing the clinical and nonclinical factors that could help or impede desired changes in clinical behaviors [7–10,77]. The theory of planned behavior [9,10] is amenable to developing such a framework, as is the predisposing, enabling, and reinforcing (PRECEDE) model [77]. PRECEDE was developed for adult health education programs by Green and Kreuter [77], and proposes factors influencing three sequential stages of behavior change (predisposing, enabling, and reinforcing factors). *Predisposing* variables include such factors as awareness of a consensus guideline on appropriate use of a thrombolytic agent, knowledge of clinical relationships supporting such a guideline (e.g., major actions of thrombolytics in the artery), beliefs in the efficacy of treatment (e.g., probability of survival), attitudes or values associated with recommended behaviors (e.g., risk of intracranial hemorrhage associated with therapy), and a myriad of other potential factors [8,52]. However, while a mailed drug bulletin or email alert may predispose some physicians to new information (if they read it), behavior change may be impossible without new *enabling* skills (e.g., skills in administering a new therapy, or overcoming patient or family demand for unsubstantiated treatments). Once a new pattern of behavior is tried, multiple and positive *reinforcements* (e.g., through peers, reminders, feedback, and incentives) may be necessary to establish the new behavior fully. Several reviews of the literature have come to a similar conclusion [20,34,52,78]: multifaceted interventions that encompass all stages of behavior change are most likely to improve physician prescribing.

Empirical Evidence on the Effectiveness of Interventions to Improve Prescribing

Does existing empirical evidence on the effectiveness of alternative prescribing interventions provide any lessons on the key characteristics of successful approaches to this problem? Illustrative findings from several research syntheses will be used to evaluate the effectiveness of the most commonly studied or applied approaches. Because of severe biases introduced by uncontrolled designs that do not measure preexisting trends in target drug use behaviors (see prior "Methodologic Problems" section), only studies using valid experimental or quasi-experimental research designs (e.g., RCTs and time-series designs) are discussed.

Educational Interventions

Printed Educational Materials and Guidelines

Distributing printed educational materials aimed at improving prescribing practice remains the most ubiquitous form of prescribing

education in the industrialized world. While the most sophisticated materials may incorporate visually arresting graphs, illustrations, and headlines to convey important behavioral and educational messages, such a strategy rests on assumptions that physicians will be exposed to the information, and that such rational information will be sufficiently persuasive to change clinical practices. Unfortunately, several reviews provide consistent evidence that use of disseminated educational materials *alone* (such as drug bulletins, self-education curricula, objective, graphically illustrated "un-advertisements," or other professionally prepared educational brochures) may affect some of the predisposing variables in the change process, but will have a minimal (and often no) effect on actual prescribing practice [11,19,23,52,78–81].

Clinical practice guidelines are a distinct subset of educational materials. Although primarily educational in nature, they are also a codification of current best practice, and are intended to improve quality and decrease costs by minimizing unnecessary variations in practice. However, faith in the simple act of guideline dissemination presupposes that information alone, regardless of how reliable or well referenced, can change behavior. In general, when rigorously studied, guideline dissemination *alone* does not influence prescribing behavior or other practices to a clinically important degree [11,19,34,80–86]. Given the proliferation and availability of numerous guidelines, dissemination of a particular guideline should be considered part of "usual care," and so unlikely to change practice, and to provide a reasonable control "intervention" with which to compare more effective interventions or strategies. The failed IHI 100,000 Lives Program cited earlier also relied only on printed guidelines to avert hospital deaths [87].

In summary, simple dissemination of educational materials does not appear to be effective by itself in altering prescribing patterns, but these materials may provide a necessary *predisposing* foundation for other *enabling* and *reinforcing* strategies.

One-to-One Education (Academic Detailing)

A number of controlled studies support the conclusion that programs with brief face-to-face visits (15–25 minutes) by pharmacists, physician counsellors, or peer leaders (academic detailers) are effective in promoting evidence-based practice and improving patient outcomes [11,19,88–91]. For instance, a Cochrane review of 30 trials suggests a 6% increase in compliance with practice guidelines when any intervention in which educational meetings were a component was compared to no intervention [19], and another indicates interventions involving peer leaders were associated with a 12% increase in compliance with practice guidelines [88]. The principles and methods of this approach are described in detail elsewhere [12], and include (i) targeting of physicians with higher than average needs for education (e.g., through analyses of administrative data); (ii) conducting motivational research (e.g., surveys of focus group interviews) in advance of the intervention to understand the causes of suboptimal prescribing patterns; (iii) sponsorship by authoritative and credible medical organizations; (iv) two-way communication with prescribers to increase clinician involvement and relevance to different patient populations and settings; (v) presentation and discussion of counterarguments to which physicians have been exposed; (vi) brevity; (vii) use of high-quality, graphical educational materials; (viii) repetition of major messages; and (ix) follow-up visits for positive reinforcement. Of course, pharmaceutical industry detailing also shares many of these principles and methods. What sets academic detailing apart from industry efforts is that the messengers and the messages of the former are independent, objective, and evidence based.

A formal economic analysis of academic detailing in this study, conducted from a societal

perspective (in this case, a Medicaid program), concluded that targeting moderate to high prescribers of propoxyphene, cephalexin, and vasodilators using administrative claims databases could lead to a benefit-to-cost ratio of more than 2, even without considering positive spillover effects to nonparticipating physicians, improved quality of care, or possible cost savings due to elimination of adverse drug effects [84]. The main barrier to more widespread use of the strategy is its *perceived* labor intensiveness. Nevertheless, academic detailing is a consistently effective method for changing physician practice [11,19,88,90–93].

Group Education and Group Detailing

Although rounds, seminars, and other group didactic educational programs are among the most universal methods for prescribing education, controlled studies of this approach are almost nonexistent in the literature, especially in nonteaching settings. Nevertheless, small group discussions conducted by clinical leaders in academic primary care settings have been shown to improve use of antibiotics [40] and agents for hypertension treatment and control [94]. These successful approaches have included reviews of patient records to establish the need for change and participatory methods based on adult learning theory, and have more in common with academic (individual or group) detailing than traditional modalities of continuing medical education. Traditional large-group, didactic continuing medical education seminars have not been as successful, by themselves, in improving physician performance [19,20,95,96]. Even the most rigorous internet-based extensions of traditional continuing medical education had yielded only negligible incremental advantage over more traditional approaches [96]. The results of one early but important RCT of continuing medical education were summed up by the authors as follows: "Put simply, in terms of the effects of continuing education on the documented quality of care, wanting continuing education … was as good as getting it" [95].

A number of controlled trials have replicated the positive results of one-to-one outreach with smaller group outreach sessions, often referred to as "group detailing" [97]. Group detailing has the potential advantage of encouraging discussions within the group, which may enhance the diffusion of ideas and increase their impact. For example, in a cluster RCT to improve the use of antihypertensive medications in primary care in the US, Simon *et al.* randomly allocated three practice sites to group detailing (n = 227 prescribers), three to individual detailing (n = 235 prescribers), and three to usual care (n = 319 prescribers). Individual detailing entailed a physician-educator meeting individually with clinicians to address barriers to prescribing guideline-recommended medications. The group detailing intervention incorporated the same social marketing principles in small groups of clinicians. Results of this study suggested that both group and individual academic detailing improved antihypertensive prescribing (adjusted odds ratio [OR], 1.40; 95% confidence interval [CI], 1.11–1.76 and adjusted OR, 1.30; 95% CI, 0.95–1.79, respectively) compared to usual care, but may require reinforcement to sustain improvement [98].

It is likely that as long as the group size is kept relatively small (i.e., fewer than 5–10 participants), and the other precepts of academic detailing are adhered to, group detailing is a reasonable alternative approach to individualized educational outreach.

Local Opinion Leaders

The role of local opinion leaders in the adoption of new pharmaceutical agents has been well documented by Coleman *et al.* [2]. Their data indicated that after opinion leaders adopted particular drugs, other less integrated physicians eventually followed in a classic curve of technology diffusion. In several studies of the diffusion of scientific information on treatment

of arthritis and the inappropriate use of Cesarean sections [85,99], local opinion leaders or educationally influential physicians have been identified and encouraged to consult informally with colleagues. These opinion leaders are approached frequently for clinical advice, are trusted by their colleagues to evaluate new medical practices in the context of local norms, have good listening skills, and are perceived as clinically competent and caring [3,69,85,89,99–101]. In addition to opinion leader involvement, these interventions generally included a brief orientation to research findings, printed educational materials, and encouragement to implement guidelines during informal "teachable moments" that occur naturally in their ongoing collegial associations. The success of these programs was attributed to "the importance of the local community's norms, the orientation of practitioners to locally credible individuals, and the need to translate the research findings into a locally applicable message" [100]

Although the recruitment and use of opinion leaders show great promise in accelerating the adoption of evidence into practice, overall the results of rigorous opinion leader studies have been mixed [88], and whether or not such interventions are reproducible across diseases and settings [101], can improve prescribing for multiple conditions outside the hospital setting, and are cost effective remains to be determined.

Monitoring and Feedback

Prescribing, Audit, and Feedback

A popular approach to improving physician performance has been some form of "feedback" of prescribing patterns to individuals or groups of physicians. It has been estimated that, annually, more than one-half of all US physicians receive some clinical or economic feedback regarding their prescribing practices [25,102].

Audit and feedback interventions often compare practice patterns with peers or predetermined standards such as practice guidelines. The former is typified by interventions of peer comparison feedback, while the latter are typified by formal drug utilization review programs. Systematic reviews consistently conclude that peer comparison feedback has a statistically significant, but clinically minimal, effect on prescribing or other physician behaviors [11,21,25,102]. For instance, a Cochrane review of 49 trials suggests a 4.3% increase in healthcare professionals' compliance with practice guidelines and a 0.4% decline in dichotomous patient outcomes (e.g., the proportion of patients with appropriate management) [102].

Furthermore, it seems these programs would be unlikely to offset the costs of the interventions themselves, much less lead to cost savings. The conclusions of these reviews were supported by a methodologically rigorous RCT of the effect of peer comparison feedback on the prescription of five unrelated groups of medication [103]. These Australian investigators went so far as to conclude, based on their null results, that "feedback is not worthwhile and should not be seen as a high priority by government agencies" [103].

In addition to the type or content of the feedback, a number of variables must be considered. Communication channels could be by letter, computer, or face-to-face encounter with a supervisor or colleague. Even more importantly, the credibility of the source of the feedback information probably influences its effectiveness more than the content of messages. Thus, feedback programs operated by a government regulator or managed care organization may be less effective than professionally based educational programs in which an ongoing relationship exists between the sender and receiver of information [103–108].

Lastly, if physicians are not able to respond immediately to the feedback delivered, by altering prescribing during a specific patient encounter, they may not respond at all. It is not

necessarily true that physicians will generalize behavior from one specific encounter to similar clinical situations [104,105].

One important advance in the area of audit and feedback, which attempts to address many of the aforementioned problems, is the development of the concept of the "achievable benchmarks of care" by Kiefe *et al.* [105]. The underlying theory is that viewing one's personal performance within the context of peers' performance should be a powerful motivator for change [89]. In essence, the achievable benchmark represents the average performance of the top 10% of local physicians being assessed [105]. By design, achievable benchmarks are higher than the group mean – and group mean data are what are most often provided in audit and feedback programs. Kiefe *et al.* undertook a cluster RCT and allocated physicians (n ~ 100) and their diabetic patients (n ~ 2000) to either "usual care" (in fact, it was a standard quality improvement intervention that profiled physicians and provided them with individual and group mean performance feedback on five different quality indicators, such as influenza vaccination, foot examination, and measurement of glycosylated hemoglobin) or to an experimental intervention (usual care plus the provision of top 10% achievable benchmark data). The intervention was associated with 15–57% relative improvements in all indicators compared with usual care; three out of five of these improvements were also statistically significant [105].

Drug Utilization Review

DUR programs have been defined as "structured, ongoing initiatives that interpret patterns of drug use in relation to predetermined criteria, and attempt to prevent or minimize inappropriate prescribing" [14,17]. DUR has many synonyms, including drug use review, drug use evaluation, and medication review. It involves a comprehensive review of patients' prescription and medication data before, during, and after dispensing to ensure appropriate medication decision making and positive patient outcomes. DUR programs provide prescriber feedback at the patient level.

Prospective or retrospective DUR are well-studied forms of prescriber feedback. It has frequently been hypothesized that simply making clinicians aware of all of the medications a patient may be prescribed might be an effective method for reducing use of excessive, duplicative, or interacting medications. The best controlled trials of this approach confirm that simply distributing such profiles, without explicit suggestions for changes in practices, has no detectable effect on prescribing practice [103,109,110]. Likely reasons for the failure of this intuitively appealing approach include that (i) much of the generated information was probably clinically irrelevant; (ii) unsynthesized and voluminous data may cause information "overload" and desensitization of busy clinicians; (iii) there was no provision of alternative measures to improve care; and (iv) the feedback was not derived from credible sources of information. This approach represents one of the few instances in which the volume of negative findings from methodologically rigorous studies strongly supports the exclusion of this strategy from future research.

Many existing DUR programs attempt to review the appropriateness of medication prescribing for individual patients (e.g., drug interactions and dosage). Since the majority of feedback messages are likely to be clinically unimportant [14,17,18,103], the clinically relevant messages could be unintentionally ignored. Recent systematic reviews of medication review in adult hospitalized patients and nursing home residents found no evidence that medication review reduces mortality or hospitalizations [111,112]. In fact, the best-controlled studies do not yet support the effectiveness of either retrospective or prospective DUR, even though both are mandated for all state Medicaid programs [14,17,18].

Reminders and Computerized Decision Support Systems

Often, physicians are predisposed to certain therapeutic interventions, but simply omit them due to oversight or lack of coordination in the healthcare/communications system. In these cases, computerized reminders can enable physicians to reduce these errors of omission by issuing alerts to perform specific actions in response to patient-level information such as laboratory findings or diagnoses.

Several studies in hospitals, managed care organizations, and primary care settings have provided strong evidence that such systems can prevent the omission of essential preventive services such as deep venous thrombosis prophylaxis, influenza immunization, and others [57,75,113–115]. It is noteworthy that computerized reminders and decision support systems (see later discussion) are perhaps the most-studied aspect of the various functionalities present within the electronic health record. A rigorous review of 28 trials examining real-time point-of-care computerized reminders demonstrated that, when compared with controls, the median improvement in process-of-care measures was only 4%; the median improvement in appropriate medication prescribing was only 3% (interquartile range 1–11%) [113]. Although statistically significant, the magnitude of improvements is far smaller than expected and in many cases might not be considered worthwhile. Other systematic reviews [114,115] also concluded that reminders probably slightly improve quality of care, in terms of compliance with clinical guidelines, but little evidence exists on whether reminders improve patient outcomes. The effects of reminders on improving quality of care vary across settings and conditions. Such systems are more likely to be effective if the reminder requires a response from the clinician and provides an explanation of the reminder's content or advice [114]. "Reminder fatigue," with concurrent bypassing of computer screens or generalized neglect of all alerts, is an important problem that has not been well addressed [116,117].

A major component of health information technology (HIT) is computerized decision support systems (CDSS) integrated with electronic health records. They are intended to support physicians' prescribing decisions at the point of ordering, including alerts regarding dosage, drug interactions, schedule, suboptimal choices, and prevention of adverse drug events [113,118,119]. This promise, however, should not be assumed [57,72,73,113,119]. In one older but very rigorous study of advanced computer decision support, Eccles *et al*. conducted a cluster RCT of 60 busy primary care practices in the UK [10]. These practices already had electronic records and electronic prescribing. Eccles *et al*. randomized them to a computerized guideline/decision support intervention that was fully integrated into the electronic clinic record; half of the practices were allocated to a symptomatic coronary disease guideline (n = 1415 intervention patients) and the other practices to an asthma guideline (n = 1200 intervention patients). After one year, there were no significant improvements in any one of more than 40 different quality indicators for either condition [10]. Available systematic reviews suggest that CDSS might moderately improve process of care such as rates of laboratory monitoring and prescribing decisions, and that they may help reduce the length of hospital stay compared with routine care while comparable or better cost-effectiveness is achieved, but there is no evidence that CDSS have fulfilled their promised effect on healthcare costs, mortality, or other clinical adverse events [120–124]. Furthermore, there have also been well-documented harms and adverse events induced by various CDSS [72,73]. With these cautionary notes, we refer the interested reader to a more detailed examination of adverse drug events in general, and the potential roles of CPOE and computerized decision support, in recent systematic reviews [57,108,113,120–123,125].

Multimedia Campaigns

Occasionally, the discovery of important adverse effects of marketed drugs is accompanied by dissemination of educational materials to physicians as part of a broader warning campaign involving the medical and popular press, internet, newspapers, television, and radio. When the adverse effects are severe and preventable, alternative agents exist, and the messages are simple enough to convey in mass communications, such multimedia campaigns may be effective in changing prescribing patterns in large populations.

Figure 19.2 provides data from a US study suggesting that widespread reporting by the medical and lay press of the risk of Reye's syndrome associated with pediatric aspirin use was associated with declines in Reye's syndrome incidence. This media campaign was conducted after several epidemiologic studies identified the association between Reye's syndrome and aspirin use and antecedent viral illnesses [126]. The authors concluded, based on this and other studies, that mass media warnings may be effective in changing both consumer and physician behavior when the illness is severe or life threatening, the behavioral message is simple, no or few barriers to alternative behaviors (e.g., acetaminophen versus aspirin) are present, and the campaign is comprehensive, involving both health professionals and consumers.

Figure 19.3 provides data from another example of the effects of multimedia campaigns. A recent study [127] examined the effects of widespread reporting by the medical and lay press of suicidality risk associated with pediatric antidepressant use. In a 10-year interrupted time-series analysis in 11 health plans across the US, the authors found that the drug safety warnings and hyped media coverage led to substantial reductions in antidepressant use and small, visible increases in psychotropic drug poisonings treated in emergency rooms and hospitals.

Formulary Interventions and Financial Incentives

In response to escalating drug costs, an increasing number of physician practices in the US are entering into capitated drug risk-sharing arrangements with managed care organizations [22–24]. These innovative drug payment mechanisms are designed to control drug costs by encouraging physicians to prescribe "preferred" drug products (e.g., generic drugs or those that are on the health plan's formulary). Some analysts assert that capitation encourages physicians to examine their prescribing more critically, resulting in the choice of appropriate, effective, and low-cost medications. This belief is based on a number of untested assumptions: (i) practices are large enough to absorb risk, so that costly but appropriate prescribing decisions for the individual patient are not unduly affected; (ii) performance feedback to prescribers is timely and provides specific advice about costs, risks, and possible substitutions; and (iii) physicians understand and are sensitive to differences in drug pricing. Because it is unlikely that these assumptions (in general) are met, any intervention using financial incentives must be considered experimental. This is perhaps most true for various "pay-for-performance" schemes that have been introduced in many settings [128–130]. The most mature pay-for-performance program is that linked to the UK Quality and Outcomes Framework for primary care [128]. There were more than 100 indicators introduced, and by most standards the incentives were considered generous – up to an additional 25% of an individual physician's income could be generated within the scheme, and collectively the equivalent of about $1 billion annually

was spent by the National Health Service. Rigorous studies, using time-series methods, demonstrated small, if any improvements in performance indicators; protracted follow-up, however, demonstrated that performance plateaued and in fact quality of care may have even decreased for those conditions or indicators that were not incentivized [128–130]. In a recent RCT [131] of a pay-for-performance intervention, physicians were randomized to receive economic incentives for each patient who met target cholesterol levels, whereas physicians in the control groups received no economic incentives for achieving better outcomes. Results of this RCT suggest that physician payments did not produce any meaningful changes in quality of care compared with an equivalent group receiving no incentives.

Preferred drug lists (PDLs) are commonly used in the US and elsewhere by policymakers to contain drug costs; prescribing of nonpreferred drugs requires prior authorization. Well-controlled studies have assessed their effects on the quality of prescribing, unintended consequences, and patient outcomes. Rigorous, longitudinal studies reported that prior authorization is associated with lower use of nonpreferred cardiovascular drugs [132,133], and with treatment discontinuity among patients with severe mental illness such as schizophrenia and bipolar illness [134–136] with few cost savings. Following treatment discontinuation associated with prior authorization, a pre–post design with a control group study [137] found significant and concerning reductions in psychiatric visits among the sickest patients with bipolar illness and increases in emergency room visits among less severely ill patients, which may reflect attempts by patients to improve access to medication. An interrupted time-series study found that prior authorization was associated with substantial reductions in initiation of nonpreferred medications [138] for severe mental illness without offsetting increases in use of preferred agents. These results suggest that prior authorization acts as an administrative barrier and is associated with underuse of maintenance medications. This is a major concern for the quality of care of this population, because underuse of maintenance medications could lead to acute episodes of illness, suicide, and hospitalization. Moreover, targeting essential drug classes with heterogeneous patient responses and side effects could reduce appropriate care, adversely affect health status, and cause shifts to more costly types of care. Assessing inappropriate use of high-cost drugs before implementing regulations and instituting simple mechanisms to exempt high-risk patients could maximize savings and minimize harm.

The Future

Based on this synthesis of the research literature, it is clear that our knowledge of the characteristics of successful interventions to improve prescribing is growing rapidly. Passive dissemination of evidence is a necessary but insufficient method for improving most prescribing behaviors. In general, the achievement of long-term changes in practice will depend on the inclusion of multiple strategies that predispose, enable, and reinforce the desired prescribing behaviors. The following characteristics seem to recur in successful interventions:

- Using theoretical and conceptual frameworks to identify key factors influencing prescribing decisions through surveys, focus groups, or in-depth interviews.
- Targeting physicians in need of education (e.g., through review of prescribing data) to increase effectiveness and efficiency.
- Recruitment and participation of local opinion leaders.
- Use of credible and objective messengers and materials.

- Face-to-face interaction, especially in primary care settings.
- Audit and feedback (*if they are used at all*) that incorporate achievable benchmarks, comparisons with peers, and patient-specific data.
- Repetition and reinforcement of a limited number of messages at one time.
- Provision of acceptable alternatives to the practices that are deemed necessary to be extinguished.
- Brief, graphic educational guidelines and evidence summaries to predispose and reinforce messages.
- Use of multiple evidence-based strategies to address multiple barriers to best practice.
- Emphasis on the goal of improvement in the quality of prescribing and patient safety, not just cost minimization in the guise of quality improvement.

There is also a tremendous need for carefully controlled research of some existing and new methods for improving prescribing, and how best to combine various evidence-based strategies to allow for rapid local implementation of prescribing guidelines. New models are needed to predict the most effective types of intervention for specific problem types, and a number of broader questions still need to be answered: What is the correct, or at least most reasonable, rate of adherence to a given prescribing guideline? Are face-to-face interventions (either one on one or in small groups) always necessary to address strongly held incorrect beliefs? What should we consider a "clinically important" improvement for a complex practice change strategy? Can reminder systems that are sometimes effective in correcting errors of omission change more resistant errors of commission? Even if single reminders are effective, is there a point of multiple reminder fatigue and diminishing clinical returns? Lastly, are advanced CDSS safe and effective, and, if so, are they worth the time, effort, and opportunity costs necessary to implement and use them? The most recent, rigorous research questions the efficacy, efficiency, and safety of health information technology mandated by the economic stimulus of 2008 [87].

Practice settings may also influence the choice of interventions to be evaluated. For example, organized systems of clinicians (e.g., medical groups, independent practice associations, integrated delivery systems) may be conducive to participatory approaches in which practicing physicians, and possibly patients, work with a facilitator/educator to explore current practices and barriers to change, and then develop or modify practice guidelines, along with methods to measure guideline adherence. These group meetings also serve as vehicles for active learning and begin to converge with the strategy of group detailing described earlier. In addition, we believe more attention needs to be paid to the study of changing the behavior of busy physicians in community practice. Many successful strategies may not be transferable from a university hospital to a busy ambulatory clinic.

Most of the studies we reviewed were designed to assess only whether an intervention changed behavior; few studies have undertaken formal cost–benefit analyses [22,93]. Several formal economic analyses of academic detailing trials demonstrated that the interventions led to a net saving from the societal or organizational perspective [83,93,139]. This is a clear illustration of what Eddy described as "getting more for less," the potential to improve quality and reduce costs simultaneously [140]. There are still relatively few controlled studies that compare the costs and benefits of alternative approaches to improving practice, and little has been published on when (or at what cost) it is reasonable to introduce an intervention to change physicians' practice [93].

Although we know that prescribing problems exist, we still know surprisingly little about their prevalence or determinants. This paucity of

data is all the more remarkable considering that three-quarters of all physician visits end in the prescription of a drug. In a study of more than 30 000 hospital admissions, drug-related complications were common and estimated to account for 19% of all adverse events, and almost one-third of adverse drug events were preventable [141]. Less is known about the ambulatory setting [142–144], with estimates of preventable adverse drug events ranging from 11% to 28%. One retrospective analysis of a New England malpractice insurance carrier observed that 6% of all malpractice claims were related to adverse drug events, and that half of these claims occurred for events in the outpatient setting [144]. These investigators also estimated that three-quarters of these adverse drug events were preventable, and that most medication errors occurred as a result of system deficiencies (e.g., inadequate monitoring) or performance errors (e.g., wrong drug or wrong dose). Like most descriptions of adverse drug events, these studies documented only errors of commission; the extent of omission (e.g., underuse of effective therapies) has been extremely understudied (see Chapter 24).

Finally, studies examining the economic outcomes of interventions as well as studies that include patient-reported outcomes would advance the field. While policy-induced reductions in the use of essential medications have been associated with adverse events [145], few analogous patient outcomes studies exist in the literature on interventions to improve prescribing. Important effects of medications on many health outcomes have been demonstrated in clinical trials; therefore, it is reasonable to hypothesize that more appropriate use of some medications could reduce morbidity and mortality, increase patient functioning, and improve quality of life. Whether improved prescribing is a surrogate measure, or an outcome that directly leads to improved health outcomes, it remains a critically important area for future study.

Vaccines are among the most cost-effective and prevalent primary public health interventions [1,2]. Where immunizations are widely practiced, rates of targeted vaccine-preventable disease (VPD) have declined considerably [3,4]. However, no vaccine is perfectly safe or effective [5]. With high rates of vaccinations and a low incidence of VPD, adverse events following immunizations (AEFI) are understandably of concern, and have received increasing attention [6–10]. Unfortunately, this concern has often negatively affected the stability of immunization programs [11]. For example, questions about the safety of pertussis vaccine in Japan and elsewhere during the 1970s reduced the coverage rate for this vaccine, resulting in the resurgence of pertussis [12]. Similar concerns in the US led to lawsuits, substantial vaccine price increases, and loss of vaccine manufacturers [13], and were a potential deterrent to the development of new vaccines [14]. In the 1990s, concerns about the safety of mercury-based thimerosal preservative used in vaccines [15,16] and the safety of vaccines for anthrax [17] and smallpox [18] affected the stability of US civilian and military immunization programs, respectively. In the UK, a case series report of autism following measles–mumps–rubella (MMR) vaccination in a small number of patients (n = 12; subsequently retracted) precipitated widespread vaccine safety concerns, leading to reduced MMR vaccination rates and subsequent measles outbreaks [19,20]. Similarly, vaccine safety concerns have affected public acceptance of hepatitis B vaccine in France [21], oral polio vaccine (OPV) in Nigeria [22,23], human papilloma virus (HPV) vaccine [24], and 2009 influenza A (H1N1) pandemic (pH1N1) vaccine in several countries [25,26].

More recently, parents have expressed concerns about the safety of the immunization schedule as a whole, worrying that children receive too many vaccines at a very young age and that the recommended immunization schedule overwhelms the immune system [27–29]. These sentiments cause parents to delay or refuse certain or all vaccines for their children, contributing to the adoption of

The findings and conclusions in this report are those of the authors and do not necessarily represent the official position of the Centers for Disease Control and Prevention.

Pharmacoepidemiology, Sixth Edition. Edited by Brian L. Strom, Stephen E. Kimmel and Sean Hennessy.

alternative immunization schedules in several high-income countries.

In the early 1990s, the US Institute of Medicine (IOM) – later renamed the National Academy of Medicine (NAM) – reviewed vaccine safety knowledge and research capacity [30,31] and noted it had been limited by (i) inadequate understanding of biologic mechanisms underlying AEFI; (ii) insufficient or inconsistent information from case reports and case series; (iii) inadequate size or length of follow-up of many population-based epidemiologic studies; (iv) limitations of existing surveillance systems in providing persuasive evidence of causation; and (v) few experimental studies published relative to the total number of epidemiologic studies published. IOM/NAM concluded that, "if research capacity and accomplishments [are] not improved, future reviews of vaccine safety [will be] similarly handicapped." Many research and knowledge gaps continue to be identified in each IOM/NAM review of specific immunization safety controversies since 2001, ranging from autism to unexpected infant deaths [17,32–40]. Pharmacoepidemiology has played a vital role since in providing the scientific methods for assessing vaccine safety in the US [41], Europe [42,43], and globally [10,44]. In this chapter, we discuss the major differences in how epidemiology is applied to vaccines versus other pharmaceutical products, giving consideration to both policy and methodology.

Clinical Problems to Be Addressed by Pharmacoepidemiologic Research

Policy Issues

Vaccines share many characteristics with other pharmaceuticals, such as their phased development and licensure, but differ fundamentally in other ways [41]. Understanding these differences is important to appreciate the policy context of vaccine safety and the role of pharmacoepidemiology. Vaccines, for example, are biologic products that are inherently more complex than most small-molecule drugs – both constituent components and the production process [45,46]. Each component of the vaccine formulation – the immunogen, conjugated protein [47], preservative [15], adjuvant [48,49], stabilizer [50,51], diluent [52], and other excipients – has its respective safety considerations (e.g., sourcing, production, quality assurance, safety profile), individually as well as combined [53]. Programmatic errors such as mixing up vaccine vials and unsafe injection practices can also be a concern, especially with poverty [52,54] and in the context of conflicts [55].

A higher standard of safety is also expected of vaccines. In contrast to other pharmaceuticals administered mostly to persons who are ill for curative or therapeutic purposes, vaccines are generally given to healthy people to prevent disease. Tolerance of adverse reactions to products given to healthy people – especially healthy babies – is especially low. This lower risk tolerance for vaccines translates into a need to detect and investigate the possible causes of much rarer events than would be acceptable for other pharmaceuticals. Events that occur at ~$1/10^5$–$1/10^6$ doses administered, such as acute encephalopathy after whole-cell pertussis vaccine [30], Guillain-Barré syndrome (GBS) after swine [56] or 2009 pH1N1 [57] influenza vaccines, and OPV-associated paralytic polio [58], are of concern for vaccines. In contrast, side effects are essentially universal for cancer chemotherapy, and gastrointestinal side effects are very common (10–30%) among people on high-dose aspirin therapy [59].

The cost and the difficulty of studying events increase with their rarity, however (see Chapter 3). Furthermore, conclusions from epidemiologic studies of rare events are less definitive. Attributable risks at about $1/10^5$–$1/10^6$ are considered to be at the margin of resolution for epidemiologic methods [30,60]. The whole-cell pertussis vaccine safety concern in the late 1970s

[12,30] illustrated this challenge. All British children from 2 to 35 months of age hospitalized for several neurologic illnesses over three years (n = 1167) were enrolled in a very large case–control study; however, the finding of a statistically significant association between vaccine and permanent brain damage was based on a small number of exposed cases with wide confidence intervals [61]. Whether or not this study finding was valid, it generated much controversy in and out of the courts [30,62]. Recent advances suggest rare *de novo* genetic mutation and not vaccine as the likely cause [63].

Despite considerably more robust data linking GBS with the 1976–1977 swine influenza vaccine [56], subsequent controversy resulted in a court-ordered independent reexamination of the data and ultimately to a partial repeat of the study, confirming the initial findings [64]. Robust results from two studies on rhesus-rotavirus vaccine and intussusception [65,66] were also challenged [67], until the risk was also shown with the second-generation vaccine, albeit one log rarer [68].

Perhaps not surprisingly, but adding to the confusion, much of the published literature on vaccine safety (and resultant media scares) historically has been in the form of case reports and case series (e.g., a subsequently retracted *Lancet* article alleging links between measles vaccination and autism [19]) rather than controlled studies with adequate power [30,31]. This problem is being ameliorated with the advent of carefully controlled large-linked database studies in several, mostly high-income countries [69,70].

A higher standard of safety is also required for vaccines because of the large number of people who are exposed, some of whom are compelled to be vaccinated by law or regulation for public health reasons [71]. Public health authorities have implemented such requirements because many VPDs (e.g., measles) are highly infectious. When a high proportion of the population is immunized, it creates "herd immunity," so that some of the remaining unimmunized people will still be protected [72]. Without such mandates, a "tragedy of the commons" may occur where high vaccine coverage is reached and the individual benefit/risk ratio diverges from the societal benefit/risk ratio [73,74]. Persons may try to avoid the risks of vaccination while being protected by the herd immunity resulting from others being vaccinated. However, this "commons" provided by herd immunity may disappear if too many people avoid vaccination, with the resulting tragedy that outbreaks return [75], as was experienced in the UK with both pertussis [12] and measles [20], and in the US with measles [76]. A similar policy consideration occurs for some mandatory military vaccinations like those against anthrax [17] and smallpox [18], where a higher vaccine reaction rate may be accepted in exchange for force readiness.

Because of the need for almost universal exposure to many vaccines, the medical maxim "first do no harm" applies even more in public health than in clinical medicine (where decisions usually affect fewer people). Inadequately inactivated polio vaccine (IPV) was administered to about 400 000 people in the "Cutter Incident," resulting in 260 cases of polio [77]. The following incidents and others [78] have fortuitously not resulted in any documented harm to date. Nevertheless, they highlight the importance of ensuring the safety of a relatively universal human-directed "exposure" like immunizations.

- Polio vaccine contaminated by simian virus 40 may have been received by millions of people during the 1950s [35].
- Some vaccines may have contained gelatin stabilizers produced in cattle infected with bovine spongiform encephalopathy [79].
- Some US infants might have been exposed to doses of ethylmercury from thimerosal preservatives in vaccines, exceeding some federal safety guidelines established for ingestion of methylmercury, another form of organic mercury [15].
- Two of the new rotavirus vaccines were contaminated by porcine circovirus [80].

These concerns are the basis for strict regulatory control and other oversight of vaccines by national regulatory authorities such as the US Food and Drug Administration (FDA), European Medicines Agency (EMA), and World Health Organization (WHO) [45,81,82]. Modern technology will continue to improve the ability to detect contaminants in vaccines and influence regulatory decisions during manufacturing [83]; postlicensure monitoring will continue to be important should such findings raise safety concerns.

Very high standards of accuracy and timeliness for results are needed because vaccine safety studies have extremely narrow margins for error. Unlike many classes of drugs for which other effective therapy may be substituted, vaccines generally have few alternative strains or types (OPV and IPV being the best-known exceptions). The decision to withdraw a vaccine [84] or switch between strains may also have wide ramifications [85]. In 1992, the UK authorities stopped procuring mumps vaccines with Urabe strain after studies suggested a high rate of vaccine-associated meningitis [86]. The manufacturers subsequently withdrew this product worldwide, leaving countries without an alternative vaccine if the Urabe strain was their sole licensed mumps vaccine [87]. Safety concerns led to the withdrawal in the early 2000s of what were then the only licensed vaccines against rotavirus [65,66] and Lyme disease [88], rendering these vaccines unavailable anywhere. Establishing associations of AEFI with vaccines and timely measurement of the attributable risk are critical in placing AEFI in the proper benefit/risk perspective. An erroneous association or attributable risk, especially with misinformed media or websites, can undermine confidence in a vaccine and have negative consequences for vaccine acceptance and disease incidence [20]. On the other hand, denials of association despite accumulating evidence can erode public confidence and compromise vaccination programs. For example, public dismay with delayed action on Urabe mumps vaccine-associated aseptic meningitis in Japan forced the Ministry of Health to rescind compulsory school MMR vaccination requirements in 1993 [89].

Because many vaccinations are mandated for public health reasons and no vaccine is perfectly safe, several countries have established compensation programs for people who may have been injured by vaccination. Accurate assessment of whether AEFI can be caused by specific vaccines is essential to a fair and efficient vaccine injury compensation program [90]. In the US, for example, the Vaccine Injury Table (VIT) contains the vaccines, adverse events, onset intervals, and other criteria after which no-fault decisions are made in favor of the claimants. Periodic revisions of the VIT are necessary to reflect the best scientific information on associations between vaccines and adverse events, especially following the introduction of new vaccines [91].

Finally, recommendations for the use of vaccines represent a dynamic balancing of risks and benefits. Vaccine safety monitoring is necessary to weigh this balance accurately. In the face of a meningococcal B epidemic in New Zealand, it was prudent to fast-track the licensure of a new vaccine with limited prelicensure safety data but assurances of good postmarketing surveillance [92]. Even though the second-generation rotavirus vaccine still increases the risk of intussusception, its lower attributable risk (1–6 excess cases/10^5 vaccinees) has been accepted relative to the major reduction in rotavirus disease [68]. When the target diseases are close to eradication, high vaccine complication rates relative to that of the target wild-type disease may lead to discontinuation or decreased use of the vaccine, as was done with smallpox vaccine [93]. Another example was the shift from live OPV to IPV to control OPV-associated paralytic polio and circulation of OPV-derived polio virus [94]. There may be a tradeoff between safety and cost, however. Some countries continue to use Urabe mumps vaccine despite its higher risk for

aseptic meningitis, after the manufacturer lowered the price [95].

With the fears of bioterrorism and importation of previously eliminated VPDs like measles and polio, stopping immunizations and allowing formation of gaps in herd immunity no longer seems advisable [96]. Almost all immunizations will likely be needed indefinitely, with their attendant adverse reactions and potential for loss of public confidence. Because of the success of immunizations in the near elimination of their target diseases, most healthcare providers (let alone parents) have not ever seen a case of some wild-type VPDs. Each future generation must therefore be convinced of the need to be immunized, despite an increasingly remote experience of wild-type disease but contemporary fear of AEFI.

Research on vaccine safety – while applying pharmacoepidemiologic principles – can help to distinguish true vaccine reactions from coincidental events, estimate their attributable risk [56,61,66,97–99], identify risk factors that may constitute valid contraindications [100,101], and, if the pathophysiologic mechanism becomes known, develop safer vaccines [102]. Equally importantly, such research demonstrates a commitment to reducing disease from all causes, vaccine preventable and vaccine induced, and may help to maintain public confidence in immunizations and the credibility of immunization programs.

Clinical Issues

Vaccines, like other pharmaceutical products, undergo extensive safety and efficacy evaluations in the laboratory, in animals, and in phased human clinical trials before licensure (see Chapter 1). Phase I trials usually include a small number of subjects, and can only detect extremely common AEFI. Phase II trials generally enroll hundreds of subjects. When they are carefully coordinated, important conclusions such as the relationship between concentration of antigen, number of vaccine components, formulation technique, effect of successive doses, and profile of common reactions can be drawn from such trials [103]. Such studies can also affect the choice of the candidate vaccine for Phase III [45].

Sample sizes for Phase III vaccine trials generally range between 5000 and 10 000 people, which is larger than most drug trials. *In extremis*, >600 000 schoolchildren were enrolled in the famous Francis field trial of inactivated Salk poliovirus vaccine [104]. To help rule out links with a rarer outcome like intussusceptions (background rate ~5 per 1000 infant years), the second-generation rotavirus vaccine trials enrolled ~70 000 infants [68]. Traditionally, however, sample sizes for Phase III vaccine trials have been based primarily on efficacy considerations; inferences on safety are drawn to the extent possible based on the sample size (~100–100 000) and the duration of observation (often less than 30 days) [45,105]. This usually means that observations of the common local and systemic reactions (e.g., injection site swelling, fever, fussiness) have been possible. Because of the experimental randomized, double-blind, placebo-controlled design of clinical trials, inferences on the causal relationship of an AEFI with the vaccine are relatively straightforward [30,31]. Brazilian investigators also used such a design to compare the risk of aseptic meningitis among three mumps vaccine strains [106]. However, study of rarer outcomes, vaccine exposures (e.g., specific permutation of vaccine antigens administered simultaneously), or subpopulations is usually only practical postlicensure.

Better standardization of safety evaluations in prelicensure clinical trials is needed so that safety data across trials and vaccines can be compared (see also "Classifications and Case Definitions"). In the Phase III trials for infant diphtheria, tetanus, acellular pertussis (DTaP) vaccine, a standard case definition was developed for efficacy, but ironically not for safety – the main reason for the development of DTaP.

For example, definitions of high fever across trials varied by the temperature (39.5 °C versus 40.5 °C), the mode of measurement (oral versus rectal), and time after vaccination measured (48 versus 72 hours) [107]. However, for rarer events, it may be difficult to have standardized assessments across cultures and health systems, as illustrated in the Swedish and Italian trials, in which major differences were detected in rates of hypotonic-hyporesponsive episodes after the same whole-cell pertussis vaccine [108].

The finding of delayed excess mortality in some recipients of high-titer measles vaccine in developing countries [109], now believed by some researchers to be due to a change in vaccine sequence [110] or nonspecific effects of vaccinations [111], led to a call for increasing the current limited duration of follow-up for AEFI in most trials [112,113]. This need was reinforced recently when, six years after the trial, recipients of a new dengue vaccine not previously infected by the virus developed more severe disease with subsequent dengue infection [114].

Many other new vaccines under development (e.g., malaria, tuberculosis) or recently licensed (e.g., rotavirus) are targeted for initial introduction in resource-limited settings. Both pre- and postlicensure safety studies will be needed, for longer follow-up periods in settings where the pharmacovigilance infrastructure is limited or nonexistent [115,116].

Ideally, pharmacogenomics (see Chapter 34) and biobanking can be integrated into prelicensure trials (continuing through to postlicensure) to begin improving our understanding of the biologic/genetic basis for why some persons underrespond and others overrespond to an immunization with respect to immunogenicity and reactogenicity, as we shift from "one size fits all" to more personalized vaccinology [117,118]. Historically, the strategy to deal with vaccine recipients with insufficient immune response was straightforward, consisting of a multidose schedule. Those with overly vigorous reactions on the other hand were more problematic, and potentially at risk of being unfairly labeled "anti-vaccine" if they questioned the safety of receipt of subsequent doses.

Despite over 200 years since Jenner pioneered the smallpox vaccine, the medical science of diagnosing, managing, preventing, or treating rare, serious vaccine reactions remain relatively rudimentary. The reasons are multifold and the challenges are as much logistic as scientific. Modern medicine cannot make progress on rare disorders like leukemia (or rare serious vaccine reactions) by relying on primary care providers alone. Instead, tertiary subspecialties with an adequate referral base and research funds (e.g., hematology/oncology) are needed. With the exception of certain regions in Italy [119], Australia [120], and seven civilian Clinical Immunization Safety Assessment (CISA) project sites [121] and four military Regional Vaccine Safety Hubs [122] in the US, a similar well-organized, well-identified subspecialty infrastructure has been missing for the study of rare vaccine reactions in most countries. Such centers can also potentially play a role for studying newly hypothesized AEFI syndromes [19,123]. The diversity of vaccine exposures (active/passive, live/inactivated, single/combined, etc.), combined with the range of adverse event outcomes (in essence the entire medical textbook, including some not yet defined), means that the new subspecialty will need to play a "case manager" role of drawing upon other subspecialty expertise as needed. However, most importantly, such CISA-type centers could potentially prevent outliers (for example, based on genetic susceptibility) in reactogenicity response from becoming anti-vaccine by recruiting them into mutually beneficial opportunities to improve our scientific understanding and prevent vaccine reactions [124,125] (e.g., a trial of a safer booster dose in children with extensive limb swelling after pertussis vaccination) [227].

Methodologic Problems to Be Addressed by Pharmacoepidemiologic Research

Signal Detection

Because biologics like vaccines are generally manufactured in living systems rather than via chemical synthesis like drugs, variation in rate of adverse reactions by manufacturer or even lot might be expected. Surveillance systems need to detect such potential anomalies in the expected number and type of AEFI in a timely manner. Some factors make identification of true safety signals difficult. Many vaccines are administered early in life, at a time when the baseline risk is constantly changing and may be affected by other infant events. Furthermore, by definition, if vaccination rates are high, most people with adverse medical events will have had a history of vaccination. Distinguishing causal from coincidental events on a case-by-case basis is rarely possible (see Chapter 33), particularly for events where the pathophysiologic mechanisms are not known, regardless of vaccination. Since many vaccinations are administered to individuals either simultaneously or as a combination vaccine, unless the number of people who also receive that exact permutation of vaccine exposures (including manufacturer and lot number) is known so that AEFI rates can be calculated, it may be difficult or impossible to know if an aberration has occurred. Similarly, when vaccine coverage rates are high and multiple vaccinations are administered concurrently, it can be difficult to disentangle the individual effects of each component, since simultaneous vaccination patterns are likely to be uniform across the population.

Unlike many public health surveillance systems, which focus on either a single exposure (e.g., lead) or a single disease outcome (e.g., measles), vaccine safety surveillance systems need to examine multiple exposures – for instance, different vaccine antigens (frequently administered in combination or simultaneously), manufacturers, and lot numbers – and multiple disease outcomes. Until the recent advent of data-mining methods (see Chapter 46), detection of a vaccine safety signal occurred as much due to a persistent patient [126] as due to data analysis [127]. The tradeoff between sensitivity and specificity depends critically on whether the goal of the surveillance is the detection of a previously unknown illness or syndrome (sensitivity > specificity) or tracking a known disease (specificity > sensitivity). Vaccine safety surveillance systems are asked to monitor *both* previously known and previously unknown AEFI in the same system, however [128]. Nevertheless, the goal of early detection of an aberrant cluster of new AEFI remains identical to other pharmacovigilance and public health surveillance systems.

Standard Definitions and Evaluative Protocols

Case definitions can be used at the time of reporting or at the time of analysis to improve specificity. Applying definitions at the time of reporting may reduce the number of reports processed and lower the operating cost [129]. The sensitivity of surveillance may be lower and the difficulty of assessing misclassification greater, however. Alternatively, if the reporting form is open-ended [130], this may increase the sensitivity of surveillance, but only at the cost of sorting through many nonspecific reports. Definitions can then be applied at the time of analysis. Nevertheless, substantial variation in diagnostic work-up and description of events makes *post hoc* classification difficult without additional follow-up information, which in turn is usually costly.

Historically, it was challenging if not impossible to compare and collate vaccine safety data across clinical trials or surveillance systems in a valid manner because of lack of standard case definitions. We can advance our scientific knowledge of immunization safety by using a

common vocabulary, particularly helpful in the prelicensure setting where maximizing the yield of safety data may help with limited sample sizes. The Brighton Collaboration (see "Solutions: Classifications and Case Definitions") is addressing this gap [107].

Assessment of Causality

Aside from events like local reaction or anaphylaxis, assessing whether any AEFI was actually caused by vaccine is generally not possible unless a vaccine-specific clinical syndrome (e.g., myopericarditis in healthy young adult recipients of smallpox vaccine [18]), or repeat exposures resulting in the same AEFI (e.g., alopecia and hepatitis B vaccination [126]), or a vaccine-specific laboratory finding (e.g., Urabe mumps vaccine virus isolation [131]) can be identified. Whenever the adverse event can also occur in the absence of vaccination (e.g., seizure), a very large clinical trial or more affordable epidemiologic study is necessary to assess whether vaccinated people are at higher risk than unvaccinated people. As noted earlier, when multiple vaccinations are administered simultaneously, determining whether events are attributable to particular components or one of several combinations is frequently difficult or impossible.

Exposure

Misclassification of exposure status may occur if there is poor documentation of vaccinations. Unlike children of school age where vaccination documentation is often required, ascertaining vaccination status in adults may be particularly difficult. In the US, recent and likely future increases in the number of licensed vaccines, the relative lack of combination vaccines, plus, historically, the high mobility among immunization providers (up to 25% annually) because of changes in health insurance plans have led to a potentially confusing maze of vaccination history misclassifications [132].

For example, even though only the acellular pertussis vaccine is available in the US, AEFI reports of the old whole-cell pertussis "DTP" vaccine continue to be received – presumably due to errors in recording by immunization nurses. An infant may have started their immunization series with one provider who uses DTaP combination vaccine from manufacturer A, but switched to another provider to complete the series with DTaP combination vaccine from manufacturer B. Add in the complexity of whether other vaccines like those against polio or hepatitis B are administered simultaneously, at different dose series in the schedule, at different ages, or using different lots of vaccine, and the number of permutations of vaccine exposures that need assessment for potential safety concerns quickly escalates. The availability of complete documentation of vaccine exposure on a large cohort of children in the Vaccine Safety Datalink (VSD) project allowed evaluation of the safety of thimerosal preservatives and the immunization schedule via multiple studies [133].

Outcome

Because of the higher standard required for vaccine safety (as discussed previously), events being assessed are frequently rare (e.g., encephalopathy, GBS) and identifying enough cases for a meaningful interpretation of study findings can be a major challenge. Even when technically feasible, a study may be logistically infeasible or the findings likely to be too inconclusive to justify the resources. This was the conclusion of a 1989 IOM/NAM committee that evaluated whether the UK's National Childhood Encephalopathy Study should be replicated in the US [62].

The difficulty in achieving adequate study power is further compounded in assessing rare events in populations less frequently exposed (e.g., early use soon after introduction on the market, vaccines given to travelers, or subpop-

ulations with special indications). This challenge is well illustrated in studies of the potential association between GBS, which occurs at a background rate of about 1 per 100 000 person-years, and various vaccines. Study of GBS after newly introduced meningococcal conjugate vaccine required assembling data from 9 million adolescents [134]. A retrospective study of GBS after the 1992–1994 influenza vaccinations required assessing hospital records of over 20 million people for 2 years [135]. Active GBS case finding among a population of 45 million may have detected an attributable risk of one additional case of GBS per million 2009 pH1N1 vaccinations [57]. Whenever both the rarity of the adverse outcome and the number of exposures limit the ability to assess a small potential increased risk, identifying risk factors of such rare associations imposes an additional (and possibly prohibitive) level of sample size requirements – unless multinational collaborations are organized.

Many AEFI hypothesized to be caused by vaccines have poorly defined etiologies (e.g., encephalopathy [61], GBS [56], chronic fatigue syndrome [136], narcolepsy [137], sudden unexplained infant deaths [138]). Attributing the outcome to vaccination can only be done after all other potential etiologies have been ruled out, and even then causality cannot be certain. Our scientific understanding of some diseases is frequently limited in the absence of vaccination, let alone with vaccination. This poor understanding severely limits clinical and epidemiologic studies of these illnesses. Furthermore, in highly vaccinated populations, risk-interval analyses (where a specific risk/exposure period is assigned) may be the only epidemiologic study design possible (see "Study Designs, Analyses, Confounding, and Bias"). Predicting the onset of illness following an environmental exposure is critical in calculating the biologically plausible risk interval. For certain hypothesized AEFI, there is no known biologic mechanism to allow prediction of the risk interval. Diseases with insidious or delayed onset like autism [19], inflammatory bowel disease [139], and multiple sclerosis [36] do not permit prediction of the risk interval and are therefore also difficult to study.

Study Designs, Analyses, Confounding, and Bias

Analyzing observational studies of vaccine safety poses several methodologic challenges. Traditional epidemiologic study designs, such as the cohort and case–control designs, are limited because a large percentage of the population tends to be vaccinated. This implies that few unvaccinated individuals are available for analysis, and the unvaccinated tend to differ from the vaccinated by several potential confounding variables, including ethnicity, socioeconomic status, use of the healthcare system, and underlying health disorders [140,141].

Another challenge is that serious AEFI are rare. Cohort studies typically require hundreds of thousands or even millions of study subjects to be able to detect an association between vaccination and the suspected adverse event [56,61,64–66,131]. Such studies can be prohibitively expensive, unless all the requisite information is automated and linkable.

A possible alternative to the cohort design is the case–control study design, in which cases are sampled from the source population and compared to a group of randomly selected event-free controls. This design is well suited for rare events, and has been used for several studies of vaccine safety [65,98,142–144]. It is, however, particularly difficult to choose an appropriate control group without introducing selection bias if the study is not population based. Moreover, because childhood vaccines are generally administered on an age schedule and many childhood illnesses that may be potential AEFI are age dependent, age may confound exposure–outcome relations, for example DTP vaccine and febrile seizures or sudden infant death syndrome (SIDS) [145].

Consequently, such factors must be controlled, generally by matching and subsequent adjustment in the statistical analysis.

To help address these limitations, self-controlled study designs have been developed and implemented [146,147]. These designs involve cohorts of vaccinated individuals (risk interval) or analyses where vaccinated cases are compared to themselves (self-controlled case series). Such designs have been shown to be efficient and valid alternatives to the traditional epidemiologic study designs [148–150]. For details on these methods, see "Methodologic Approaches."

More difficult to control are factors leading to delayed vaccination or nonvaccination [140,141]. Such factors (e.g., low socioeconomic status, preceding illness, parental choice) may confound studies of AEFI and lead to underestimates of the true relative risks. The extent of distortion introduced by confounding can be examined as a function of six variables (Table 20.1). Relatively little is known about the nature, frequency, and implications of these variables, however [140].

Table 20.1 Variables determining the extent of bias attributable to confounding in studies of vaccine adverse events (AE).

Variable	Description
S	Risk of AE in unvaccinated children who lack the contraindication*
R	True relative risk of AE associated with vaccination
D	Relative risk of AE associated with the contraindication
C	Proportion of children with the contraindication
V	Proportion vaccinated among children without the contraindication
P	Proportion vaccinated among children with the contraindication

*"Contraindication" used here to mean any factor associated with avoidance or delay of vaccination.

Currently Available Solutions

Prelicensure

Standardized toxicity grading scales, initially developed to evaluate products treating cancer and AIDS, have been developed for preventive vaccine trials [151]. Their use allows for meaningful interpretation of prelicensure safety data, including rules for stopping the trial, especially when combined with standardized case definitions for adverse outcomes [107,152].

Whenever potentially important safety signals are detected in prelicensure trials (e.g., intussusceptions after rotavirus vaccine [153]), it is critical that they are pursued postlicensure [154]. Given the need for improved understanding of the safety of vaccines administered universally to healthy babies and the methodologic difficulties of assessing safety postlicensure, some researchers have argued that larger experimental trials may be needed to better assess rare but serious vaccine risks [105,155]. This could be done either with larger prelicensure trials, as has been done with antipyretics in children [155–157] and the post-rhesus rotavirus vaccine trials [68], or in some organized stepwise manner postlicensure (e.g., registry of the first million vaccinations), prior to universal recommendation of the vaccine for entire birth cohorts [156]. Even with these measures, separate large-scale, long-term randomized intervention trials would theoretically be the only way to study unforeseen delayed adverse effects [105,158] or nonspecific effects of immunizations [111]. Such trials would have to avoid withholding efficacious vaccines from people in need. Therefore, maximizing both the pre- and postlicensure assessment processes, as discussed in this chapter, remains optimal.

Data and Safety Monitoring Boards (DSMBs) represent an area of potential improvements in the prelicensure process. Currently, such DSMBs are constituted uniquely for each clinical trial. If instead there is greater overlap across prelicensure trials for the same vaccine, the DSMB may have a better ability to oversee the safety data for the experimental vaccine. The Council of International Medical Organizations (CIOMS) has also proposed an internationally harmonized Development Safety Update Report (DSUR) for summarizing the safety experience for a clinical trial (or entire development program). When aligned with the postapproval Periodic Safety Update Report (PSUR) for marketed products, these could be integrated into a single harmonized safety report that would cover a product throughout its life cycle [159].

Furthermore, despite its name, there is currently no requirement for the DSMB to include someone with drug/vaccine safety experience. For vaccine trials, someone with rare disease (versus infectious disease) epidemiology skills, usually fine-tuned from postlicensure safety monitoring experience, should be considered for the DSMB.

Another area of potential improvement is the method used to determine the likelihood of a causal relationship of an AEFI with the experimental exposure (e.g., a new vaccine; see Chapter 33). Traditionally, the principal investigator of a clinical trial makes an assessment of the causal relationship; this procedure is difficult to standardize and is prone to bias [160]. In an era of increasing automation of medical records and sophistication of methods for detecting nonrandom clusters or elevated rates, similar approaches to assessing prelicensure safety data are required. Finally, there is a need to improve clinical trial infrastructure in resource-limited settings for assessing the safety and efficacy of various preventive and therapeutic products for poverty-related diseases [115,161,162].

With the biotechnology revolution, new candidate viral vector vaccines targeting challenging VPDs like Ebola and HIV are entering human clinical trials. The Brighton Collaboration Viral Vector Vaccines Safety Working Group (V3SWG) was formed to improve the ability to anticipate potential safety issues and meaningfully assess or interpret safety data, thereby facilitating greater public acceptance of a vaccine when licensed [163]. The V3SWG has a standardized template describing the key characteristics of a novel vaccine vector to facilitate the scientific discourse among key stakeholders and increase the transparency and comparability of its risk/benefit information [164]. The V3SWG is also developing standardized guidance on critical issues such as potential risk of recombination between vaccine vector and wild-type virus strains [165].

Postlicensure

Passive Surveillance or Spontaneous Reporting Systems

Informal or formal passive surveillance or spontaneous reporting systems (SRS) have been the cornerstone of most national vaccine safety monitoring systems because of their simplicity and relatively low cost [41,166]. As these terms imply, AEFI reports are generally voluntarily submitted to public health or regulatory agencies, and in some cases to vaccine manufacturers who in turn report, and the agencies passively receive these reports, rather than actively collecting information on AEFI. The national reporting of AEFI can be done through the same reporting channels as those used for other adverse drug reactions [166], as is the practice in many European countries [167] and Japan [168]. Historically, however, few countries have forwarded their AEFI reports to the Uppsala Monitoring Center [169] (see also Chapter 10). An increasing number of countries are collecting safety data specific to vaccinations, either with reporting forms and/or surveillance systems different from the drug safety monitoring systems. These countries include Australia [170],

Brazil [171], Canada [172], China [173], Cuba [174], Denmark [175], India [176], Italy [177], Germany [178], the Netherlands [179], New Zealand [180], Switzerland [181], and the US [182]. Vaccine manufacturers also maintain SRS for their products [183], which are usually forwarded subsequently to appropriate national regulatory authorities [45].

Because of their importance in infectious disease control, a significant proportion of vaccines in many countries is purchased or administered by national public health authorities. For example, in the US the public sector (federal, state, and local governments) purchases over half of the childhood vaccines administered. In many developing countries, the Ministry of Health in conjunction with the WHO's Expanded Program for Immunizations (EPI) administers almost all vaccines. Potential AEFI commonly are first reported by the healthcare providers who administered the vaccine. In many countries, such healthcare providers also participate in public health surveillance for other diseases. Public health authorities (e.g., the US Centers for Disease Control and Prevention, CDC) therefore commonly lead or collaborate with the vaccine licensure and regulatory agency (e.g., the FDA) in developing and administering AEFI reporting systems. A similar model for harmonization and avoiding duplication is followed in Canada and six European countries [167], and is highly recommended for other countries [184].

The US Experience

The US National Childhood Vaccine Injury Act of 1986 mandated for the first time that healthcare providers report certain AEFI [71,185]. The Vaccine Adverse Event Reporting System (VAERS) was implemented jointly by the CDC and FDA in 1990 to provide a unified national system for collection of reports of AEFI, including but not limited to those mandated for reporting [130,182]. To increase sensitivity, the VAERS form is designed to permit narrative descriptions of AEFI. All people, including patients or their parents and not just healthcare professionals, are permitted to report to VAERS, especially on medically important events. Vaccine manufacturers are required to report any AEFI that comes to their attention.

In 2016, 22% of US VAERS reports were submitted by patients, parents, or other unidentified sources, 27% by healthcare providers, and 51% by vaccine manufacturers; in recent years leading up to and including 2016, VAERS received around 40 000 US reports annually (CDC, unpublished data). There are no restrictions set on interval between vaccination and onset of illness or requirements that a patient must have received medical care in order for the event to be reported. Reports are accepted without judgment on whether the vaccine caused the AEFI. Although reporting is encouraged as soon as possible after the AEFI, there is no time limit for reporting.

Web-based reporting became available in 2002; experience to date shows it to be more complete and timely [186] and it was therefore heavily used during the 2003 US smallpox [187] and 2009 pH1N1 vaccination campaigns [188]. In 2017, the CDC and FDA implemented a revised VAERS reporting form and reporting process, called VAERS 2.0, which, along with the FDA eVAERS initiative using the FDA Electronic Submissions Gateway, allows for fully electronic reporting for the public and healthcare providers, and vaccine manufacturers [189]. Future potential developments include (i) enriched passive surveillance in VAERS using clinical decision support systems in electronic health record (EHR) systems to facilitate physicians' identification of possible AEFI, automatically populate data elements of an AEFI report, and enable direct electronic reporting, resulting in more accurate, complete, efficient, and timely transmission of VAERS reports [190]; and (ii) incorporating immunization information system (IIS) data to estimate denominators for AEFI reporting rates in VAERS [191]. The latter is

especially important to overcome the problem of interpreting VAERS data in the face of the increasing heterogeneity of vaccine exposures in the US.

Enhancements to VAERS passive surveillance since its inception have included capability for near real-time report review by CDC and FDA physicians and scientists, collaborations with professional medical associations, development of a user-friendly public use data query tool, multiple options for web-based reporting for consumers and healthcare providers, and direct electronic reporting for vaccine manufacturers. There is also more frequent review and dissemination of safety data via publications and reports to advisory committees. "Enhanced passive" surveillance via VAERS has been successfully used to date in safety surveillance for rotavirus [192], yellow fever [193], smallpox vaccine [187], 2009 pH1N1 vaccine [188], tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis (Tdap) vaccine and inactivated influenza vaccine in pregnant women [194,195], and would likely be implemented in any future new vaccine or counter-bioterrorism-related wide-scale vaccination program [196].

Approximately 7% of US VAERS reports are classified as serious (documenting death, life-threatening illness, permanent disability, hospitalization, or prolongation of hospitalization), although the percentages of serious/nonserious reports vary by age group and type of vaccine. A contractor, under CDC and FDA supervision, collects, codes (using the Medical Dictionary for Regulatory Activities or MedDRA; https://www.meddra.org), and enters VAERS data and reports into a database. Trained nurses follow up on AEFI classified as serious to obtain additional medical information and recovery status. The CDC and FDA have access to the VAERS database, the original VAERS reports, and medical records obtained on follow-up, and focus their efforts on analytic tasks of interest to the respective agencies. VAERS data with personal identifiers removed are available to the public as downloadable datasets and through a user-friendly data query tool at https://vaers.hhs.gov/data.html.

Other High-Income Nations' Experiences

Several other countries also have substantial experience with passive surveillance for vaccine safety, including Canada [197] and the Netherlands [198]. The UK and many members of the Commonwealth (e.g., Australia [170]) use the "yellow card" system, where a reporting form is attached to officially issued prescription pads [199]. Korea employs a multipronged approach that includes spontaneous surveillance, rapid response and AEFI investigation, and compensation when appropriate [200]. Data on adverse drug (including vaccine) events from many nations are compiled by the WHO Collaborating Center for International Drug Monitoring in Uppsala (www.who-umc.org), which has also begun a vaccine focus [201].

Various approaches (short of database linkage) have been taken to supplement passive systems to help overcome their methodologic weaknesses. Canada (the Immunization Monitoring Program – Active or IMPACT, operational since 1990 [197], with a new variant for influenza [202]), Australia (the Paediatric Active Enhanced Disease Surveillance or PAEDS system [203], and Singapore [204] have active, pediatric hospital-based surveillance systems that searches all admissions for possible relationships to immunizations. In Canada, an Advisory Committee on Causality Assessment, consisting of a panel of experts, previously reviewed the serious passive reports [205].

Low- and Middle-Income Countries' (LMIC) Experience

As recently as 2012, 65% of WHO member states, including the majority of LMIC, did not have a functional postmarketing monitoring system [206,207]. In response, a comprehensive global manual on surveillance of AEFI was developed by WHO [208] as part of the Global

Vaccine Safety Initiative [209]. The manual provides guidance on (i) the objectives of vaccine and immunization safety surveillance; (ii) the AEFI surveillance system: reporting, investigation, causality assessment and classification of cause-specific AEFI; (iii) understanding vaccine reactions for better decision-making; (iv) the best use of surveillance data; and (v) response processes, including a communication strategy on immunization safety for the public and the media. The introduction of single-use autodisable syringes, "bundled" with vaccine procurement by donors, has significantly reduced the number of correctable programmatic errors like injection site abscesses (due to inadequate sterilization) [210].

As more new vaccines are (or are planned to be) first introduced in LMICs, there is increasing awareness of the need to improve currently inadequate pharmacovigilance systems in these countries [115,211]. The decades-long delay in discovering serious AEFI after yellow fever vaccination [212] and BCG vaccination in human immunodeficiency virus-infected infants [213] further highlights this urgent need. The WHO launched the Global Vaccine Safety Initiative in 2012, addressing many of the needs identified in the Global Vaccine Safety Blueprint [209]. While some progress has been attained despite limited funding, much capacity-building remains [207,211]. For example, some of the challenges with causality assessment of AEFI identified by countries in South East Asia included poor quality of data (e.g., lack of autopsies for deaths), high staff turnover rates, and deficits in AEFI investigation training and timely investigation (due to inadequate financial support for AEFI committees and investigation teams [214].

Classifications and Case Definitions

AEFI can be classified by frequency (common, rare), extent (local, systemic), severity (hospitalization, disability, death), causality (probable, possible, unlikely, etc.), and preventability (intrinsic to vaccine, faulty production, faulty administration). Wilson developed the first classification system with a focus on errors of production (e.g., bacterial, viral, toxin contamination) and administration (e.g., nonsterile apparatus) [5]. In 2012, CIOMS/WHO updated its classification of AEFI (Table 20.2) [215].

The distinction between *vaccine induced* and *vaccine precipitation*, as first clarified for DTP and DT vaccine and infantile spasm [216], has

Table 20.2 Types of adverse event following immunization (AEFI) by cause.

Cause	Definition
Vaccine product-related reaction	An AEFI that is caused or precipitated by a vaccine due to one or more of the inherent properties of the vaccine product
Vaccine quality defect-related reaction	An AEFI that is caused or precipitated by a vaccine that is due to one or more quality defects[1] of the vaccine product including its administration device as provided by the manufacturer
Immunization error-related reaction	An AEFI that is caused by inappropriate[2] vaccine handling, prescribing or administration and thus by its nature is preventable
Immunization anxiety-related reaction	An AEFI arising from anxiety about the immunization
Coincidental event	An AEFI that is caused by something other than the vaccine product, immunization error or immunization anxiety

Notes: [1] Any deviation of the vaccine product as manufactured from its set quality specifications; [2] Usage (handling, prescribing, and administration) other than what is licensed and recommended in a given jurisdiction based on scientific evidence or expert recommendations.

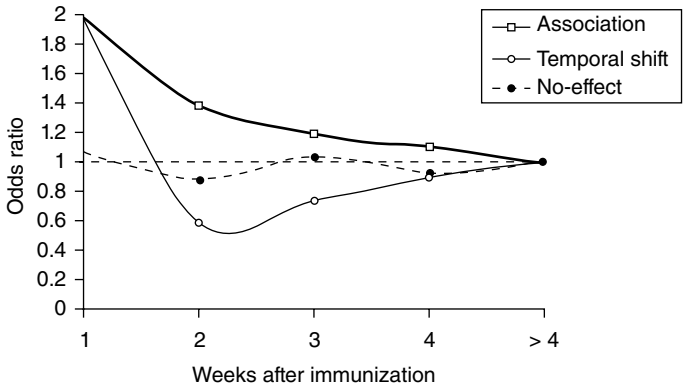

Figure 20.1 Three theoretical models of the temporal relationship between immunization and an adverse effect: (i) Association: the risk exceeds 1 at all time windows postimmunization; (ii) temporal shift: the risk exceeds 1 initially but then falls below 1, but coming back to 1 eventually, such that the area under the curve above and below 1 is similar; and (iii) no effect: the risk stays around 1. *Source:* Goodman M, Lamm SH, Bellman MH. Temporal relationship modeling: DTP or DT immunizations and infantile spasms. Vaccine 1998; **16**: 225–31. Reproduced with permission of Elsevier.

been useful because vaccine precipitation does not result in excess vaccine-attributable risk over time, whereas vaccine induced does (Figure 20.1).

The Brighton Collaboration was established in 2000 as an international voluntary effort to enhance vaccine safety science; it focused initially on the development, evaluation, and dissemination of standardized case definitions of AEFI [107]. Global workgroups of experts are convened to develop case definitions that are then peer reviewed. The Brighton case definitions for each AEFI are arrayed by the level of evidence presented (insufficient, low, intermediate, and highest); therefore, they can also be used in settings with a range of resources (e.g., from prelicensure trials to postlicensure surveillance, or from LMIC to high-income country settings). Over 50 Brighton case definitions are now available for use at www.brightoncollaboration.org, including many related to safety assessment of immunization in pregnancy [217].

Adding the Brighton case definition into the Canadian national reporting form in 2009 increased the proportion of seizure cases meeting the case definition three- to sixfold [172]. Alternatively, in a more open reporting system like VAERS, these definitions can be applied to reports to develop a case series for further investigation [218,219]. Real progress in implementation of similar standards across national boundaries is being realized with the advent of the International Conference on Harmonization (ICH) [220] and the Brighton Collaboration [107]. For example, the wide use of Brighton case definition for studies of GBS after the 2009 pH1N1 pandemic influenza vaccine facilitated meta-analyses and cross comparisons [57].

Standardized Clinical Assessment Protocols and Centers

There has been an increasing awareness that the utility of SRS and vaccine injury programs [221] as potential registries of rare AEFI and the immunization safety infrastructure can be usefully augmented by tertiary clinical centers with expertise in vaccinology and vaccine safety. The US initiated its Department of Defense Vaccine Healthcare Centers Network [124] and the CDC's civilian Clinical Immunization Safety Assessment (CISA) Project [121] to take advantage of this opportunity. These programs bring

together infectious disease epidemiologists, immunologists, neurologists, dermatologists, and other subspecialists from multiple participating sites as needed for various tasks [32]. Among these tasks is the standardized assessment of complex clinical cases of AEFI in individual patients to improve our scientific understanding of the pathophysiology and risk factors of the reaction, and to provide guidance on future vaccination for patients who have experienced AEFI [121,205,222–225]. New understanding of the human genome, pharmacogenomics, and immunology may now make it possible for us to better understand rare or newly recognized reactions for several vaccines (see also Chapter 34) [63,117].

Through these centers, standardized assessment protocols can be developed to examine patients with similar AEFI to see if they constitute a rare or a previously unrecognized clinical syndrome. If so, a case definition can be developed that permits identification of cases for follow-up validation studies examining the potential role of vaccination in causing this syndrome [226].

For patients who have had AEFI that generate concern but do not contraindicate completion of a vaccine series or further vaccination, such as hypotonic-hyporesponsive episodes [222], extensive limb swelling after acellular pertussis vaccination [227], and sterile abscesses following aluminum adjuvant-containing vaccines [228], the standardized clinical assessment centers, such as CISA, can provide assessment and guidance for the management of subsequent vaccinations.

Finally, standardized clinical assessment centers can provide regional referral and advice services – with the opportunity to follow up and document compliance with the advice provided and the outcomes, so that the rare experience can be added to our scientific knowledge. Ultimately, many AEFI diagnostic or management protocols can be made available on the internet for other clinicians to use (and to provide a mechanism for them to contribute their experience) [229]. Both the development and application of standardized case definitions and standardized evaluation of clinical syndromes play a "hypothesis-strengthening" role, intermediate between hypothesis generation and hypothesis testing.

Assessment of Causality

The formal process of assessing causality in the association of an adverse event and an exposure (e.g., vaccine) is complex and can be considered in terms of the answers to three questions: Can It? Did It? and Will It? [230]. The answer to *Can It?* (i.e., the potential for a causal link) was the focus of the IOM/NAM reviews [30,39,231]. It is usually based on population-level inferences drawn from epidemiologic studies and the following considerations: (i) strength of association, (ii) analytic bias, (iii) biologic gradient/dose–response, (iv) statistical significance, (v) consistency, and (vi) biologic plausibility/coherence [232].

For individual case reports, the *Did It?* question is more relevant. If the answer is yes, then *Can It?* is also answered in the affirmative. It is natural to suspect a vaccine to be the cause when an AEFI occurs in temporal association following vaccination. To base causal inference purely on temporal association, however, is to fall for the logical fallacy of *post hoc ergo propter hoc* ("after this, therefore because of this") [31]. Information useful for assessing causality in individual case reports includes (i) previous general experience with the vaccine (e.g., duration of licensure, number of vaccinees, whether similar events have been observed among other vaccinees or nonvaccinees, existence of animal models to test the vaccine as a cause); (ii) alternative etiologies; (iii) biologic plausibility; (iv) individual characteristics of the vaccinee that may increase the risk of the AEFI; (v) timing of events; (vi) characteristics of the event (e.g., laboratory findings); and (vii) rechallenge [233,234] (see also Chapter 33).

When a vaccine *can* cause an AEFI, *Will It?* refers to the probability that an individual will experience the event, or, for populations, the proportion that will experience the event as a result of vaccination (i.e., the attributable risk fraction). These data are critical for developing valid precautions and contraindications for the individuals and benefit/risk policy decisions for the population. *Will It?* is usually very difficult to answer, however, as it can only be addressed based on epidemiologic studies [31]. Furthermore, the sample sizes of such studies may be large enough to establish whether the vaccine can cause a given event, but yet inadequate to stratify by subgroups to examine risk factors that can help delineate potential contraindications [138].

Specific AEFI may be considered to be caused by a specific vaccine if the event is associated with a unique laboratory finding, and/or a very specific clinical outcome. For example, Urabe mumps vaccine virus was implicated as a cause of aseptic meningitis because mumps virus was isolated from the cerebrospinal fluid (a normally sterile body site) and was shown to be a vaccine and not wild-type strain by genetic sequencing [131]; or vice versa for wild-type varicella-induced paralysis, which was initially blamed on the vaccine [123]. The detection of IgG antibodies to the stabilizers in vaccine in children with hypersensitivity reactions confirms the etiology [51]. Demonstrations that severe local swelling following tetanus toxoid tended to occur in people with extremely high levels of circulating antitoxin (due to excessive tetanus boosters) support the proposed mechanism of an Arthus reaction [235]. Acute flaccid paralysis, especially shortly after receipt (or contact with a recipient) of OPV, is almost pathognomonic of OPV-associated paralytic polio in countries where wild-type poliovirus is unlikely to be circulating [58]. Similarly, acute myopericarditis in otherwise healthy recent smallpox vaccinees also supports a causal relationship [18]. Causality can sometimes be inferred if a specific and uncommon clinical finding occurs after each vaccination (i.e., challenge–rechallenge), as in cases of alopecia after hepatitis B vaccination [126]. However, unlike in drug safety, dechallenge (disappearance of the adverse event by stopping the medication) is usually not feasible with immunizations.

If the adverse event is known to be associated with the wild-type VPD (e.g., acute arthritis and idiopathic thrombocytopenic purpura [ITP] after rubella), its association with the live, attenuated vaccine at a lesser frequency is not surprising [236]. This relationship is not universal, however, as pregnant women who receive live attenuated rubella vaccine, unlike those exposed to wild-type rubella, have not been shown to have illness compatible with congenital rubella syndrome [237]. Clustering of events in time after vaccination can also suggest causation if "reporting bias" can be ruled out. Such bias may occur since parents and doctors are most likely to link AEFI with vaccinations the shorter the time interval between the two and the more serious the event. Febrile seizures associated with killed bacterial vaccines tend to occur within a day of vaccination, while those due to live viral vaccines are delayed by about a week due to viral replication [97,238]. Onset of GBS after the swine influenza vaccination was delayed by up to six weeks, but clustered at two to three weeks following vaccination, as autoimmune demyelination is a slower process [56]. The pattern of the risk by time since vaccination may suggest that the relationship to vaccination is more one of temporal shift or triggering of an underlying susceptibility (Figure 20.1) [138,216].

Unfortunately, most serious reported AEFI lack these unique features that permit informed inferences on causality. Autism, chronic fatigue syndrome, SIDS, and GBS either have multiple or as yet unknown etiologies. In a highly vaccinated population, it is not surprising that most cases of any adverse event have a history of prior vaccinations. Epidemiologic studies have to be relied upon to ascertain likelihood of association and, if related, the attributable fraction.

Because of these challenges, some vaccine injury compensation programs may simplify their administrative proceedings by making a blanket assumption that all AEFI occurring within particular periods after vaccination are "caused" by the vaccine, irrespective of whether they were truly causal or just coincidental. This, unfortunately, may lead some individuals to imply inaccurately that all such compensated cases are *caused* by vaccinations. Despite these caveats, the timing of the onset interval after vaccination plays a major role in most causality assessment algorithms, as AEFI after live viral vaccines usually occur later than those of killed vaccines [97,238].

In some countries, expert committees of specialists in relevant disciplines (e.g., pediatrics, infectious disease, neurology) review reports. This "global introspection" approach [230] has been used by some countries [200,239] to classify reports of AEFI in gradations of probable association to vaccination (see also Chapter 33).

The CISA Project developed a standardized algorithm to assist in collecting and interpreting data, and to help assess causality after individual AEFI, building on Canadian lessons [239] and review of 2009 pH1N1 AEFI [240]. The classifications were based on the reported symptoms, the interval between vaccination and onset of symptoms, and a set of case definitions. Final classification generated by the process includes four categories in which the event is either (i) consistent; (ii) inconsistent; or (iii) indeterminate with respect to causal association. This algorithm (with a fourth unclassifiable category) has since been adapted by the WHO [241], with refinements proposed [242].

Because the opinions of experts play such a major role in this form of causality assessment, the results are less satisfying than results obtained from rigorously conducted scientific studies. After a review of available approaches, the European Vaccine Adverse Event, Surveillance & Communication (VAESCO) project concluded: "the usefulness of individual causality assessment of AEFI remains to be demonstrated. Well documented cases and proper case definitions may be more important than causality assessment especially for signal detection and evaluation" [233].

Signal Detection

Identifying a potential new vaccine safety problem ("signal") requires a mix of clinical intuition, epidemiologic expertise, the application of statistical data-mining tools, and, frequently, a large increase in vaccine exposure. Unusual clinical features and/or AEFI clustering in time or space may suggest that something may be awry. Traditionally, a signal occurs when an observed number of events exceeds the number of events expected by chance alone for the specific data source (i.e., the background rate). For example, no illness other than GBS was reported more commonly in the second and third weeks than in the first week after swine influenza vaccination, leading to further validation studies [56]. In general, an acceptable type I error rate is set at 5%, with 80% statistical power to detect a signal. Once a signal has been detected, additional methods such as a temporal scan statistic can be used to detect nonrandom clustering of onset intervals

Several recent examples in the US and elsewhere highlight the importance of rapidly identifying and responding to serious AEFI identified following new vaccines or newly reintroduced vaccines. After a prelicensure signal [243], passive reports to VAERS of intussusception among children vaccinated with rhesus rotavirus vaccine were the first postlicensure signal of a problem [192], leading to several studies to verify these findings [65,66]. Similarly, initial reports to VAERS of a previously unrecognized serious yellow fever vaccine–associated viscerotropic disease [101] and neurotropic disease [193] have since been confirmed elsewhere [244] and as early as 1973, in retrospect [245]. Acute myopericarditis has been a relatively unexpected finding among people vaccinated against smallpox in the US for bioterrorism preparedness [18].

Less clinically serious, but important vaccine safety signals nonetheless, have also been detected. Oculorespiratory syndrome was found in association with influenza vaccines from one Canadian manufacturer in one season [246]. Bell's palsy was detected in recipients of a new Swiss intranasal influenza vaccine [98]). While several GBS cases were reported to VAERS after the introduction of tetravalent meningococcal conjugate vaccine in adolescents in the US, subsequent large controlled studies found no association [247]. Febrile seizures in young children were observed more than expected in passive reporting in Australia and the US following administration of two formulations of trivalent inactivated influenza vaccine (TIV) [248]; after evaluation in the VSD project, this signal was verified, with simultaneous administration of another vaccine contributing to the increased risk [249].

Historically, automated screening for signals using SRS reports had been challenging [250], largely because of the inherent methodologic problems of spontaneous reports (see earlier discussion and Chapter 10). For example, automated signal generation will not flag events that are not uniquely coded (e.g., the coding system may lack a specific term for Sjögren's disease or other rare conditions). However, new tools developed for pattern recognition in extremely large databases have increasingly been applied. VAERS is one of the largest databases for rare AEFI in the world, with hundreds of thousands of reports. Because of its continuously increasing size and the need to monitor a large number of vaccine–symptom combinations, there has been a substantial effort to apply various computer-assisted techniques for automated detection of unusual trends and patterns.

Several different data-mining methods (see Chapter 27) that have been evaluated in VAERS to date include empirical Bayesian [251–253], association rule discovery [254], multi-item gamma Poisson shrinkage [255], proportional morbidity distribution [256], and proportional reporting rate ratio [257,258]. No single method appears to be superior [259]. Rational approaches to prioritizing the large numbers of potential signals generated using automated algorithms on large passive AEFI report databases may involve the utilization of complementary approaches, such as data visualization and an array of different data-mining methods (each with pros and cons), where a cumulative higher score might signal cause for greater concern. Ultimately, these methods represent a useful adjunct to, but not a substitute for, traditional methods of scrutinizing spontaneous reports in increasingly complex databases such as VAERS [257].

A near real-time sequential analytic approach, called rapid cycle analysis (RCA), has been developed by the CDC VSD project (see "Automated Large-Linked Databases") to conduct active surveillance of newly licensed and recommended vaccines, existing vaccines with new recommendations or indications, and seasonal influenza vaccine annually [260,261]. RCA takes advantage of the strengths of the VSD, with its ability to gather automated vaccination exposure, outcomes, and medical care utilization data from enrolled members in several integrated healthcare organizations. The process analyzes data weekly, or when a predetermined number of doses of a vaccine have been administered, and uses statistical techniques to account for multiple comparisons and data lags. RCA in the VSD has not only successfully simulated but also detected an observed increase in febrile seizures after the combination measles–mumps–rubella–varicella (MMRV) vaccine [262] and an increase in febrile seizures in young children following inactivated influenza vaccine (later determined to be associated with concomitant 13-valent pneumococcal conjugate vaccination) [249].

The VSD has a covered population of about 12 million persons per year, which, while large, may still encounter difficulties detecting associations between rare exposures and very rare outcomes, or more common exposures or outcomes among a specific subpopulation, such as

pregnant women. In RCA, outcomes under surveillance are prespecified based on prior knowledge of the vaccine safety profile of the product from clinical trials or vaccine safety concerns in general, and tend to be limited in number compared to data mining, where outcomes are not identified *a priori* and are essentially unlimited. Therefore, RCA is more consistent with hypothesis testing rather than hypothesis generation, and is not a true source of *de novo* signals. New information theory approaches may provide a way of detecting previously unexpected associations after vaccination, including data mining in large-linked databases [263]. Until these new procedures are validated, a large national passive surveillance system such as VAERS is still necessary as an early harbinger of potential vaccine safety signals for very rare or unusual events.

Large Immunization Campaigns

Whenever very large numbers of vaccine doses are administered over a short time interval, this can either result in more prominent clusters of AEFI or, by their absence, can demonstrate their safety. Note that this occurs irrespective of whether the vaccine exposure is part of a planned mass immunization campaign or not. For example, the link drawn between hepatitis B vaccine and demyelinating disease in France was due in part to increased vaccinations beyond the intended adolescent age group [264]. Surveillance of AEFI around the time of mass immunization campaigns have been extremely useful in generating signals, either positive (e.g., allergic reaction after dextran-stabilized measles vaccine [51], viscerotropic disease following yellow fever vaccine [212], aseptic meningitis after mumps vaccine [265], GBS with swine influenza vaccine [56], GBS after OPV [266], allergic reactions after Japanese encephalitis vaccine [267], neuropathy after rubella vaccine [268] or absent (e.g., events after meningococcal vaccine [269], GBS after measles [270]. Such signals still require validation, however, since some, after more careful scientific studies, are not confirmed to represent a true association [271,272]. Mass psychogenic illness can plague mass vaccination campaigns, especially among adolescents in school settings [273].

Preparation in advance of mass vaccination campaigns is critical. During mass campaigns with new group A meningococcal conjugate vaccine [269] and during the large vaccination effort for 2009 pH1N1 influenza vaccine in the US and elsewhere [191,274], several systems were put in place to identify signals early. For the latter, in the US, VAERS offered the earliest available data to determine if there was a safety concern. An active GBS case finding project among a population of 45 million was also able to determine rapidly if there was an increased risk of GBS following 2009 pH1N1 vaccination. Both systems had strength in the population size and the rapid review of reports [275,276]. Additionally, near real-time sequential monitoring for multiple prespecified outcomes was performed in the VSD during the 2009 pH1N1 influenza vaccination campaign in the US [277]. Assessing and having background rates for likely AEFI during mass campaigns is also very helpful [56,274,278]. Special registries or studies are needed, however, to monitor the outcome for subpopulations like pregnant women [279], who may need to be vaccinated with limited safety data during such campaigns. Even with planning, unexpected AEFI (e.g., narcolepsy) combined with media attention may create biases that are difficult to sort out via epidemiologic studies [98,280].

Lessons Learned to Date

Lessons have emerged from SRS like VAERS [182,281–284]. Such systems worldwide have successfully detected previously unrecognized reactions and helped to obtain data to evaluate whether AEFI are causally linked to vaccines [18,98,126,192,193,246,248]. VAERS has also successfully served as a source of cases for further investigations of known associations such

as idiopathic thrombocytopenic purpura after MMR [285], anaphylaxis after MMR [286], and syncope after immunization [287]. VAERS has been of great value for answering routine public queries such as "Has adverse event X ever been reported after vaccine Y?" and describing the postlicensure safety profile of new vaccines [288–292]. Additionally, VAERS has been useful for rapidly assessing the safety of vaccines recommended in special populations when limited safety data existed at the time of the recommendation, such as the case of Tdap being recommended during each pregnancy regardless of prior Tdap vaccination history [293]. More recently, VAERS has demonstrated its usefulness in monitoring preventable vaccine administration program errors [294,295].

When denominator data on doses are available from other sources (e.g., net doses distributed, vaccine coverage surveys, immunization registries), VAERS can be used to evaluate changes in reporting rates over time or when new vaccines replace old vaccines. However, reporting rates may be susceptible to biases from media attention, systems enhancement efforts, or other environmental changes that can increase reporting, making comparison over time difficult. In addition, doses distributed in the marketplace do not necessarily equate with doses administered (i.e., influenza vaccine wastage at the end of each influenza season), and it is not possible to estimate reporting rates in special populations (i.e., those with specific medical conditions) based only on information on gross doses distributed. Comparing the proportion of reports for specific events may be helpful to minimize this type of bias. For example, analysis of VAERS data showed that after millions of doses of DTaP had been distributed, the reported rate for serious events like hospitalization and seizures after DTaP in toddlers was one-third that after DTP [256]. Reports to VAERS of OPV-associated paralytic polio disappeared after the shift from OPV to IPV in the US [283]. The proportion of GBS reports following inactivated influenza vaccines over several seasons did not vary, including following 2009 pH1N1 vaccines, even though the reporting rates for GBS were higher following 2009 pH1N1, which was likely due to stimulated reporting from heightened media attention [296]. VAERS is also currently the only surveillance system that covers the entire US population, and the data are available on a relatively timely basis. It is, therefore, the major means available currently to detect possible new, unusual, or extremely rare AEFI, including whether certain lots of vaccines are associated with unusually high rates of AEFI [283], especially when combined with estimates of lot use denominator obtained from statistical models [297].

Data from SRS such as VAERS have helped to inform the potential clinical management [298] of AEFI and to identify potential risk factors for such events, such as advanced age [101] and thymic dysfunction [299] associated with yellow fever vaccine complications, concurrent zoster infection in varicella vaccinees resulting in meningitis [300], personal and family history of convulsions in pertussis vaccinees [100], and factors associated with postvaccinal syncope-related injuries [301]. Conversely, a review of VAERS reports of febrile seizures in young children following inactivated influenza vaccine confirmed that they were clinically similar to typical uncomplicated febrile seizures [248], providing reassurance to clinicians and the public.

The reporting efficiency or sensitivity (i.e., the proportion of total AEFI reported) of an SRS can be estimated if the expected rates of AEFI generated from carefully executed studies are available. A study using this method showed that a higher proportion of serious events like seizures that follow vaccinations are likely to be reported to VAERS (or its predecessor, the Monitoring System for Adverse Events Following Immunizations or MSAEFI) than milder events like rash, or delayed events requiring laboratory assessment, such as thrombocytopenic purpura after MMR vaccination

Table 20.3 Reporting efficiencies* for selected outcomes, two passive surveillance systems for adverse event following immunization, US.

		Reporting efficiency(%)		
Adverse event	**Vaccine**	**MSAEFI**	***VAERS* (overall)**	**VAERS (public sector)**
Vaccine-associated polio	Oral polio vaccine (OPV)	72	68	**
Seizures	Diphtheria–tetanus–pertussis (DTP)	42	24	36
Seizures	Measles–mumps–rubella (MMR)	23	37	49
Hypotonic–hyporesponsive episodes	DTP	4	3	4
Rash	MMR	<1	<1	5
Thrombocytopenia	MMR	<1	4	<1

Notes: *Calculated as the ratio of the rates at which adverse events were reported to each passive surveillance system divided by their rates. **Public- and private-sector information is missing on these cases.

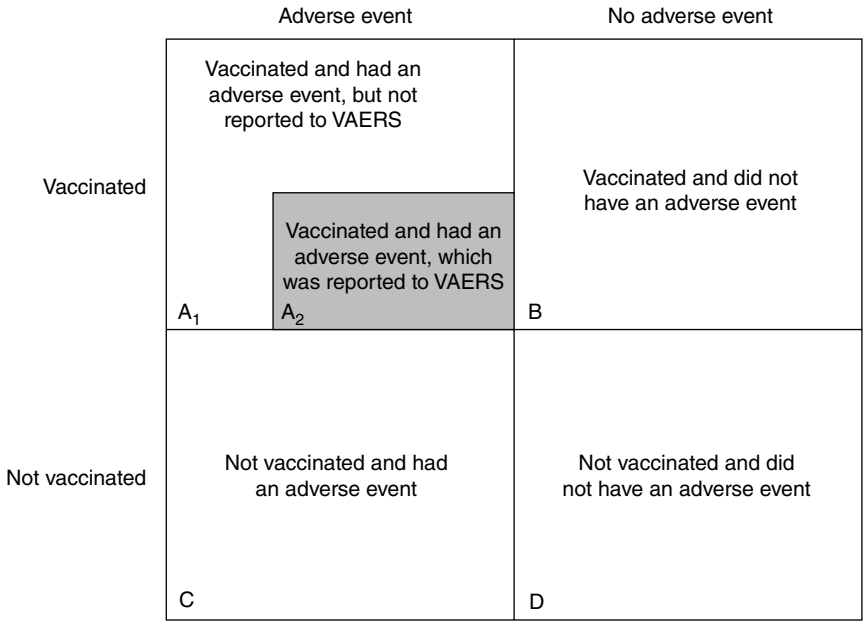
(Table 20.3) [302]. The real incidence of smallpox vaccine myopericarditis in healthy military recruits (presumably averse to admitting chest pain) was ~200-fold higher than passive surveillance [124]. "Capture–recapture" methods, when at least two independent sources are available to ascertain incident AEFI cases in the same population and enough identifying data on the cases are also available to identify individuals ascertained in both dataset sources, can help assess the sensitivity of the reporting systems. Using this method, only an estimated 47% of rhesus rotavirus vaccine–attributable cases of intussusception were reported to VAERS, despite the substantial associated media publicity [303]. Although formal evaluation has been limited, the probability that a serious event reported to VAERS by a healthcare provider has been accurately diagnosed (i.e., predictive value positive) is likely to be high. Of 26 patients reported to VAERS who developed GBS after influenza vaccination during the 1990–1991 season and whose hospital charts were reviewed by an independent panel of neurologists blinded to immunization status, the diagnosis of GBS was confirmed in 22 (85%) [304]. In general, the validity of diagnoses reported to VAERS is highly variable depending on condition.

Despite these uses, SRS for drug and vaccine safety have a number of major methodologic weaknesses (see also Chapter 10) and pitfalls for the unwary in the use of public use datasets [182,284]. Biased and incomplete reporting is inherent to all such SRS and potential safety concerns may be missed [284,302]. Aseptic meningitis associated with the Urabe mumps vaccine strain, for example, was not detected by SRS in most countries about a decade after licensure [87,97,131]. Most importantly, however, the information content of such spontaneous reports represents just cell "a" of a two-by-two table of vaccination versus adverse



A_2 = VAERS database

$$\text{Incidence of AE in vaccinated individuals} = \frac{A_1 + A_2}{(A_1 + A_2)+B}$$

$$\text{Reporting efficiency to VAERS} = \frac{A_2}{A_1 + A_2}$$

$$\text{Incidence of AE in unvaccinated individuals} = \frac{C}{C+D}$$

Safety monitoring in the Vaccine Adverse Event Reporting System (VAERS). *Vaccine* 2015; **33**(36): 4398–405. Reproduced with permission of Elsevier.

event (Figure 20.2), and incomplete and biased content at that [305].

Use of data from SRS is further complicated by heterogeneity in reported clinical syndromes, absence of laboratory confirmation of many of the events, and simultaneous vaccinations that make proper attribution of the causal vaccine difficult. MedDRA and WHO Adverse Reaction Terminology (WHO-ART) codes used to classify signs and symptoms documented in AEFI reports do not necessarily represent medically confirmed diagnoses. Since much of "signal detection" relies on specific diagnoses and their coding into databases, new AEFI clinical syndromes may not be "recognized" and analyzed as such until hypothesis-strengthening procedures such as the development of standardized case definitions and/or clinical/laboratory evaluation are undertaken. Researchers in Canada did a series of such studies to characterize then "new" oculorespiratory syndrome after the 2000–2001 influenza vaccination [246], which, in retrospect, probably also occurred in other influenza seasons [306] and other countries with other influenza vaccine manufacturers [307].

Current SRS are also prone to detecting increases in AEFI reporting that are not true increases. Instead, they may be due to an increase

in (i) reporting efficiency; (ii) vaccination coverage; (iii) public awareness about vaccine safety from media attention (i.e., stimulated reporting or awareness bias); or (iv) increases in the incidence of known or unknown etiologies for a particular AEFI. SRS are usually unable to sort out causally related from coincidentally related AEFI because of inherent methodologic weaknesses. For example, an increase in GBS reports to VAERS in 1993–1994 influenza vaccinees compared to 1992–1993 influenza vaccinees was found to be due to improvements in vaccine coverage and increases in GBS background incidence, while the vaccination-associated risk remained unchanged [135]. An increased reporting rate of an AEFI following one hepatitis B vaccine brand compared to another was likely due to differential distribution of brands in the public versus private sectors, which have differential VAERS reporting rates (higher in the public sector) [308]. A signal of venous thromboembolic events in HPV vaccinees in VAERS was probably due to confounding from concurrent use of oral contraceptives [290]. Finally, an approximately two- to threefold increase in 2009 pH1N1 reports to VAERS as compared to the 2009–2010 seasonal influenza vaccine occurred, most likely due to heightened public awareness and enhancements made to VAERS for safety monitoring efforts of the 2009 pH1N1 vaccine [296].

These observations highlight the crude nature of the "signal" generated by VAERS, and the difficulty in ascertaining which vaccine safety concerns warrant further investigation. Not only are there problems with reporting efficiency and potentially biased reporting, but precise denominators for calculating true rates are usually not available. Instead, crude measures such as *doses distributed* must often be used as surrogates for *doses administered*. Because of these difficulties, the requirement for manufacturers to notify FDA whenever they receive an increased number of reports has been dropped [309].

Historically, most (especially resource-limited) countries have relied on SRS alone for postlicensure vaccine safety monitoring. The inadequacy of scientific information on vaccine safety found by the IOM/NAM is related to the methodologic weaknesses inherent to SRS. The establishment of new population-based immunization information systems in which all vaccines administered are entered may provide more timely submission of spontaneous reports, as well as more accurate and specific denominators for doses administered, providing information necessary to calculate more accurate AEFI rates [310].

Clinical Trials

Prelicensure Clinical Trials

To demonstrate that a new vaccine candidate is safer than a previous vaccine, the two products can be compared head to head in a randomized trial, as was done for acellular and whole-cell pertussis vaccine [103]. Alternatively, active surveillance in a large trial can be done to show that the attributable risk for a specific AEFI (e.g., intussusception) was lower for a new rotavirus vaccine, compared to the old one [68]. When another vaccine (vs. placebo) is used for comparison, however, there may be challenges in interpreting the safety signals detected [311]. Separately, when a new AEFI like myopericarditis was recognized after smallpox vaccination, trials of new vaccine candidates using a similar viral vector may require more safety assessment (e.g., electrocardiogram) [312]. The challenges and lessons learned from safety monitoring of recent trials of a new group A meningococcal conjugate vaccine in Africa have been published [313].

Postlicensure Clinical Trials

To optimize vaccine use, clinical trials may be conducted after vaccine licensure to assess the effects of changes in vaccine formulation [314], vaccine strain [106,315], age at vaccination [316], the number and timing of vaccine doses [317], simultaneous administration [318], and

interchangeability of vaccines from different manufacturers [319] on vaccine safety and immunogenicity. The importance of such trials was demonstrated when studies showed an unanticipated differential mortality among recipients of high- and regular-titer measles vaccine in resource-limited countries [109], albeit lower than among unvaccinated children [320]. This finding resulted in a change in recommendations by WHO for the use of such vaccines [321]. The development of automated large-linked databases (LLDB; see later discussion) may permit an improved ability to monitor the safety of such postlicensure changes in vaccine use without necessarily conducting such clinical trials.

Postapproval Surveillance Studies

To improve the ability to detect AEFI that are not detected during prelicensure trials, most recently licensed vaccines in developed countries have undergone formal postapproval surveillance studies on populations with sample sizes of 100 000. These studies have usually used computerized data from cohorts in health maintenance organizations supplemented by diary or telephone interview. These methods were first extensively used after the licensure of polysaccharide and conjugated Hib [322,323], DTaP [324], and varicella vaccines (including multiyear evaluation for disease incidence, herpes zoster, and a pregnancy registry) [325,326]. Postapproval studies are now routine for newly licensed vaccines like MMRV vaccine [99], HPV vaccine [24], and second-generation rotavirus vaccines [68]. Postapproval studies in Mexico and Brazil have found an increased risk of intussusception in the newer rotavirus vaccines, albeit one-tenth that of the first-generation vaccine [68]. Postapproval evaluation has even been extended to less frequently used vaccines, like Japanese encephalitis vaccine [327]. A large postlicensure randomized trial for this vaccine was also completed in China to improve the available data on its short-term safety [328].

Ad Hoc *Epidemiologic Studies*

Historically, *ad hoc* epidemiologic studies have been conducted to assess signals of potential AEFI generated by SRS, the medical literature, or other mechanisms. Traditional analyses of secular trends (ecologic studies), cohort studies, and case–control studies have been used to gather information necessary to measure or compare risks of an AEFI following vaccination with risk in the absence of vaccination. Occasionally, data collected for other study outcomes may be reanalyzed to see if the vaccine was causally related or not. Examples of *ad hoc* follow-up studies to signals of vaccine safety issues are the investigations of poliomyelitis after IPV [77] and OPV [329]; SIDS after DTP vaccination [37,138]; encephalopathy after DTP vaccination [61,62]; meningoencephalitis after mumps vaccination [131]; injection site abscesses postvaccination [330]; intussusception after Rotashield vaccine [65,66,68]; vaccinations and autism [39,70]; GBS after influenza vaccine [56,135,275]; and GBS after meningococcal conjugate vaccine [247]. Many such studies have been compiled and reviewed by the IOM/NAM. While automated LLDB (see next section and Chapters 11–14) provide a more cost-effective and flexible framework for hypothesis testing, *ad hoc* epidemiologic studies may still be needed in settings without automated LLDB [98,246], or where the statistical power of the automated LLDB may be inadequate to answer a question in a timely manner [134,135,304].

Automated Large, Linked Databases

Ad hoc epidemiologic studies of vaccine safety, while potentially informative about vaccine causality, are costly, time consuming, and usually limited to assessment of a single or small number of outcomes. As with drug safety research (see Chapters 11–14), efforts have increasingly turned to record linkage between automated exposure (immunization records in lieu of pharmacy) files and outcome medical files. This is nicely illustrated by comparing the methods of

the first rotavirus vaccine intussusception studies, *ad hoc* [65] versus LLDB [66], the latter being more timely and efficient.

The US Experience

Vaccine Safety Datalink Project

The CDC participated during the late 1980s in two pilot vaccine safety studies using automated LLDBs in Medicaid and Managed Care Organizations (MCO) populations, respectively [331–333]. While validating this approach for vaccine safety studies and providing scientifically rigorous results, these studies were limited by their relatively small sample sizes, inability to prospectively study new hypotheses, and focus on the most severe reactions [236]. These limitations, the constraints of VAERS, and the recognition of the need for improved monitoring of vaccine safety prompted the CDC to initiate the VSD project in 1990 [334]. To help overcome the previously identified shortcomings, the VSD prospectively collects vaccination, medical outcome (e.g., hospital discharge, outpatient visits, emergency room visits, and deaths), and covariate data (e.g., ethnicity and socioeconomic data on birth certificates, census) under joint protocol at multiple MCOs. Selection of staff model prepaid health plans also minimized potential biases for more severe outcomes resulting from data generated from fee-for-service claims, a problem prior to the implementation of diagnosis-related group (DRG) billing [335]. To increase patient confidentiality, the VSD shifted from annual data file submissions from the MCOs for data pooling and analysis at CDC to a distributed network data management model [336]; in parallel, the VSD is also increasing transparency via public access data sharing and external input [261].

Originally, the VSD conducted active surveillance on approximately 500 000 children from birth through 6 years of age (75 000 birth cohort, approximately 2% of the US population in these age groups) [334]. Expansion to eight MCOs (including data on all age groups at three MCOs) was accomplished in 2000 [337]. The VSD focused its initial efforts on examining potential associations between immunizations and 34 serious neurologic, allergic, hematologic, infectious, inflammatory, and metabolic conditions. The VSD is also being used to test new *ad hoc* vaccine safety hypotheses that arise from the medical literature [16,338–340], from VAERS [66,308], from changes in immunization schedules [341,342], or from the introduction of new vaccines [262,343]. In addition, the VSD has conducted influenza vaccine safety studies in which large cohorts of children are screened for evidence of increased medically attended events following vaccination [344]. The size of the VSD population also permits separation of the risks associated with individual vaccines from those associated with vaccine combinations, whether given in the same syringe or simultaneously at different body sites [262,345]. Near real-time surveillance was conducted on several combination vaccines [346,347]. Surveillance on the safety of the influenza vaccine, including subgroups such as pregnant women [342], is ongoing.

When the VSD identifies an AEFI as being associated with a vaccine, data on the incidence rate attributable to the vaccine are available [66,262,340], permitting accurate benefit/risk assessment by both the public and policymakers [348]. Subgroup analyses may permit identification of risk factors for AEFI (or vaccine failures), which may be useful in identifying contraindications to vaccinations [349]. Data from VSD have been useful in calculating background rates of illnesses in the absence of vaccination that can serve as expected rates when comparing rates of vaccine-associated events in an SRS [278]. Also, incidence rates of vaccine-associated AEFI derived from VSD can be used to evaluate the sensitivity of passive reporting systems [303]. The VSD data also aid the Vaccine Injury Compensation Program in determinations of what events should be compensated as vaccine "injuries" [71].

In addition to *ad hoc* epidemiologic studies, an RCA team was formed within the VSD to

conduct near real-time active surveillance on newly licensed vaccines [260,261]. The RCA relies on analytic datasets that are created weekly from the automated MCO data. The weekly analytic datasets are used to investigate potential associations between vaccines and AEFI that are defined *a priori*. Statistical analysis for signal detection is conducted with methods that account for the multiple testing of accumulating data. The RCA team developed a statistical method known as the maximized sequential ratio probability test (MaxSPRT) to detect safety signals in near real time, while accurately accounting for repeated testing of the data [350]. The first application of MaxSPRT was in safety assessment of the newly licensed meningococcal conjugate vaccine in 2005 [351]. RCA methods also were used to detect a twofold increased risk for febrile seizures following MMRV vaccination compared to MMR and varicella (MMR + V) administered separately [262]. This finding precipitated changes in US immunization policy for MMRV and MMR + V in children.

The VSD has some limitations, however. The IOM/NAM, in its 2013 report, recommended that the VSD expand collaborations to include more diversity in its study population. In response, the VSD is collaborating with Denver Health, an integrated safety net healthcare system serving a large proportion of Denver's indigent and minority populations, to integrate its data into the VSD [352]. More importantly, because of the high coverage attained in the MCOs for most vaccines, few nonvaccinated controls are available. Therefore, the VSD often relies on some type of "risk-interval" analysis [331–334] (Box 20.1). The capability of this approach to assess associations between vaccination and AEFI with delayed or insidious onset (e.g., neurodevelopmental or behavioral outcomes) is limited [16]. The VSD also cannot easily assess AEFI that do not result in a healthcare visit, and therefore are not currently captured in existing MCO databases, because they do not result in a healthcare consultation (e.g., fever) [334]. The current VSD is also not large enough to examine modest increased risks of extremely rare events such as GBS after each season's influenza vaccine. Finally, because the VSD relies on observational studies, it may not successfully control for confounding and bias in each analysis [140], and inferences on causality may be limited [353].

Despite these potential shortcomings, the VSD provides an essential, powerful, and relatively cost-effective complement to ongoing evaluations of vaccine safety in the US [69].

Postlicensure Rapid Immunization Safety Monitoring

In 2009, the Department of Health and Human Services initiated the Post-Licensure Rapid Immunization Safety Monitoring (PRISM) program in response to the need to supplement the preexisting active surveillance for the safety of the 2009 pH1N1 influenza vaccine [191]. To ensure its sustainability, PRISM became the immunization safety monitoring component of the FDA's Sentinel project (see Chapter 25), a postmarketing safety surveillance network to actively monitor the safety of medical products [354]. PRISM is a distributed data network that utilizes claims data from four national health insurers and vaccine data from eight immunization registries, and has the largest cohort size in the US for active vaccine safety surveillance, making it possible to study rare AEFI [355]. However, its limitations include updating of the data quarterly only and limited accessibility to medical records. PRISM has conducted several vaccine safety evaluations, including on the safety of monovalent pandemic 2009 pH1N1 influenza vaccine during 2009–2010 [356], febrile seizures after 2010–2011 TIV [357], risk of venous thromboembolism after quadrivalent HPV vaccination [358], and intussusception risk after rotavirus vaccination in US infants [359]. Since the VSD and PRISM have different data sources and populations, they complement each other and serve as a check on the validity of results.

Box 20.1 Example of method for risk-interval analysis of association between a universally recommended three-dose vaccine (with a few unvaccinated people for comparison) and adverse event following immunization.

1) Define "risk interval" for adverse event after vaccination (e.g., 30 days after each dose).
2) Partition observation time for each child in the study into periods within and outside of risk intervals, and sum respectively (e.g., for a child observed for 365 days during which three doses of vaccine were received; total risk interval time = 3×30 person-days = 90 person-days; total nonrisk interval time = 365 – 90 = 275 person-days).

o————————x====————————x====————————x====————————//————————>|

Birth Dose 1 Dose 2 Dose 3 365 days

Add up (i) total risk interval and nonrisk interval observation times for each child in the study (=person-time observed; for mathematical convenience, the example below uses 100 and 1000 person-months of observation), and (ii) adverse events occurring in each time period to complete 2×2 table (for illustration, the example uses 3 and 10 cases):

Adverse event yes		*Person-time observed (months)*	*Incidence rate*
Vaccinated in risk interval yes	3	100	0.03
Vaccinated in risk interval no	10	1000	0.01
Total	13	1100	

Incidence rate adverse event$_{vaccinated}$ = 3/100 = 0.03

Incidence rate adverse event$_{unvaccinated}$ = 10/1000 = 0.01

Relative risk vaccinated: unvaccinated = 0.03/0.01 = 3.0

Probability finding due to chance: <5/100

Conclusion: There is a threefold increase in risk of developing the adverse event within the interval following vaccination.

PRISM is currently evaluating new data-mining techniques such as TreeScan, which can be used to simultaneously evaluate multiple unsuspected but potential AEFI while adjusting for multiple comparisons [360]. If it works, it could be an invaluable tool for signal detection. However, since this would not be able to adjust for all possible confounders, the statistical signals of public health concerns would still need evaluation using carefully designed epidemiologic studies [263].

Other High-Income Nations' Experience

In view of the methodologic and logistical advantages offered by automated LLDB, Denmark [70], the UK [97,131], France [361], Germany [362], and Canada [363] have also developed large automated databases linking immunization registries with medical files. Building on their experience with 2009 pH1N1 influenza vaccine safety surveillance, Europe [42] and Taiwan [274] have converted their systems into large, linked databases for routine vaccinations [138]. The European Accelerated Development of VAccine benefit–risk Collaboration in Europe (ADVANCE) consortium (http://www.advance-vaccines.eu) is a public–private partnership under the Innovative Medicines Initiative [44,364]. The Taiwan system links a National Immunization Information System with the outcomes from a successfully implemented National Health Insurance scheme [138]. Most high-income countries should have similar capabilities if they prioritize vaccine safety.

Low- and Middle-Income Nations' Experience

The first pilot LLDB in an LMIC was established in one province in Vietnam in 2002 [365]. Given that many vaccines against many poverty-related diseases like rotavirus, malaria, and tuberculosis will be introduced first in such countries, there is a need to develop VSD-like infrastructures there, too [44,115,211,366]. Affordable options in the near term include adapting hospital-based surveillance for serious AEFI [162], building on existing demographic surveillance systems like the International Network for the Demographic Evaluation of Populations and Their Health (INDEPTH) [367], pilot implementation projects associated with the introduction of new vaccines [368], and others [369,370].

Injury Compensation

Many high-income countries in Europe, North America, and Asia have programs to compensate individuals who may have been injured by vaccines [71,371]. A global no-fault program has been proposed to facilitate the development of new vaccines for public health emergencies [90]. Although differences exist across countries, some common principles and procedures guide the administration of compensation programs. These are mostly no-fault programs designed to be fair and as efficient and generous as possible. Vaccinations are in some situations mandatory and often recommended by public health authorities, and most AEFI and injuries are not due to negligence or malice (i.e., they are not foreseeable or preventable at the individual level). Therefore, a formal government-managed program outside of the traditional tort system is advisable to protect individuals, vaccination programs, and vaccine manufacturers. Depending on the type of program, claims of vaccine injury may be adjudicated through legal or administrative processes. Funding sources to compensate individuals include general revenues, manufacturer contributions, or specific taxes on vaccine doses sold. Standard of proof generally follows a civil or modified civil standard, rather than a scientific standard for causality [71,371].

In the US, the National Vaccine Injury Compensation Program (VICP) was authorized by the US National Childhood Vaccine Act of 1986 [71,372]. This no-fault program is administered by the Health Resources and Services Administration of the US Department of Health and Human Services. The US Department of Justice represents the government and cases are heard before the US Court of Federal Claims. Covered vaccines include those routinely recommended by the CDC for use in children; however, there is no age limit and anyone who receives a covered vaccine is covered by the program (e.g., an adult receiving an IPV prior to travel would be covered, since IPV is routinely recommended by the CDC for children). Claims can be conceded by the government if they meet the requirements for a VIT injury; the VIT is designed to streamline adjudication of claims by allowing the government to concede causality in certain circumstances [91]. Claims can also be settled (both injuries listed on the VIT and "off-table" injuries), or cases decided by special masters of the US Court of Federal Claims. Funding for the program is through an excise tax on each dose of covered vaccines sold in the US [71,372].

Injury compensation programs have helped vaccine-injured individuals and their families deal with injury-related financial burdens, improved confidence in vaccinations and immunization programs, and helped stabilize vaccine supply and prices [71]. An aspirational goal should be to extend injury compensation programs to all countries that manage national immunization programs [90,371].

Methodologic Approaches for Observational Epidemiology Studies

Exposures

In countries where vaccinations are required for entry into daycare, kindergarten, schools, and/or colleges, documentation via vaccination

cards or medical records is usually available and of good quality for most infants and children. In the US, documentation of the vaccine type, date of vaccination, manufacturer, lot number, and vaccine provider in a permanent medical record has been required since 1988 for certain routine childhood vaccinations [372]. This requirement, along with improvements in technology, has prompted state and local authorities, in collaboration with healthcare providers and health systems, to capture patient vaccination status, particularly for children, in electronic immunization information systems (formerly known as immunization registries) that often communicate with EHRs, which are increasingly common in higher-income countries [310].

Although vaccination records can be manually retrieved and reviewed for any study design, automated vaccination records greatly ease the logistics of organizing such studies. Whenever sampling is necessary in the design, automated records also ease the selection of samples that are representative. Assessing the accuracy of such automated data is important in any study [373,374]. When people receive their vaccinations from several providers (not uncommon in the US), their exposure status may be misclassified [375]. This error could be minimized if a centralized Immunization Information System (IIS) was implemented to track all vaccinations from birth. Such IISs have been implemented in Australia [376], Canada [377], China [378], Denmark [70], Latin America [379], the UK [380], and the US [310]. Mobile phones and other sources of digital identification may aid adherence to vaccinations and their capture as data [381], including in LMICs [382].

The availability and quality of vaccination records generally decrease as people age, especially beyond school age, where documentation is often required for school attendance. Some vaccines for older people may be administered in settings other than primary healthcare (e.g., tetanus–diphtheria boosters in emergency rooms, hepatitis B vaccinations for healthcare personnel). In addition to review of primary medical records, interviews or a review of data from secondary vaccination sites may therefore be necessary to accurately ascertain exposure status in AEFI studies of these vaccines in older populations. To increase the accuracy of exposure data in a study of adverse reactions to plasma-derived hepatitis B vaccine among Alaskan natives, medical records from the village, the hospital, and the regional public health nurse, in addition to the automated vaccination record, were reviewed [383]. Studies of GBS and 2009 pH1N1 influenza vaccine relied on patient/family interview, hospital medical record, and/or validation with primary care providers for exposure ascertainment [275]. Interestingly, reliance on provider verification may lead to underascertainment of vaccination status, either because of poor record keeping [375] or concerns about liability in vaccine safety studies [135].

Standards are needed to improve the accuracy and efficiency of transfer of vaccine identification information from the vaccine vial to automated or paper immunization records. They include (i) abbreviations for new vaccine antigens and vaccine manufacturers; (ii) peel-off labels; (iii) bar codes; (iv) lot numbers [384]; and (v) presentation of key identifier information on vaccine packaging (as on the nutrition label). The WHO has identified as a priority the development of a vaccine dictionary that will allow differentiation of vaccine formulations from various manufacturers [385].

Outcomes

To ensure both high sensitivity and specificity for an AEFI, a multistep approach is usually required for case ascertainment [338,340,344]. In step one, the automated databases are screened to identify International Classification of Diseases, 10th edition (ICD-10) diagnostic codes for the condition of interest. The ICD-10 codes typically represent medical encounters in the inpatient, outpatient, and emergency department settings. Additional data sources,

such as laboratory and pharmacy files, can also be used to identify potential cases. This initial screening definition tends to be highly sensitive but less specific. After the electronic cases have been identified, a trained abstractor, blinded to vaccination status, often reviews the medical records of the patients. On a standardized data collection form, the abstractor records detailed clinical information on presenting symptoms, sequelae, medications, underlying health conditions, diagnostic test results, and potential confounding variables. For outcomes with insidious onset like multiple sclerosis, multiple dates (e.g., first symptom, first medical visit, first diagnosis) and sources of information (patient recall, medical chart) may also need to be collected [386]. In the last step of the case ascertainment process, clinical experts review the abstracted medical information to determine if patients meet the final study case definition. For difficult diagnoses like GBS, a panel of specialists may also be asked to review the medical records after exposure status has been masked [64,135].

This process minimizes the likelihood of a false negative conclusion (due to bias toward the null) by ensuring that only cases meeting the most specific case definition are included in the analysis. It is also possible, however, that using such a narrowly focused outcome definition may miss broader syndromes or groups of symptoms related to the outcome. Follow-up analyses of rhesus rotavirus vaccine reports to VAERS suggest that intussusception [192] may have been just the "tip of the iceberg" of a broader syndrome that also included bloody stool, vomiting, diarrhea, and abdominal pain [288]. Adverse neurologic outcomes other than GBS were reported among the 1976–1977 and 2009 pH1N1 influenza vaccinees [240,387]. Unfortunately, whether these associations are causal remains unknown and controversial, as formal studies have not been done.

Should the concern be a new previously undescribed syndrome, analyses of existing databases may be inadequate. A study of Gulf War Syndrome and vaccinations relied on a thorough interview of patients meeting a *de novo* complex case definition before linkage with vaccination history [388].

In the context of real-time surveillance, influenza vaccine safety monitoring is hindered by the rate at which LLDBs capture medical encounter data. In the VSD, for example, some of the MCO sites contract with independent hospitals to provide inpatient care. Therefore, there is often a considerable lag between the inpatient encounter and the date at which the encounter (outcome) is captured in the databases. At some sites, the average lag can be as long as four months [389]. For influenza vaccine safety monitoring, the influenza season may be over by the time the outcome data is fully captured, thereby rendering the real-time analysis moot.

Study Design and Analytic Methods

Different analytic strategies are needed depending on how a vaccine is used in the population. For vaccines used infrequently and typically in vaccinees who are generally no different than nonvaccinees (e.g., travel vaccines), comparison between two groups with adequate matching or adjustment is relatively straightforward. For example, in a cohort study, groups of vaccinated and unvaccinated individuals may be matched on several factors such as sex, study site, age, high-risk condition, and calendar time. The cohorts of vaccinated and unvaccinated individuals are then followed forward in time, and the incidence of events in the two groups is compared within predefined exposure windows following vaccination. These exposure windows are defined *a priori* based on the current understanding of the most plausible biologic mechanism, should such an association actually exist. For most acute events, exposure windows of 0–1, 1–14, 1–30, and 1–42 days are often used [334,340,344]. This study design provides a direct estimate of effect (the incidence rate ratio, IRR), is well suited for rare exposures

(but not rare outcomes), and can be used to analyze multiple outcomes [390,391]. Matching on age and calendar time helps to adjust for time-varying variables that can confound the results when the vaccine and outcome are either seasonal or highly dependent on age. When the outcome is rare, however, the cohort design can be costly to implement and, for childhood vaccines that are universally recommended, there may be too few unvaccinated children for the comparison group. The design is also susceptible to selection bias that can be introduced by comparing vaccinated and unvaccinated populations, as these groups may differ by factors frequently missing from LLDBs such as ethnicity, socioeconomic status, and underlying health state [140].

In contrast to the cohort design, case–control studies are conducted by first identifying individuals who experienced a particular event over a predefined time period. This group of cases is then compared to a control group of outcome-free individuals from the same time period. Cases are often matched to controls by variables such as sex, age, study site, and calendar time [65,142,144]. This design tends to be more economical than the cohort design, and it is well suited for rare illnesses. As with the cohort method, however, the case–control design is limited when vaccine coverage rates are high and few unvaccinated cases and controls are available for analysis. In contrast to the cohort design, matching on confounding variables in a case–control study will bias the results to the null hypothesis (i.e., toward no effect) if not explicitly adjusted for in the analysis [390]. It is also difficult (and sometimes impossible) to estimate the attributable risk in a case–control design.

To address some of these limitations, alternative methods known as the risk-interval (or vaccinated cohort) and self-controlled case series (SCCS) study designs have been developed for vaccine safety epidemiology [97,146,392,393]. These designs differ from more traditional epidemiologic methods in that time intervals both before and after vaccination *within the same individual* are used to classify a person as exposed or unexposed. In the risk-interval design, incidence rates for risk and nonrisk time periods are compared, but only vaccinated individuals are included in the analysis. A time period shortly following vaccination is defined as the exposed risk interval, and events that occur during this period are classified as exposed cases. Time periods outside of the risk interval – before and after the vaccination – are considered the nonrisk (or unexposed) periods, in which occurrences of events are classified as unexposed cases. Because only vaccinated individuals are included in the study, the design eliminates biases associated with fixed factors that remain constant over time in the same individual, but differ between vaccinated and unvaccinated populations. In addition, because control time periods both before vaccination and after the risk period are included in the analysis, the design is used to examine the risk of acute, self-limiting events following vaccination.

The SCCS method is a similar design in which incidence rates for risk and nonrisk time periods are compared, but only cases with an event are included in the analysis [146,393,394]. The study population comprises cases that occur over a predefined observation period, and each case acts as its own control, thereby controlling for both measured and unmeasured confounding variables that do not vary over time (i.e., fixed confounding). With the SCCS method, multiple occurrences of independent events within an individual can be analyzed. Since only cases are required for the analysis, the SCCS study population is considerably smaller than that of the cohort, case–control, and risk-interval designs. As discussed shortly, the SCCS has nearly as much statistical power as the cohort approach when a high proportion of the population is vaccinated. Both the risk-interval and SCCS designs are analyzed with conditional Poisson regression to generate incidence rate ratios (IRRs).

Possible limitations of the risk-interval and SCCS methods stem from their inability to implicitly control for time-varying confounders, such as seasonality or age. In contrast to the matched cohort analysis, these time-varying variables must be explicitly defined as either continuous functions or categorical variables and added to parametric Poisson regression models [392,395]. Misspecifying such variables can lead to biased results – particularly when the event is rare [393]. Alternatively, it has also been shown that semi-parametric Poisson regression models can be used to analyze SCCS data in which the time-varying effects of age do not have to be explicitly defined before analysis [396].

An additional important limitation of the SCCS is that bias can be introduced if the occurrence of an event influences the probability of receiving vaccination. For example, individuals with a history of contraindicating or precautionary conditions to vaccination – such as GBS, idiopathic thrombocytopenia, anaphylaxis, and HIV – may have their immunizations either delayed or withheld indefinitely. In such a situation, the SCCS design would be limited, since only cases (i.e., those with an event) are followed forward in time, and time periods before vaccination could not be included in the analysis. This assumption of event-independent exposure (vaccination) is not required for the more traditional epidemiologic methods, because vaccination status is ascertained retrospectively from the date of diagnosis in a case–control study, and the onset of an event is ascertained prospectively from the date of vaccination in a cohort study. An analytic method has been developed to account for the post-event dependence in an SCCS analysis when the postvaccination risk period is short and when the event is both rare and nonrecurrent [397]. Simulation analyses demonstrated that the estimation method helped to correct for bias associated with event-dependent exposures, but it also produced IRR estimates that were attenuated to the null hypothesis (i.e., they underestimated the true effect). Future research is needed to develop this analytic technique further.

The characteristics of cohort, case–control, risk-interval, and SCCS designs have been compared empirically with simulation studies [392,398]. In a study using VSD data and simulated cases of a rare, acute illness (immune thrombocytopenic purpura or ITP) after MMR vaccination [340], the risk-interval, SCCS, and case–control study designs produced valid IRR estimates that were within 3% of a cohort gold standard. The case–control design, however, produced estimates that were less powerful, less precise, and biased by unmeasured fixed confounding when compared to the other study designs. The SCCS and risk-interval, in contrast, were as powerful as the cohort design and produced unbiased estimates in the presence of unmeasured fixed confounding. Of note, the SCCS design displayed similar characteristics to those of the risk-interval and cohort, but required only a fraction (0.01%) of the study population for analysis. On average, the size of the simulated cohort, risk-interval, and SCCS study populations were 2.7 million, 1.4 million, and 200 individuals, respectively.

Using similar simulation analyses, the characteristics of these four designs were evaluated in the context of real-time, active surveillance of AEFI [148]. When the exposure and outcome were acute, the cohort proved to be the best study design for active surveillance, in terms of bias, statistical power, and signal detection time. When selection bias was a concern, the risk-interval design was shown to be valid alternative. Of all the designs, the case–control design had the longest signal detection time and most biased relative risk estimates. Although the SCCS lagged behind the cohort and risk-interval designs in signal detection time, it was acceptably accurate and powerful and required only a minimum of data. Thus, the results from these simulation studies demonstrate that the SCCS

design is a valid, powerful, and economical epidemiologic tool for studying vaccine safety.

Clearly, the current methods for studying vaccine safety have contrasting strengths and limitations. In some instances, researchers employ multiple methods to address the various factors that can bias the results [98,340,389,395]. Studying the safety of the influenza vaccine, as an example, poses multiple methodologic challenges that cannot be addressed with one particular design. In a typical influenza season, more than 85% of the vaccines are administered in October and November [389,399]. It is also likely that certain conditions of interest – such as febrile seizures, gastrointestinal disorders, or rash – have a seasonal distribution across the influenza season from October through April, with the incidence peaking in winter months. Such distributions would make season a strong confounder, as it would be highly associated with both vaccination and the outcome of interest. The correlation may, in fact, be so high that one could not disentangle the individual effects of vaccination and season in the analysis. Although little can be done to rectify this potential problem with any design, the SCCS and risk-interval designs are particularly susceptible to this type of seasonal bias.

A newer strategy to account for seasonal time-varying bias in vaccine safety studies is the case-centered approach [399]. It was initially developed for assessing the effectiveness of influenza vaccines in the elderly, and has been adapted to evaluate the safety of vaccines in postmarketing settings [400]. In cases occurring during an influenza season, the method uses data from the entire cohort (cases and noncases) to calculate the probability of exposure (vaccination) for the day of the event. The logit of this probability is then placed into logistic regression model as an offset term. In essence, this method provides a seasonal adjustment for exposure by conditioning on the odds of vaccination over the course of an influenza season. This strategy has been used to study the risk of GBS following the monovalent inactivated and seasonal influenza vaccines [401] and various vaccine safety hypotheses [147,402,403].

In addition to seasonality, studying the safety of influenza vaccination is challenged by the potential for selection bias. Even where the influenza vaccine is universally recommended, it is possible that individuals who receive influenza vaccination are different from those who do not. Moreover, in large-linked MCO databases, it is possible that a certain proportion of the population received influenza vaccination outside of the MCO, which may not be captured in the automated databases [389]. As described earlier, this potential for selection bias and exposure misclassification is problematic for the cohort and case–control designs.

Impact of Larger Sample Size

The continued accumulation of data from larger study populations with common data dictionaries (e.g., by more sites and/or calendar time) has allowed new scientific evidence to emerge on longstanding vaccine safety questions.

Stratification of Risk Groups in Association Studies

Despite SIDS being reported among millions of DTP vaccinees annually since 1933, the likely association of a "temporal shift" phenomenon (Figure 20.1) was only unraveled recently with the availability of nationwide large-linked databases in Taiwan. A study assembled ~2400 SIDS cases over 10 years (~tenfold larger than most past studies), allowed stratification of risk by days since vaccination with statistically significant results for the first time (RR = 1.66; 95% confidence interval: 1.05–2.60) for the first 24 hours postvaccination, followed by a compensatory decreased RR < 1.0 for the subsequent postvaccination periods) [138]. Similarly, assembling a cohort of all recipients of measles-containing vaccinations at VSD sites over 10 years allowed analyses showing that the risk of fever and seizures was lower among vaccinees 12–15 months of age versus 16–23 months old [404].

Studies of Very Rare Outcomes/Associations

While vaccine-induced anaphylaxis and GBS were known to be rare, their true rates were difficult to ascertain. Combining LLDBs to identify potential cases that meet the Brighton Collaboration case definition for each AEFI have finally allowed such rates and association to be estimated with greater precision [57,405–407] than classical meta-analysis without Brighton validation [408,409]. For serious outcomes usually requiring hospitalization like GBS, combining hospitalization data and SCCS methods allows contribution of data from more sources [410].

The Future

Although considerable progress has been made in the development of vaccine safety analytic methods, several challenges remain. Areas of particular importance include (i) identifying optimal risk windows; (ii) characterizing a lifetime dose–response relationship from multiple influenza and tetanus-containing vaccinations; (iii) evaluating the safety of the entire childhood immunization schedule; and (iv) data mining for unknown AEFI in real-time active surveillance.

Although risk window lengths are often based on prior biologic knowledge, they are also somewhat arbitrarily defined (e.g., 0–1, 1–14, 1–42 days after vaccination). Inaccurate specification of the risk window can result either in including the true control period in the risk window or including a segment of the risk window in the control period, both of which would introduce bias. After an elevated risk has been identified in a prespecified risk window, a two-step data-driven approach to identify the period of greatest risk has been proposed. Step 1 begins by specifying a minimum risk window length, for which a risk estimate is calculated using an appropriate regression model. The risk window is incrementally lengthened and risk estimates are generated for each subsequent window. The risk estimates are plotted against the variable risk window lengths, and the researcher notes where risk is maximized. If the specified risk window is longer than the true risk window, an analytic approach is possible in step 2. Preliminary simulation and theoretical work applied to the SCCS design with conditional Poisson regression has shown that there is a linear relationship between the calculated risk and risk window length [411]. The analytic approach calculates an optimal risk window length based on maximum likelihood methods and the study design of interest. Future work should focus on applying the approach to other study designs and regression models.

Unlike all other vaccines, influenza vaccine is administered on an annual basis indefinitely. It is currently not known if the risk of certain AEFI increases with each subsequent dose. For children in particular, studying this relationship is problematic, since dose number is likely to be strongly correlated with age. In other words, since both age at vaccination and cumulative dose increase over time, it would be difficult to explain how much of the risk associated with a particular dose can be explained by age. To study adequately the relationship between dose number and the risk of AEFI, new methods for disentangling the correlation between dose and age are needed.

An increasing number of parents are choosing to either delay or refuse some or all vaccines for their children, often citing safety concerns [412–415]. These sentiments reflect the number, frequency, and timing of vaccines, leading parents to undervaccinate and adopt immunization schedules that differ from the ACIP recommended schedule, known as the alternative immunization schedule [141,415–419]. In its 2013 report, IOM/NAM recommended that additional observational research was warranted to compare the health outcomes between children vaccinated according to the

ACIP schedule and those on an alternative schedule [420]. Using observational studies for these comparisons could be methodologically challenging, because health- and healthcare–seeking behaviors may differ systematically between the two groups [141,421]. In addition, it involves defining exposure to multiple different immunization schedules, identifying biologically plausible AEFI outcomes to study in the context of the immunization schedule, and identifying epidemiologic and statistical methods to assess the safety of the schedule as a whole [133].

Defining exposure is particularly challenging, because even though undervaccination is common, there is considerable variability in patterns of undervaccination and there could be multiple ways to assess it. A 2013 study showed that 48.7% of children under age 2 years were undervaccinated for at least one day, and there were 1399 different patterns of undervaccination using the eight recommended childhood vaccines and categorizing them into three groups of all doses received on-time, no doses received, or some doses either missing or not received on time [141]. These patterns did not consider other factors related to the schedule such as the age, spacing, or order of vaccinations, which would result in millions of different combinations of vaccination patterns. Different approaches for identifying patterns of undervaccination have been proposed using the average days undervaccinated and proportion of days undervaccinated metrics, which quantify the number of calendar days for which a child is undervaccinated across all recommended vaccines [141,422–424]. Another problem with defining the exposure is the potential for misclassification of the vaccination status in EHRs. This could be minimized if there is an ICD code for vaccine refusal in the EHR, but these children would likely be too few to be able to study rare AEFI [425].

In the context of the entire immunization schedule, the outcomes to be studied need to be based on biologic plausibility, feasibility in the context of the overall immunization schedule, epidemiologic evidence, public health significance, and public concern [133,420]. Studying short-term acute outcomes poses challenges, as they may occur before the completion of the schedule, and are typically associated with short risk periods following specific vaccines, doses, or combination of vaccines. Moreover, short-term outcomes may influence parents' future decision to vaccinate their child and may lead to reverse causality.

The VSD vaccine schedule study team along with subject matter experts have prioritized a list of 20 plausible long-term or chronic outcomes [133]. Some of the outcomes on this list are very rare events, such as meningitis, encephalopathy, and development of type 1 diabetes, and very large cohorts of children will have to be studied to be able to identify differences in risk. More common outcomes on the list, such as asthma and allergy development, would entail intensive primary data collection resources to address the potential for misclassification. A particular challenge is the study of outcomes that have an insidious onset. Early symptoms of disease may alter parents' vaccination decision for their child, but before any formal clinical diagnosis has been made, leading to reverse causality [133].

Deciding on study designs and analytic plans to evaluate the safety of the schedule can be complex, because these may be susceptible to selection bias, confounding, and misclassification. Undervaccinated children differ from children who receive the recommended vaccines on time on important variables such as baseline health and healthcare utilization, race/ethnicity, socioeconomic status, parental education, and family history of illness. These data are difficult to capture using EHRs and should be addressed using methods including directed acyclic graphs (DAGs), control outcomes, restriction, matching, primary data collection, and sensitivity analyses [133].

Lastly, data-mining methods have been developed to identify signals for unexpected AEFI. These methods for vaccine safety have been

applied to passive surveillance systems and *ad hoc* epidemiologic studies [344,426]. In these respective settings, however, data-mining analyses have been limited by reporting bias, lack of denominator data, and low statistical power for rare events. Conducting data-mining analyses in LLDBs with real-time active surveillance will address some of these limitations. Such methods would be a natural complement to targeted active surveillance, in which AEFI are specified *a priori*. For targeted active surveillance (see Chapter 46), sequential testing methods have been developed to protect against false positive signals (type I error) when data are analyzed on a weekly or monthly basis. The potential for type I error, however, will increase significantly when multiple unspecified outcomes are analyzed at the same time.

New analytic tools for using LLDBs to identify unsuspected AEFI in real time have recently been developed [360,427]. These methods should be sensitive enough to detect potentially serious AEFI, but also conservative enough to protect against too many false signals. Such methods also need to account for seasonality, selection biases, and other factors that can distort the findings. Perhaps most importantly, a process for signal validation (e.g., controlled epidemiologic studies with medical chart review) and a plan for risk communication must be in place should a signal arise [428].

More broadly, major integration (and possible reorganization) of the vaccinology enterprise writ large may be needed to allow a shift from a historically largely empiric "one size fits all" paradigm to one allowing "personalized medicine" requiring knowledge in various "systems biology" processes [117]. One such process, adversomics, hopes to identify, characterize, and predict adverse or maladaptive immune responses [125]. To do so will eventually require linkage of basic science, clinical trial, and postmarketing surveillance databases, with appropriate analytic tools and graphic displays. Gaps in knowledge or processes identified (e.g., biobanking of samples from persons with serious AEFI) will need resolution. As ongoing immunizations of a substantial proportion of the human population against an ever-increasing list of VPDs globally is probable, both the sample size and logistic requirements are manageable, so the challenges are likely to be more financial and political. Advances in genomics may allow other improvements in vaccine safety. Deep sequencing assays can detect DNA/RNA sequences that have contaminated the vaccine production process [429], help document exposure to them in vaccinees, or monitor for circulation of risky live vaccine strains [430]. Homology between vaccine candidate and human genomic sequences can identify potential causes of autoimmunity [431].

As recently as 2012, only one-third of WHO member states had an effective vaccine safety monitoring system [206]. While progress has been made, significant challenges in capacity building remain – to initially establish an SRS, followed by effective response to any signals detected [209]. The recent availability of funding from the Global Alliance for Vaccines and Immunizations (GAVI) for these purposes in eligible LMICs should hopefully turn the tide [432].

Medical devices save lives, prevent disease, improve health, and help patients live productive lives. The last decade has seen an explosion in medical device technologies worldwide. It has been recently estimated that the global medical device market exceeded $389 billion in 2017 [1].

Groundbreaking innovations in the areas of transcatheter interventions, nanotechnology, telemedicine, robotic procedures, sophisticated health information technology software, and smart applications continue to offer new diagnostic and therapeutic options to patients and clinicians. Recent approval of the first medical device that uses artificial intelligence to aid in diagnosis of retinopathy is a good example of the dynamic landscape where software as a medical device will play a more prominent role in the delivery of healthcare [2].

From the public health perspective, the availability of diverse health technologies demands both the capacity and commitment to development of new methodologic approaches for evidence generation, appraisal, and synthesis. Medical device epidemiology is well suited not only to studying the extent of utilization of medical devices, but also to studying utilization patterns and quantifying risk/benefit for certain outcomes in defined populations. Furthermore, an attractive feature of modern device epidemiology is the implementation of techniques to integrate information available from the growing body of heterogeneous data. Operating at the intersection of scientific knowledge and healthcare, it is the practice of epidemiology that ensures consistently reliable approaches to combine and update information in order to maximize quality, minimize bias, and reduce uncertainty in understanding the risks and benefits of new devices.

What Is a Medical Device and How Is It Different from a Drug?

The definition of a medical device varies somewhat by country (Table 21.1). The US government defines a medical device as:

> an instrument, apparatus, implement, machine, contrivance, implant, in vitro reagent or other similar or related article, including any component part or accessory which is: (1) recognized in the official National Formulary, or United

Pharmacoepidemiology, Sixth Edition. Edited by Brian L. Strom, Stephen E. Kimmel and Sean Hennessy.

States Pharmacopeia or any supplement of them; (2) intended for use in the diagnosis of disease or other conditions or in the cure, mitigation, treatment or prevention of disease in men or other animals; or (3) intended to affect the structure or any function of the body of man or other animals, and which does not achieve its primary intended purposes through chemical action within or on the body of man or other animals and which is not dependent upon being metabolized for the achievement of any of its principal intended purposes. [3]

Definitions used in the European Union (EU), Canada, Australia, and Japan are slightly different (Table 21.1) [3–9].

There is a long history of international harmonization efforts in the regulation of devices. The Global Harmonization Task Force (GHTF), formed in 1992 in an effort to respond to the growing need for international harmonization in the regulation of medical devices, produced a harmonized definition of a medical device [9]. To build on the strong foundation of the GHTF, the International Medical Device Regulators Forum (IMDRF) emerged in 2011 as a driver of harmonization and convergence efforts among regulatory authorities on medical devices [10]. This voluntary organization brings together regulators from Australia, the EU, Canada, the US, Singapore, China, Japan, and Brazil. The IMDRF has made major steps toward a

Table 21.1 International definitions of medical device.

Country	Definition of Medical Device
United States	An instrument, apparatus, implement, machine, contrivance, implant, in vitro reagent or other similar or related article, including any component part or accessory which is: 1) recognized in the official National Formulary, or United States Pharmacopeia or any supplement of them; 2) intended for use in the diagnosis of disease or other conditions or in the cure, mitigation, treatment or prevention of disease in men or other animals, or, 3) intended to affect the structure or any function of the body of man or other animals, and which does not achieve its primary intended purposes through chemical action within or on the body of man or other animals and which is not dependent upon being metabolized for the achievement of any of its principal intended purposes.
European Union	"Medical Device" means any instrument, apparatus, appliance, material or other article, whether used alone or in combination, including the software necessary for its proper application intended by the manufacturer to be used for human beings for the purpose of: • diagnosis, prevention, monitoring, treatment or alleviation of disease, • diagnosis, monitoring, treatment, alleviation of or compensation for an injury or handicap, investigation, replacement or modification of the anatomy or of a physiological process, control of conception, and which does not achieve its principal intended action in or on the human body by pharmacologic, immunologic or metabolic means, but which may be assisted in its function by such means. "Accessory" means an article which whilst not being a device is intended specifically by its manufacturer to be used together with a device to enable it to be used in accordance with the use of the device intended by the manufacturer of the device. "Device used for in vitro diagnosis" means any device which is a reagent, reagent product, kit, instrument, equipment or system, whether used alone or in combination, intended by the manufacturer to be used in vitro for the examination of samples derived from the human body with a view to providing information on the physiological state, state of health or disease, or congenital abnormality thereof.

(*Continued*)

Table 21.1 (Continued)

Country	Definition of Medical Device
Canada	Any article, instrument, apparatus, or contrivance, including a component, part or accessory thereof, manufactured, sold or represented for use in a) the diagnosis, treatment, mitigation or prevention of a disease, disorder or abnormal physical state, or its symptoms, in human beings or animals, b) restoring, correcting or modifying a body function or the body structure of human beings or animals, c) the diagnosis of pregnancy in human beings or animals, or d) the care of human beings or animals during pregnancy and at and after birth of the offspring, and includes a contraceptive device but does not include a drug.
Australia	Any instrument, apparatus, appliance, material or other article (whether used alone or in combination, and including the software necessary for its proper application) intended by the person under whose name it is to be supplied, to be used for human beings for the purposes of one or more of the following: • diagnosis, prevention, monitoring, treatment or alleviation of disease, • diagnosis, monitoring, treatment, alleviation of or compensation for an injury or handicap, • investigation, replacement or modification of the anatomy or of a physiological process, • control of conception, and does not achieve its principal intended action in or on the human body by pharmacologic, immunologic or metabolic means, but which may be assisted in its function by such means; or an accessory to such an instrument, apparatus, appliance, material or other article.
Japan	Instruments and apparatus which are intended for use in the diagnosis, cure or prevention of diseases in man or animals, or intended to affect the structure or any function of the body of man or other animals, and which are designated by Cabinet Order.

convergence of activities in the area of adverse event reporting, patient registries, software as a medical device, and the implementation of Unique Device Identification (UDI), among other efforts [11,12].

While there are similarities among countries regarding medical device definitions and classifications, the differences exist in the rigor required for device approval. For example, before a medical device is allowed to enter the US market, a reasonable assurance of its safety and effectiveness must be established. Operationally, this goal is accomplished through the US Food and Drug Administration's (FDA) use of regulatory controls and the classification process. Based on the varying levels of potential benefit and risk, devices are classified into one of three regulatory classes. Class I devices (e.g., elastic bandages, surgical gloves, manual surgical instruments) are subject to general controls such as labeling and good manufacturing processes. These devices present minimal potential for harm to the patient and require neither clinical testing nor special controls to establish a reasonable assurance of safety and effectiveness. Class II devices by definition are higher risk (e.g., infusion pumps, diagnostic ultrasound machines) and are subject not only to general controls, but also to special controls such as guidance and standards. Certain of these devices may require additional clinical testing as well. Medical devices with the highest level of risk (e.g., implantable deep brain stimulators, coronary stents, and hip resurfacing systems) are categorized as class III and receive the highest level of scrutiny for regulatory

approval. In addition to general and special controls, these devices require submission of clinical data in support of premarket submissions. In addition, the effectiveness and safety of these devices need to be determined based on valid scientific evidence, defined as "evidence from well controlled investigations, partially controlled studies, studies and objective trials without matched controls, well documented case histories, by qualified experts, and reports of significant human experience from a marketed device. More recent regulatory initiatives introduced a number of new opportunities for shifting scientific evidence generation to the postmarket setting and leveraging real-world evidence for regulatory decision-making" [13–16].

Other countries have similar classifications. In Canada, devices of classes III and IV are subject to in-depth regulatory evaluation, while class II devices require only the manufacturer's declaration of device safety and effectiveness, and class I devices are exempted from premarket submission. In the EU, manufacturers of devices of classes II and III, as well as devices of class I with either a measuring function or sterility requirements, must submit to the regulator (competent authority) (i) a Declaration of Conformity to the appropriate European Commission (EC) Directives, and (ii) details of the conformity assessment procedure followed. In addition, for higher-risk class devices that require design examination or type examination, the corresponding EC Certificates issued by a notified body must also be submitted to the competent authority [17]. In Australia, the risk-based evaluation system also requires that all "registrable" devices must undergo rigorous premarket evaluation before market entry; "listable" devices are less rigorously regulated, but may be evaluated for safety (not efficacy) if there are regulatory concerns about the risk profile of the product. Registrable products include prescription and nonprescription medicines and implantable medical devices (e.g., active implantables and devices of animal origin), while listable goods include vitamins, minerals, herbal medicines, sunscreens, and most medical devices [18]. In Japan, all devices above class II must obtain a central government license for market entry.

Many countries are in the process of implementing new regulatory requirements to strengthen regulatory evidence, while relying more on the data generated by patient registries and other real-world data sources. The common regulatory theme underpinning classification and requirements across regions and countries is the level of risk, despite the differences in how the risk is defined.

In this chapter, we concentrate on implantable devices (US classes II and III) because of their significant public health impact, high risk for adverse events, and uncertainties surrounding the effects of long-term exposure.

Implantable medical devices comprise an important device category in the very heterogeneous world of medical devices. As is true of other devices, implantables share characteristics that distinguish them not only from other devices, but also from regulated drugs. Table 21.2 highlights the characteristics that are further distinguished between medical devices or drugs in general.

Implantable devices, most of which are in class III (highest risk), can be further differentiated. This device category in general has longer product life cycles, although incremental changes do occur. Implantable devices may comprise multiple components (such as a total hip implant) or single components (such as a pacemaker lead). Exposures to such devices are typically chronic (an exception being temporary implantables, such as inferior vena cava filters), with the onset of exposure clearly defined at the time of implantation. Exposure ends at the time of device removal, but may not be clear cut if part of the device remains (e.g., in case of silicone leakage from ruptured breast implants, or components that are absorbed over time such as with biologically based dermal fillers or barrier adhesion devices).

Table 21.2 Characteristics of medical devices as compared to drugs (US regulations).

	Characteristics of medical devices as compared to drugs	
Characteristic	**Device**	**Drug**
Product life cycles	Short to long	Short
Incremental changes	Common	Rare
Equivalence	Technological (class I and II)	Therapeutic (for generics)
Clinical trials required	n = 1 (class III, some II)	n = 2 (NDAs)
Trial reimbursement	Frequent	Rare
Orphan designation	4000	200 000
Assuring manufacturing quality	ISO 9000	Good Manufacturing Practices (cGMP)
Required postmarket studies	Postapproval studies Section 522 studies	Phase IV studies
Product identification	Product codes Unique Device Identifiers	NDCs
Components/ingredients	Single or multiple (may change over time)	Single or multiple
Exposures	Acute, chronic, intermittent, episodic	Similar
Stopping exposure	Simple to complex	Typically, simple
User interface	Patient or clinician	Typically, patient
Users of same product	Single or multiple	Single
How used	Single use/disposable, reusable, implantable, durable	Typically, multiple use
Product effects	Typically localized Acute or chronic	Systemic, Typically, acute
Product hazards	Human factors	Less prominent
	Noncompliance	Same
	Interactions	More prominent
	Malfunctions (manufacturing)	Drug quality problems
	Environmental hazards	Same
	Toxic/allergic	More prominent
	Packaging defects	Same
	Software glitches	
	Poor maintenance	

NDA, New Drug Application; NDC, National Drug Code.

Outcomes associated with implantable devices are affected not only by underlying patient factors and device factors (such as biomaterials), but also, importantly, by user interface (e.g., operator technique, operator experience). Adverse effects of implantable devices are typically localized, but may be more systemic (e.g., secondary to toxic, inflammatory, allergic, autoimmune effects). Additional hazards may be related to human factors (e.g., proper programming of pacemakers) and interactions (e.g., magnetic resonance imaging [MRI] interaction with deep brain stimulator leads). Lastly, malfunctions may derive from several sources, including manufacturing problems, design-induced errors, and anatomic or engineering effects (e.g., repetitive flexing of an implantable cardioverter defibrillator lead causing fracture).

Clinical Problems to Be Addressed by Pharmacoepidemiologic Research

Diffusion to Clinical Practice and Utilization

The introduction and adoption of new medical devices may induce a breakthrough transformation of clinical practice [19]. The rate of diffusion of medical device technology to clinical practice is influenced by many factors, including device complexity, relative advantage when compared with similar available treatments, positions of opinion-leading organizations, healthcare reimbursement decisions, commercial competition, evidence-based guidelines, publication of key research papers, regulatory actions, medical liability issues, and legislative environment [20]. Accordingly, the adoption of different new devices and their dissemination into routine clinical practice often follow different and sometimes unpredictable patterns. These diffusion pathways may contribute considerably to variations in patient outcomes and may have a prominent impact on the frequency of adverse events seen in the usual healthcare settings, when compared to patient experience in premarket clinical trials. An epidemiologic assessment of factors that can potentially influence the adoption of new technology can inform regulatory science (both premarket and postmarket), help in the development of clinical guidelines and policies, and can significantly shape national reimbursement strategies [21].

Evaluating Device Performance in the Real World

When traditional randomized clinical trials (RCTs) for new devices are planned, elite investigators are often selected to participate. For example, in RCTs of devices used in surgery, the operators are typically early adopters, highly skilled, and quick learners, which influences the learning curve. The learning curve can be defined as a constant proportional improvement in performance, such as clinical outcomes of medical procedure, with each doubling of cumulative experience [22]. The rate of learning (the shape of the learning curve) and the interaction with other variables for an average surgeon are very difficult to gauge from RCTs, which include only a small number of selected surgeons. It is only once the approved device enters clinical practice where observational data are collected on patient outcomes for a wide range of surgeons and hospitals that it is possible to estimate the effect of the learning curve on patient outcomes.

The operator's learning curve can be steep, protracted, or anywhere in between, and can have a substantial impact on patient outcomes. Traditionally, the learning curve is studied using the volume–outcome relationship. Some volume–outcome studies have demonstrated that increased surgical volume has an inverse relationship with the likelihood of poor outcomes such as complications, revision surgery, length of stay, and mortality

[23–25]. Other studies have shown a volume threshold for procedures, above which increasing volume is no longer associated with improved outcomes [26,27].

Lastly, other researchers have noted a trimodal institutional learning curve: rapid initial phase, followed by declining success, representing new adopters, and then recovery to an improved steady state [28]. These observations indicate three distinct components of the volume–outcome relationship that can be studied: (i) lifetime experience (operator's volume); (ii) operator's annual volume; and (iii) hospital volume where operators practice. Other factors beyond volume that relate to the learning curve, including the type of procedure (e.g., diagnostic vs. interventional) and practice setting (e.g., institutional teaching status), are also readily available in many observational databases and can be studied. Adequate study of learning curves can establish thresholds for proficiency based on background expertise related to physicians' specialties [29]. This has been the case with the stenting of carotid arteries by operators from varying specialties (e.g., radiologists, cardiologists, and neurosurgeons).

By the nature of their design, RCTs involve select, nonrepresentative patient populations. A number of studies have highlighted the disparities in disease prevalence, progression, and health outcomes of medical device technology in subgroups of the population [30,31]. Premarket medical device trials often lack sufficient representation of important patient populations (women, children, the elderly, racial and ethnic minorities, and others), which hampers the application of the results to real-world populations. Well-designed observational studies can provide more information on device performance in the subpopulations of interest in a real-world setting. The public health utility of observational studies has been increasing, with advances in medical device data capture in medical records, electronic databases, and prospective registries, and the development of innovative analytic tools using observational data [32,33].

The recent increase in US interest in comparative effectiveness, facilitated by the American Recovery and Reinvestment Act of 2009 and subsequent healthcare reform legislation [34], has begun focusing the national attention on building methods and infrastructure for emerging comparative effectiveness research (CER; see Chapter 26). CER, as defined by the US Institute of Medicine (IOM), is "generation and synthesis of evidence that compare the benefits and harms of alternative methods to prevent, diagnose, treat and monitor or improve the delivery of care" to "assist consumers, clinicians, purchasers and policy makers to make informed decisions that will improve health care at both the individual and population levels." CER is vital for the improvement of healthcare quality, better regulatory decisions, and thoughtful guidelines for clinicians and patients [35].

In recent years, several other countries have established agencies to evaluate health technologies and inform healthcare policy decisions [36]. These organizations are different in terms of structures, methods, and processes, but in all of them CER is an effort that aims to address the needs of payers, patients, clinical professionals, and policymakers. Rapid growth of new medical devices, modifications of existing models, and dramatically shorter device life cycles will continue to create demands for dynamic and up-to-date comparative effectiveness and safety efforts [37,38]. Epidemiologic research will play a prominent role in medical device evidence synthesis in the context of health technology evaluation

Long-Term Safety and Effectiveness

Device premarket clinical trials are typically of short duration (e.g., 1–2 years) and generate limited information on long-term safety and effectiveness. Due to the inherent complexity of

implantable devices, it is often difficult to predict fully their long-term safety and effectiveness based solely on preclinical testing and premarket clinical trials. The FDA's postmarket attention is therefore increasingly directed toward ensuring that studies/surveillance of sufficient size and length of follow-up are conducted in the postmarket setting to better illustrate and assess problems occurring long term [39]. Other countries have established national registries of procedures involving implanted medical devices that collect long-term patient outcomes and device performance (e.g., orthopedic registries in Sweden, the UK, Australia, Canada, and other countries) [40–43]. During the past decades the US has also seen a growth in national registries (e.g., National Cardiovascular Data Registry, Kaiser Permanente National Joint Replacement Registry (NJRR), American Joint Replacement Registry (AJRR), and National Breast Implant Registry (NBIR) [44].

Methodologic Problems to Be Addressed by Pharmacoepidemiologic Research

Evidence generation for implantable medical devices requires accounting for unique issues that typically do not arise when evaluating the benefits and risks of drugs. Key issues arise from the interaction of device, operator, and the setting (e.g., hospital, outpatient clinic) in which the device is being used. Furthermore, the device's design, complexity, and specific biomaterial and mechanical characteristics can be as important to outcomes as the device's clinical applications, such as the type of the lesion being treated, the severity of the disease, and concomitant therapy. In the commonly used device epidemiologic research databases, these details are often only partially available, and sometimes are missing.

Challenges in Individual Patient Exposure Assessment

The UDI captures critical device information, such as manufacturer name, brand, version or model, and device group terms. The UDI system has only recently been established, and the UDI is now entering data systems within the US, unlike pharmaceuticals, where the National Drug Code (NDC) Directory has a long history and is broadly used. Consequently, many databases still lack specific device identifiers, making exposure assessments challenging. For example, procedure codes may capture device groups (such as hip implants), but lack specificity to the manufacturer level. Characterization of the sensitivity and specificity of device identifiers found in medical records, clinical registries, or insurance claims databases will be important to understand errors in device exposure. Promoting routine documentation of UDIs in medical records and in other health databases will contribute to a better understanding of device-specific performance [45].

Another challenge associated with medical device epidemiology relates to device complexity: devices are frequently approved or used as *systems* involving several components. Device components are often used in combination with components of the same or different brands. Thus, experience with capturing complete device exposure information is far more complex for devices than it is for drugs. Once completely adopted, such a robust, widely incorporated medical device nomenclature will significantly further safety surveillance and epidemiologic studies of medical devices [46].

Challenges in National Population Exposure Assessment

Incident and prevalent exposure data provide the necessary context for interpretation of the possible relationship between device exposure and outcome. Therefore, strategies to develop

the necessary infrastructure, methodologies, and partnerships will have to include incorporation of UDIs into data systems, including electronic health records, and routine documentation of device use and patient problems associated with that use. Since 2010, under its Medical Device Epidemiology Network (MDEpiNet) Initiative, the FDA has worked with its partners to launch a series of strategic demonstration projects designed to advance and test-drive novel approaches to methods and infrastructure development. To build on this foundational work, in 2012 the FDA launched a strategy to work with all stakeholders to develop a national system for evaluation of medical devices [26–28], leading to the establishment of the National Evaluation System for health Technology (NEST) Coordinating Center and partnering organizations [47].

Currently, in a less-than-ideal national surveillance environment, population exposure data for medical devices have to be derived from a variety of sources including, among others, medical billing claims data, registries, national surveys, nationally representative samples of providers, and market data. In addition, these sources differ in their level of device specificity (e.g., by device group in claims data compared to specific brand in registries). While these sources differ in the level of completeness and reliability, they may complement each other.

Challenges in Comparative Studies

Epidemiologic population-based research relies on nonexperimental (or observational) approaches to develop evidence about the safety and effectiveness of medical products. While there is a recognition of the limitations related to observational data as compared to RCTs [48], we also need to recognize two facts. First, trial design characteristics such as randomization, allocation concealment, and masking/blinding, which are recognized as critical characteristics of high-quality studies, are often difficult to adopt in device trials. Second, observational data frequently complement experimental data rather than replace them. In addition, observational data derived from routine clinical practice are required to determine if the device can be successfully deployed or implanted (learning curve issues) outside of centers and subjects who participate in clinical trials, to quantify risks of adverse events in larger populations, and to assess any modifications to the product. These features are very real issues that affect the safety and effectiveness of medical devices, but are only partially applicable to pharmaceuticals.

Ensuring Comparability of Study Groups

Cohort designs offer the opportunity to create comparable groups of patients exposed to devices of interest. These observational studies should take advantage of statistical adjustments for known and measured confounders, rely on models with few parametric assumptions, and employ methods that demonstrate robustness of findings to deviations from assumptions [4]. For example [49], the "no unmeasured confounder" assumption underlies most epidemiologic studies, and methods are available to characterize the impact of residual confounding (see also Chapter 43). Prospective data collection can minimize the risk of unmeasured confounders through *a priori* determination and collection of such factors. Consecutive patient enrollment provides critical information to inform operator learning behaviors.

We have good tools to address unequal distribution in observed patient characteristics (confounders) that is not severely confounded by indication (see Chapter 43). Most of the adjustment techniques deal with imbalances in confounding factors between the study groups. In addition to addressing known imbalances, one can also theoretically remove the bias related to unobserved prognostic factors if the unobserved factors are highly correlated with the measured prognostic factors [50]. Of course,

this is an assumption which cannot be tested, but the size of the unmeasured confounders required to change the results can be quantified and reported. Additionally, including a "falsification outcome" may help diagnose residual confounding. For example, implantation of a coronary stent should not reduce in-hospital mortality.

Several analytic methods are available to deal with selection factors and confounding. These methods involve stratification, regression models, or a combination of the two using a propensity score [51,52]. Each approach relies on a set of assumptions, which may or may not be appropriate in the particular setting. When it is felt that there is unmeasured confounding present beyond that accounted for in the collected information, another potential approach is using instrumental variable-based methods, if a valid instrument can be found (see Chapter 43) [53–55].

Addressing Issues of Sample Size, Real-World Performance, and Long-Term Outcomes

As mentioned previously, premarket clinical trials are powered first and foremost for efficacy outcomes. Powering these trials based on less common or rare but serious side effects is not feasible in most instances (see Chapter 4). As is true for drugs, clinical trials of devices, because of small sample size and participant selection, often lack generalizability, defined as the extension of research findings and conclusions from a study conducted on a target population to the population at large.

Systematic reviews with meta-analyses (see Chapter 36) are observational studies that attempt to capitalize on the detailed data collection within the studies that are the subject of the review. Systematic reviews are one mechanism to address the small study problems of clinical trials. Systematic reviews with meta-analysis are based on the premise that most of the individual clinical trials of devices and surgery carefully record relevant clinical outcomes and offer a great opportunity to conduct evidence appraisal and synthesis when a reasonable number of studies are available.

Well-designed cohort studies are often large and involve consecutive patient enrollment and data collection that is comprehensive. They are the best-suited tools to evaluate the safety and effectiveness of devices in the real-world populations and are based on solid scientific knowledge accumulated about the devices.

With the explosion of electronic data acquisition and exchange technologies, computing resources, and linkability across data sources, newer statistical methods that exploit high-dimensional data (e.g., the number of features can exceed the number of observations) provide more opportunities for medical device epidemiology researchers. With higher-dimensional data, additional assumptions are required to prevent overfitting or to ensure that a unique solution exists. These additional assumptions are implemented using "regularization methods" that effectively penalize the inclusion of many predictors. One group of regularization methods assumes sparseness, that a small number of variables represent the underlying data structure. Approaches such as LASSO (least absolute shrinkage and selection operator) [56], sparse additive models [57], or sparse prior distributions for regression coefficients are examples in this group. For instance, a weakly informative default prior distribution for regression coefficients that centers the coefficients at zero but permits nonzero coefficients through the use of heavy tails falls into this category [58]. Another group of methods combines a large number of models in order to obtain a stronger model by averaging across models. Bagging (e.g., random forests), boosting, and stacking (e.g., Super Learner) [59,60] are algorithms that fall into this category. The intuition for these methods exploits the belief that more than one model may "fit" the data, so that averaging across multiple models may lead to better conclusions. With large observational studies, one

can evaluate relevant subgroup effects as well as rare safety and effectiveness endpoints that cannot be captured by RCTs.

Currently Available Solutions

Passive Surveillance

Once a device has received marketing approval, manufacturers must follow Good Manufacturing Practices and monitor the safety of their products, including keeping a complaint file and forwarding reports of adverse events to the regulatory authorities. For example, in the US manufacturers are required to submit reports of device-related deaths, serious injuries, and malfunctions to the FDA. Healthcare providers and consumers submit reports voluntarily through MedWatch [61]. These reports, obtained through passive surveillance (see also Chapter 10), are housed in the Manufacturer and User Facility Device Experience (MAUDE) database, established in 1996. As of May 2018, MAUDE contained more than 6 million reports and received approximately 80 000–110 000 reports per month. The vast majority of reports are from manufacturers, with a small percentage from user facilities, voluntary sources, and importers [62].

Regulatory agencies, including those participating in IMDRF, have the authority to monitor the safety of devices by reviewing adverse event reports from users, sponsors, other available data sources, and the scientific literature [9]. In assessing these reports, in addition to specific patient characteristics, regulatory bodies consider the following factors: failure potential resulting from design or manufacturing problems; use error potential from improper device assembly, misreading instructions, or improper surgical technique; incorrect clinical use; and inadequate instructions for use. Possible packaging errors, support system failure, adverse environmental factors, maintenance error, adverse device interactions such as electromagnetic interference, or toxic/idiosyncratic reactions are also considered [63]. Some manufacturers conduct failure analyses on retained or returned products (including implantables) in the event of a reported device problem.

To enhance the usefulness of reported data, statistical tools are used to assist in detecting new signals [64,65] (see Chapter 27). Bayesian and other data-mining methods are used to estimate the relative frequency of specific adverse event–device combinations, as compared to the frequency of the event with all other devices (in the same group) in the database. To aid in this effort, and reporting and signal detection in general, an extensive hierarchical vocabulary for adverse device outcomes (e.g., high impedance in pacemakers) also has been developed [66].

Passive reporting systems have noticeable weaknesses, including (i) data may be incomplete or inaccurate and are typically not independently verified; (ii) data may reflect reporting biases driven by event severity or uniqueness or publicity and litigation; (iii) causality cannot be inferred from any individual report (see Chapter 29); and (iv) events are generally underreported and this, in combination with a lack of denominator (exposure) data, precludes the determination of event incidence or prevalence. The latter point is particularly important for implantable devices, since reports may capture device-associated events (such as thrombosis, infection, stroke, revision, or replacement) for which estimation of incidence is of paramount importance.

Enhanced Surveillance

To enhance the understanding of clinical issues for medical devices, the Medical Product Safety Network (MedSun) was established to provide national medical device surveillance based on a subset of user facilities in the US [67,68]. MedSun currently includes approximately 350 hospitals nationwide. Through its ongoing bidirectional interactions, including educational

fora, problem-solving and posting of reports, and targeted surveys, this enhanced surveillance network provides more timely amplification of potential safety signals.

Reports received through passive and enhanced systems have resulted in significant public health notifications, including those related to injuries (i) from transvaginal placement of surgical mesh [69]; (ii) associated with use of recombinant bone morphogenetic protein in cervical spine fusion [70]; and (iii) from MRI-induced interactions in patients with implanted neurologic stimulators [71]. Reports received have also spurred the development of significant observational studies elucidating risk factors for meningitis associated with cochlear implants [72], and hemorrhagic complications associated with the use of hemostasis devices, including one high-risk device [73,74].

Signal Detection/Outlier Identification Using a Variety of Data Sources and Methods

Cumulative Sum of Outcomes (CUSUM) Methodology

CUSUM is a sequential statistical analysis method with graphic application that allows online identification of changing rates of device failure or surgical complications. For example, a likelihood-based scoring method of calculation of CUSUM is used by the Scottish Orthopedic registry, described as part of the International Consortium of Orthopedics (ICOR) series [75]. Outlier device/surgeon status is identified at a point set in advance and is named the prediction limit. Setting the statistical thresholds at agreed levels helps balance the risk of failure against that of false alerts. Setting a prediction limit is not an exact science, and changing the statistical criteria will change outlier identification. Hence, the results should be interpreted as a potential signal that does not yet mean a poorly performing implant or device in general. One of the advantages of the CUSUM method is the ability to track both surgeons and the introduction of the new device to evaluate the surgeon/surgical team/device "combination." For example, CUSUM allows tracking of outcomes of high-volume surgeons with changes in practice over time, and determination of periods of outlier performance that were linked with the introduction of new implants [76].

Cumulative Revision Rate over Time

Depicting an unadjusted cumulative revision rate over time after implantation of the device is a simple but powerful technique allowing identification of outlier implants when compared to the overall or group average. The method also allows calculation of accompanying 95% confidence intervals using various methods. For example, the Australian orthopedic registry process identified the ASR artificial hip as an outlier device using this method followed by Cox proportional-hazards modeling to calculate the hazard ratios and adjust for age and sex, in order to conduct a comparative analysis of revision rate between groups [77].

Funnel Plots

Another graphic approach is funnel plots, which are based on the application of Shewhart charts in medicine [78]. Through the use of funnel plots such as that shown in Figure 21.1, it is possible to compare the observed events (e.g., specific device failure) against the national average within the population [79]. For instance, devices falling above the 95% or 99.8% control limits (set in advance) for risk are deemed outliers. For various true event rates around the gold-standard rate, the funnel plot shows which devices can be called outliers. Like several other methods, this approach is heavily dependent on assumptions about equivalent underlying risk. If there is heterogeneity in the underlying risk (as might occur with differing standards of care across sites, differing expertise of operators, or differing disease progression among patients between sites), then departures outside the limits may be more

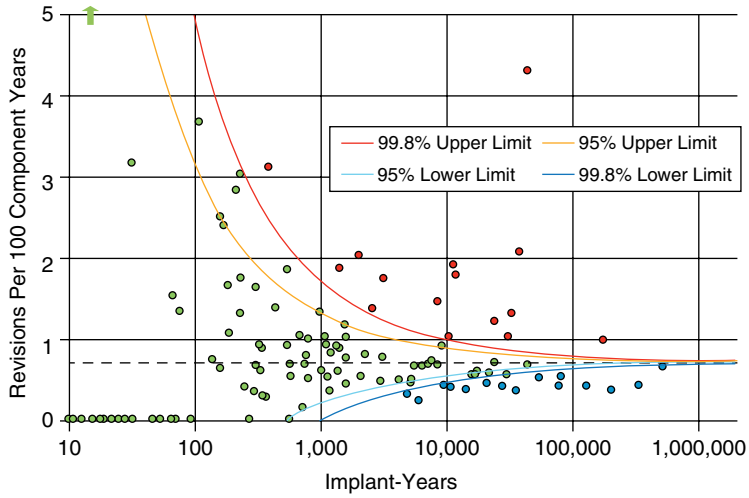

Figure 21.1 Hypothetical funnel plot. In this hypothetical funnel plot from the Joint Replacement Registry, each circle represents one device. The X axis denotes the number of devices combined with the number of years followed up for a particular device tracked by the registry. The Y axis represents the "true" event rate (unobserved). Devices falling above 95% or 99.8% control limits (set in advance) for risk are deemed outliers. For various "true" event rates around the gold-standard rate, the funnel plot shows which devices can be called outliers.

reflective of issues with the assumptions broadly, than with issues in the performance of those points outside the limits [12].

Automated Surveillance

In-hospital safety signals (such as myocardial infarction) for recently introduced interventional cardiovascular devices (such as drug-eluting coronary stents) are possible to explore using an automated computerized safety surveillance system, DELTA (Data Extraction and Longitudinal Trend Analysis), which was designed to support flexible safety surveillance applicable to a broad range of medical devices [80,81]. The system is compatible with a broad array of potential data sources and supports a variety of statistical methods, allowing for both unadjusted and risk-adjusted safety monitoring for prospective and retrospective analyses.

Data Linkages for Long-Term Follow-Up

Linking registry data to other data sources is often necessary to capture longitudinal data [82] and yield an enriched data source for regulatory purposes, clinical decision-making, and reimbursement purposes. In addition, linkage is often used for validation processes of patient registries. Complementary data may include but are not limited to other registries, national death records, electronic medical records, or longitudinal administrative medical claims/discharge databases.

There are two broad methods of data linkage:

- ***Deterministic (direct)***. Deterministic linkage algorithms aim to determine if record pairs agree or disagree on the available set of identifiers and when there is agreement on a given identifier.
- ***Probabilistic (indirect)***. Probabilistic approaches to link large datasets aim to use limited identifiers applied methodologically in a way that maximizes the probability that a data field agrees given that a record pair matches, minimizes the probability that a data field agrees given that a record pair is unmatched, and provides greater precision from nonuniformly distributed fields [83]. It is a method that enables the combination of record information in different datasets to form a new linked dataset. The probabilistic link uses several identifiers, in combination, to identify and evaluate links. Probabilistic binding is usually used when a unique identifier is not available or is of insufficient quality

(Australian Government, National Statistical Service, Data Linking) [12].

Both matching approaches have their strengths and their limitations. It is generally recommended to evaluate the probability of successful matching as a rule, and then employ a combination of deterministic and probabilistic methods that optimizes the combination of completeness of the population and accuracy of matching [12].

Registries and Strategically Coordinated Registry Networks

Patient registries (see also Chapter 16) constitute a great infrastructure for conducting large-scale medical device studies. A pragmatic and adequate medical device registry is defined in the International Medical Device Regulators Forum (IMDRF) report [11] and the subsequent *Lancet* publications [84] as an

> Organized system with a primary aim to improve the quality of patient care that continuously collects relevant data, evaluates meaningful outcomes and comprehensively covers the population defined by exposure to particular device(s) at a reasonably generalizable scale (e.g. international, national, regional, and health system).

One important value that registries add is their ability to collect data on large numbers of patients and clinical settings and, through linkages (see earlier discussion), on outcomes over time. Device registries have been historically designed to address issues related to clinical performance and quality improvements in healthcare. They have been more recently involved in comparative research, assessing technology for reimbursement, and monitoring postmarket device performance. Depending on the questions to be addressed, registries can be designed to capture data on exposures and/or conditions of interest, type of healthcare service delivered (e.g., surgical treatment or diagnostic procedure), or outcome of interest (e.g., adverse event, disorder, or disease). In the absence of a UDI code in many healthcare data sources, the added value of registries includes capturing brand/model-specific information crucial for signal identification and comparative effectiveness/safety studies. The complexity and scientific rigor of a registry can vary from those designed to evaluate the quality of healthcare delivered, those specifically established to study the sustained effectiveness and safety of a specific procedure, and those designed to systematically collect long-term data on many different types of treatment, including risk factors, clinical events, and outcomes in a defined population. Once the framework of a registry is in place, studies with various designs can be performed using registry data (cohort, case–cohort, case–control, cross-sectional, quasi-experimental), both mandated and discretionary.

To build on the concept put forward in the 2015 MDEpiNet National Medical Device Registry Task Force Report, the medical device ecosystem (including industry, regulators, the clinical community, public health agencies, and academia) increased efforts to foster the development of strategically coordinated registry networks (CRNs) as a valuable tool for capturing the utilization of devices, identifying early signals, and studying the postmarket performance of medical technology. The CRN is an analytic paradigm with an emphasis on the development of strategically partnered electronic health information systems that support both the implementation of structured device identifiers, core minimum data elements, and definitions within registries, and the ability to share complementary data across a number of information systems [85].

In the past seven years, the MDEpiNet Science and Infrastructure Center has implemented more than 14 CRNs (see the examples in Table 21.3). The existing CRNs are used to monitor the performance of high-risk devices,

Table 21.3 Selected examples of strategically coordinated registry networks (CRN) in the US and their international registry consortia.

CRN Name – US	Examples of medical devices captured	US registry members	Linkage to other data sources	International registry consortium
Vascular Implants and Interventions Surveillance and Outcomes Network (VISION)	Carotid artery stents Abdominal aortic aneurysm (AAA) Peripheral stents	Vascular Quality Initiative (VQI)	Administrative claims data	International Consortium of Vascular Registries (ICVR)
Orthopedic Devices CRN (Ortho-CRN)	Hip and knee arthroplasty devices	AJRR – American Joint Replacement Registry Kaiser Permanente NJRR – National Joint Replacement Registry MARCQI – Michigan Arthroplasty Registry Collaborative Quality Initiative Health East Arthroplasty Registry Virginia Arthroplasty Registry FORCE TJR – Function and Outcome Research for Comparative Effectiveness in Total Joint Replacement Registry	Administrative claims data	International Consortium of Orthopedic Registries (ICOR)
National Breast Implants Registry (NBIR) CRN	Breast Implants (silicone, saline)	NBIR – National Breast Implants Registry PROFILE – Registry for Breast Implants and Anaplastic Large Cell Lymphoma Outcomes, Epidemiology and Etiology	Administrative claims data	International Collaboration of Breast Registry Activities (ICOBRA)

such as the transcatheter aortic valve replacement (TAVR) device (designed to repair a narrowed aortic valve via a transcatheter approach) in the national Transcatheter Valve Therapy (TVT) registry; endovascular repair devices for abdominal aortic aneurism via the VISION initiative; and an orthopedic device (OrthoCRN) and other devices within their respective CRNs [59].

In other countries, national registries of procedures involving implanted medical devices have significantly augmented their national surveillance efforts [55–58]. Experience from these international registries used for surveillance and observational research provided valuable insights into the development of CRNs and served as a solid platform for building a novel international surveillance infrastructure for regulatory evidence synthesis (e.g., ICOR and ICVR; see Table 21.3).

Mandated Postmarket Studies

The FDA has a unique statutory authority to mandate postmarket studies, either as a condition of approval or "for cause" later in the postmarket period. For class III devices, the FDA may utilize its premarket approval authority to order studies as a condition of approval. A major regulatory/public health challenge that the FDA is facing is to strike an appropriate balance between pre- and postmarket data collection, such that only data essential to premarket clearance/approval be submitted to ensure reasonable safety and effectiveness, while collecting other data best suited for collection in the postmarket period (such as longitudinal outcomes). Appropriate postmarket questions that can be answered in a mandated postapproval study include long-term safety and effectiveness, real-world experience of the device as it enters broader user populations (clinicians and patients), effectiveness of training programs and learning curve effect, and device performance in certain subgroups of patients not well studied in the premarket clinical trials. Depending on the nature of the postmarket questions, a variety of study designs and approaches can be employed. Designing scientifically sound but practical studies and achieving adequate patient and physician recruitment rates through adequate minimization of loss to follow-up can be particularly challenging for implantable device studies.

In addition, Section 522 of the US Food and Drug Administration Modernization Act (FDAMA) and added regulation (21CFR 822) allows the FDA to require a postmarket surveillance study for class II and III devices (i) that are intended to be implanted in the human body for longer than a year; (ii) that are life sustaining or life supporting (and used outside of the user facility); (iii) whose failure would reasonably be likely to have serious health consequences; or (iv) that are anticipated to have significant use in the pediatric population. Possible study designs vary from detailed review of complaint history and the literature, nonclinical testing, use of registries, observational study designs, and randomized clinical trials [86]. These studies may be ordered at the time of device clearance or approval, or "for cause" later in the postmarket period.

In a series of FDA public workshops held in 2012, the FDA unveiled its National Medical Device Postmarket Surveillance Plan. In 2014, the National Medical Device Postmarket Surveillance System Planning Board and the National Medical Device Registries Task Force were established to guide implementation of this national plan, ultimately leading to the establishment of NEST. The importance of these efforts is that other sources of data, such as national registries, electronic health records, and administrative claims data, are increasingly being used in the conduct of mandated studies in lieu of traditional, one-off studies that require *de novo* data collection.

Administrative Claims Data

Claims and administrative databases have been used to evaluate devices and procedures in multiple clinical areas (see also Chapter 12). The scope

of research ranges from comparative effectiveness to longitudinal assessment of safety events. Results of these studies provide critical information and evidence for physicians and patients to facilitate informed clinical decision-making.

Because administrative data often cover a large and representative population, studies based on these data can provide robust estimates and overviews of population trends in device and procedure use, although not specific to the brand level. Studies based on national and regional databases investigating population use of a novel device or surgical technique reflect the real-world adoption of devices after commercialization. These trends in device use, often assessed with trends in population disease status [87] or healthcare costs [88], can provide a comprehensive evaluation of the dissemination of new technologies and associated practice or population disease change. Furthermore, the representativeness and generalizability of administrative databases make them good candidates for assessing policy-related changes, such as practice change following regulatory activities [89].

Administrative data have also been utilized in the comparative effectiveness assessment of devices and procedures in surgical care. A variety of new devices and techniques have been increasingly adopted in surgical cancer care, including minimally invasive and robot-assisted surgeries and other treatment modalities. National and regional administrative databases and linked databases of administrative data and cancer registries are useful data sources for this type of research. The scope of these studies range from short-term effectiveness, including postoperative complications, length of stay, and readmissions, to long-term safety and effectiveness, such as healthcare costs and patient survival [90]. Apart from the comparison between surgical approaches, the comparative effectiveness of cancer surgery and other treatment modalities such as radiation therapy [91] and stent implantation [92] can also be assessed using these databases.

The usefulness of comparative effectiveness research utilizing administrative data is not limited to cancer surgical care. This type of study is useful in assessing real-world outcomes for certain devices. Administrative data can provide a unique opportunity to evaluate devices such as surgical mesh for pelvic organ prolapse [93] and implants used in hysteroscopic sterilization [94].

Some national and regional databases not only provide representative cross-section estimates, they also have the ability to follow patients up longitudinally and across facilities. For these reasons, administrative data can be used to study safety patterns of permanently implanted devices over the long term [95]. Moreover, some administrative bases record the providers that performed the procedures, making it possible to evaluate provider-level (hospital-level or surgeon-level) effects on patient and device outcomes [96].

The use of administrative databases for epidemiologic research has the strengths of studying large numbers of patients with diverse characteristics and a wide variety of clinical practices, as well as the inclusion of longitudinal data from the continuum of clinical care, and a good representation of vulnerable populations. All these features lead to increased external validity (generalizability) [97] (see Part IIIb). The large number of diverse patients presents opportunities to study treatment effect heterogeneity and to advance methods such as high-dimensional propensity scores and instrumental variables (see also Chapter 43). With regard to medical devices, the limitations of administrative databases include the lack of UDIs, potential inaccuracy of coding of diagnosis, and missing data on laterality and type of revision procedure performed. The lack of clinical information in the administrative billing data can be supplemented by linking the billing data to data from registries or other clinically rich data from other data sources. The FDA has used these data to estimate patient characteristics and in-hospital

mortality rates associated with aortic valve replacements and pacemaker implantation [98,99]. Other researchers have used the data to perform studies on artificial hips [100–104].

Methods for Implantable Device Outcome Evaluation

A methodologic framework for implantable device epidemiology and surveillance involves understanding factors affecting the decision to implant the device, identifying the comparison group(s), and estimating the safety and effectiveness of the device compared to the alternative strategies. In the context of the multiple clinical issues and methodologic challenges noted previously, we believe that a key issue in addressing these goals relates to the multiple sources of variability that exist with implantable devices. These sources relate to systematic and random variations due to the patient, to the surgeon/operator and the center, and to the device itself.

Sources of Variation

Patient Variation (X)

Measurable patient characteristics may predict what type of device is received as well as clinical and device outcomes. For instance, in the case of total hip replacements [104], it has been reported that advanced age, co-morbidities such as heart failure and diabetes, and nonelective admissions were associated with inferior patient outcomes. However, advanced age is also associated with increased use of metal-on-polyethylene hip systems compared to hip systems constructed from other bearing surfaces [103]. The primary reason for the device implant also drives the clinical endpoints. For example, a left-ventricular assist device could be implanted as a "bridge-to-transplant" or as "destination" therapy. In the former, the implant is meant as a relatively short-term solution, whereas for the latter, the implant is meant as a permanent therapy.

Surgeon/Operator and Center Variation (Z)

Surgeon and surgical center skills may have a large impact on the type of hip replacement surgery and clinical outcomes. Several features of the surgical procedure in which the device is implanted vary. For example, orthopedic surgeons may opt to use tissue-sparing surgery when implanting a total hip replacement system. This technique, which differs from the standard lateral direct Hardinge approach, involves smaller incisions and less tissue disruption, which are associated with less pain, reduced blood loss, and shorter hospital stays. However, complications can increase if the surgeon is still early in his/her learning curve [105]. The surgical volume of the surgeon and of the center relate to procedural success. Other features of the surgery can affect the clinical success of the procedure. For example, computer-assisted navigation can increase the accuracy of the positioning of the device.

Device Variation (D)

Several measurable characteristics of devices have been shown to be predictive of device use and outcome. Returning to hip replacement systems, the type of bearing surface is related to revision rates. In particular, hard femoral head and hard cups, such as metal-on-metal or ceramic-on-ceramic, result in lower wear rates. Additionally, large-diameter femoral head size may result in lower dislocation rates. The process of implantation fixation to the bone also results in variations in clinical outcomes. Hip systems can be implanted with bone cement that helps position the implant within the bone, or the systems may have a porous surface that permits bone to grow into its surface.

Understanding the Treatment Assignment Mechanism

A key principle of utilizing observational data for safety surveillance is to view observational studies as approximations to randomized studies.

As such, the first step involves determining how devices are "assigned" to patients. In an RCT the investigator has control over the assignment, whereas in the surveillance setting this mechanism must be estimated. A statistical model uses baseline patient and surgeon characteristics to predict who gets which device. The type of statistical model and type of predictors will depend on the number of alternative competing therapies. For example, if the competing therapy is not a device, patient and surgeon characteristics must be commonly identified predictors. In comparing multiple devices with multiple nondevices, treatment and surgeon characteristics within each type of treatment strategy can vary.

In the case of two different devices, a natural choice to model device selection is a logistic regression that accounts for surgeon-specific random effects. With more than two devices, extensions using multinomial or nested logit models can be estimated [106]. In the latter case, device characteristics can be included to differentiate among devices within a similar class. For example, the treatment options may include the use of a number of different hard-on-hard total hip replacement systems compared to other types of hip replacement systems, such as metal-on-polyethylene. Center-specific effects can be included through the incorporation of an additional variance component. An understanding of the factors associated with device use will identify comparable patients in terms of measurable characteristics for estimating safety and effectiveness for particular cohorts of patients.

Estimating Comparative Effectiveness and Safety

Estimation of the treatment assignment algorithm provides a numeric score for each patient (i.e., the propensity score, or probability of getting the particular device versus the alternative device), and this may be used to validate assumptions required to estimate causal effects. These assumptions relate to unmeasured confounding, positivity of device assignments, and additive device effects. The positivity assumption [107] asserts that an individual subject is eligible to receive all the devices under study. For example, if a device comes in different sizes, some subjects may never receive a particular type of device, as the device is simply too big. In this situation, the positivity condition is violated and the researcher would need to eliminate the subject from the comparison as a causal effect, as the subject is not defined or stratified by device size. The additive treatment effect assumes that the outcome for a subject implanted with device A differs by a constant amount from the outcome had the subject been implanted with device B, and effectively implies no treatment modification by patient subgroups. The definition of a favorable device effect if the device effect is *not* additive requires stating the effect in different patient subgroups.

Semi-parametric estimators, such as matching estimators, weighted estimators, or double-robust estimators that augment weighted estimators with regression estimators [108], can then be used to make inferences. Importantly, with high-dimensional data, machine learning algorithms modified to adhere to assumptions for causal inference can often provide more robust conclusions than standard propensity-score approaches. For example, targeted maximum likelihood estimation is an approach that focuses on estimating a specific parameter rather than the entire likelihood and boasts many desirable statistical properties [109].

Simultaneously Combining All Available Evidence

Assume that rather than a single study, many studies involving a device are available. These studies may reflect different populations, such as registries from different countries or from similar patient populations, or different comparison groups. Novel methods involve assembling all

the available evidence in order to reduce uncertainty about the performance of any particular device. To do this requires assuming that particular relationships among the devices exist, although uncertainty about the relevance of these relationships remains. These uncertainties may relate to how the performance characteristics of different devices relate to patient outcomes; how devices that have been compared in other studies on *similar* outcomes but not to each other are related; and how devices that have been compared in other studies on *different* outcomes but not to each other are related. The appendix to this chapter provides details regarding how to combine the data.

The Future

Device Epidemiology and Digital Health

The broad scope of digital health includes categories such as mobile health (mHealth), health information technology (IT), wearable devices, telehealth and telemedicine, and personalized medicine. These technologies open new opportunities for patients and consumers to better manage and track their health and wellness through greater access to information. The interface of these devices and healthcare will continue to offer new opportunities for medical device epidemiology to lead evidence generation, synthesis, and appraisal.

Translational Epidemiology

Epidemiologic data have an enormous potential to help guide basic science investigations (e.g., guiding the development of biomarkers for detection of patient risks for development of adverse responses to implantable devices). In addition, when combined with preclinical and other data sources (e.g., genetic, explant retrieval), epidemiologic findings could significantly advance evidence generation. In addition, epidemiology could leverage preexisting implant-related data from observational data sources, in individuals with and without implant-related adverse outcomes, to improve our understanding of implant safety and effectiveness. These types of interdisciplinary application of epidemiology could lead to more effective identification of candidate biomarkers predictive of certain implant-related responses (both local and systemic) in different patient subgroups. For instance, *in silico* approaches could combine epidemiologic and other data sources to help guide the development of biomarkers.

Device Epidemiology and Evidence-Informed Practice and Policy

Medical device epidemiology will continue to draw from advances in electronic health records, electronic data capture, standard taxonomy, global patient identifiers, integrated security, and privacy services. Thus, contemporary device epidemiology will be able to mobilize the advances of translational health research sciences through new methods that combine basic science and clinical data, leading to evidence about the choices of best available treatment targeted to specific populations. In doing so, the epidemiology will have to balance the strengths and limitations of systematic review, quantitative, interpretive, narrative, sequenced, and other synthesis approaches within the context of specific public health policy and healthcare settings,

Device Epidemiology and Regulatory Science

MDEpiNet is a global public–private partnership that seeks to advance the collection and use of real-world data to improve patient outcomes. It brings together stakeholders from across the health ecosystem to develop and improve real-world data infrastructure, and carry out studies to better understand how devices perform in

the real world. This international effort is uniquely focused on medical devices and it comes at a particularly opportune time, when many recent developments, ranging from the creation and expansion of device registries to significant strides toward the universal adoption of electronic health records, provide new and promising opportunities for the epidemiologic study of medical devices. The intent is to have a comprehensive, up-to-date risk–benefit profile of specific medical devices at any point in their life cycle, so that optimally informed decisions can be made and provide more useful information to practitioners, patients, and industry. Evolution of public–private partnerships including NEST in the US will drive collaborative knowledge-sharing between members of the ecosystem. Important challenges for MDEpiNet will be to develop and test novel methods for the synthesis and systematic evaluation of all available evidence relevant to a device's risk–benefit profile, including premarket bench, animal, and clinical studies; postmarket surveillance studies; and adverse event reports to advance regulatory needs.

Device Epidemiology and International Infrastructure

The accelerating pace of emerging medical technologies worldwide will continue, and the information science applications are expected to further shape IT-based healthcare, dealing with new demands for storage, transmission, management, and analysis of patient data. The future global impact of epidemiology on our understanding of implantable devices will depend on technological and policy solutions for international collaboration to achieve consistency between global data sources, regulations, and methodologic approaches for various medical device implant applications.

Collaborative research efforts can particularly help to fill a major gap via international consortia. Examples of such collaborative effort are ICOR [110], ICVR [111], and the International Coalition of Breast Registries Associations (I-COBRA) [112]. The development of an international infrastructure creates opportunities for novel method developments for epidemiologic studies. The methods for harmonization, sharing, and combining data are not well developed and require innovative approaches. Such international collaborations, coupled with increasing regulatory convergence driven by IMDRF, present an unprecedented opportunity for influencing clinical and policy decision-making, with enormous public health implications.

Appendix: Simultaneously Combining All Available Evidence

Assume that Y_{sjkm} denotes the m^{th} outcome associated with the k^{th} device for the j^{th} group of patients within the s^{th} study. A model that reflects heterogeneity among the outcomes assumes that the expected or average outcome, denoted $E(Y_{sjkm})$, can be modeled linearly using a link function g(.), generically as

$$g\left(E\left(Y_{sjkm}\right)\right) = \alpha_m + \beta_k + \gamma_{mk} + a_s + b_{j(s)} + c_{k(s)} + d_{m(s)}$$

where α_m = average for m^{th} outcome; β_k = effect of k^{th} device in the average study and for the average outcome; γ_{mk} = deviation from the average of device *k* on outcome *m*; a_s = main effect of s^{th} study; $b_{j(s)}$ = study-specific effect of j^{th} group within s^{th} study; $c_{k(s)}$ = study-specific effect of treatment *k* within s^{th} study; and $d_{m(s)}$ = study-specific effect of outcome *m* within the s^{th} study.

The observed outcomes are summaries, e.g., the average failure rate, rather than at the patient level, although it is a simple modification to include patient-level data. The model assumes that the observed outcomes are connected, in that any observed outcome defined

by (s,j,k,m) is related to or "reached" from any other outcome defined by (s*,j*,k*,m*). This assumption permits borrowing of information from like-devices studies to better estimate the performance of particular devices. Heterogeneity among outcomes is permitted by assuming that γ_{mk}, a_s, $b_{j(s)}$, $c_{k(s)}$, and $d_{m(s)}$ are random effects. Fixed characteristics of the device, D, and of the patient groups, X, can be easily included in the model. Expected differences in outcomes for one device compared to another device averaged over all patient groups can be obtained as functions of the parameters in the model.

Research on the Effects of Medications in Pregnancy and in Children

Daniel B. Horton[1], Sonia Hernandez-Diaz[2], Tamar Lasky[3], and Krista F. Huybrechts[4]

[1] *Department of Pediatrics, Rutgers Robert Wood Johnson Medical School, Rutgers Center for Pharmacoepidemiology and Treatment Science, New Brunswick, NJ, USA*
[2] *Department of Epidemiology, Harvard T.H. Chan School of Public Health, Boston, MA, USA*
[3] *Office of Biostatistics and Epidemiology, Center for Biologics Evaluation and Research, US Food and Drug Administration, Silver Spring, MD, USA*
[4] *Division of Pharmacoepidemiology and Pharmacoeconomics, Department of Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston, MA, USA*

For ethical and other reasons, pregnant women and children have traditionally been excluded from premarketing clinical trials, under the assumption that findings of efficacy and safety can be extrapolated from nonpregnant adult populations. These well-intentioned protections from the risks and burdens of trials have paradoxically left pregnant women and children more susceptible to the potential risks of drugs used in everyday practice, frequently off-label and without high-quality evidence of efficacy, effectiveness, or safety. The field of pharmacoepidemiology has an important role in supplying critical missing evidence about the beneficial and harmful effects of drugs, both old and new, in pregnant women and children. However, pharmacoepidemiologic research in these populations presents numerous methodologic and practical challenges. Rapid and dramatic changes in growth, development, and physiology during pregnancy, infancy, and childhood can alter drugs' pharmacokinetics, pharmacodynamics, and, thus, efficacy and safety. The specific biology and varying incidence of clinical conditions that affect each stage of pregnancy and childhood also require consideration of separate subgroups. Given the infrequent use of most specific medications in these populations and the rarity of many serious outcomes of interest, problems arise related to sample size. In addition to random error, observational studies in pregnant women and children are subject to systematic errors – some errors that are shared with any pharmacoepidemiologic study and others that are fairly specific to these populations.

Case–control studies can efficiently estimate associations, provided the drugs are relatively commonly used. However, this design faces the challenge of retrospective data collection, selection of valid controls, and samples restricted to motivated volunteers. Exposed pregnancy registries can more efficiently oversample exposed pregnancies for uncommonly used drugs, collect drug utilization before outcomes are known, and estimate absolute risks rather than associations

The authors wish to thank Bruce Carleton, PharmD, Susan dosReis, PhD, Alan C. Kinlaw, PhD, Andrea V. Margulis, MD, ScD, Jonathan Slaughter, MD, MPH, and Rachel E. Sobel, DrPH, for their valuable input and suggestions. This book chapter reflects the views of the authors and should not be construed to represent the FDA's views or policies.

Pharmacoepidemiology, Sixth Edition. Edited by Brian L. Strom, Stephen E. Kimmel and Sean Hennessy.

alone. However, this design still includes populations of volunteers and requires long, costly study periods to recruit and follow sufficient participants. Moreover, case–control designs are restricted to a few outcomes, and pregnancy registries are restricted to a few drugs. Administrative healthcare or clinical databases can provide large study samples to address these difficulties, and pooling efforts across data sources is increasingly common. However, for research in pregnant and pediatric populations, automated databases may lack important dates (for instance, of conception or birth) and other key clinical information (such as children's weight). For other limitations of automated databases, see Chapters 11–14.

Various forms of bias can occur in observational research in pregnant and pediatric populations. Confounding may involve unmeasured factors (e.g., health-seeking behaviors related to prenatal screening or parenting style, environmental exposures, income, genetics) and long latencies between maternal or early life exposures and long-term pediatric outcomes. Moreover, when selecting the study population of pregnant women or children, sources of bias may include depletion of susceptibles (e.g., lethal malformation resulting in undocumented pregnancy losses), left truncation (e.g., enrollment of pregnancies after prenatal screening), right censoring (e.g., exclusion of terminations), and selective inclusion, exclusion, or dropout of vulnerable populations (e.g., children in foster care). Variability in the duration of pregnancy due to health problems may introduce spurious associations due to differential opportunities for drug exposure (e.g., acute drug exposure in the third trimester and a lower risk of preterm delivery) and competing risks (e.g., an increase in spontaneous abortions results in a lower risk of preeclampsia). Importantly, both pregnant and pediatric populations are marked by important genetic and environmental interdependencies: the pregnant woman and the embryo, fetus, and infant; children and their families. These intimate relationships have critical implications for health; information about family members can be instrumental to measuring certain exposures (e.g., prenatal medicines preceding congenital anomalies), controlling for confounding (e.g., family history of psychiatric illness), and identifying effect modifiers. Studies of siblings discordant for prenatal or early life exposures may permit better control for certain unmeasured confounders than traditional cohort studies. Father's medication use can serve as a negative control to differentiate *in utero* drug exposure from familial confounding. Nonetheless, not all data sources have available and valid linkages within families that facilitate such approaches.

This chapter focuses on two populations underrepresented in clinical trials – pregnant women and children – that have specific characteristics necessitating adaptations of study designs and other methodologic considerations. Certain considerations relate to shared interests in safety outcomes in children, as both maternal exposures and childhood exposures can adversely affect pediatric health. We will discuss (i) unique clinical aspects of pregnant and pediatric populations that relate to exposures, outcomes, and confounding; (ii) methodologic issues and considerations for pharmacoepidemiologic research in pregnant women and children; and (iii) potential solutions and settings to study drug utilization and effects in these populations. Each section of the chapter is organized by topic, and each topic contains material specific to pregnant women and/or children, sometimes preceded by information that applies to both populations.

Clinical Problems to Be Addressed by Pharmacoepidemiologic Research

Unique Biology and Epidemiology

Pregnant Women

A woman's body undergoes vast physiologic changes in pregnancy to accommodate and enable

fetal growth, development, and childbirth. These biologic processes lead to rapid changes in baseline risks of maternal conditions and treatment indications that may occur in other stages of life, such as nausea, diabetes mellitus, gallstones, and thromboembolism. However, some outcomes are unique to pregnant women (e.g., ectopic pregnancy, preeclampsia, placental abruption) or their offspring (e.g., neural tube defects, prematurity, cognitive delays). One must consider the fluctuating timelines of risk for outcomes and susceptibility to treatment effects. For example, the risk of pregnancy losses is highest during the first trimester, and the risk of preeclampsia due to endothelial dysfunction increases toward the end of pregnancy. Regarding teratogenicity, while critical portions of organogenesis occur in the first trimester, fetal organs continue to develop later in pregnancy, which explains later susceptibility to certain effects of treatment (e.g., nephrotoxicity from use of angiotensin-converting enzyme inhibitors in the second or third trimester). Furthermore, epigenetic changes and alterations of germline cells can lead to adverse outcomes across generations (e.g., diethylstilbestrol [1,2]), presenting additional challenges in measuring the timing of exposure.

Children

The epidemiology of pediatric diseases varies considerably from that for adults: acute illnesses are considerably more common than chronic diseases; some medical conditions are unique to children, while other conditions seen in adults do not affect children; and some pediatric diseases may have different clinical presentations, treatments, and prognoses from analogous conditions in adults. Considerations of timing of exposure and follow-up are also crucial when studying the treatment of children, who grow and develop dramatically across multiple health axes (e.g., physical, immunologic, nutritional, cognitive, social, behavioral, etc.) and whose own medical needs and risks change throughout childhood. Preterm infants might face any number of life-threatening acute events (e.g., respiratory distress syndrome, necrotizing enterocolitis) and long-term conditions (e.g., retinopathy of prematurity, bronchopulmonary dysplasia) that spare nearly all term infants. These differences underscore the importance of having information such as gestational age at birth, birth weight, and a granular consideration of age when evaluating outcomes in infants. Certain chronic early-onset pediatric diseases, such as type 1 diabetes and some forms of juvenile idiopathic arthritis, differ in incidence, pathophysiology, and clinical course from analogous diseases in adolescents and adults (e.g., type 2 diabetes, rheumatoid arthritis) and thus require independent validation. Other conditions, such as asthma, depression, or infections, may occur in children and adults, but have different treatments or prognoses based on age. For example, compared with adults, children have a substantially greater risk of developing rheumatic heart disease following group A streptococcal pharyngitis [3]. Researchers must consider carefully these age-related clinical differences when designing, conducting, or interpreting pediatric pharmacoepidemiologic research.

Treatment Responses and Patterns

Pregnant Women

The physiologic changes associated with pregnancy can markedly alter pharmacokinetics. Extrapolating conclusions regarding dosing, efficacy, and safety from nonpregnant populations will often be incorrect [4]. For example, the effectiveness of specific drug dosages may be affected by changes in drug clearance, while drug safety for the fetus throughout pregnancy may be affected by changes in the permeability of the blood–placental barrier and may pertain to the ongoing processes of structural development and fetal growth.

Drug utilization patterns (see Chapter 18) and medication adherence (see Chapter 38) also vary

more markedly around pregnancy. By 2008, over 90% of women in the US reported the use of at least one prescription or over-the-counter (OTC) medication during pregnancy, marking a steady increase since the 1970s [5,6]. Some agents are contraindicated (e.g., live vaccines) while others are strongly recommended (e.g., inactivated influenza vaccine). Clinicians frequently change or discontinue chronic medications due to perceived or real risks associated with use during pregnancy (e.g., lithium, valproate) or expected improvement of symptoms during pregnancy (e.g., disease-modifying therapies for multiple sclerosis). Women often decide themselves to discontinue their medications upon learning of their pregnancy because of concerns over fetal toxicity. Treatment decisions during pregnancy are frequently not evidence based and may result in inadequate and ineffective treatments that, nonetheless, expose the fetus to treatment-related risks [6]. Nonadherence or inappropriate discontinuation could also lead to undertreatment of diseases (e.g., asthma, systemic lupus erythematosus) that could adversely affect outcomes of pregnancy, of offspring, and of women after pregnancy [7]. These changing, often unrecorded patterns of maternal drug usage can lead to misclassification of exposure.

Children

As in pregnancy, pharmacokinetics changes rapidly in childhood with the maturation of the various organs needed to absorb, distribute, metabolize, and excrete drugs [8–10]. The pharmacokinetic machinery is particularly underdeveloped in premature infants, for whom there are special considerations in drug dosing [11]. Pharmacodynamics also change over time because of age-related alterations in receptor density and molecular pathways [8,12–14]. Pediatric drugs are generally dosed based on body size, usually weight. Because of developmental changes in metabolism and excretion, in proportion to body size, per-kilogram dosing tends to be lowest in infants (particularly premature infants) and highest in toddlers and younger children; dosing for adolescents tends to be similar to that in adults, but this may not be true for all drugs or all stages of adolescence and requires drug-specific verification [15]. Drug labels for approved pediatric medications specify dosing based on weight and/or age. Guidance for dosing of off-label drugs in children may come from institutional, regional, or national formularies, but this guidance may reflect expert opinion more than sound evidence. The frequency of off-label drug usage in children combined with a lack of pediatric pharmacokinetic/pharmacodynamic data and universal formularies for many pediatric drugs raises questions about both effectiveness and safety.

Rates of medication use among children have changed over time, with rises in the use of drugs for chronic disease such as asthma and attention deficit hyperactivity disorder, and of drug classes such as contraceptives and glucocorticoids [16–19]. About 22–25% of children in the US take a prescribed drug each month [17], while over half of Canadian children receive at least one prescribed medication per year [20]. The prevalence of use of medicines at different ages reflects, in part, the changing prevalence of diseases throughout childhood [16,21]. The ability and willingness of children to take medications also change with age. Young children, for example, may be unable to swallow pills or unwilling to take unpalatable oral medications. Older children and adolescents with more control and independence may also be less adherent to medications or more likely to take medicines that are ineffective or unsafe [22]. Thus, children's adherence, and consequently drug effectiveness, may depend on available formulations, palatability, access (e.g., at school), and the capacity of caregivers to give medication despite children's refusal. Further, parents may inadvertently give incorrect doses of liquid medicines because of confusion about dispensing devices, drug

concentration, or directions [23,24]. These physical measurement issues may not be apparent in either prescribing or dispensing data, but could still compromise the effectiveness or safety of drugs given to children in liquid formulations. Childhood is also a time of experimentation, ranging from the toddler who finds an open medicine bottle to adolescents abusing prescribed or diverted psychotropic or pain medications, leading in some situations to misclassification of exposure or dosage as well as additional concerns for drug safety.

Biologic Plausibility for Teratogenicity: Pregnant Woman

Teratogens are agents that cause birth defects in the embryo (in Greek, *terato* means monster and *genesis* means birth). Whereas one can often predict a drug's adverse effects based on its molecular structure or class and its pharmacologic or toxicologic properties, this is not the case for teratogenic effects. There are a few instances where *in vitro* and animal experiments support the biologic plausibility of drug–defect associations: these include the increased risk of anomalies derived from neural crest cells among infants exposed to retinoids [25] and the decreased risk of neural tube defects among infants exposed to folic acid [26,27]. However, biologic mechanisms remain unknown for many accepted human teratogens, including thalidomide. Thus, we cannot dismiss effects simply because they lack a biologically plausible explanation [28].

Growth and Development: Children

Multiple factors regulate pediatric growth and development, including genetics, hormones, nutrition, and the environment, as well as diseases and their treatments. States and rates of growth and development, thus, provide critical windows into pediatric health. Pediatric health professionals routinely monitor children's growth using national or international growth charts. Absolute measurements can be useful if they deviate markedly from typical values, for example in defining pediatric obesity [29], wasting (low weight), and stunting (low height) [30]. Even when growth measurements are not extreme, changes in growth trajectory can also indicate important changes in health [31,32]. Like growth, there are multiple standards for charting development across multiple axes (e.g., cognitive, motor, social, skeletal, sexual) from early infancy through puberty.

Ethical and Regulatory Context for Research in Pregnant, Lactating, and Pediatric Populations

Regulations are in place throughout the world to guide the approval and surveillance of medications used by pregnant and lactating women and by children. These are based on ethical principles that have been debated and modified over time [33]. In general terms, a historical emphasis on protecting pregnant women and children from research has been counterbalanced by the realization that exclusion of pregnant women and children exposes these populations to treatments with inadequate evidence about efficacy and safety and blocks their access to new medications (e.g., new drugs for resistant tuberculosis undergoing Phase III trials [34]). The ethical concern about protection of pregnant women and children has been based, in part, on their designation as "vulnerable populations." However, the term "vulnerable" is a broad reference to different types of vulnerability and carries varying nuances in different contexts, including different definitions used by regulatory bodies of different countries and organizations [35,36]. As noted by Bracken-Roche, in the case of pregnant women, "vulnerable" historically referred to concerns about drugs that may cross the placenta and adversely affect the fetus; the

term was also an acknowledgment that pregnant women have dual concerns for the welfare of the fetus and themselves [36]. Additional issues may arise in societies where women have limitations on their autonomy. The categorization of pregnant women as vulnerable has been challenged by some bioethicists in ways that might influence our thinking about clinical research in the future [37,38]. In many circumstances, children are considered vulnerable subjects because they are developing the cognitive and emotional abilities to make decisions and to protect themselves, and must rely on someone else (typically a parent or caregiver) who has the capacity to protect their interests [35,36]. Children's vulnerability also relates to increased susceptibility to infectious diseases (including higher risk of mortality at young ages) and to long-term impacts of exposures on health and development [35,36].

Pregnant Women

Regulatory issues around research on medications used by pregnant women are intertwined with general research policies regarding the inclusion of women, pregnant and nonpregnant, in drug trials [39]. Revelations of the teratogenicity of thalidomide led to the passing in the US of the Kefauver–Harris Amendments in 1962 requiring evidence of efficacy for drug approval, but this legislation did not require any evidence for efficacy or safety in pregnancy [40]. Then in 1977, the US Food and Drug Administration (FDA) recommended exclusion of women of childbearing age from participating in Phase I and early Phase II trials. This well-intentioned guideline inadvertently led to the exclusion of the same population from Phase III and IV trials as well. This pattern reversed in 1994 with the establishment of an FDA Office of Women's Health to promote the inclusion of women in clinical trials and the implementation of new policies [41]. However, no mandate emerged to collect clinical trial data specifically in pregnant women.

In 2002, the FDA issued a Guidance to Industry providing recommendations on how to establish pregnancy exposure registries to monitor for outcomes of pregnancies exposed to drug products (see Chapter 16) [42]. In Europe, the 2014 EU Clinical Trial Regulation (No 536/2014) defined the conditions for inclusion of pregnant and lactating women in clinical trials, as well as protective measures to consider for all women of child-bearing age [43,44]. The FDA's Pregnancy and Lactation Labeling Rule (PLLR), effective in 2015, required changes to the content and format of information presented on prescription drug labels, including separate sections for pregnant women and for lactating women [45]. The labeling information is intended to assist clinicians in assessing benefit versus risk and in counseling pregnant women and nursing mothers about medications. The US 21st Century Cures Act (2016) established the Task Force on Research Specific to Pregnant Women and Lactating Women to study the effectiveness and safety of therapies and inform drug regulation in these populations [46]. Additional guidance on research protections of women of child-bearing age has come from the Council for International Organizations of Medical Sciences (CIOMS), a nongovernmental organization. The CIOMS ethical guidelines discuss the importance of informed consent regarding potential risks to a fetus in future pregnancies, as well as access to family planning services (e.g., contraception) and, if needed, obstetric medical care to help women manage unplanned pregnancies [47]. Multiple governments and organizations continue to develop new guidance and resources to address the complexities in this arena.

Children

The CIOMS ethical guidelines note:

> Children and adolescents must be included in health-related research unless a good scientific reason justifies their exclusion. As

> children and adolescents have distinctive physiologies and health needs, they merit special consideration by researchers and research ethics committees. However, their distinctive physiologies and emotional development may also place children and adolescents at increased risk of being harmed in the conduct of research. Moreover, without appropriate support, they may not be able to protect their own interests due to their evolving capacity to give informed consent. Specific protections to safeguard children's rights and welfare in the research are therefore necessary. [47]

The International Conference on Harmonization of Technical Requirements of Pharmaceuticals for Human Use (ICH) has worked to harmonize international policies on pediatric clinical trials [48]. Both Europe and the US have regulations in place requiring clinical data from pediatric populations; these regulations balance the ethical imperative to protect children alongside the ethical need to provide children with treatments that have been adequately tested. In the US, the 2003 Pediatric Research Equity Act authorized the FDA to require pediatric studies of drugs or biologics if the product was likely to be used in a substantial number of pediatric patients, or if it would provide meaningful benefits for children over existing treatments [49]. In Europe, the 2007 Pediatric Regulation dramatically changed the regulatory environment for pediatric medicines [50]. This regulation established the Pediatric Committee (PDCO), which determines the studies that companies must conduct in children as part of pediatric investigation plans (PIPs). The PIP covers the studies needed to support a pediatric indication with an age-appropriate formulation. In addition to regulations requiring studies in children, legislation such as the Food and Drug Administration Modernization Act (1997) and the Best Pharmaceuticals for Children Act (2002) has provided financial incentives (in the form of patent extensions) to pharmaceutical companies that study medications in children. Such legislation has led to increases in pediatric drug research and approvals over time, even though many drugs used in children (including orphan drugs for rare diseases) continue to lack pediatric labeling [51–53].

Evidence to Inform Clinical Practice and the Role of Pharmacoepidemiology

There is usually very little premarketing information on the safety and efficacy of drugs in pregnant or pediatric populations. Given that a drug's safety can rarely be predicted based on its structure and function alone, animal studies are often used to identify pregnancy-related or pediatric toxicity. However, animal studies are limited in their ability to predict human maternal, fetal, or pediatric toxicity, both because of considerable variations in teratogenic and other toxic effects (even among various nonhuman mammalian species) and the usual absence of concordance between effects in animals and humans [54].

Because of the typical exclusions of pregnant women and children from clinical trials, most information regarding the benefit/risk profile of drugs in these populations is collected after a drug's initial approval. In practice, women take drugs while pregnant either intentionally or unintentionally – intentionally because some conditions require treatment during pregnancy, and unintentionally because a large proportion of pregnancies are unplanned [55]. Embryonic exposure to medications at the most vulnerable period of development can, thus, occur before a pregnancy is detected. Similarly, many children are prescribed drugs approved for analogous adult conditions under the potentially wrong assumption of analogous efficacy and safety. Postmarketing data from case reports and case series can offer clues, but except for selected drugs with obvious and dramatic toxicity (e.g., thalidomide), they do not provide conclusive

evidence regarding causality. Selected reporting of exposed cases can lead to false alarms or exaggerated effects, while underreporting may keep other important effects unrecognized [56].

Therefore, postapproval controlled observational studies provide the primary mechanism for identifying potential teratogenic and toxic effects in pregnant and pediatric populations. More generally, pharmacoepidemiologic studies can contribute evidence on the comparative safety and effectiveness of therapeutic strategies during pregnancy and childhood to inform clinical decision-making and policies, and ultimately improve health outcomes in pregnant women and children of all ages. The newer analytic techniques developed to help mitigate confounding in studies of unintended and perhaps intended consequences should prove useful in the context of pregnant and pediatric populations as well (see Chapters 33 and 43).

Methodological Problems to Be Solved by Pharmacoepidemiologic Research

Defining the Population

Pregnant Women

As in any study, it is crucial to specify the target population, inclusion and exclusion criteria, and start and end of follow-up. To prevent biases, including immortal time bias (see Chapter 43), the study design should ideally align start of follow-up, specification of eligibility, and treatment assignment [57]. For example, to assess whether influenza vaccination during the first trimester triggers spontaneous abortion, the follow-up should start at the time of vaccination for the exposed, and at the same gestational time for the unexposed. The peculiarities of pregnancy research start when defining the target population, since the unit of observation may be the mother, the pregnancy (sibling clusters within mother), or the fetus (multifetal clusters within pregnancy). Sometimes twinning or parity is an outcome of interest itself; when it is not the outcome, some studies exclude multiples or select one pregnancy per woman to simplify the analyses, while others account for the correlation within pregnancy and within the mother [58]. In certain cases of treatments with epigenetic or germline effects (e.g., diethylstilbestrol [1,2]), the time of first relevant exposure might occur in grandparents or earlier generations, and relevant outcomes might similarly affect grandchildren or their offspring. Practically, however, most studies will begin at or after conception and continue through the end of pregnancy for maternal outcomes, and through childhood for outcomes of offspring. Given the unplanned and unrecognized nature of many pregnancies, identification of pregnancy at conception and its earlier stages is challenging in routinely collected data. Similarly, given the variability of exposures and risks across stages of pregnancy, identification and consideration of gestational age can be important for many research questions.

Children

The age cutoff for pediatric populations varies across countries, organizations, and agencies, including ages under 17 (US FDA Center for Drug Evaluation and Research and Center for Biologics Evaluation and Research) [59] and under 18 (EMA [50] and the US National Institutes of Health [60]). Biologically, any such cutoff can be misleading; some individuals (usually boys) continue to grow after age 18, and cerebral white matter (along with executive function) continues to mature into one's 20s [61]. For these and other reasons, the American Academy of Pediatrics has discouraged the use of an arbitrary age limit to define pediatrics [62]. Irrespective of how we define pediatrics, age-related developmental changes and the heterogeneity of the pediatric population require consideration of study-specific subgroups in pediatric research, such as infants (premature

and term), children (preschool and school age), and adolescents. As with definitions of pediatrics, the age cutoffs of these subgroups vary across regulatory bodies (US FDA [59], US Census [63], International Conference on Harmonisation [64], EMA [65]). The number and ranges of age subgroups applied to pediatric studies vary even more widely, depending on the study question [66]. Studies that combine children of all ages or combine children with adults, without consideration of differential effects by age, could miss an important source of effect modification and be uninterpretable.

Sample Size Requirements and Challenges

An important practical hurdle when studying the effects of medications in pregnancy and in children is the ability to attain adequate sample sizes because, more often than not, exposures are uncommon, and diseases and outcomes of interest are also uncommon. The importance of considering subgroups and effect modification by stage of pregnancy or pediatric age may increase the sample size needed.

While use of many medications in pregnancy and in children has increased over time (see "Treatment Responses and Patterns"), the proportion of pregnant women or children using a specific medication is still relatively low for most medications [17,21,67]. Likewise, many maternal, fetal, and pediatric adverse outcomes of interest are uncommon. An outcome of particular interest in studies of pregnant women is congenital malformations, which are diagnosed in 2–3% of liveborn infants [68,69]. The prevalence of specific malformations ranges from about 1 per 1000 live births (e.g., oral clefts [70]) to less than 1 per 10000 (e.g., biliary atresia [71]). Similarly, serious outcomes in pediatric populations, such as anaphylaxis, upper gastrointestinal bleeding, diabetes mellitus, or malignancy, are generally rare [72–74]. In the absence of large effects, the study size needed to study the association between less common exposures and outcomes rapidly becomes prohibitive (see Chapter 4 on sample size) [75–77]. To compensate for lack of statistical power, researchers often revert to grouping ("lumping") exposures or outcomes, a potentially problematic solution (see "Exposure Ascertainment, Timing, and Misclassification" and "Outcome Definition and Ascertainment").

A challenge of examining multiple rare exposures in association with multiple rare outcomes is the risk of chance findings in the context of multiple comparisons. All tested results, including the negative and nonsignificant ones, should be reported within studies. Selective interpretation, reporting, or publication of only positive or statistically significant results (e.g., reporting of associations with at least five exposed cases) would lead to publication bias. New findings should be replicated, and the tenability of alternative explanations, including both chance and bias, should be examined before we conclude there is a presence or absence of causal effects [78,79].

Exposure Ascertainment, Timing, and Misclassification

The main goal in ascertaining drug use in any pharmacoepidemiologic study is to minimize the misclassification of the exposure. As a general principle, we strive to define exposure during the etiologically relevant window with high specificity. In the tradeoff between sensitivity and specificity, we prioritize specificity in order to reduce the likelihood that a sizable proportion of women or children classified as exposed are, in fact, unexposed (i.e., false positives). In the context of uncommon exposures, this likelihood is quite high when using an exposure definition with low specificity. Misclassifying unexposed women or children as exposed would dilute the association if one truly exists. There are many approaches to ascertain and define exposure that can be applied to pregnant and pediatric populations (see Chapter 3). Nonetheless, research in pregnancy and children

presents important challenges in defining such exposures accurately.

Pregnancy and childhood are highly dynamic times in medication management, including use of OTC medications [6,80] (see "Changes in Treatment Responses and Patterns"). These challenges are compounded by the frequent lack of a clear definition of the etiologically relevant window and the potential brevity of this window. Inclusion of exposures outside the relevant window generally leads to exposure misclassification and bias toward the null. For many severe birth anomalies, the period of interest is the first trimester, but a narrower window is appropriate for specific anomalies (e.g., the first few weeks after conception for neural tube defects). Given the rapidity of physiologic changes in young children, etiologically relevant windows may be similarly short in duration (weeks to months long) for infants, particularly premature infants, and are likely longer for older children. The etiologically relevant window may be unclear if the pathophysiology of the outcome is poorly understood (e.g., autism spectrum disorder, cognitive delays) or multifactorial (e.g., preeclampsia, childhood obesity), or if the mechanism by which the drug confers excess risk is not known. In these circumstances, it is important to explore different, potentially relevant windows, always acknowledging the exposure windows explored.

To ascertain exposures, we can either rely on secondary data (such as medication dispensings) or primary data collection (such as interviews). Users of secondary data sources should be aware of the disconnect between prescribed, dispensed, and consumed medications and work with highly specific definitions of exposure (see Chapters 12–13). Studies with primary data collection rely on maternal, parental, or adolescent interviews for drug exposure information, which is often the only feasible way to obtain information on OTC drug use and verify the intake of medications. This approach raises concerns about the overall accuracy of recall. Moreover, researchers often conduct such interviews retrospectively after the outcome of interest has occurred (e.g., birth anomalies, pediatric cancer), raising concern about recall bias or differential misclassification of exposure. In theory, the birth of a malformed child or a severe pediatric condition may affect recall of prior, remote exposures (e.g., during pregnancy or infancy). More complete exposure recall among mothers of cases would create a false association between the drug and the birth anomaly or pediatric condition, or overestimate an association if it exists [81–83]. One approach to reducing this bias is improving accuracy by using well-designed interviews with highly structured questions to maximize recall and minimize errors in exposure assessment [84]. Some studies of birth anomalies have used infants with other malformations as controls. Assuming that recall is unlikely to be outcome specific, using mothers of malformed infants as controls helps ensure that reporting accuracy is comparable among mothers of cases and controls [85]. When interviews are used to measure exposure, one should also consider the potential for misclassification due to social desirability bias, for example in studies of opioid use during pregnancy [86] or adolescence [87].

Pregnant Women

Not all pregnancies are 40 weeks in duration, and many outcomes of interest are associated with shorter gestational length (e.g., preterm delivery, preeclampsia, stillbirth). In those instances, one must avoid defining the exposure window in a way that creates *differential opportunity for exposure* in affected and unaffected pregnancies (e.g., exposure during the third trimester), as this will bias the association measure [88,89]. A few different strategies are available to avoid this bias, including (i) ending the exposure window prior to the start of follow-up (e.g., at 22–24 weeks of gestation, the earliest time for viable birth); (ii) defining exposure in a fixed look-back window (e.g., 30 days) from time of delivery; and (iii) using a

time-varying exposure definition (e.g., with a Cox model). Moreover, one outcome affects the opportunity for other outcomes in pregnancy (e.g., competing risk between prematurity and preeclampsia). Depending on the specific question of interest, one may consider using fetuses-at-risk approaches to assess risks that vary with gestational age at birth [90–92] or other methods to account for competing risks (e.g., fetal death) [93,94].

A methodologic concern in pregnant populations related to the grouping of medications is known as the fallacy of "class action" teratogenesis. In reality, members of a given drug class do not necessarily have the same teratogenic or nonteratogenic potential. For instance, we may not know whether teratogenesis results from the chemical structure *common* to a medication class or from the part of the structure that *differentiates* one class member from another. For example, two glutarimides, thalidomide (phthalimidoglutarimide) and glutethimide (phenylglutarimide), are both sedative-hypnotics. Despite these structural and clinical similarities, thalidomide was identified as a high-risk teratogen, and glutethimide was not. Thus, we cannot assume that if one drug is a high-risk teratogen, all other members of its class will share that effect. Conversely, we cannot assume that the safety of one drug in a given class connotes the safety of another. There are, however, some exceptions in which we can hypothesize a potential teratogenic effect based on the existing biologic evidence (e.g., folic acid antagonists and other antimetabolites, which may exert toxic effects through impairment of growing cell division) [95].

Children

Because pediatric dosing is frequently weight based, studies of dose effects in children may rely on accurate determination of weight. Some automated data sources, including administrative claims and some electronic heath record (EHR) databases (see Chapters 12–13), may lack reliable or any data on children's weights. One potential solution is to estimate pediatric dosage by imputing weight based on age and sex, using the appropriate pediatric growth charts (e.g., national, World Health Organization [WHO]), and creating broad weight-based dose categories based on quantiles or prespecified cutoffs [96]. This approach allows for examination of the population-level effects of dose in children whose weight distribution is expected to resemble that of the source population. This assumption may be false when studying conditions that affect pediatric weight, such as malnutrition or other chronic diseases, for whom additional information should be incorporated into any systematic imputation of weight. Additionally, imputed weight-based dosage becomes less valid for more granular estimations of dose, which are more susceptible to misclassification at the individual level. Of note is that weight is not a universal determinant of drug dosing, which may also vary based on other (potentially unmeasured) growth measurements (e.g., body surface area) or pharmacokinetic/pharmacodynamic factors [97,98].

Outcome Definition and Ascertainment

To obtain valid information on outcomes in pregnant and pediatric populations, some studies have direct access to patients and families and use expert clinicians (e.g., teratologists or other pediatric specialists, pathologists) to adjudicate all outcomes. Other studies using administrative claims or EHR data may use restrictive algorithms or validate outcomes using medical records (see also Chapter 37 on validation) [99–101]. It should be noted that birth certificates can be inaccurate records of birth anomalies and are not recommended as gold standards [102].

Replication of a known association (i.e., positive control) can provide reassurance of valid outcome ascertainment. For example, as a positive control, one could replicate the association

between pregestational diabetes (or insulin as a proxy) and major malformations.

Differential misclassification of outcomes with respect to exposure leads to additional analytic challenges. Diagnostic bias may occur if exposed children or mothers-to-be receive more testing (e.g., because of suspicion of teratogenic or other drug-induced effects), resulting in more complete diagnosis or overdiagnosis of subclinical conditions (e.g., minor anomalies or viral illnesses).

Evaluation of long-term outcomes following prenatal or early life exposures, such as developmental or neuropsychiatric disorders, is particularly challenging. First, identification of certain long-term outcomes requires large longitudinal studies with information ranging from less frequent, clinically relevant conditions (e.g., psychotic disorders, malignancies) to more frequent outcomes with less readily available measures (e.g., cognitive impairment based on formal testing, scholastic performance, or educational attainment) or that do not consistently come to medical attention (e.g., autism spectrum disorders). Practically, such studies may be difficult to conduct in settings with high turnover (e.g., local EHR or US administrative claims databases), where relatively few children can be followed continuously for many years after birth. Transition of care from pediatric to adult health professionals can also lead to loss to follow-up because of difficulties in finding new clinicians or transfers to different health systems or insurance. Methods for dealing with censoring should be applied, but loss to follow-up could compromise statistical power and lead to bias if dropout is not random and censoring is informative.

Second, evaluations of the effects of prenatal or early life drug exposure on child development face multiple potential sources of confounding, such as shared home and family environment, genetic predisposition, and the impact of maternal or childhood illness on parenting and healthcare utilization (see "Confounding"). Adjustment for time-varying confounders affected by prenatal or early life exposures (e.g., postpartum maternal mental health) can be problematic, since time-varying factors (e.g., maternal anxiety postpartum) might be affected by prenatal exposures (e.g., maternal use of antidepressants) and affect the outcome of interest (e.g., infant mental health) [103,104]. In this situation, adjustment for such covariates would violate the principle of not adjusting for factors on the causal pathway between exposure and outcome; but not adjusting would violate the principle of adjusting for confounders (e.g., if maternal anxiety postpartum is the only measure of maternal mental health available).

Pregnant Women

Drugs can induce a wide range of reproductive outcomes, including hampering fertility and interacting with contraception. Drugs given to pregnant women may also lead to adverse obstetric outcomes, perinatal complications, and even neurodevelopmental delays in offspring later in life. Effective drugs can also reduce adverse outcomes induced by the underlying condition (e.g., reduction in obstetric complications by improving glycemic control in women with diabetes). Among outcomes of interest for pregnant women, teratogenesis has received special attention for being a rare but dramatic event. In recent years, however, pregnancy researchers and regulators have expanded their attention to include fetal losses and long-term consequences in the child.

Researchers sometimes lump together various fetal malformations, partially for conservation of statistical power [105]. However, given the etiologic heterogeneity of malformations, the combination of multiple malformations into a single outcome may lack a sound embryologic basis, even when such outcomes are classified by organ system (e.g., cardiovascular) [106]. A more appropriate approach may be to create categories that reflect the embryologic tissue of origin (e.g., neural crest [107]) or teratogenic mechanism (e.g., disruption of the embryonic vasculature [108]), when known [109].

Depending on the outcome definition, the risk of malformations overall can range from 1% to over 10% [110]. Common exclusion criteria when evaluating teratogenicity include chromosomal anomalies, known genetic disorders, minor anomalies, birth marks, positional deformations, subclinical anatomic findings by ultrasound, and complications of prematurity [111]. In some circumstances, confirmation may require specific procedures (e.g., an echocardiogram to measure the size of a septal defect) or follow-up (e.g., patent foramen ovale persistent six weeks after birth). Another source of heterogeneity comes from the period of observation: some studies may include prenatal diagnoses and over one year of follow-up after birth; other studies may focus on an outcome ascertainment window of days around delivery [112]. Therefore, estimates of the risk of malformations from one study might not be comparable with estimates from birth anomaly surveillance systems or other studies with different inclusion and exclusion criteria [113]. Consequently, investigators should strongly consider including an internal reference group with consistent data collection and applying the same criteria to measure outcomes [114].

To estimate the risk of fetal losses, *ad hoc* pregnancy cohorts need to enroll women soon after conception to consider miscarriage, and they require large sample sizes to consider stillbirths (expected frequency 6 per 1000 in the US [115]). When comparing treatments, researchers must ensure that all groups have comparable gestational age at enrollment and that differential enrollment time (left truncation) is handled correctly in the analysis [116].

Children

Given the many clinical and epidemiologic differences between children and adults (see "Unique Biology and Epidemiology"), pediatric researchers should be careful when applying validated definitions from adult populations to children. For example, depression (like many chronic diseases) is rarer in children than in adults, thus reducing the positive predictive value of a given algorithm, assuming equal sensitivity and specificity. One should also not assume that conditions with the same name or code represent the same disease in children as in adults, for instance neutropenia, since children are much more likely to have cyclic or chronic neutropenia [117]. As another example, compared with adults, children with diabetes mellitus are more likely to have type 1 diabetes, for which more specific diagnostic codes exist (although they may not reliably be used). Furthermore, type 1 diabetes is quite distinct from type 2 diabetes in pathophysiology, clinical presentation (e.g., thin children who are more likely to present with diabetes ketoacidosis than adults with incident type 2 diabetes), and treatment (i.e., exclusively with insulin). Even conditions that are managed more similarly in pediatric and adult populations (e.g., juvenile idiopathic arthritis versus rheumatoid arthritis, bipolar disorder) may have differences in prevalence, clinical presentation, coding, or outcomes that necessitate independent validation [118]. Thus, depending on the study question and setting, an outcome validated in adults should not be presumed to be valid in children, and vice versa.

As already mentioned, milestones in growth and development can serve as important outcomes in pediatric studies. For diseases that impair growth or delay puberty, for instance, by disrupting nutrition, absorption, or metabolism (e.g., thyroid disease, inflammatory bowel disease, juvenile idiopathic arthritis), improved or normalized growth and development can be measures of drug effectiveness [119–121]. Additionally, growth and development can also be important markers of safety (e.g., slowed vertical growth with glucocorticoids [122], impaired weight gain with stimulants [123], excessive weight gain with antibiotics [124]).

Confounding

Because of the lack of randomization in observational studies, there is no guarantee of balance in characteristics between comparison groups. Confounding by indication can occur if children or pregnant women who receive a drug are more likely to have an underlying condition, or a more severe or active form of that condition, which is associated with the risk of the outcome. Available approaches to minimize confounding by indication include (i) adjusting for the presence of the underlying condition; (ii) restricting both the treated and reference group to individuals with a recorded diagnosis for the underlying condition; (iii) restricting to pregnant women or children with the indications and using an active reference group; (iv) comparing continuers with discontinuers of the medication of interest (more applicable to studies of pregnancy); and (v) sibling discordance study to control for stable family factors (see "Currently Available Solutions, Newer Designs"). Confounding by disease severity poses additional challenges in observational research on medication safety and effectiveness (see also Chapter 33).

Aside from confounding by indication and disease severity, other putative risk factors for the outcome may be associated with exposure. One advantage of using large EHR or claims databases for research in pregnant women and children is that the researcher can exploit the richness of the data to identify and control for a large number of potential confounders or proxies for these variables. Given that outcomes tend to be rare, and the set of prespecified potential confounding variables may be large, the use of data-reduction techniques such as propensity scores can help avoid problems with model overfitting (see Chapter 43).

Many secondary data sources, including EHR and claims data, do not have robust or complete information on certain potential confounders (e.g., socioeconomic status; smoking, alcohol use, or recreational drug use in adolescents, pregnant women, or caregivers; test results such as prenatal testing) and lack information on OTC medications (e.g., multivitamins, folate, analgesics and antipyretics; see Chapters 11–14). Several approaches can mitigate potential residual confounding from unmeasured factors, including the use of high-dimensional propensity score analyses (if unmeasured confounders are correlated with measured ones) [125] or external adjustment for unmeasured confounders [126,127]. After utilizing all approaches to minimize confounding during the stages of study design and analysis, one can conduct quantitative bias analysis, a sensitivity analysis that incorporates the level of uncertainty in estimates based on suppositions about unmeasured confounders (see Chapter 43) [128]. Another approach that provides reassurance about control for confounding is replication of a null association (i.e., negative control). For example, one could document a null association between paternal use of the drug at the time of the pregnancy and the risk of fetal growth restriction.

Pregnant Women

Although many treatment indications are not traditional risk factors for adverse outcomes of pregnancy, certain indications may be confounded due to strong associations with other conditions or behaviors that are risk factors for the outcome. For example, women treated with antidepressants (including women with depression and/or anxiety) may also be more likely to smoke, use substances, eat poorly, and have chronic conditions such as diabetes, hypertension, and obesity – all factors that predispose to congenital heart anomalies [129]. In addition, women with anxiety may utilize more healthcare resources, including fetal or early-life testing (e.g., echocardiography), than their unaffected counterparts. Hence, anxious women are more likely to have infants diagnosed with mild

cardiac malformations that might have gone clinically undetected in children of other women, such as small muscular ventricular septal defects, which often remain subclinical before resolving spontaneously [130]. Failure to account for such sources of confounding when studying the safety of psychotropic medications might bias the results.

Children

Certain sources of confounding may play a large role in pediatric studies, including second-hand smoke exposure, parental income and occupation (e.g., measures of socioeconomic status or environmental exposure), parenting styles (including behaviors related to healthcare utilization; e.g., requests for testing or antibiotics, etc.), early childhood feeding practices (e.g., breastmilk or formula), medical conditions of parents and siblings (and more fundamentally, genetics), and vaccination status [131]. Birth weight and gestational age at birth can be particularly important to understanding the indications and effects of treatment in the earliest days and months of life, especially in premature neonates and infants. Many of these variables can be difficult to measure in large data sources, particularly in administrative claims data.

Analyses of pediatric populations often need to adjust for age or stratify by age group with greater precision than in adult studies. Whereas 10-year age groupings in studies of adults may be highly appropriate, there are dramatic differences between a 4-year-old and 14-year-old child, and even between a preterm infant, a term infant, and a 2-year-old (see "Unique Biology and Epidemiology" and "Defining the Population"). Thus, representation of age and age groups must consider the pediatric population and clinical question of interest. Date of birth, a variable that is unavailable in some de-identified data sources, can be an especially important consideration in studies of newborns, infants, and other young children. For example, date of birth can relate to seasonal events (e.g., viral and bacterial infections) and other temporal changes (e.g., changes in vaccination practices) in ways that are critical to interpreting associations between key drug exposures (e.g., antibiotics) and outcomes (e.g., asthma) [132]. Date of birth and birth cohort could, thus, be considered as a confounder, effect modifier, or even instrumental variable. At the earliest extreme, neonatal studies may require information about the hour of birth to evaluate outcomes that occur within several hours or days of birth.

In addition to considerations of age, states of growth and development could also be sources of confounding. For instance, malnourished or obese children may have increased risks for receiving treatment (e.g., antibiotics) and experiencing an outcome of interest (e.g., treatment-refractory infection). Growth and development can also be a source of effect modification. For instance, the robust skeletal turnover and repair in growing children may protect them from adverse effects of drugs that damage bone in fully grown adolescents and adults [96,133,134].

Selection Bias

When selection into or retention in the study is directly or indirectly affected by the exposure and the outcome, selection bias may occur and distort the estimate of risk [135].

Pregnant Women

In nonpregnant populations, the importance of including new users to avoid a selection of exposed subjects nonsusceptible to potential adverse effects is well recognized [136]. In pregnancy, there are also situations in which considering prevalent users complicates the interpretation of results [136]. For example, in evaluating the effect of certain antipsychotic medications on the risk of gestational diabetes, inclusion of women on the drug at conception

who do not have diabetes at baseline might exclude patients susceptible to the cardiometabolic effects of the antipsychotics; those pregnant women entering the cohort, therefore, might not be susceptible to developing diabetes with drug exposure, biasing results to the null [137].

In clinical practice, recommendations for interventions in early pregnancy often affect not only women actively trying to become pregnant, but also any women of childbearing age, given that a large proportion of pregnancies are unplanned and there is no time to switch treatments before organogenesis and after pregnancy is recognized [55]. Similarly, in research, the ideal pregnancy cohort begins at or before conception, if not at the time of first exposure [138]. This situation occurs rarely in reality. More often studies enroll women after confirmation of a pregnancy. This form of left truncation may underestimate the risk of early pregnancy events (e.g., miscarriages). Differences in gestational age at enrollment between exposed and reference groups could lead to biased relative risk estimates if the risk varies with gestational age. For example, consider a study investigating how a vaccine given during the first trimester affects the risk of miscarriage, which decreases after week 10 of gestation. A design that erroneously started follow-up for exposed individuals after vaccination and for unexposed individuals after a positive pregnancy test would introduce selection bias. To prevent this bias when evaluating the risk of early miscarriages, the safest approach is to enroll subjects as soon as possible after conception, and to start follow-up of exposed and unexposed at comparable gestational ages.

Selection bias may also occur if the outcome affects enrollment differently in exposed and reference groups [116]. For example, concerning results from prenatal screening may motivate women on specific medications to enroll in a pregnancy registry. This scenario would lead to overestimation of risks among exposed women [116]. On the other hand, a study could preferentially select low-risk pregnancies if the investigators declined to enroll women with concerning prenatal screening results, or if women were less likely to enroll after a therapeutic abortion. To prevent this bias when evaluating the risk of birth anomalies or other complications of pregnancy, the safest approach is to enroll subjects before the risk of the outcome is known; that is, before the completion of informative screening tests.

An issue unique to the study of birth anomalies is the possibility of pregnancy losses, whether spontaneous or induced. Many studies are restricted to live births, and studies that include pregnancy losses almost always lack information from pathology reports on the presence of structural anomalies. Moreover, some malformations become detectable at early stages of pregnancy, and some women decide to terminate these pregnancies. Studies of liveborn infants, thus, underestimate the risk of lethal and prenatally detectable anomalies. The proportion of fetuses identified to have birth anomalies after termination varies by type of malformation, ranging from under 5% for oral clefts to more than 40% for neural tube defects [139,140]. Bias could occur in instances where exposed and reference groups had different proportions of terminations of affected fetuses. For example, if women exposed to a putative teratogen were more likely to terminate a pregnancy with a malformed fetus, and this situation was not captured within the study, the relative risk estimate would be biased toward the null. Although the likelihood of terminating a pregnancy based on an adverse prenatal diagnosis might not be affected by drug utilization [141], this assumption is usually untestable. Sensitivity analyses can be used to assess the uncertainty around the relative risk estimates due to selection bias, together with misclassification and confounding [142]. These methods do not substitute for a valid and carefully conducted study design, but can produce a plausible range of estimates under realistic assumptions [143].

Sometimes, studies include pregnancy losses without fetal autopsy information on structural malformations. These studies can include all pregnancies in the denominator of risk estimates, but still face the challenge of outcome classification in the numerator. Missing data after spontaneous abortions or terminated pregnancies could lead to false negatives. If this outcome misclassification preferentially affected exposed women, this ascertainment bias would underestimate the relative risk of the drug. This situation can be considered a problem of right truncation, where follow-up ends with unknown outcomes; or of competing risk where fetal demise competes with the risk of being born with a malformation. Similar competing risk circumstances arise at the end of pregnancy, where pregnancy ends before an outcome can occur (e.g., competing risks between preterm delivery and the development of preeclampsia).

Case–control studies confront an additional type of selection bias resulting from inappropriate control selection. In some studies of birth anomalies, controls comprise infants with malformations other than the ones of interest affecting cases [144]. This approach is valid under the assumption that teratogens do not increase the risk of all malformations, including the specific malformation among controls [145,146]. The goal of using a malformed control group is to reduce the opportunity for differential recall of exposure between mothers of cases and controls. Whether malformed or not, controls should be sampled from the same population that gave rise to the cases. In multicenter case–control studies that identify cases from a large number of hospitals, controls should be identified from the same hospital catchment area [147], and the analyses should account for matching of cases and controls by center [148].

Lastly, one can introduce selection bias during the analysis by adjusting for variables that share common causes with the outcome or are affected by it. Thus, adjusting for these variables (e.g., low birth weight) will not reduce confounding and can introduce selection bias [135,149,150]. For example, adjustment for low birth weight is unwarranted when the analytic goal is to estimate the overall effect of prenatal variables, such as maternal drug use, on infant mortality, or when the goal is to estimate the direct effect but there is an unmeasured common cause of low birth weight and mortality [150]. Knowledge of the causal structure is a prerequisite to accurately labeling a variable as a confounder. In studies of pregnancy, events that occur after organogenesis cannot cause structural birth anomalies arising during the first trimester and, therefore, are not confounders. Nonetheless, they could be proxies for strong unmeasured confounders, in which case investigators may want to use them for statistical adjustment to reduce confounding.

Children

Large longitudinal cohorts and registries can be valuable settings to study the effects of drugs in pediatric populations (see "Prospective Cohorts" and "Registries"). However, differential entry or loss to follow-up because of factors associated with the outcome (e.g., disease severity, psychosocial risk) can introduce selection bias [151,152]. Selection bias may also affect research of other special pediatric populations at high risk of poor outcomes. Research in very premature infants is often conducted within highly specialized referral neonatal intensive care units. Studies in which referral patterns and, thus, study inclusion relate to the risk of exposure (e.g., indomethacin) and outcomes (e.g., intraventricular hemorrhage, mortality) may result in selection bias [153,154].

Another highly vulnerable pediatric population is children in foster care, who are subject to early trauma and inconsistent preventive medical care, leading to psychosocial disruption and potential overtreatment (e.g., with psychotropic drugs) [155,156]. One may use Medicaid claims data to study this vulnerable population, but Medicaid eligibility codes misclassify children who are in and not in foster care; correctly classified children may be more likely to have higher

levels of healthcare utilization and case management support [157,158]. As a result, studies on the effects of certain drugs in foster children may be biased in samples in which excluded children (e.g., those with low levels of support) have different risks of both exposure (e.g., to antipsychotics) and the outcome of interest (e.g., diabetes mellitus). Studies may reduce the risk for selection bias by accounting for these coding practices and utilizing supplemental data to better classify foster care status.

Currently Available Solutions

In this section we review the main pharmacoepidemiologic designs used for pregnant and pediatric populations to quantify the risk/benefit profile of medication exposure during pregnancy, infancy, or childhood, and the solutions they offer to common forms of bias.

Prospective Cohorts

Pregnant Women

Prospective inception (or follow-up) cohorts of pregnant women have the advantage of identifying drug exposure before the adverse outcomes are recognized. This approach involves the identification of a population of women to be followed as soon as possible after conception or at the stage of pregnancy planning, to allow the evaluation of early pregnancy events. Such studies should periodically collect information on demographic characteristics, exposures, and potential confounders, as well as formally evaluate offspring at birth (or fetal death) and ideally throughout childhood. Unless regular pregnancy tests are conducted, studies will not detect fetal losses that occur before pregnancy is recognized. Because birth anomalies and stillbirths are rare outcomes, and because usually a small fraction of pregnant women will take particular drugs, inception cohorts need to be large. Even exceptionally valuable research resources such as the Danish National Birth Cohort [159] or the Norwegian Mother and Child Cohort Study (MoBa) [160], with over 90 000 pregnancies, were too small to examine the risks of specific birth anomalies related to specific drugs taken in pregnancy.

Children

Prospective cohorts may also permit evaluation of a variety of pediatric exposures and outcomes of interest, while allowing for detailed adjustment for confounders. Birth inception cohorts of premature infants and children are particularly useful to study the link between early life treatments and subsequent outcomes [161,162]. Birth inception cohorts have been used to study term infants as well, for example the link between probiotic use in the first month of life and subsequent development of type 1 diabetes-related autoantibodies among genetically predisposed children [163]. Disease-focused prospective cohorts may also be useful for pharmacoepidemiologic research on children with rare diseases, such as chronic kidney disease [164], congenital heart disease [165], inflammatory bowel disease [166], juvenile idiopathic arthritis [167], psychotic disorders [168], and venous thromboembolism [169]. Disease-inception cohorts of treatment-naive children may be less susceptible to selection bias than other prospective cohorts that voluntarily enroll children who have already received treatment for their condition (see "Selection bias"). Like other observational settings for pediatric research, prospective cohorts are subject to a variety of methodologic limitations, including confounding and limited sample size (see "Methodological Problems").

Registries

Pregnant Women

For new or infrequently used drugs, it is more efficient to assemble cohorts of women exposed to a drug of interest in pregnancy and follow them to determine outcomes (known as exposure pregnancy registries) [170,171]. The pri-

mary objective of many exposure registries is to assess the relative risk of major congenital malformations in the offspring. However, registries can evaluate multiple maternal, obstetric, fetal, and infant outcomes [171]. These efforts are critically important for the detection of major adverse effects (e.g., isotretinoin teratogenicity) [25] that affect large proportions of exposed fetuses. However, the small size of most registries (usually with no more than a few hundred women) prohibits the identification or disproof of small or moderate effects involving rare outcomes [172].

To avoid selection bias, women should be enrolled into a pregnancy registry before the pregnancy outcome is known. As in other studies based on volunteers, self-referral often results in a nonrepresentative population. Similarly, the participants who complete follow-up may be even less representative. Selective inclusion or follow-up may affect the generalizability of absolute risk estimates, and may bias the relative risk if selection or retention is related to both the exposure and the outcome.

In any pharmacoepidemiologic study, it is important to include comparable reference groups. Many registries only enroll exposed women and compare the incidence of malformations with estimates from surveillance systems. This approach raises concerns about the comparability of control groups, including demographic and clinical characteristics as well as the ways in which outcomes are defined, detected, and validated. Other registries compare the observed risks in exposed women to those in pregnancies without exposure or with exposure to unrelated (e.g., presumed nonteratogenic) drugs. These approaches rarely consider confounding by indication. As discussed earlier (see "Confounding"), one should compare women exposed to a drug of interest with other women who have similar indications, whether untreated or treated with alternative drugs [173]. Therefore, when feasible, it is preferable to establish multidrug pregnancy registries that allow comparisons among drugs from the same class or indication. More recently, both private and government initiatives have launched pregnancy registries using health apps for direct data collection from large populations of pregnant women (e.g., PregSource®). The validity of these data for drug safety research has not yet been established.

Children

Like other prospective disease cohorts, pediatric registries for children with rare chronic diseases can provide rich information about exposures, outcomes, and confounders [174–176]. Rare pediatric disease registries may also collect biologic specimens that facilitate molecular pharmacoepidemiology [177–179]. Some pediatric registries are population based and comprehensive in their ascertainment of affected children and, therefore, can minimize selection bias and yield generalizable knowledge [180]. Other registries rely on participants or families to voluntarily enroll and may be, thus, subject to selection bias or reduced external validity [181,182].

Retrospective Cohorts and Nested Case–Control Studies within Automated Healthcare Databases

Population-based automated healthcare databases, including national registries (e.g., Nordic registers), administrative claims databases (e.g., Medicaid), and EHR databases (e.g., Clinical Practice Research Datalink®, CPRD®), are frequently used sources of information for pharmacoepidemiologic studies (see Chapters 11–14) [183]. These databases allow researchers to conduct large-scale observational postmarketing studies on multiple rare or long-term consequences of drug use [184]. While these resources have their own strengths and limitations, they all offer detailed, longitudinal records of healthcare utilization, diagnoses, procedures, and drug data (prescriptions, dispensings, or

both) across a range of healthcare settings. The clinical care represented in these databases reflects the real world, and study populations may include minorities and other marginalized populations that are often excluded from volunteer-based studies. Although the cost and time of working with large administrative and EHR datasets can be high, this approach is usually less costly and has greater breadth than primary data collection. The size and generalizability of population-based automated healthcare databases can make them excellent settings for studies of rare exposures or outcomes in pregnant women and children. However, some automated healthcare databases have substantial limitations due to lack of child–mother linkages or routinely collected data on gestational age, birth weight, maternal obesity, smoking, or use of nonprescription drugs [185].

Pregnant Women

Linkage of children's records with those of their mothers is relatively comprehensive in Nordic countries, which have nationwide registries with national identification numbers that help link family members. Linkage between maternal and children's records in US healthcare databases, integrated health systems, and most EHR databases is also feasible [186–189]. US administrative claims databases lack information on gestational age, which needs to be estimated based on codes for preterm, term, or post-term delivery [190,191].

When exposure to the specific drug of interest involves a small fraction of the pregnant population, even these large cohorts are constrained in their information. In this scenario, multisite collaborations offer a solution. The Medication Exposure in Pregnancy Risk Evaluation Program (MEPREP) is a collaboration among government, academic research centers, and healthcare organizations to combine large administrative databases, linking data together from mothers, babies, and birth certificates [189]. This work has been continued in the Sentinel network [192] and is an important tool to study outpatient dispensing of medications during pregnancy and a number of validated pregnancy outcomes. More recently, international collaborations have allowed the identification of exposed pregnancy cohorts nested in multiple large healthcare databases with the goal of conducting not only surveillance but also etiologic research on the safety of medications during pregnancy. For example, the goal of the International Pregnancy Safety Study (InPreSS) consortium is to provide the best available human data on the safety of prescription medications during pregnancy by combining large-scale data from several countries [193]. Currently, it includes nationwide US Medicaid data that capture nearly half of all pregnancies, plus the national registries in the five Nordic countries that capture virtually all pregnancies. Identification of exposed cohorts nested within an international network of population-representative, prospectively collected datasets replicates the traditional exposure pregnancy registries in a cost- and time-efficient manner. This approach also avoids many of the potential biases that face *ad hoc* pregnancy registries [194]. One can also use collaborative research programs to rapidly follow up on safety signals initially identified in a single data source, thus reducing the chance for widespread worry based on concerning early findings that are not later substantiated. Premature dissemination of such false alarms creates challenges for pregnant women and their clinicians trying to make the best treatment decisions.

Children

A variety of automated databases have been used to study drug uses and effects in large pediatric populations, include encounter-based databases [195–198] and national EHR databases [199–201]. EHR databases are more likely to contain relevant pediatric data, such as birth weight, gestational age at birth, and growth measurements (see also Chapter 13). Some

databases that are also used to study pregnant women can be used to assemble retrospective birth inception cohorts that can jointly examine prenatal and postnatal exposures (e.g., antibiotics) in relation to subsequent outcomes [202,203]. As in pregnancy-related research, multinational collaborations of pediatric researchers, such as the Global Research in Paediatrics (GRiP) Network of Excellence and the Task-force in Europe for Drug Development for the Young (TEDDY) Network, have allowed for large-scale studies on drug utilization and effects, including rare outcomes, in children [72,204,205]. Within the US, there are several collaborative networks of pediatric EHRs that can facilitate pharmacoepidemiologic research, including the Comparative Effectiveness Research through Collaborative Electronic Reporting (CER^2) Consortium [206,207] and PEDSnet [208]. One population-representative EHR database in Italy, Pedianet, is composed completely of data from family pediatricians (see Chapter 13).

Several hospital-based databases have been used for pediatric pharmacoepidemiology research (see also Chapter 14). These include the Pediatric Hospital Information System (USA, >40 freestanding children's hospitals), Pediatrix (USA, >350 neonatal intensive care units), and the Vermont Oxford Network (global, >1000 neonatal intensive care units). Inpatient pediatric databases can provide useful settings for studying inpatient drug uses and effects in children with serious diseases, including extreme prematurity, rare diseases, and children with complex chronic conditions [209–213]. A common limitation of all these databases is the lack of generalizability based on the settings of care (predominantly academic pediatric hospitals) and the lack of outpatient data.

For certain pediatric outcomes, linkage of children's records to mothers as well as other family members, including fathers and siblings, may also be as important, because of concerns for confounding from genetic factors or other shared household factors (see "Confounding" and "Newer Designs") [214,215]. Databases with household/family identifiers (e.g., Medicaid, The Health Improvement Network® [THIN®]) or information on biologic relationships (e.g., Swedish registries) facilitate linkage to family members [124,216,217]. Of note is that residence identifiers do not necessarily specify which household members are biologically related, and one might need to make assumptions about relationships based on age and gender (e.g., mother vs. father).

Outside of the home, school is one of the most important places in a child's life and, thus, a unique setting for studies on medications and devices used by children. Pediatric researchers may want to study the impact of medications on outcomes such as attendance, promotion, behavior, and test performance. In some settings, it may be possible to link health or medication data to scholastic or testing information [218,219]. In settings where one cannot easily link clinical data to school records, researchers may need to rely on self-report [220] or direct cognitive assessments [221,222].

Case–Control Studies

Case–control studies identify individuals with the outcome of interest (e.g., a specific birth anomaly or childhood illness) and compare their frequency of exposure to that in a control group without this outcome. This design offers advantages in the evaluation of associations between prenatal or early life exposure to relatively common medications and the risk for rare events [223,224]. Case–control studies have some important limitations, however. They collect information on exposure retrospectively [225,226], rarely have a sufficiently large sample size to evaluate infrequently used medications, and sometimes do not properly select controls from the same source population as the cases. Furthermore, case–control studies typically focus

on only one type of outcome (e.g., major congenital malformations) and can estimate relative risks, but not the absolute risks associated with the drug, unless the study is nested within a defined cohort or otherwise contains additional information.

Pregnant Women

Case–control studies on birth anomalies are often based on interviews, thus allowing the collection of information on actual use of the drug (versus prescription or pharmacy dispensing), nonprescription drugs, and important covariates such as smoking, socioeconomic factors, or obesity, which are often missing from other data sources. Examples include the Slone Epidemiology Center birth defects study [35]; the National Birth Defects Prevention Study [67], which involved a number of state birth anomalies surveillance programs and was coordinated by the US Centers for Disease Control and Prevention; EUROmediCAT, which incorporates data on prenatal drug exposures and birth anomalies from multiple European registries [227]; and the ECLAMC (Latin-American Collaborative Study of Congenital Malformations) network from Latin America [228].

Children

Many pediatric case–control studies are limited to particular outcomes of interest on a study-by-study basis. In contrast, the Canadian Pharmacogenomics Network for Drug Safety uses a systematic case–control approach to study pharmacogenomic factors associated with a variety of serious outcomes in thousands of children. The network's focus is on children with cancer, because of their high burden of exposure to toxic medications. The network collects detailed clinical information and genomic data on children with recognized serious adverse drug effects and matched controls. In the future, this network plans to make its database and analytic tools publicly available to other pediatric researchers.

Newer Designs

Epidemiologists continue to explore more valid and efficient approaches to study pregnant women and children. In specific circumstances, when carefully conducted with clearly stated assumptions and interpretation of estimates, novel designs may bring advantages to the field.

Pregnant Women

To avoid between-person confounding, one might study the risk of birth anomalies using multiple exposure windows within one pregnancy (i.e., self-controlled design) [229] or multiple pregnancies in the same woman with discordant exposure status (i.e., sibling discordance study) [230]. However, the risk of time-varying within-person confounding remains (e.g., indication for the drug at a particular time) [229]. In a self-controlled design, one studies the presence and timing of exposure in people with the outcome of interest (see also Chapter 43 on self-controlled designs). For example, to study whether flu vaccine administration triggers miscarriage, one could compare the frequency of vaccinations during the month before the event with the frequency in a one-month control window three months before the event. However, in the presence of gestational time trends of drug utilization, case-crossover designs do not offer clear advantages over cohort or case–control designs to study birth anomalies [229]. In a sibling discordance study, the comparison is made between siblings born to the same parents but who differ with respect to their pregnancy exposure status (i.e., matching within mother rather than within pregnancy). This design exploits the fact that siblings share stable aspects of family context as well as half their genome, therefore accounting for unmeasured genetic and environmental factors that may be important sources for confounding. Sibling discordance studies are particularly valuable to test associations identified in studies of unrelated individuals where unmeasured confounding is a concern [231].

Children

Self-controlled designs, including case-crossover and self-controlled case series, have also been applied to drug and vaccine safety research in children [232,233]. Self-controlled designs are particularly appropriate for studies of incident, short-term exposures (common in children [21]) and acute outcomes, including rare conditions that occur in pediatric populations. As in research on pregnancy, self-controlled designs in children could be problematic if study periods extend across times of considerable personal change (e.g., first year of life) without adequate adjustment for age and other time-varying confounders [234]. Sibling discordance studies have also been used successfully to validate, and sometimes refute, pediatric treatment–outcome associations first suggested in traditional cohort studies [202,235]. In research on treatment effectiveness, instrumental variables [236–238] and pragmatic trials [239,240] have been applied to pediatric populations.

The Future

Professional organizations and governments have increasingly supported policies and regulations that prioritize research on medicines and devices for pregnant women and children. Large-scale, longitudinal, collaborative research using multiple data sources across multiple countries will become increasingly common and important for generating generalizable, actionable evidence for pregnant and pediatric populations. Collaborative networks and pooled resources, potentially through distributed data models, will enable the conduct of robust research on rare exposures and rare outcomes in pregnant women and children, including studies on specific drugs, drug dosage, and polytherapy in individuals with chronic conditions. Advancements in pregnancy-related and pediatric pharmacoepidemiologic research will require not only larger data sources and collaboration, but also more transparency and sharing of protocols, data, and analytic code and tools. In particular, future efforts must help build capacity, expertise, and infrastructure to conduct pharmacoepidemiologic studies in underserved settings and low- and middle-income countries.

The epidemiology of diseases of pregnancy and childhood continues to evolve, with the rising worldwide prevalence of obesity and associated ailments, emerging infectious diseases affecting pregnant women and children (e.g., Zika virus), increases in survival from life-threatening pediatric diseases (e.g., cystic fibrosis, malignancy, neuromuscular disorders), and many others. These changes in disease epidemiology will necessitate the generation and sharing of new evidence regarding drug safety and effectiveness for new indications in pregnant women and children. There remains a dearth of high-quality research on treatment effectiveness in these populations, in part because of the fundamental challenges of conducting observational effectiveness research (see Chapter 33). New methods on studying effectiveness and controlling for confounding by indication and disease severity will help improve the quality and quantity of effectiveness research for pregnant women and children. More research and better methods are also needed to study drug uses and effects in lactating mothers and breastfed infants. Another population that warrants further attention is pregnant youth under age 18, who represent an ethically challenging and potentially high-risk subgroup that is commonly excluded from pregnancy-related research.

New and growing linkages between complementary types of data – automated databases, registries, patient-generated data, biobanks containing genomic and other -omic data, and others – will open up new frontiers for the discovery and validation of personalized treatment regimens. From a methodologic perspective, linkage between datasets will also facilitate the validation of outcomes and better

control for confounding through techniques such as propensity-score calibration [241]. Because large healthcare databases will not be sufficient or appropriate for all research questions about pregnant and pediatric populations, we should continue to use, improve, and teach field methods for primary data collection (including biospecimens for pharmaco-omic studies) from patients and families. With advancements in technology and expansions in information, clinicians, pregnant women, and families will need enhanced resources to curate and interpret the deluge of available data. Bedside tools for data analyses (e.g., pharmacogenomic risk stratification) as well as shared decision-making will help clinicians, patients, and families understand and discuss the risks and benefits of treating pregnant women and children in the face of clinical uncertainty, and make informed, personal decisions [242–245].

Study of Biologics and Biosimilars

Jeffrey R. Curtis[1] *and James D. Lewis*[2]

[1] *Division of Clinical Immunology & Rheumatology, University of Alabama at Birmingham, Birmingham, AL, USA*
[2] *Department of Medicine, Division of Gastroenterology, and Department of Biostatistics, Epidemiology, and Informatics, Perelman School of Medicine University of Pennsylvania, Philadelphia, PA, USA*

Biologic therapies are complex molecules that include a variety of products, such as recombinant therapeutic proteins, vaccines, blood components, gene therapy, and others. Their components or precursors are derived from living sources. From the perspective of pharmacoepidemiology, biologic drugs are therapeutic agents used to prevent or treat a health condition. They typically take one of three constructs: (i) fusion proteins that link a receptor with a protein (e.g., Fc region of an antibody) or a polyethylene glycol (PEG) fragment, which extends the half-life of the receptor portion of the construct; (ii) custom monoclonal antibodies that can be humanized or chimeric (e.g., with both human and murine components); and (iii) an agent that mimics the human native signaling mechanism, such as erythropoietin, growth hormone, insulin, or human parathyroid hormone.

Biologics are typically more difficult to synthesize than traditional small molecules and require synthesis in a bioreactor. Examples of the molecular constructs for several biologics used for the treatment of autoimmune and inflammatory diseases are shown in Figure 23.1. Currently available biologics are administered parenterally, typically by intravenous infusion or subcutaneous injection; those given by injection are often but not always self-administered by the patient.

In the US, biologics were approved for use in humans as early as 1986 [1], although development efforts accelerated dramatically in the late 1990s. Their clinical indications have expanded from somewhat narrow, niche uses (e.g., organ transplantation, adjunct treatment to percutaneous coronary intervention, treatment of specific types of malignancies) to more widespread use for a variety of autoimmune and inflammatory diseases, including rheumatoid arthritis (RA) and other forms of inflammatory arthritis (e.g., psoriatic arthritis, ankylosing spondylitis, gout), inflammatory bowel disease (IBD), psoriasis, and multiple sclerosis (MS); see Table 23.1. Over time, the indications for biologic use have expanded and now include noninflammatory conditions (e.g., osteoporosis). Although the specific mechanisms of action (MOA), safety concerns, and effects of various biologics are highly variable, the general principles that underlie use of these drugs as related to pharmacoepidemiologic research will be reviewed in this chapter.

Pharmacoepidemiology, Sixth Edition. Edited by Brian L. Strom, Stephen E. Kimmel and Sean Hennessy.

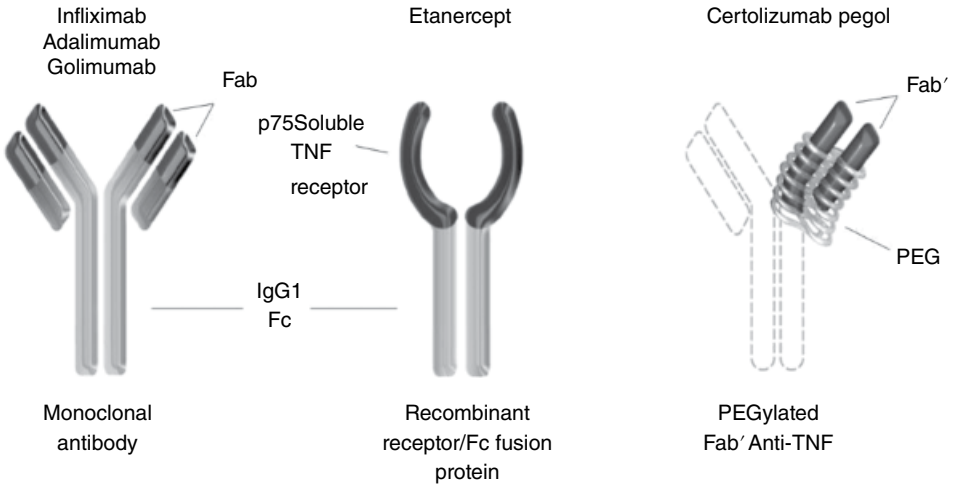

Figure 23.1 Examples of the molecular constructs for several biologics used for the treatment of autoimmune and inflammatory diseases.

Clinical Problems to Be Addressed by Pharmacoepidemiologic Research

The pharmacoepidemiology questions that surround the use of most biologics are generally similar to those of other immunosuppressant medications. Because many of the disease indications for biologics (e.g., RA, IBD) have a relatively low prevalence (e.g., population prevalence of each of approximately 1%), pharmacoepidemiologic methods to study rare safety events have been particularly valuable to characterize the risks and benefits of these medications. Some safety concerns are common to all biologics, including risks for serious infections (both bacterial infections such as pneumonia and sepsis, as well as rare opportunistic infections such as tuberculosis) and malignancy. Others are more mechanism specific and related to particular effects of biologic pathways (e.g., lipid metabolism) that may increase concern for increased risk for particular types of events (e.g., myocardial infarction). There are a few unique types of adverse reactions that have been associated with biologics that are thought to be related to the consequences of administering large, biologically active proteins. Each of these will be briefly discussed in what follows.

Serious Infections

All medications that suppress the immune system are thought to increase the risk of infection. Unfortunately, it is difficult to quantify how much any specific medication suppresses the immune system. In general, infections that typically only occur in the setting of immunosuppression are referred to as opportunistic infections. Some medications may increase the risk of common infections (e.g., pneumonia), while others predispose to selected types of opportunistic infections. The complex nature of the human immune system results in different patterns of infection based on the aspect of the immune system that is being targeted.

Shortly after the marketing of anti-TNF (tumor necrosis factor) drugs to treat immune-mediated diseases, there was a signal in postmarketing reporting of an increased risk of opportunistic

Table 23.1 Examples of biologics, their mechanism of action, and FDA-approved indications for non-malignant conditions.

MOA	Name (construct)	Examples of FDA-approved indications
Cytokine or cytokine receptor inhibition		
TNF inhibitor (TNFi)	Etanercept (fusion protein)	RA, PsA, AS, JIA, PsO
	Adalimumab (humanized monoclonal antibody)	RA, PsA, AS, JIA, PsO, uveitis
	Infliximab (chimeric monoclonal antibody)	RA, PsA, AS, IBD, PsO
	Golimumab (humanized monoclonal antibody)	RA, PsA, AS, PsO
	Certolizumab (PEGylated protein)	RA, PsA, AS, PsO, IBD
Anti-IL6R	Tocilizumab (monoclonal antibody)	RA, sJIA, GCA
	Sarilumab (monoclonal antibody)	RA
Anti-IL1R	Anakinra (fusion protein)	RA, periodic syndromes
IL-1	Rilonacept (soluble decoy receptor)	Periodic syndromes
Anti-IL-1β	Canakinumb (monoclonal antibody)	sJIA, periodic syndromes, AOSD
IL-17	Secukinumab, Ixekizumab (monoclonal antibody)	PsO, AS, PsA
IL-12/23		PsO
IL-23	Ustekinumab (monoclonal antibody)	PsO, Crohn's disease
	Guselkumab (monoclonal antibody)	PsO
RANK/RANKL	Denosumab	Osteoporosis
Anti-interferon beta-1	Multiple, directed against beta-1a or beta-1b	MS
Other mechanisms of action		
B-cell depletion	Rituximab (monoclonal antibody)	RA, vasculitis
T-cell co-stimulation blockade	Abatacept (fusion protein)	RA, PsA, JIA
B-lymphocyte stimulator antagonist	Belimumab (monoclonal antibody)	SLE
Recombinant mammalian urate oxidase (uricase)	Pegloticase (PEGylated protein)	Gout
Antagonist to α4 integrin	Natalizumab (monoclonal antibody)	MS, IBD
Antagonist to α4β7 integrin	Vedolizumab (monoclonal antibody)	IBD

AOSD, adult-onset Still's disease; AS, ankylosing spondylitis; GCA, giant cell arthritis; IBD, inflammatory bowel disease; JIA, juvenile idiopathic arthritis; MOA, mechanism of action; MS, multiple sclerosis; PsA, psoriatic arthritis; PsO, psoriasis; RA, rheumatoid arthritis; SLE, systemic lupus erythematosus.

infections. Specifically, there were multiple spontaneous reports of tuberculosis among patients treated with infliximab [2]. Given the rarity of tuberculosis in the US, this relatively large case series (70 events) was unusual, and, extrapolating from estimates of the number of patients who had been treated with the drug up that point in time, the incidence of tuberculosis appeared higher than would have been expected. This prompted a black box warning from the US Food and Drug Administration (FDA) and a change in clinician behavior, with routine testing for prior tuberculosis exposure before initiation of treatment.

Subsequently, investigators have examined the association of biologics used in the treatment of immune-mediated diseases with the risk of other opportunistic infections and more common infections. For example, use of anti-TNF drugs has been associated with an increased risk of pneumonia among patients with inflammatory bowel disease [3]. Similar to tuberculosis, which can result from either *de novo* infection or reactivation of latent infection, there have been many cohort studies describing reactivation of hepatitis B among patients treated with anti-TNF therapy [4]. Numerous systematic reviews and meta-analyses have addressed this question. A 2016 systematic review of clinical trials of anti-TNF therapies for RA, ankylosing spondylitis, or psoriatic arthritis reported that anti-TNF therapy was associated with a 20% increase in any infection and a 40% increase in serious infections. This risk translates into an absolute rate difference of approximately 1–2 per 100 patient-years. There was no reported increase in opportunistic infections other than tuberculosis, but the authors noted that the rate of reporting of opportunistic infections in the clinical trials was very low [5].

Emphasizing the importance of the specificity of the targeting of different aspects of the immune system, two similar biologic drugs that target alpha-4 integrins have been marketed for the treatment of Crohn's disease. Natalizumab, which is also approved for the treatment of multiple sclerosis, targets α4β1 and α4β7; vedolizumab, which is also approved for the treatment of ulcerative colitis, targets only α4β7. Because α4β7 only directs lymphocytes to the gut, whereas α4β1 directs homing of lymphocytes to the gut and the brain, the risk of opportunistic infections between these two medications has proven to be quite different. Natalizumab has been associated with development of a typically severe, often fatal brain infection, progressive multifocal leukoencephalopathy (PML) [6]. However, this potentially fatal reactivation of JC virus infection has not been observed in patients treated with vedolizumab [7]. In the absence of immunosuppressant medication exposure, PML is typically only observed in the setting of other diseases associated with immunosuppression, such as HIV infection or malignancy. However, like most adverse drug reactions, PML is not uniquely associated with natalizumab and has been observed with other biologic therapies, most notably rituximab in RA [8], although cases with anti-TNF therapy have also been reported [9].

Neoplasia

Perhaps due to the dreaded nature of the disease, the fear of cancer has proven to be one of the major factors that limit the use of anti-TNF medications for the treatment of immune-mediated diseases. Early after the marketing of anti-TNF drugs, concern was raised about whether these medications increased the risk of cancer, particularly lymphoma. In *post hoc* analyses from premarketing clinical trials, there was evidence of an increased incidence of lymphoma among patients with RA who were treated with anti-TNF medications compared to rates expected in the general population. This led to black box warnings for anti-TNF medications for the risk of lymphoma [10–12]. However, these estimates were not based on

comparisons to patients with comparably severe RA who likely also had an increased risk of lymphoma [13,14]. Indeed, patients with more active RA may be at appreciably higher risk for lymphoma [15], consistent with the mechanistic explanation related to a greater burden of systemic inflammation and chronic immune activation. This hypothesis remains under study [16], and its relevance to pharmacoepidemiology lies in the potential for confounding by disease activity and associated systemic inflammation. In addition, many patients who are treated with anti-TNF drugs may have been previously or simultaneously treated with other medications that increase the risk of lymphoma, such as thiopurines [17]. This is particularly true in patients with IBD. Ultimately, many further studies have been published on this topic, often coming to differing conclusions in part due to low statistical power [18–23]. A recent large study from Sweden suggested that anti-TNF therapy was associated with a small increased risk of lymphoma, and that concomitant therapy with thiopurines increased that risk further [24].

The risk of other cancers with biologic therapies for immune-mediated diseases seems to be small, if it is increased at all. There are some reports of a potential increased risk of melanoma with anti-TNF drugs, but this has not been universally reproduced [25,26]. Because the incidence of melanoma in this population is so low (less than 1 per 1000 patient-years), recent efforts have pooled data from a variety of data sources (e.g., multiple European registries) and have not confirmed this association [27]. As with lymphoma, all assessments of cancer risk need also to take into consideration the potential impact of other prior and concurrent immunosuppressant medications [28]. In patients with a history of prior cancer, these medications are generally avoided until there is evidence that the cancer has been cured in that patient. However, with the possible exception of nonmelanoma skin cancer [29], the available data suggest that use of anti-TNF medications is relatively safe once prior cancers are thought to be cured [30,31].

Studies of the association of newer biologic drugs, in classes other than anti-TNF, focusing on cancer have been relatively small, limiting the ability to draw strong conclusions [32,33].

Paradoxical Reactions

There are a few scenarios where treatment with biologic drugs results in a paradoxical reaction, meaning that the drug causes a syndrome similar to one that it is used to treat when being used to treat a different disease. The prototypical example of this is the development of a psoriaform rash in patients treated with anti-TNF drugs [34]. The rash often responds to similar medications as are used to treat psoriasis, and frequently recurs with switching between anti-TNF drugs. The exact mechanism that drives these paradoxical reactions is unknown.

Other Adverse Events of Interest with Biologic Drugs

There are a number of other adverse events that have drawn attention with the biologic drugs used to treat immune-mediated diseases. Tocilizumab, an interleukin-6 receptor antagonist used to treat RA, has been associated with bowel perforation, typically of the lower gastrointestinal (GI) tract [35,36]. This pattern is distinct from the more typical sites of GI perforation in RA patients that are associated with nonsteroidal anti-inflammatory drugs, which are in the upper GI tract. Numerically adverse changes in low-density lipoprotein (LDL) have also been observed with some biologic therapies, including anti-TNF agents [37], and particularly the anti-IL6R class of medications (e.g., tocilizumab) [38]. While the ratio of LDL to high-density lipoprotein is unchanged, the potentially adverse changes in lipid profiles initially raised safety concerns for an increased risk

of cardiovascular disease (CVD) related events. Reassuringly, CVD event rates from the tocilizumab clinical trial program [39] and recent results from a large safety trial of more than 3000 patients with a CVD endpoint [40] showed no difference between anti-TNF therapy and tocilizumab. These results were confirmed by several observational analyses [41, 42, 43] that also suggested tocilizumab does not increase CVD risk.

The anti-TNF drugs frequently result in a positive antinuclear antibody and occasionally cause drug-induced lupus [44]. Notably, reports of severe liver injury and pancreatitis with the biologic drugs for immune-mediated disease have been relatively infrequent [45,46]. There have also been cases of new-onset IBD or exacerbations of preexisting IBD associated with anti-IL17 therapies, used for psoriasis and psoriatic arthritis, although a more systematic evaluation has not confirmed this association [47].

In contrast to the biologic drugs that are designed to suppress the immune system, the immune checkpoint inhibitors, such as ipilimumab and nivolumab, which are used as treatment for cancer, are designed to increase activity of the immune system. The prototypical adverse reaction to these agents is the onset of colitis that mimics IBD [48].

Finally, as might be expected with a complex molecule, hypersensitivity reactions to administration of biologics are a potential safety concern. These range from infusion reactions of mild severity that do not preclude continued treatment (generally with concomitant diphenhydramine and intravenous glucocorticoids), to anaphylactic reactions that may be life threatening and result in death. Although a few medications have associated biologic markers that suggest that the risk of hypersensitivity reactions may be increased (e.g., increasing serum uric acid for patients treated with pegloticase) or assays that can detect antidrug antibodies (ADAs; discussed shortly), some hypersensitivity reactions are idiosyncratic and unpredictable. This type of rare but often serious safety event may be particularly suitable to study using pharmacoepidemiologic methods (e.g., self-controlled study designs, see Chapter 43) [49], given the rather predictable temporal association between exposure and outcome. For example, anaphylactic-type reactions would be expected within 24 hours of intravenous administration.

Comparative Effectiveness of Biologic Drugs

Because many biologic drugs are foreign proteins, many have been routinely administered in combination with other immunosuppressant medications, with the hope of reducing the incidence of the development of ADAs and improving both efficacy and durability of response [50,51]. For most disease indications, biologic drugs have been shown to have enhanced effectiveness if given as combination therapy with a background conventional therapy (e.g., TNFi plus either methotrexate or thiopurines), as demonstrated in high-quality randomized controlled trials [52,53]. In contrast, a few trials have attempted to combine multiple biologics together. These have generally shown negligible incremental clinical benefit and a higher rate of adverse events, especially infections [54,55]. For the time being, it is therefore reasonable to assume for the purpose of characterizing exposure in a pharmacoepidemiologic study that patients are not simultaneously receiving two biologic medications for the same disease indication.

While being on two immunosuppressive or immunomodulatory treatments may have synergistic effects with respect to clinical effectiveness, use of the combination may affect safety. However, designing pharmacoepidemiology studies to compare combination therapy to monotherapy presents a unique challenge. Some patients will "step up" from monotherapy with one of the two medications to combination therapy,

while others will switch from one therapy to the other, and yet a third option is to start both medications around the same time, although generally not on the same day. Determining which treatment pattern applies to which patient can be difficult when using administrative claims data or even electronic health records. One often needs to observe several months of treatment to determine whether the first medication has been continued, in order to know whether the patient added the second medication and is now on two treatments, or switched to the second medication as monotherapy. To avoid immortal time bias, one approach is to start follow-up for all groups several months after the second drug was added to allow for clarity over to which treatment group each patient should be assigned [56]. Unfortunately, this approach limits the ability to study outcomes that occur shortly after the initiation of combination therapy.

The reasons that patients may not continue the background treatment (e.g., methotrexate) may also be important when studying outcomes. Some patients may discontinue the background therapy due to fear of future side effects in the setting of lack of perceived benefit when taken as monotherapy. Some patients may not continue treatment due to intolerance or other "nuisance" side effects (e.g., alopecia, oral ulcers) that have minimal impact on major health outcomes. Other patients may not continue background conventional treatment because of co-morbidities (e.g., chronic liver disease) or nonadherence to the required laboratory monitoring (e.g., liver enzyme testing). Thus, the underlying reasons why patients are not receiving combination therapy may be important from a pharmacoepidemiologic perspective, and may affect the risk for other types of adverse events. Measuring and controlling for these factors underlying use of monotherapy (versus combination therapy) are likely to be important to control for in any pharmacoepidemiologic study if these reasons (or proxies for them) are available in the analytic data source.

For most biologic indications, the large, Phase III studies conducted for regulatory purposes have compared biologics against placebo, and randomized comparative effectiveness trials are infrequent. In RA and IBD, for example, only a small handful of direct comparisons between biologics are available that are powered for superiority [57]; others have been designed as noninferiority studies against anti-TNF therapy [58]. Anti-TNF therapy is commonly used as the referent comparator agent, given that it was the first biologic class of drugs approved for most autoimmune and inflammatory conditions and has the greatest uptake worldwide. Indirect comparisons and meta-analyses have suggested relatively comparable efficacy between therapeutic agents, although changing from first anti-TNF therapy to a biologic with a different MOA may be preferable for patients with inadequate clinical efficacy [59]. Unfortunately, "inadequate clinical efficacy" and "loss of response" are imprecisely defined clinically and vary greatly by disease. More recently, newer biologics with different MOAs have been compared against anti-TNF therapy. Results from randomized controlled trials in psoriasis suggest that biologics targeting the IL-12/23 [60] and IL-17 pathways likely have superior efficacy in psoriasis compared to TNFi therapy [61]. IL-17 therapy appears to have superior efficacy even to ustekinumab [62]. However, this effect does not appear to extrapolate to other conditions, even those that are closely related (e.g., psoriatic arthritis, PsA).

While clinical effectiveness of improvement in inflammatory arthritis (RA, PsA), in gut inflammation (IBD), or in the skin (psoriasis) are endpoints that are difficult to assess in claims or electronic health record (EHR) data sources used for pharmacologic research, a number of attempts have been made to create and validate algorithms to serve as proxies for clinical endpoints that can be applied to administrative data. In RA, for example, an algorithm that requires patients to remain on the biologic

with good adherence, not add a new conventional therapy, undergo intra-articular injection or increase systemic glucocorticoids, has been shown to mirror the clinical effectiveness of RA treatments with good sensitivity, specificity, and positive predictive value [63]. For other biologic indications, the relevant outcome measures may be directly available in claims or EHR data sources. For example, effectiveness outcomes such as avoidance of bowel surgery (IBD) [56] or fracture (osteoporosis) [64,65] can be studied directly with good validity in these data sources.

Safety of Switching and Restarting

Unlike with traditional small-molecule drugs, a unique challenge of using biologic drugs is that each drug is seen by the patient's immune system as a foreign protein. Therefore, the patient's immune system is programmed to make ADAs directed against the biologic drug. These neutralizing antibodies lead to loss of response and increase the likelihood of having an allergic reaction to the medication.

Much has been learned about the risk of developing antibodies to biologics since the introduction of infliximab. When infliximab was initially approved for RA and Crohn's disease, it was used episodically, being administered when the patient became symptomatic again. This strategy allowed most patients to have sufficiently long gaps in therapy that the drug was completely cleared from the circulation. However, this would prime the immune system to recognize the drug at the next infusion and manifest with high levels of ADAs. The result was high rates of infusion reactions and loss of response. A landmark trial in Crohn's disease clearly demonstrated that induction therapy with three doses of medication followed by maintenance dosing was superior to on-demand dosing for maintenance of remission and prevention of ADAs [66].

In clinical practice, even when induction and maintenance dosing are employed, there are times when patients may need to have gaps in therapy or will desire to restart a biologic drug after a period off medications. Such gaps put the patient at risk for allergic reactions driven by ADAs, although in the era of maintenance dosing this seems to be less common [67]. Of importance is that the risk for ADAs is somewhat disease specific, such that patients with RA and IBD are at higher risk than patients with PsA, psoriasis, and ankylosing spondylitis. Regardless of the risk, concomitant therapy with methotrexate or thiopurines appears to significantly attenuate the risk of ADA formation, although does not abrogate it completely [68–71].

Switching drugs within the same class of biologics is common when considering the anti-TNF drugs, where there are five approved for a variety of indications. The most common indication for switching within class is loss of response to a drug within the same class. At least in IBD, measuring drug levels and antidrug antibodies can help guide this strategy. When there are high levels of ADAs and low or absent drug levels, this suggests that the loss of response was mediated by the ADAs and that the patient would be more likely to respond to another drug within the same class [72]. In contrast, if there are high drug levels and low or absent antidrug antibodies, switching to a drug of a different class is more likely to be effective [72]. At this point, measuring drug levels and/or ADAs is unique to the management of IBD. However, the relevance of this strategy may increase given the expected future availability of multiple biosimilar anti-TNF medications that could increase use of this class of medications relative to other biologics with different MOAs that do not have a biosimilar equivalent available.

There are circumstances where patients may choose to switch drugs within the same class for convenience. For example, patients may switch from an intravenous drug to a self-injected drug to avoid the need to schedule infusion visits. There are relatively little data on the safety of

such switches. A small trial in patients with Crohn's disease suggested that patients who were in remission on infliximab were more likely to stay in remission and without adverse events if they remained on infliximab than if they switched to adalimumab [73]. However, even though biologics may have the same mechanism of action and therapeutic target (e.g., TNF), it should not be assumed that the clinical response to one agent in the class will necessarily mirror the clinical response to another.

An evolving area of research is the question of switching between the originator drug and the biosimilar of the same drug. There are multiple definitions of biosimilars, but all are generally consistent with the FDA's definition that the compound is highly similar to the reference product, and that there are no clinically meaningful differences from the reference product in terms of safety, purity, and potency [74]. Approval of biosimilars for marketing has generally relied on a single clinical study showing noninferiority or equivalence, in which one group receives the originator drug and the other group the biosimilar. The potential cost savings of biosimilars are appreciable, up to 40–70% in Europe [75], although the savings are likely to be appreciably less in the US (e.g., 20–30%). There is interest in knowing whether one can safely switch between originator and biosimilar drugs in patients who are currently receiving therapy with the originator drug. The strongest evidence of the safety of this strategy comes from the NOR-Switch trial, in which patients with RA, Crohn's disease, ulcerative colitis, psoriasis, PsA, and spondyloarthritis who were stable on treatment with infliximab for at least 6 months were randomly assigned to continue the originator infliximab or switch to CT-P13 (infliximab-dyyb, Inflectra®). The primary outcome was disease worsening. The overall adjusted rate of worsening slightly favored the originator drug, but was not significant, and it met the predefined 15% threshold for equivalence (−4.4%, −12.7% to 3.9%) [76]. Although reassuring, there remain additional questions, such as the safety of repeated switching and switching between multiple biosimilars with respect to immunogenicity and the formation of ADAs.

Currently Available Solutions: Methodologic Problems to Be Solved by Pharmacoepidemiologic Research

Accurate Identification of Biologic Exposure in Pharmacoepidemiology Data Sources

By their nature, biologic agents must be administered parenterally, either subcutaneously or by intravenous administration. Some therapies (e.g., abatacept, tocilizumab, golimumab) can be given via either route of administration, and ustekinumab, when used for Crohn's disease, is given intravenously for the first dose and then subcutaneously thereafter. For some biologics, clinicians can vary either the dose and/or the frequency of administration. Dosing variation generally takes one of three forms, specific to each biologic and its indication(s): (i) fixed dose and frequency (e.g., Etanercept 50 mg once weekly for RA); (ii) fixed dose, with the possibility of increased frequency depending on clinical response (e.g., adalimumab 40 mg every 2 weeks, with possibility of increase to 40 mg once weekly); and (iii) weight-based dosing (e.g., infliximab 5 mg/kg every 8 weeks, with possibility to both increase the dose and increase the frequency depending on clinical response). Self-injected drugs are reimbursed under a pharmacy benefit (e.g., Medicare part D), and intravenous treatments are reimbursed under a medical benefit (e.g., Medicare part B). Infused biologics will be identifiable in most administrative data sources using Healthcare Common Procedure Code System (HCPCS) Level II codes as claims for medical procedures (e.g., infliximab, J1745). A few biologics can be reimbursed under either

the pharmacy benefit (e.g., certolizumab SQ, self-administered) or under the medical benefit (certolizumab SQ, administered once monthly by a healthcare provider).

Biologics identified in pharmacy data using National Drug Codes (NDC) are generally straightforward to classify in terms of the dose and quantity dispensed, given the specificity of NDC codes. Biologics billing as medical procedures will typically have dose represented based on the units appearing on the medical procedure claim. For example, the HCPCS code J1745 for infliximab represents 10 mg, so 30 units would reflect a dose of 300 mg. Given that the starting dose of this medication is generally fixed by disease indication, one can infer the patient's weight (or weight category) based on units dispensed. For example, in IBD, the starting dose is typically 5 mg/kg, so an initial dose of 300 mg, 400 mg, or 500 mg could be reasonably used to assume that the patient's weight was approximately 60 kg, 80 kg, or 100 kg, respectively. While not perfectly precise, given that the drug is provided in 100 mg vials and healthcare providers typically round up to the nearest whole vial, this approach is nevertheless potentially helpful to infer the patient's weight category in data sources where it is not directly available (e.g., health plan claims).

One challenge in identifying biologics given as medical procedures is that after a biologic is approved, it is assigned a "nonspecific" HCPCS code by the Center for Medicare and Medicaid Services. This is typically replaced during the next year (or two) by a permanent HCPCS code that uniquely identifies the drug. Until this occurs, however, the drug is reimbursed under J3490 (Unclassified drug) or J3590 (Unclassified biologic). A combination of the associated disease indication (using International Classification of Diseases, ICD) codes, units dispensed, submitted or allowed amount, and other features associated with the procedure claim can be used to specifically identify the drug [77]. The relevance for pharmacoepidemiology studies is that if this approach is not followed, it will fail to identify the earliest users of the medication, and it will misclassify the date of first use. The implications are that any new user study design [78] of biologics in their first 1–2 years after licensure may be meaningfully compromised if this issue is not appropriately addressed methodologically.

An additional consideration is to understand the duration of exposure in relation to each biologic administration. As with other therapies, the effect of biologic drugs reflects not only the half-life of the agents (i.e., pharmacokinetics), but also the duration of their effect on the body (i.e., pharmacodynamics). Subject matter expertise is therefore needed to understand whether an "extension" to current exposure might be warranted. This decision depends on the drug, its pharmacokinetics and pharmacodynamics, and the outcome being studied. For outcomes with a short expected interval between exposure and outcome, a relatively short (e.g., 30–90-day extension) is likely warranted [79]. As with all pharmacoepidemiology studies, researchers also must consider whether the relative hazard of the outcome is likely to be constant or time varying. For example, the association between biologic exposure and serious infections has been shown to peak early and then flatten [80]. A variety of factors may account for this, including a true biologic effect reflecting a reduction in systemic inflammation (which has been associated with infection risk), subsequent reduction in glucocorticoid use, or depletion of susceptible patients [81]. In contrast, for an outcome like malignancy, where the shape of the hazard curve between exposure and outcome is not clear, "ever exposed" may be preferable, and risk with increasing cumulative exposure in discrete time intervals should be estimated over the follow-up period. Because switching of therapies is common, particularly when the first medication fails to achieve complete symptom control, all of these studies must also consider the biologic plausibility of very early outcomes and those that occur long after a medication is discontinued, and the potential impact of prior, concomitant, and subsequent treatments on the outcome of interest.

Biosimilar Naming Conventions and Representation in Administrative Data Sources

With generic drugs, the generic product is referred to solely by the name of the generic compound, since the medication is an exact replicate of the active ingredient. Biosimilars are not exact replicates of the referent biologic. Therefore, it is necessary for each biosimilar to have a unique name, but still have a name that reflects the nature of the product. Based on this, the FDA has proposed that biologics all have a four-letter suffix added to the generic name. By requirement, this suffix can have no clinical meaning. For example, the original infliximab (Remicade®) has the suffix -hjmt (although current guidance on nomenclature suggests to omit the suffix for the reference biologic product), while the biosimilar Inflectra® is infliximab-dyyb. These unique suffixes will allow for accurate identification of the biosimilars within claims data and electronic health records [82]. Biosimilars administered by healthcare facilities will continue to be identified by HCPCS codes in the US. Prior to January 1, 2018, the HCPCS codes for biosimilars to the same originator product were the same, but with a unique modifier that would be included in the billing data. For example, Inflectra® and Renflexis® share the same HCPCS code (Q5102) but have unique modifiers (ZB and ZC, respectively) [83]. However, when biosimilars are first released, before an HCPCS code is assigned, they may need to be identified by a generic J code, similar to the challenges of identification of any new biologic administered by a healthcare facility. After January 1, 2018, these rules have changed and guidance is now available from the Centers for Medicare and Medicaid Services [83]. Drug-specific codes for individual biosimilars are now assigned. For example, new medical procedure codes were created to uniquely identify the infliximab biosimilars, Q5103 (Inflectra®) and Q5104 (Renflexis®). A relatively similar system has been proposed for the European Union, but complete harmonization has not yet occurred and seems highly desirable [82].

Confounding by Indication

As with all pharmacoepidemiology and comparative effectiveness studies, confounding by indication is an important consideration. This may be an even greater concern with studies of biologic medications, due to the high cost of these medications leading to restrictions on access by some insurance plans until patients have failed to adequately respond to other less expensive medications or through other means [84,85]. The methods to address confounding by indication (see Chapter 43) in studies of biologics do not differ from those of other medications, but should take into consideration this channeling process. Patients who are being treated with a second or third biologic are also likely to be more refractory to therapy than those receiving their first biologic drug. For example, in patients with IBD, those receiving vedolizumab were much more likely to respond to therapy if they had not been previously treated with an anti-TNF drug [86,87]. The reasons for switching from a first to a second (or subsequent) biologic are also likely important. For example, if patients with RA have had an inadequate clinical response to the first TNF drug, they are more likely to have an inadequate response to a subsequent TNF drug [88]. However, if they discontinued the first TNF drug for a safety or tolerability concern, then the clinical response to the subsequent TNF drug was unaffected, but it is more likely to fail for safety or tolerability reasons. In most administrative data sources, the reasons for discontinuing or switching therapy are not known, but some registries or EHR data sources may capture this information.

More refractory patients who have received multiple biologics in the past also will typically have longer disease duration, a higher comorbidity burden, and may be at higher risk for serious adverse events such as infections [89].

Thus, having sufficient historical data to fully account for the number of prior medications (both biologic and conventional therapies) with which the patient has been treated, particularly the number of different biologic and conventional medications that the patient has received, is important to fully capture the disease severity. Ascertainment of prior treatment history is likely to be optimal if an extended baseline period of observation is available, and a variable "baseline" period (e.g., 12 months, plus all available prior data) may be useful for assessment of these specific covariates [90,91].

To overcome confounding by indication, a number of considerations relevant to biologic access may be useful. Because health plans often dictate the selection of which biologic must be used first (and sometimes second), in what are called "fail-first" policies, then selection is not predicated on individual patient characteristics, and patients with the same condition treated with different first-line biologic agents may be compared between health plans. Assuming the health plan does not also dictate which second-line biologic treatment the patient may receive, there are major evidence gaps with respect to which biologic should be optimally be used next, and physician judgment (in the absence of evidence) may prevail. Instrumental variable methods (Chapter 43) using provider preference (which may be affected by financial motivations to use infusion-based treatments [92]) or other logistics related to biologic use (e.g., driving distance to the infusion center for once-monthly infusion treatments) may be useful methodologic considerations to address confounding by indication and reduce bias.

Measuring Treatment Discontinuation

A related concept is measuring treatment discontinuation. Persistence on therapy is a commonly used endpoint in comparative effectiveness studies that is used as a surrogate for sufficient response to therapy to justify continued use of these expensive immunosuppressive therapies [56,93–95]. Similarly, assigning an exposure category to an event requires knowledge of whether the patient was exposed to the therapy when the event occurred. Because many biologic drugs are dosed intermittently due to long half-lives, defining discontinuation can take several months after the last dispensing to determine whether the patient discontinued the medication. Furthermore, because many biologic drugs suppress the immune system, clinicians may temporarily hold these medications around the time of elective surgeries or if there is evidence of an infection. Thus, it is important to account for potential gaps when considering persistence on therapy. Defining the optimal duration of "gap" time while considering a patient to have continuous therapy as opposed to reinitiation of therapy can sometimes be determined empirically from the available data by examining the pattern of drug dispensing, particularly focusing on dispensing that appears to be a reinitiation regimen based on the dose. Finally, as noted previously, because patients who have lost response to other biologics are more likely to lose response to the next biologic, accounting for prior biologic use is important in studies examining persistence on therapy.

The Future

New Therapies

Although biologics have proved very effective for the treatment of autoimmune and inflammatory diseases, new small-molecule targeted therapies have emerged that have similarly rapid onset (e.g., demonstrable benefit in the first 2 weeks of treatment and near-maximal effect by 12 weeks) and comparable effectiveness and safety to biologics. Unlike conventional and slower-acting immunosuppressive drugs for these same indications that have may have multiple biologic effects, new synthetic immunomodulatory drugs that target specific immune and inflammatory pathways (e.g., the JAK/STAT signaling pathway)

have emerged and proven very effective compared to biologics [96]. Some are already approved in the US (e.g., tofacitinib for RA, PsA, and UC; baricitinib for RA) and Europe (e.g., baricitinib for RA) and have particular safety concerns based on their mechanisms of action (e.g., increased rate of herpes zoster observed with janus kinase inhibitors, likely as a consequence of effects on interferon gamma, and possibly increased rates of venous thromboembolism when JAK/STAT drugs are used at higher doses) [97]. Several other compounds targeting the JAK/STAT pathway, as well as other immune-related pathways (e.g., spleen tyrosine kinase, Syk) are in development and will continue to spur interest in real-world evidence comparing these therapies to current and future biologics.

New Data Sources and Linked Data to Generate Real-World Evidence

To date, many studies of biologic safety have been conducted in large administrative healthcare databases, and disease-specific or drug-specific (biologic) registries [98–101]. Recognizing the limitations of each of these types of data, there has been growing interest in expanding both the kinds of data sources used for comparative evaluation of biologic safety and effectiveness, as well as linking between data sources. Large-scale EHR data such as that available in the Patient-Centered Clinical Research Network (PCORnet) [102–104] and from specialty-specific registries such as the American College of Rheumatology's (ACR) Rheumatology Informatics System for Effectiveness (RISE) [105] offer the potential for large-scale data analysis on patients treated with biologics. EHR data will generally provide more precise phenotypic information (including laboratory results) than that available in health plan claims data alone. Beyond the many traditional registries available for the study of biologic safety and effectiveness, a growing number of patient-focused research registries in IBD, RA, psoriasis and PsA, multiple sclerosis, and juvenile idiopathic arthritis [106,107] have also been established and may provide unique information from a patient's perspective. Many of these capture information on biologic use and outcomes using validated patient-reported outcome (PRO) instruments, such as those available from the National Institute of Health's Patient-Reported Outcome Management System (PROMIS) [108].
