A variety of methods may be used to link administrative claims, EHR, and traditional registry data together, and combine them with other data (e.g., disease-specific biomarker data). Deterministic methods applied to unique identifiers (e.g., social security numbers or health plan identifiers) can be used for linkage, but doing so may invoke privacy-related concerns. Probabilistic linkage using multiple, non-unique identifiers (e.g., patient date of birth, visit dates, national provider identifiers, number of a patient's physician, dates of outpatient clinic visits, or admission/discharge dates of hospitalization (for hospitalized patients, or those undergoing in-hospital procedures) has been used successfully to link patients [109]. When no identifiers can be shared, a variety of privacy-preserving methods are also available (e.g., one-way hashing algorithms) to allow for sharing of minimally identifiable information, fully encrypted data, or statistical coefficients [110–112]. A number of use cases that have linked clinical information (e.g., disease activity) to registries or lab-based data sources with outcomes commonly available in health plan data (e.g., healthcare costs, all-cause hospitalization) have been published in biologic-exposed patients [113,114].

Value-Based Care

Given the high cost of biologics, often in the range of several thousands of dollars per patient per month or more, increasing attention is placed on demonstrating and maximizing the value of these therapies. While value-based reimbursement, risk-sharing contracts, and so on are by no means unique to the use of biologic agents, their high cost and the need to

characterize the safety profile of new molecular entities compared to existing treatments places great importance on the careful study of these medications. Pharmacoepidemiologic research is therefore likely to continue to play a prominent role in filling evidence gaps to demonstrate improved clinical and patient-focused outcomes, and to promote the rational use of biologic therapies in the form of evidence-based guidelines.

Risk Management

Claudia Manzo[1], Emil Cochino[2], Lubna Merchant[1], and Giampiero Mazzaglia[2]

[1] *Office of Surveillance and Epidemiology, Center for Drug Evaluation and Research, US Food and Drug Administration, Silver Spring, MD, USA*
[2] *European Medicines Agency, Amsterdam, The Netherlands*

Risk management is widely used across a variety of settings to identify, quantify, and characterize risks, and to institute measures to mitigate these risks. Such measures can be used to minimize medical errors in healthcare settings; limit financial liability in the business sector; minimize or eliminate work-related or recreational-related injuries in industrial and leisure settings, respectively; reduce transportation-related accidents in the airline, automobile, and railroad industries; and for many other purposes. Because of the wide-ranging scope of risk management endeavors, the methods of assessing risk vary according to the specific setting. Similarly, the measures used to mitigate risk vary across settings, again depending on the specific risk being managed. While specific measures may vary from setting to setting, at their core, these risk mitigation measures involve a structured approach – generally in the form of some combination of policies, procedures, processes, or engineering solutions – designed to reduce or eliminate one or more specific risks.

Regarding the use of medicines, risk management is used to ensure that the potential benefits of a medicine exceed its potential risks, and to minimize those risks throughout the life cycle of the product. As in other fields, risk management of medicines is not new, though it has received increased attention in the past few decades. Current understanding of the risks of medicines is based on the premise that the risk of a medicine derives not only from the inherent properties of the medicine, but also from how the medicine is used in actual clinical practice. Thus, current risk management efforts are geared toward understanding not only the harm that can result from the intrinsic properties of the medicine, but also the harm that can result from inappropriate use of a medicine in a complex medical care system.

In the context of human medicines in the US, the Food and Drug Administration (FDA) has defined risk management as:

> an iterative process of 1) assessing a product's benefit–risk balance, 2) developing and

---

The views expressed in this chapter are those of the authors, and not necessarily those of the US Food and Drug Administration or the European Medicines Agency.

Pharmacoepidemiology, Sixth Edition. Edited by Brian L. Strom, Stephen E. Kimmel and Sean Hennessy.

> implementing tools to minimize its risks while preserving its benefits, 3) evaluating tool effectiveness and reassessing the benefit–risk balance, and 4) making adjustments, as appropriate, to the risk minimization tools to further improve the benefit–risk balance. This four-part process should be continuous throughout a product's lifecycle, with the results of risk assessment informing decisions regarding risk minimization. [1]

In the European Union (EU), the concept of risk management is established in legislation. Article 1 (28b) of Directive 2001/83 EC, as amended, defines a risk management system as "a set of pharmacovigilance activities and interventions designed to identify, characterize, prevent or minimize risks relating to a medicinal product including the assessment of the effectiveness of those interventions" [2]. Thus, in the EU, risk management incorporates:

- the identification or characterization of the safety profile of the medicinal product, with emphasis on important identified and important potential risks and missing information, and also on which safety concerns need to be managed proactively or further studied (the "safety specification");
- the planning of pharmacovigilance activities aimed at characterizing and quantifying clinically relevant risks, and identifying new adverse reactions (the "pharmacovigilance plan"); and
- the planning and implementation of risk minimization measures, including the evaluation of the effectiveness of these activities (the "risk minimization plan").

As a result, in both the US and the EU, risk management measures are iterative processes frequently leading to the generation of similar data needs and conceptually similar risk management tools.

Clinical Problems to Be Addressed by Pharmacoepidemiologic Research

All medicines have risks. For marketed medicines, at the time of authorization the benefits of the medicine are judged to outweigh the risks, provided that the medicines are used according to the licensed or approved indication. Knowledge of a medicine's benefits and risks is developed prior to approval, and refined after approval when the exposed population, as a result of "real-world" usage, increases and becomes more heterogeneous, with potential diminishing responsiveness to the beneficial effects and increasing likelihood of detecting adverse drug effects. The traditional tools used to manage the risks of prescription medicines have been the prescription status itself (i.e., whether the drug was approved for prescription-only use or whether it could be obtained without a prescription), labeling for healthcare professionals, and the requirement that pharmaceutical manufacturers monitor and report to regulatory authorities adverse events that occur with use of the medicine once it is marketed. In the past few decades, additional steps or minimization strategies have been undertaken to manage more proactively the risks of certain medicinal products. These measures have included increased communication to patients as well as to healthcare professionals, and measures to restrict, in various ways, the usage of certain medicines. This chapter will explore these efforts in more detail.

The Complexities of the Medication Use System

The medication use system is a complex network of stakeholders, including patients, their families, physicians, nurses, pharmacists, other health professionals, healthcare organizations and healthcare facilities (e.g., hospitals, clinics),

manufacturers, and regulatory agencies. Not only does each individual stakeholder have a role in ensuring the safe use of a medicine, the interactions among the various stakeholders are crucial to ensuring the safe use of a medicine. Thus, risk management strategies must consider not only the individuals and groups, but also the entire medication use system. The complexity of the medication use system implies that individual risk management measures must be directed at the appropriate part or parts of the system specific to the risk being managed. The accurate identification of these parts of the system will vary from one drug to the next, will depend on the specific risk, and will depend on how the medicine is used within the healthcare system. In this context, the approach to risk management must span the entire life cycle, be proactive, be scientifically driven, engage all relevant stakeholders, and consider all environments where the medicine will be used (e.g., hospitals, long-term healthcare facilities, physicians' offices, outpatient home care).

Because the risks of medicines can occur at any point in the complex medication use system, managing the risks of medicines requires that the entire medication use system be involved. Involvement of the entire system can pose challenges, and some parts may be harder to involve than others. It is difficult, though perhaps not impossible, to compel each part of the system to do what it must to manage the risk of a medicine. While the involvement of the entire system is a strength of risk management systems, reliance on each part of the system is a limitation.

Sources of Risk from Medical Products

There are several sources of risks from medical products (Figure 24.1). The known risks of a product are based on prior experience or, in some cases, on the pharmacologic or other properties of the medicine (e.g., the dosage or route of administration). In some cases these risks are preventable, while in others they are not. Preventable risks can occur when a product is administered under a condition of use that imparts a risk that would not be present under a different condition of use. For example, if drug A, when used in combination with drug B, results in an unacceptable risk that is not present when

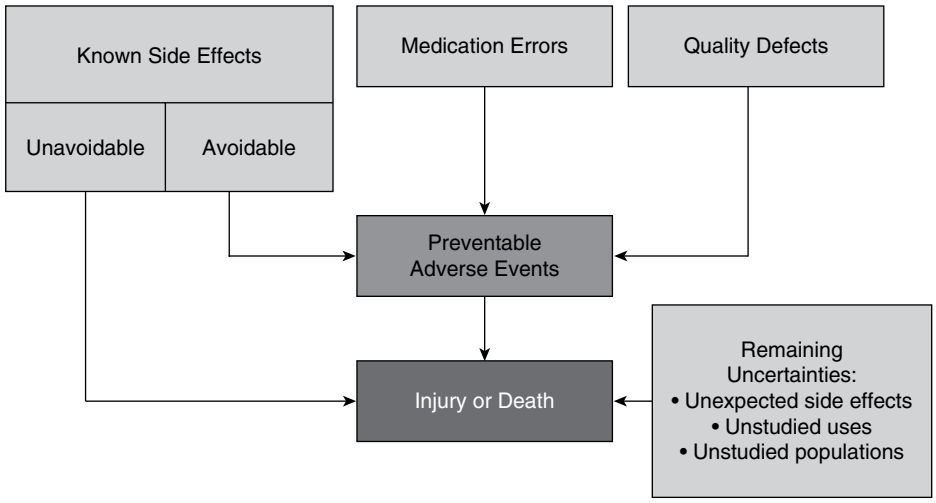

Figure 24.1 Sources of risk from medical products.

either drug is used alone, this unacceptable risk is preventable by ensuring that drug A and drug B are never co-administered. Contraindicating concomitant use is a regulatory step that can be used to warn against concomitant use; actual avoidance of concomitant use can only be achieved by health professionals' adherence to this labeled contraindication. Risk management efforts beyond approved labeling such as additional targeted communication can be used to further minimize preventable adverse events.

Unavoidable risks are those that might occur when all the known necessary conditions for safe use of a product are followed. In these circumstances, risk minimization activities might be directed toward identifying the adverse consequences as early as possible, with the aim of preventing more serious harm. For example, a drug may be known to cause hepatic damage, but its occurrence in a specific patient may not be predictable or preventable. In this case, risk minimization activities might be directed toward regular monitoring of hepatic enzyme levels to identify any hepatic damage as early as possible, and thus to stop or modify the treatment to prevent serious hepatitis or hepatic failure.

In addition, risk management efforts can be used to ensure that medicines are not administered to patients at higher risk for a serious adverse event, or that they are administered only to patients for whom the benefits outweigh the risks, including the unpreventable risks. Thus, removing all risks from the use of all medicines is not the overall goal of managing the risks of medicines. Rather, careful consideration of the benefit/risk balance, both for the individual patient and for the target population, is an important consideration of risk management.

Managing the known risk of medicines is a core activity of risk management programs. For most products, this can be achieved through product labeling; in some cases, as will be discussed later in this chapter, additional steps are needed. Other sources of preventable adverse events are medication errors and, occasionally, injury from product quality defects.

Medication errors (also see Chapter 41) are defined by the National Coordinating Council on Medication Error Reporting and Prevention (NCCMERP) as follows:

> A medication error is any preventable event that may cause or lead to inappropriate medication use or patient harm while the medication is in the control of the health care professional, patient, or consumer. Such events may be related to professional practice, health care practice, procedures, and systems, including prescribing; order communication; product labeling, packaging, and nomenclature; compounding; dispensing; distribution; administration; education; monitoring; and use. [3]

A similar definition is in place in the EU [4].

Because they are preventable, medication errors are well suited to risk management efforts. Each year in the US, serious preventable medication errors occur in 3.8 million inpatient admissions and 3.3 million outpatient visits [5,6]. A landmark study published in 2000 estimated that as many as 98 000 people die each year in the US from medical errors occurring in hospitals. The report described medication errors as a significant public health concern that accounts for an estimated 7000 deaths annually in the US [7]. In 2011, the Network for Excellence in Health Innovation reported that outpatient and inpatient preventable medication errors cost approximately $20 billion each year [8]. A recent study in the EU showed a steady increase in the number and proportion of Individual Case Safety Reports (ICSRs) of medication errors in the EudraVigilance database between 2002 and 2015, to a peak of 5% of all ICSRs in the database. Several factors were felt to be responsible for this increase, including greater awareness of the need to report medication errors, guidance on coding for medication

error events, and increased communication to patients and healthcare professionals, as well as the general public, regarding the importance of reporting medication errors [9].

Potential sources of medication errors can include the product's proprietary (brand) name (if it is similar to the name of another medicine, especially if the two medicines have other similar characteristics), the established (generic) name, and the design of the drug product and its container closure system or the container, carton, and packaging. Errors can also occur if the product labeling for healthcare professionals or patients is not clear. Because medication errors can occur anywhere in the medication use system, efforts to minimize the risk of medication error must involve multiple stakeholders.

As already noted, other sources of preventable adverse events include injury from product quality defects. Product quality problems are unusual in both the US and the EU because of the great attention paid to product quality control and quality assurance during manufacturing [10,11]. A discussion of measures to mitigate manufacturing-associated risks is beyond the scope of this chapter.

Because not all the risks of a medicine are known at the time the product is approved, risk management efforts must continue throughout the life cycle of a medicine, as discussed shortly.

Risk Management Strives to Be Scientifically Driven

Risk management plans can be scientifically driven, to the extent that there is available science to inform each component of the plan. The science of risk identification and risk assessment, while still evolving, is well developed, and indeed much of this book describes this science. The science of risk communication is also well developed in general, though its application to communicating the risks of medicines is still being developed (see Chapter 39). The scientific basis of minimizing risks of medicines is much newer, as is the science of assessing the impact of risk management plans. The scientific approach to risk management requires the integration of data from various studies and disciplines that, when taken together, can promote the safe and effective use of a medicine. The scientific approach also compels manufacturers and regulators to examine, throughout the life cycle of the medicine, the critical gaps in knowledge that exist. Such gaps may concern the pharmacologic properties of the medicine, clinical outcomes related to its use, including that in higher-risk populations, or the way the medicine is used in actual practice. Any of these areas could lead to further postapproval studies, the results of which would lead to changes in labeling or other changes that could enhance the safe and effective use of the medicine. However, as noted in the example of cisapride in Chapter 8, changes in labeling do not always result in changes in prescribing practices.

Risk Management Proceeds throughout a Product's Life Cycle

Knowledge about a product's safety profile is always limited to some extent at the time of product approval, because of recognized practical limitations in the drug development process. For example, rare side effects and long-term side effects may not be known when a product is approved because of the relatively small size and short duration of clinical trials. Because some populations are generally not studied in preapproval clinical trials (e.g., pregnant women, children, people with diseases or conditions other than the studied indications for use) or are minimally studied (e.g., older adults), side effects may be discovered if these groups are treated with a product after it goes on the market. Already approved drugs and biologics may receive approval for new uses or in new patient populations, which may necessitate increased vigilance years after the drug was originally

approved. Even after a product has been marketed for a decade or more, uncertainties will remain. For example, a study of new molecular entities approved for use by the US FDA between 2002 and 2014 indicated that safety-related labeling changes were being made as long as 13 years after the products were approved [12]. Because of this life-cycle approach, all stakeholders – patients, practitioners, manufacturers, and regulators – must remain vigilant about the benefit/risk profile of a medicine. Such vigilance is critical for informed decision making, which is an important component of the safe and effective use of medicinal products.

Risk Management Applies to All Medicines

As has already been stressed, all medicines have risks. No medicine is free from harm in all persons who take it under all actual conditions of use. The magnitude, frequency, and severity of risks vary from medicine to medicine. For example, at one end of the spectrum, neutropenia is commonly associated with chemotherapy and other immunosuppressive agents and is a major risk factor for the development of infections. Strategies to monitor, prevent, and/or manage these infections can lead to improved outcomes and will ensure the benefits of these drugs continue to outweigh the risk. At the other end of the spectrum, many topical over-the-counter (OTC) medicines have very few side effects. The management of these risks is clearly much less intense. In the middle of this spectrum are the vast majority of medicines, mainly prescription medicines, for which a measured approach to risk management must be taken.

For most prescription medicines, the most common side effects are generally not life threatening. Rather, many are mild and self-limited. Others are bothersome, and some are so clinically significant that they require the medicine to be discontinued. Examples of these types of side effects whose significance depends upon severity are nausea, headache, and rash. For many medicines, the most serious side effects are relatively rare. Examples of rare, life-threatening side effects are acute liver failure, aplastic anemia, torsade de pointes, progressive multifocal leukoencephalopathy, cytokine release syndrome, and certain serious skin reactions, such as Stevens–Johnson syndrome. Along this continuum are other side effects that may be severe but generally not life threatening, and that are also more common than the most serious side effects such as tendon rupture, narcolepsy, and vision loss.

Over-the-counter medicines are drugs that have been found to be safe and appropriate for use without the supervision of a healthcare professional such as a physician, and they can be purchased by consumers without a prescription. Most OTC medicines are for symptomatic relief of conditions that consumers can diagnose and manage themselves. When these medicines are taken properly, most of their side effects are generally mild. However, there can be serious, even life-threatening or fatal, side effects of OTC medicines when they are not taken properly. For example, acetaminophen (paracetamol), one of the most widely used OTC analgesics, is a generally very safe when taken as recommended on the product's label. Overdose, however, can result in acute severe liver injury, which can lead to acute liver failure, and sometimes death or the need for liver transplantation. While this is a rare complication relative to the widespread use of acetaminophen, the fact that the use is so widespread means that this drug is the leading cause of drug-induced acute liver failure in the US [13].

While much attention is paid to medicines that are known to have life-threatening, fatal, or disabling side effects at therapeutic doses, there are also risks from medicines that do not have these serious side effects when taken properly, but which can cause serious side effects when taken improperly. For example, bromfenac

sodium capsules, an oral nonsteroidal anti-inflammatory agent, was introduced in the US in July 1997 for treatment of pain for 10 days or less. Despite the labeled recommendation for a treatment duration of 10 days or less, many patients received treatment courses of 30 days or longer. The FDA received several reports of hepatotoxicity resulting in death or liver transplantation attributable to bromfenac; in all cases, the patients had taken the medicine for longer than the recommended 10-day duration of treatment. In July 1998, the manufacturer voluntarily withdrew bromfenac sodium capsules from the US market [14]. This example illustrates that improper use of a medicine – in this case treatment durations that exceeded the labeled duration of use – can give rise to serious adverse events.

Risk Management Is a Proactive Process

Risk management systems must be proactive to be optimally effective. The current framework of risk management systems allows a proactive approach in many ways. The ability to identify risks in the preapproval period enables manufacturers to work with regulators on risk management planning and risk minimization strategies during the drug development phase. A proactive approach in the postapproval phase demands that manufacturers, regulators, and practitioners agree on a system to identify new risks, manage known risks, assess the effectiveness of the risk management efforts, and modify them as needed. Traditional pharmacovigilance systems based on spontaneous reports are sometimes referred to as "passive" systems (also see Chapter 10). While such systems can be used in reactive ways, these systems, along with other sources of postapproval drug safety data, can be used in proactive ways to learn as much about the safety of a medicine in as efficient a manner as possible.

Enhanced surveillance systems can be used to proactively monitor the safety profile of a medicinal product following licensure. An example of an enhanced surveillance system in EU is based on the European Medicines Agency's (EMA) seasonal influenza vaccines requirements. Flu vaccine manufacturers are operating surveillance systems enhancing the reporting of adverse reactions by providing vaccination cards to all vaccinees in a region, and raising the awareness of healthcare professionals of the events that might appear following vaccination. By collecting in near real time the usage of the vaccine, the manufacturers are able to monitor the safety profile of the vaccine and rapidly report any emerging signals to regulators, allowing suitable actions to be taken in the same vaccination season. Designs of such a system vary by manufacturer, but range from passive reporting systems with near-real-time estimation of the denominator, to solicited reports monitoring, to observational cohort studies and even clinical trial designs. A carefully designed risk management plan can identify or further characterize risks, communicate and manage risks using evidence-based tools when possible, and assess the effectiveness of these efforts in a proactive way. Like the lifecycle approach noted earlier, the proactive nature of risk management planning demands the constant vigilance of all stakeholders.

Risk Management Activities

Managing the risks of medicines is not a single activity or the province of a single profession or stakeholder group. Rather, it is an iterative process that involves a set of interrelated activities. In broad categories, these activities include risk assessment, risk minimization, and evaluation of risk minimization strategies with adjustments, as appropriate, to the risk minimization strategies to optimize the benefit/risk balance of the medicinal product. These activities occur throughout the product's life cycle, and are adjusted and refined as new risk assessments

provide new information, and as evaluations of risk mitigation activities provide data upon which risk mitigation activities can be improved or modified. Conceptually, for each risk the iterative process starts during clinical development and repeats following authorization.

In the EU, most types of activities are concentrated around important milestones in the lifecycle of the product:

- At initial approval, when the risk assessed using the information gained in the preclinical and clinical phase is balanced with choosing the optimal indication, supplemented with risk minimization recommendations in the product information or additional activities.
- At two other important fixed milestones in the postauthorization phase: (i) when the benefit/risk balance of the product is reevaluated with the first renewal of marketing authorization (MA); and afterwards, (ii) during the first periodic safety update report (PSUR) evaluation (i.e., at 8 years in the life cycle of the product). The important reevaluations of risks are concurrent with the evaluation of the effectiveness of the ongoing risk minimization activities; as a result, recommendations to optimize the safe and effective use of the medicinal product are issued.
- At other minor milestones for risk minimization review and periodic benefit/risk evaluations, or at major changes in product use (e.g., an extension of indication to a new population).

Risk Assessment

Risk assessment consists of identifying, characterizing, and quantifying the risks associated with the use of a medicine, and evaluating their importance in relation to the benefit/risk balance. The nature, frequency, and severity of the risks are assessed. In addition, if possible, the conditions under which the risk is more likely to occur are identified. For example, if a drug causes a serious adverse reaction only when used in conjunction with another specific medicine, it is important to identify this drug–drug interaction, so that risk management efforts can be directed at minimizing the use of the two medicines together.

Risk assessment occurs throughout the premarketing and postmarketing phases of a product's life cycle. Premarket, or preapproval, risk assessment is generally a very extensive process that involves preclinical safety assessments (e.g., animal toxicology testing), clinical pharmacology assessments, and clinical trials. Animal toxicology studies are performed prior to the first human exposure to a new medicine to establish the general toxicity profile of the drug and to guide initial human dosing. Further animal studies continue throughout the drug development process, and address areas such as toxicity (e.g., genotoxicity, carcinogenicity, immunotoxicity, and reproductive toxicity) or safety pharmacology (e.g., cardiovascular system, including electrocardiographic QT interval prolongation, nervous system). Additional animal studies may be needed in specific situations. In addition to animal studies, preclinical testing typically involves the use of *in vitro* bacterial and cell preparations, which can look at effects on enzymes, metabolic pathways, receptors, mutability, and some interactions.

While preclinical research answers basic questions about the safety of a medicine, it is not a substitute for clinical studies to assess how the medicine interacts with the human body. Clinical pharmacologic studies establish the pharmacokinetic profile of the medicine and exposure–response relationships, and can be used to assess drug–drug interactions. Pharmacokinetic characteristics of the medicine under certain clinical situations, such as impaired renal function or impaired hepatic function, can also be assessed. Because proper dosing of a medicine is an important component of the safe use of the medicine, clinical

pharmacologic studies are an important component of a medicine's risk assessment.

Preapproval clinical trials provide the efficacy and safety information that form the basis for an approval decision. The preapproval safety assessment generally quantifies and characterizes the common adverse events associated with a medicinal product. Depending on the number of subjects exposed prior to approval, less common adverse events might also be detected. It is important to pay careful attention to the design of the preapproval safety program to maximize the information gained from clinical trials. The extent of safety information collected prior to approval is a function of the number of patients studied, the duration of treatment, the number of scheduled visits at which safety information is collected, and the specific safety evaluations performed. The design of the preapproval safety data collection effort depends, in turn, on a number of factors, including the novelty of the product, the relative safety of any available alternative treatments, the intended population, the condition being treated, and the intended duration of use. The preapproval clinical safety program should also explore safety-related dose effects and, for chronically administered medicines, the temporal profile of adverse events. It should use the available data to explore unanticipated drug–drug interactions, drug–demographic interactions, drug–disease interactions, and drug–herbal interactions. In some drug development programs, comparative safety data can be obtained if an active comparator is used; however, in the EU and the US the licensing decision relies on the individual benefit/risk profile of the medicine.

Because even large clinical development programs cannot identify all the risks associated with a product, it is imperative that risk assessment continue in the postapproval period, when large numbers of persons will be exposed to the medicine, including many with co-morbid conditions or on concomitant medicines not present in clinical trials. Risk assessment is also imperative for products intended to treat rare diseases where smaller numbers of subjects are studied, or products intended to respond to emergencies, including terrorist events, where approval may be based on evidence of effectiveness from appropriate animal studies when human efficacy studies are not ethical nor feasible. In either scenario, greater risks may be accepted for a treatment that is an advantage over available therapy or addresses an unmet medical need.

Postapproval risk assessment can be based on either nonexperimental data or on clinical trial data. Nonexperimental data include individual case reports of suspected adverse drug reactions (spontaneous reports), case series of such reports, databases of spontaneous reports, disease-based registries, drug-based registries, electronic medical records systems, administrative claims databases, drug utilization databases, poison control center databases, and other public health databases that track usage of the medicine. The use of many of these data sources, and the methods underlying their use, are covered in other chapters of this book (see Chapters 10–17), and will not be considered further here. For the purposes of this chapter, it is important to note that new risks of a medicine will continue to be recognized after the drug is on the market. Some of these risks will be sufficiently serious to alter the benefit/risk balance of the medicine, such that postapproval regulatory action will be needed. Possible regulatory actions include updates to the professional labeling, development of or updates to the patient labeling, use of additional means of communicating risk to patients or healthcare professionals, introduction of additional risk minimization activities (e.g., checklists or monitoring requirements), restrictions on the use of the medicine, or, rarely, suspension or withdrawal of the marketing authorization.

Risk assessment of medicines, in both the preapproval and postapproval phases, often concentrates on the identification of adverse

reactions that are related to the medicine when used according to its labeled instructions. These newly identified adverse reactions can either be an exaggeration of the pharmacologic effect of the drug or an idiosyncratic reaction, the result of a previously unknown drug–drug interaction, or an adverse effect in a specific patient population.

It is also important for risk assessments to identify medication errors and the potential for medication errors (see also Chapter 41) throughout the product's life cycle. The identification and assessment of medication errors are different in some ways from the identification of adverse drug reactions. Proactive risk assessments that reflect human and environmental factors in drug product use should be employed from the earliest stages of product design to help anticipate potential medication errors. Ideally, proactive risk assessments should employ analytic approaches, for example failure mode and effects analysis (FMEA), formative evaluations, or simulated use testing. Considering the end users' needs, environments of use, and contexts of use in the development and design of a drug product alongside commercialization aspects can help reduce postapproval safety issues [15]. After approval, the identification of a medication error generally requires that someone report that an error has occurred, usually in the context of reporting an adverse reaction following the use of the medicine, though the initial report may not elucidate the reason for the error.

Because the medication use system is complex, the mere identification of an error (e.g., the patient received twice the intended dose) is usually not sufficient to understand the reason for the error. Since medication errors are, by definition, preventable events, risk assessment activities must focus on identifying the specific reason(s) for, or cause(s) of, the event. In this situation, it may be essential to conduct a root cause analysis (RCA) to understand the causes (i.e., the how and why) of the problem or medication error. This is an important tool to evaluate postmarketing problems or medication errors, and when evaluating proposed remedies for those problems or errors. Knowledge gained from evaluating the RCA of a known postmarketing medication error can also be applied to the premarket safety assessments of other products. The identified reasons and causes may relate to certain characteristics of the medicinal product itself, to the larger medication use system for the product, or to an interaction of the two. Understanding how and why medication errors occur and what would be the impact on patients are essential to any risk assessment. Only once the specific set of reasons and causes that led to the error are understood can appropriate risk mitigation and risk communication activities be developed.

An EU example of giving the medication to the wrong patient was observed during the clinical development of an autologous advance therapy medicinal product. The root cause identified was a weak identification system, relying on the initials of the patient and treating physician. Once the identification system was improved by using a unique traceability code, from harvest to implantation, no further such medication errors occurred. Additional observed examples of medication errors and the risk minimization activities put in place are provided in the EU good pharmacovigilance practice (GVP) guidelines [16].

Risk Minimization

Risk minimization or mitigation refers to a set of measures or interventions intended to prevent or reduce the occurrence of adverse reactions associated with exposure to a medicine, or to reduce the severity or impact on the patient should adverse reactions occur. Appropriate planning of risk minimization/mitigation allows for medicines with considerable risk to be approved and maintained on the market with a positive benefit/risk balance. The range of risk

mitigation activities varies from one country or region to the next, but certain common themes emerge.

First, many aspects of the modern drug regulatory system are, in fact, risk mitigation activities. The very fact that a medicine has to be approved is, in many ways, the most fundamental risk mitigation activity, in that it prohibits the marketing of medicines that have not been judged to be safe and effective, thus virtually eliminating the risks of medicines being legally marketed for which there is no demonstrated benefit. The requirement that certain medicines be available only by prescription is another form of risk mitigation. The premise underlying the prescription-only status of a medicine is that some medicines are potentially harmful or the method of their use is not safe without the involvement of an appropriately qualified healthcare professional, whose judgment can be used to ensure that, for a particular patient, the potential benefits outweigh the potential risks.

Risk Communication

Communicating information about the benefits and risk of medicines is central to minimizing the risks of these products. Risk communication is a broad field, and a full discussion is beyond the scope of this chapter (also see Chapter 39). Communication has traditionally been directed toward healthcare professionals, but in recent years increasing attention has been paid to communications directed toward patients and consumers.

The principal form of communication to healthcare professionals in the US is the product's approved professional labeling, which is designed to present to the healthcare professional information needed to prescribe the medicinal product in such a way that the potential benefits outweigh the potential risks. In the EU, this professional information is known as the Summary of Product Characteristics (SmPC).

There are several types of information in the professional label that can mitigate risk. First, the label often contains information on those clinical situations in which the drug should not be used, or should be used only with extreme caution. Second, the label contains information about the known risks of the medicine. If prescribers are aware of these risks, they can judge the individual benefit/risk balance for the patient and decide if the medicine is the best choice available; they can also advise patients on the appropriate symptoms to look for when taking the medicine. Upon hearing of these symptoms from patients, prescribers can recognize a potential adverse drug reaction and take appropriate action, such as changing the dose or stopping the medicine. Third, the label contains information about the conditions of safe use of the medicine, such as the proper dosing (including, when applicable, the dose adjustments needed for renal and hepatic impairment or dose adjustments based on age), drug–drug interactions, drug–disease interactions, use in pregnant or lactating women, and use in other specific clinical situations or special populations.

Additional communications to healthcare professionals come in the form of "Dear Healthcare Professional Letters," "Dear Doctor Letters," or "Direct Healthcare Professional Communication." These letters, typically issued by a medicine's manufacturer, are usually one to a few pages in length, and generally focus on specific, newly identified safety information. The nature of the risk is explained, and a summary of the changes to the product label or SmPC is often included. The letter usually highlights actions that the healthcare professional should take in prescribing and dispensing the medicinal product, as well as other measures that can help ensure the product's safe and appropriate use. Full prescribing information is generally attached, so that prescribers can put the new information into context.

In the EU, these letters are reserved for emerging postmarketing safety issues. The letters can be either requested by a regulatory authority,

with the content agreed as part of the safety review, or voluntarily proposed by the manufacturer. In the latter case, the manufacturer must notify the competent regulatory authorities of its intention to distribute the letter, but more often requests the text to be approved, as this enforces the message to healthcare professionals that the text has had regulatory review and endorsement.

Labeling directed toward patients and consumers is also a risk mitigation tool, in that it highlights basic information necessary for the safe use of the product, and often provides instructions for actions to take when certain symptoms are present. Information for patients and consumers is relevant for both prescription and nonprescription medicines.

In the US, information to patients can come in a variety of forms. One common form is product-specific information directed toward patients. This can take the form of approved patient labeling, which is developed by the manufacturer and reviewed and approved by the FDA. Examples of approved patient labeling include the Medication Guide, a Patient Package Insert or Instructions for Use. Medication Guides are used when there is a need to communicate certain safety information, or when certain conditions of safe use must be highlighted. By regulation, the FDA requires that Medication Guides be issued with certain prescribed drugs and biologic products when the Agency determines that:

- the drug product is one for which patient labeling could help prevent serious adverse effects;
- the drug product is one that has serious risk(s) (relative to benefits) of which patients should be made aware because information concerning the risk(s) could affect patients' decision to use, or to continue to use, the product;
- the drug product is important to health and patient adherence to directions for use is crucial to the drug's effectiveness.

The format and content of a Medication Guide as well as the distribution requirements are set forth in regulation [17].

Patient Package Inserts are another form of FDA-approved patient labeling. They differ from Medication Guides in several important respects: (i) their use cannot be mandated, except in certain circumstances; (ii) there are no specified requirements for content and format; and (iii) there is no requirement that they be distributed.

The Instructions for Use or IFU is a form of prescription drug labeling developed for use by patients for drug products with complicated or detailed patient-use instructions. The primary purpose of an IFU is to provide detailed, action-oriented, step-by-step, written and visual instructions in a patient-friendly manner. The IFU is intended to help administer drug products safely and effectively. It is developed by the manufacturer, reviewed and approved by the FDA, and provided to patients when the drug product is dispensed.

Consumer Medication Information is an alternative form of drug-specific patient information used in the US. Unlike FDA-approved patient labeling, Consumer Medication Information is neither developed by the product's manufacturer nor is it regulated by the FDA. Rather, it is developed by independent, commercial, third-party vendors who often sell this and other products to pharmacies, and is then distributed to patients in pharmacies.

In the EU, all medicines are required to have a package leaflet, sometimes referred to as a patient information leaflet, which must be provided to the patient as part of the product packaging, or in exceptional circumstances (e.g., a pandemic) as a separate leaflet, or even as online information. This leaflet is based upon the information provided in the SmPC, but written in patient-friendly language. There is a requirement that the package leaflet reflects the results of readability testing with an appropriate target group of patients/consumers and that the

results be provided to the competent regulatory authorities prior to authorization.

Both the SmPC and the package leaflet are approved by the competent regulatory authority at the time of authorization and require a specific procedure, involving evaluation of the reasons for change and agreement of the authority to the revised text, in order to change the content. Who the competent regulatory authority is depends upon how the medicine is authorized. In the centralized procedure it is the European Commission, whereas for other methods of authorization it is the appropriate regulatory authority in the Member States.

For most prescription medicines, the prescription status, the product information for healthcare professionals and patients, and the labelling are sufficient risk minimization measures to ensure that the benefits of a medicine outweigh its risks. In some cases, additional communication measures are needed.

Regulatory guidelines do not provide clear criteria or recognized algorithms to establish when additional risk minimization is warranted and what tools are best suited to do so. However, accurate recognition of important risks that need to be minimized is the basic starting point, and prioritization of safety concerns should take into account frequency, seriousness, severity, impact on public health and preventability. In addition, the burden of imposing additional risk minimization on stakeholders and the healthcare system should be balanced with the expected reduction of the frequency and/or severity of the targeted risks.

If additional measures are utilized, they are generally designed to address one, or at most a few, specific important risks associated with a medicine. While specific measures may differ from one country or region to the next, these measures may include focused risk information targeted at practitioners that are likely to prescribe the medicine or care for patients who are treated with the medicine. Specific risk information may also be targeted at healthcare professional societies to share with their members. The types of communication can include letters or other educational tools, for example a prescriber checklist or an educational brochure. Communication for patients can include a dosing card for medicines with complicated dosing instructions or a patient alert card. In some cases, the communication is focused principally on the nature of a serious risk, so that patients and prescribers can make an informed decision as to whether the potential benefits outweigh the potential risks in their individual situation. In other cases, the communication focuses on both the nature of the risk (e.g., risk factors, preventability, early signs and symptoms) and the specific steps that can be taken to prevent the event, or particular monitoring that should be carried out to detect the adverse event.

The extent to which specific information about the risk needs to be communicated will depend upon the context in which the product is used. For example, specific activities beyond the product information for a drug which has the potential to prolong the electrocardiographic QT interval will probably not be necessary if the medicine is one intended for use only by cardiologists. However, if the same risk occurs in a drug used by oncologists, additional activities targeted at informing prescribers of the need for periodic monitoring of heart function, and the risk of concomitant use with other QT interval-prolonging drugs, might be appropriate. In certain cases, these additional communication measures may be required as part of a formal risk minimization plan in the EU, or risk evaluation and mitigation strategy (REMS) in the US.

Regulatory agencies have also been engaging in increasing efforts to communicate the risks of medicines. The FDA's primary tool for communicating important new and emerging safety information about a medicine is through a Drug Safety Communication or DSC. DSCs highlight new safety issues that pose potentially serious or life-threatening risks or adverse events, about which the FDA thinks patients and healthcare

professionals should be informed. In establishing this system, the FDA recognized that there is a tension between providing early notification about potentially important safety information on the one hand, and being certain about the findings on the other. Because analyses and interpretations of drug safety information are often not clear cut, communication of findings requires a balanced and impartial approach.

In the EU, the competent regulatory authorities communicate drug safety information using different methods, which depend upon what has been established for the individual country. EMA plays a central role in coordinating these communications. When a drug safety issue has been discussed and agreed by the Pharmacovigilance Risk Assessment Committee (PRAC) or together with the Committee for Human Medicinal Products (CHMP), EMA will issue a public statement on its website giving information about the medicine, the risks, and what is being done to mitigate them. In addition, if a Member State or the European Commission has referred a public health issue to the PRAC or CHMP for a scientific opinion, then the start and reasons for the referral are also announced, as well as the final conclusions.

EMA also coordinates the release of information in Member States to avoid different information appearing at different times across Europe. Information about every medicine (including the risks and benefits) authorized via the centralized procedure is provided online by the European Public Assessment Report (EPAR). This is a scientific document which summarizes the information that EMA evaluated in giving its opinion about the medicine and how the decision to give a positive or negative opinion regarding authorization was reached. The EPAR is updated throughout the life cycle of the medicine to reflect major changes in the product's marketing authorization. In addition, the SmPC, package leaflet, labeling, risk management plan (RMP) summary, and conditions for marketing authorization also appear on the EMA website and similarly are updated throughout the life cycle of the medicine. The requirement for an assessment report to be publicly available also applies to medicines authorized by other routes (e.g., national, mutual recognition, and decentralized procedures), but the exact format in which it appears will vary.

In addition to the mechanisms already listed, manufacturers use a variety of other communication tools to reach practitioners and patients. These can include print and broadcast advertising, websites, and other communications via electronic social media. In many cases, these communications are simply a part of a manufacturer's marketing program; in some cases, however, they may be a formal risk minimization strategy. In the EU, advertising of prescription-only medicines directly to patients is prohibited.

Additional Risk Minimization Strategies

A variety of other minimization strategies can be employed when product labeling and alternative forms of risk communication are not sufficient. For example, drug product design features that predispose end users to medication errors may not always be overcome by product labeling or healthcare provider or patient education. It is therefore preferable to eliminate, or minimize to the extent possible, these hazards from the product design. It is not possible to predict all medication errors; however, medication errors can be minimized by conducting premarketing risk assessments to evaluate how users will interact with the medicinal product in various environments of use within the medication use system. Because medication errors can occur anywhere in the medication use system, efforts to minimize the risk of medication error must involve multiple stakeholders.

In the US, the FDA reviews proposed proprietary names of medicinal products to ensure that these names are not similar in spelling or pronunciation to the proprietary or established names of other medicines. In addition, the FDA

reviews the proposed container labels, carton labeling, packaging, and product design to ensure that these do not have features that could cause or contribute to medication errors.

Similarly, in the EU medicines authorized through the centralized procedure have their invented (or brand) name approved by the (invented) name review group, which checks that there are no products licensed with similar names in the EU which could lead to confusion. In the centralized procedure, the European Commission (based on a scientific assessment by CHMP) issues one license which applies to all the Member States, Norway, Iceland, and Liechtenstein. The layout, format, and wording on the immediate and outer packaging of the product are also reviewed as part of the evaluation procedure of the medicine, and these form part of the authorization. Any change to any of these aspects requires regulatory review and agreement.

There are a variety of other strategies that can be used to mitigate risks associated with a medicine. For healthcare providers, this might include specialized training for certain products, such as one that requires unique administration or insertion (e.g., implants). It may also include materials that facilitate discussions between healthcare providers (HCPs) and patients (or caregivers), such as prescriber–patient agreements. For teratogenic medications, it may include strategies to prevent fetal exposure to a medicine, including required pregnancy testing prior to prescribing or dispensing the medicine to individuals who could become pregnant, as well as contraceptive counseling and assurance that the patient is using measures to prevent pregnancy while taking the teratogenic medicine. Some medicines may require patient monitoring or periods of observation by a healthcare professional after administration, or the medicine may have to be administered in a certain type of healthcare setting that is equipped to manage the serious adverse event.

Pharmacists may play an important role in verifying that the medicine is appropriate for the patient, verifying that certain safe use conditions have been met prior to dispensing the medicine, or providing special instructions for the preparation or administration of the medicinal product. Pharmacists are also well placed to counsel patients at the point of dispensing on the use of their medicines, including other medicines or foods to avoid, special dosing instructions, or storage instructions if, for example, accidental overdose or diversion is a concern.

When determining the specific risk mitigation strategy, it is important to consider its goals and objectives. Interventions should be selected that can achieve those goals and objectives. As a starting point, the risk mitigation interventions undertaken in clinical trials should be evaluated to determine if those strategies were effective. There should be consideration of the healthcare providers likely to prescribe the medicine, the probable setting in which the medicine will be used, the population likely to use the medicine, and if those interventions would be reasonably reproduced in the setting of real-world use. In some cases, such an evaluation may lead to the conclusion that the product can be safely and appropriately used with labeling alone. In other cases, the evaluation may lead to the conclusion that labeling is insufficient, and that additional risk mitigation strategies are necessary to ensure a positive benefit/risk balance.

Some risk minimization strategies may require that prescribing and/or dispensing be limited to those willing to undertake additional steps to ensure safe use of the medicine. Measures that restrict the way a medicine is prescribed or used may introduce complexity and may require coordination with patients, pharmacists, and other stakeholders, particularly when patients move between various care settings (e.g., from an outpatient setting to an inpatient care setting).

In the EU and the US, a controlled distribution system may ensure that the medicinal product is

traceable to the pharmacy dispensing the product, to prevent the misuse and abuse of the medicine. When required, a set of additional risk minimization activities in the form of a controlled access program seeks to minimize an important risk with significant public health or individual patient impact for a product with clearly demonstrated benefits, but which would not otherwise be available. Patients' access to the medicine in such a system is contingent on fulfilling strict requirements before the medicinal product is used, such as clinical testing, completion of an educational program, enrollment in a systematic patient follow-up and data collection system, or availability of the medicine only from approved or certified pharmacies. The requirements can continue during treatment, by imposing specific tests or monitoring procedures. Since a controlled access program has large implications for all stakeholders, the use of these types of programs is generally limited and is guided by a clear therapeutic need for the product based on its demonstrated benefit (e.g., the medicine treats a serious disease without alternative therapies, or it treats patients who have failed existing therapies), the nature of the associated risk (e.g., the risk is life threatening), and the likelihood that this risk can be managed by such a program.

Evaluation of Risk Minimization and Mitigation Measures

Evaluation of risk minimization and mitigation activities is a critical component of a risk management system that follows the risk assessment and risk minimization steps. It is also a relatively new endeavor in the context of the medication use system. The evaluation of a risk mitigation activity aims to ensure that the objectives of the risk mitigation measures are fulfilled and that the activities in place are proportionate, taking into account the benefit/risk profile of the medicinal product and the efforts required to implement these measures. Such an evaluation is closely related to risk assessment activities, but it also differs in the way in which it enables modifications of the initial measures, if warranted, to improve the risk minimization strategy in the context of an iterative process of evaluation, correction, and reevaluation throughout the life cycle of a medicinal product.

In the EU, the pharmacovigilance legislation explicitly requires the active monitoring of the outcome of risk minimization activities contained in the risk management plan, placing an obligation on the manufacturers and regulatory authorities to undertake this activity. In the US, the metrics of a REMS assessment plan are approved in advance of REMS implementation. Assessment reports are submitted by the manufacturers 18 months and 3 years after the REMS is initially approved, and in the seventh year after the REMS is initially approved, with additional dates if more frequent assessments are necessary to ensure that the benefits of the drug continue to outweigh the risks.

There are a number of different conceptual models published as guides for developing efficient methods for measuring the effectiveness of risk minimization strategies. Despite some difference in the approaches, all models have the following common principles:

- Robust risk minimization evaluation is longitudinal in nature.
- A multifaceted assessment is needed for a comprehensive risk minimization evaluation.
- There are some key elements aimed at evaluating the implementation of risk minimization, such as:
  1) enablers and barriers for optimal program delivery and success;
  2) stakeholders' knowledge, attitudes, and perception of risk;
  3) intended and observed clinical behavior.
- Safety outcome data define the ultimate success of a risk minimization program.
- The unintended consequences of risk minimization measures should be taken into account.

First, evaluation of risk mitigation activities can assess if certain processes specified by the risk mitigation strategy are being followed. For example, if the risk mitigation strategy consists of providing patients with specific information about measures that can be undertaken to minimize a particular risk, this first process component of the assessment could consist of determining the proportion of patients who receive the information. The proportion of physicians aware of specific risk mitigation measures is also an example, as well as the proportion of physicians and other prescribers who received and who are using a specific risk minimization tool, such as a dosage card.

The coverage of a risk minimization tool generally does not require properly designed studies on a sampled population, as risk minimization tools are supposed to be distributed to all end users. However, monitoring of tool distribution can be required and estimates of coverage provided on the basis of agreed time frames. Results of inadequate distribution/coverage should lead to reconsideration of the delivery channels employed or help to determine whether a different tool format is required. Tool utilization can be measured using target audience surveys or via proxy indicators such as healthcare professionals' requests for refills of consumable risk minimization items (e.g., checklists and forms). Results can be analyzed as a whole or stratified to show how specific subgroups are performing, with the aim of highlighting areas where coverage, awareness, or usage is poorer and needs to be improved.

Second, the evaluation of risk minimization measures can focus on whether the target audiences understood both the purpose of the risk minimization tools and their key messages. These messages often relate to the safety risks, such as important signs and symptoms, or to actions that should or should not be taken, such as performing laboratory tests or not prescribing a drug to specific subpopulations. Common process indicators to be considered include the proportion of end users correctly responding to specific questions aimed at measuring understanding of the key messages contained in the risk minimization tool. When conducting such studies, scientifically rigorous survey methods should be applied and comprehensive guidelines for research can be retrieved from the published literature.

Overall, the following elements should be considered in the design and implementation of a survey in order to minimize potential biases and optimize the generalizability of the results to the intended population:

- The sampling frame should not be subjected to selection bias (random selection is generally the optimal approach) and recruitment sources should be appropriate (e.g., physicians lists from learned societies, patients lists from registries).
- The design and the administration of the survey questionnaire should ensure a fair and comprehensive evaluation. To build a robust questionnaire, the following three principles should be followed:
  - *Pretesting and validation*: to identify questions that are poorly understood, ambiguous, or evoke undesirable responses, and to avoid leading questions.
  - *Content validity*: the questions should capture all the aspects related to users' comprehension of the risk minimization activity, and should be clear and unambiguous.
  - *Construct validity*: the survey should be able to accurately measure (at different degrees) the risk minimization target audience's knowledge and comprehension.

Another level of the evaluation of risk minimization/mitigation activities can determine whether certain behaviors are being followed. In the previous example, measurements of behavior could assess whether patients, who have read the information they are given, take the specific actions the information recommends. Questionnaire-based stakeholder surveys are

not well suited to assess behavioral modification, because they rely on the respondent's self-reporting and might provoke socially acceptable responses, which have a large impact on the validity of the study's findings. Therefore, this evaluation strategy is better addressed with time-trends analyses, relying mainly on information from electronic medical records (EMRs) included in healthcare databases.

Data from EMRs might in fact provide rapid feedback on the effectiveness of risk minimization strategies, considering that information on drug exposure and patient clinical characteristics (which might define adherence to the recommendations contained in product labeling or educational material) is generally based on secondary data collection in an outpatient setting (i.e., primary care databases).

The ultimate measures of success of a risk minimization program are the safety outcomes. This evaluation can demonstrate whether the introduction of a risk mitigation strategy is correlated with a decrease in frequency of the health outcome that the risk mitigation strategy is designed to minimize. Safety indicators are mostly assessed by estimating incidence rates or cumulative incidence, for instance the number of new adverse reactions in subjects exposed to a certain medicinal product divided by the person-time (or size) of the (exposed) population within a specified time period. Reporting rates (e.g., number of suspected adverse reaction reports attributed to a certain medicinal product over a fixed time period) should only be used with caution, due to the well-known underreporting or due to the lack of patient-level linkage between drug exposure and adverse events. However, measuring reporting rates might be the only way to estimate the frequency of the adverse reaction in the treated population (e.g., with a rare event).

The incidence of adverse events can be evaluated in cohort studies using information from healthcare databases or registries. Disease registries are more suitable for evaluating risk minimization measures, as they may contain information on patients not exposed to the medicinal product, thus potentially providing a background rate of occurrence of the adverse events in the affected population in the absence of exposure to the medicine.

Some aspects of the risk management system, especially those that impose restrictions on the use of a medicine, may be burdensome on the healthcare system and may have unintended consequences. One potential unintended consequence is that the burdens imposed by the system will deter practitioners from prescribing a medicine to patients for whom the benefits outweigh the risks, and for whom that medicine would be the optimal treatment choice. There are few data at this time to address this potential limitation; however, methods to assess burden and ways to reduce the burden might include interviews with stakeholders or the use of focus groups, as well as assessing the workflows associated with implementing risk minimization strategies in various healthcare settings.

It is also important but challenging to identify potential barriers to patient access to the drug related to the implementation of risk minimization strategies. Patient access could be affected if providers choose not to prescribe the drug because they are unwilling to implement the risk minimization strategies. It may be difficult for a patient to find a participating prescriber in their geographic area, thus affecting the patient's access to the drug. Obtaining such data continues to be challenging, because it consists of identifying patients who would be appropriate candidates for a particular medicine, a task that involves clinical judgment, and who did not receive it, a task for which most current pharmacoepidemiologic approaches are not well suited, since they rely heavily on databases of drug exposure.

Assessing the risks of a medicine, instituting risk mitigation measures, and evaluating the impact of those measures form an iterative process. As new risks are identified, new risk mitigation measures may have to be put into effect.

These new measures will then need to be evaluated, and the risk mitigation measures may have to be modified. This iterative process occurs throughout the life cycle of the medicinal product. Pharmaceutical manufacturers are held responsible for the safety of their medicinal products, so it is usually they who fund risk assessments and put in place risk mitigation strategies and evaluations of those strategies. Regulators review the results of manufacturers' testing, proposed risk mitigation strategies, and evaluations of those risk mitigation strategies. In some instances, regulators may conduct independent assessments of drug safety.

As the academic field of pharmacoepidemiology has grown, university-based researchers also conduct drug safety research, either independently of manufacturers and regulators or in collaboration with them. A particular form of collaboration between academic researchers, public health institutions, manufacturers, and sources of public funds that can finance safety research is the public–private partnership. An example in the EU is ADVANCE (Accelerated development of vaccine benefit–risk collaboration in Europe), a publicly (Innovative Medicines Initiative, IMI) and privately (European Federation of Pharmaceutical Industries and Associations, EFPIA) funded project. One of its objectives was to develop conceptual models for public–private interaction, as part of developing best practice and a code of conduct for benefit/risk monitoring of vaccines.

Methodologic Problems to Be Addressed by Pharmacoepidemiologic Research

Roles of Pharmacoepidemiology in Risk Management

Pharmacoepidemiology can play several roles in risk management. The first, and most fundamental, role is to identify and quantify the risks of a medicine. Identification and quantification of risks can occur using a variety of pharmacoepidemiologic techniques, including clinical trials, spontaneous reports, case series, and observational pharmacoepidemiologic studies.

At the time of approval, clinical trials are the principal source of drug safety data. Clinical trials are well suited to characterizing and quantifying the common adverse effects of a medicine. For most prescription medicines, the majority of common side effects are not so serious that they require risk mitigation measures beyond professional labeling, and/or risk assessment measures beyond routine collection of spontaneous adverse event data.

Though the preapproval testing of a drug is rigorous, and the review of the data is very thorough, there are still some uncertainties about the complete safety profile of a drug when it is brought to market. These uncertainties arise because clinical trials are not well suited to detecting adverse events that are very rare or that occur only after prolonged exposure to a medicine or after a long latency period. In addition, real-world patient populations include patients with a broader range of co-morbidities, on a wider variety of concomitant medicines, and more severe underlying disease than those included in clinical trials. In practice, patients may be treated with dosing regimens, or may receive the medicines for uses that were not studied in clinical trials.

Despite these widely acknowledged limitations of clinical trials with regard to drug safety information, such trials can identify and characterize important drug safety issues that may require specialized risk management efforts. Vigabatrin, an irreversible inhibitor of gamma-amino-butyric acid, was approved in the US in 2009 for the treatment of infantile spasms and for refractory complex partial seizures in adults. It had been already approved in the UK. Several years after that approval, case reports emerged suggesting that vigabatrin was associated with peripheral visual field defects. Subsequent publications

described a slowly progressive, bilateral concentric visual field constriction. Prior to the medicine's approval in the US, the manufacturer conducted, at the request of EMA, a study to characterize better the occurrence of peripheral visual field defects. The primary endpoint was formal visual field testing every 4–6 months for 3 years. This measure allows for the detection of visual field defects that may otherwise not be detected in routine practice. Data from 524 patients who had at least one conclusive visual field measure during the course of the study were analyzed. Among adult patients, 35.6% had at least one occurrence of bilateral concentric peripheral visual field constriction; 24.6% had at least two occurrences. The corresponding figures in children were 20.0% and 15.3%, respectively [18]. These data demonstrate that clinical trials can be used to characterize and quantify specialized drug safety questions. In the US, the product was approved with a REMS to address this serious safety concern, as described later in this chapter.

An important use of pharmacoepidemiology is to measure how medicines are used in practice, especially if that is under conditions that can lead to adverse outcomes. Examples of pharmacoepidemiologic findings that could signal that a product is not being used appropriately include a finding that a medicine is being prescribed concomitantly with a contraindicated medicine, a finding that a drug is being used in a population of patients for whom the potential benefits do not outweigh the potential risks, and a finding that a medicine is frequently prescribed for a duration of treatment that is associated with an increased risk of serious adverse events. There are many other potential scenarios that can be examined. For these analyses, drug utilization databases, electronic medical record systems, and other administrative healthcare data, especially those with longitudinal patient-level data, are often useful.

Drug utilization data and medical records can also be used to identify medication errors. For example, the FDA utilized the Sentinel system to investigate whether name confusion errors could be identified by assessing the presence and absence of on- and off-label indications in claims data. Sentinel is the FDA's postmarket medical product safety surveillance system, which utilizes electronic claims and medical record data [19]. The FDA used one of Sentinel's analytic tools to identify potential prescribing and dispensing errors resulting from confusion between two medicinal products with similar proprietary names, Brilinta® (ticagrelor), an antiplatelet medicine, and Brintellix® (vortioxetine), an antidepressant medicine. The study was conducted by assessing the presence and absence of on- and off-label indications in the claims data for both products. Sentinel was used to identify new users of Brintellix, and separately new users of Brilinta, between September 30, 2013 and September 30, 2015. Members of all ages were included and had to be enrolled with medical and pharmacy coverage for ≥365 days prior to the dispensing date. Brintellix users overall were identified, including those who did not have an on- or off-label indication for Brintellix and had an on- or off-label indication for Brilinta. The reverse was done for Brilinta. The FDA identified 18 793 new users of Brintellix, of which 71 (0.4%) had no on- or off-label indication for Brintellix but had an on- or off-label indication for Brilinta in the 365 days prior to the dispensing. The claims profile review included 17 of these users, of whom 5 had no history of an on- or off-label indication for Brintellix and no dispensing of a drug in the same class as Brintellix, suggesting they may be true medication errors. The FDA identified 19 936 Brilinta users overall, of whom 90 (0.5%) had no on- or off-label indication for Brilinta but did have one for Brintellix; 21 of these were in the claims profile review; 8 may be true medication errors. Thus, this study indicated that a claims-based algorithm can be developed to identify potential name confusion medication errors in Sentinel using a combination of routine tools and claims profile review [20].

Examination of the prescribing patterns of long-acting beta agonists has been informative in the management of the risks of these agents. Long-acting beta agonists (LABAs) are indicated to treat, among other things, asthma. However, large clinical trials and meta-analyses of clinical trials have demonstrated that patients treated with these agents have a higher risk of asthma-related death, intubations, and hospitalization. Some data suggest, but do not prove, that this risk is mitigated if the LABAs are used in conjunction with inhaled corticosteroids (ICS) or other asthma controller medications. The National Asthma Education and Prevention Program's (NAEPP) Expert Panel Report 3 (EPR-3) recommends low-dose inhaled corticosteroids (ICS) as the preferred treatment for mild, persistent asthma, and that LABAs be reserved for patients whose asthma is uncontrolled by ICS monotherapy [21]. Friedman and colleagues examined drug-use patterns and clinical indicators of disease severity from a commercial insurance database to characterize use of LABA/ICS combination drugs (nearly all LABA use for asthma is in the form of a LABA/ICS combination product) [22]. Among 87 459 patients with a new prescription for a combination LABA/ICS product, 69.1% had no prior prescription for an ICS and no indicator of disease severity other than mild disease in the 365 days prior to the LABA/ICS prescription. These data suggested that LABAs were not being used in accordance with the national guidelines and that many patients were being exposed unnecessarily to the risks of LABAs [23].

A third application of pharmacoepidemiology is to provide population-based assessments of the causes and contexts in which known harm from medications can occur. For these analyses, one or more public health databases may be especially helpful. These databases can be used to estimate the burden of a given drug-related toxicity in the population. Because they are designed for the public health purposes of quantifying health and harm in society, projected national-level estimates are often available. They are especially useful when considering risk from a class of medications, or from a specific ingredient when it is a component of multiple medications.

As noted earlier in this chapter, acetaminophen is one of the most widely used medicines in the US, available in several single-ingredient and multi-ingredient, OTC, and prescription products. Although acetaminophen is generally safe when used as directed, misuse and overdose can cause acute liver failure, sometimes resulting in liver transplantation or death. Overdoses can be either intentional or unintentional. To provide context for risk mitigation activities, Nourjah and colleagues at the FDA examined several national databases to quantify this problem [24]. Using the National Hospital Ambulatory Medical Care Survey (NHAMCS), they determined that an estimated 56 000 emergency department visits occurred annually between 1993 and 1999 for acetaminophen overdoses; an estimated 12 650 of these overdoes were unintentional. Using data from the National Hospital Discharge Survey (NHDS), they estimated that for the years 1990 to 1999, there were 26 000 hospitalizations annually for acetaminophen overdoses, with 2240 of these related to unintentional overdose annually. Using the National Multiple Cause of Death Files, they estimated that 458 deaths occurred annually from acetaminophen overdose – 100 of which were due to unintentional overdose. These data provide quantitative information on the overall magnitude of acetaminophen overdoses in the US, as well as on the proportion of the overdoses that occur unintentionally. Data such as these are critical, not only for targeting risk mitigation interventions, but also for monitoring their impact once interventions have been implemented. In the UK, regulators have undertaken specific risk mitigation measures related to the potential dangers of acetaminophen, such as labeling recommendations for all medicines containing acetaminophen (paracetamol) and

restricting the amount of paracetamol that can be sold without a prescription to a patient to a maximum of 8 g per sale [25,26]. In the US, a boxed warning was added to prescription drug products containing acetaminophen highlighting the potential for severe liver injury. The FDA also requested all drug manufacturers of oral prescription products to limit the maximum amount of acetaminophen to 325 mg per tablet [27].

A fourth, emerging role of pharmacoepidemiology in the field of risk management is the assessment of risk mitigation efforts. Of all the ways in which pharmacoepidemiology can be used in risk management, understanding the best ways to assess risk mitigation efforts is the least developed. There are many challenges. First, for an effective evaluation, the risk mitigation activity must have a clearly defined goal that is relevant and measurable, even if prespecified criteria for success or failure are not established. Goals that are based on vague or imprecise metrics generally cannot be measured, and even if they are measurable, interpretations of the findings would be difficult.

Second, as already noted, assessing the effectiveness of a risk mitigation strategy can be conducted at several levels, including processes, behaviors, and health outcomes. While the traditional methods of pharmacoepidemiology may be used to assess observed behavior and health outcomes, it is quite likely that additional methods, such as those used in social sciences and health policy and management fields, may be needed for the first two levels (process and behavior).

Third, it is important to understand the relationship between each component of the risk mitigation strategy and the desired health outcomes. It is possible that practitioners and patients adhere to the processes and exhibit the behaviors desired by the risk mitigation strategy, but that the health outcome of interest is not improved or is difficult to measure. Alternatively, it is possible that practitioners and patients do not adhere to the processes or exhibit the desired behaviors, but the desired health outcome (e.g., a reduction in the specific risk) is achieved, perhaps because of other interventions or factors that were not part of the risk mitigation strategy. In either case, a critical examination of the risk mitigation strategy would be necessary.

The analysis of a risk mitigation strategy for isotretinoin illustrates how pharmacoepidemiology can be used to assess the impact of various program measures on program effectiveness. Approved in the US in 1982, isotretinoin is a medicine that is uniquely effective in the treatment of severe, recalcitrant nodular, cystic acne. It can cause severe birth defects and intrauterine fetal deaths and, to minimize the risk of fetal exposure, a series of risk management efforts have been implemented throughout the life cycle of this medicine. At the time of approval, risk messages for patients and prescribers were included in the approved labeling and initial marketing materials. In 1988, the manufacturer implemented the Accutane Pregnancy Prevention Program (PPP). The program included strengthened labeling, targeted education, reminder tools, patient informed consent forms, and patient and prescriber surveys to assess compliance with the program.

By 2000, the FDA had concluded that the PPP was not effective in minimizing exposure during pregnancy. The manufacturer then developed the System to Manage Accutane-Related Teratogenicity (SMART). An essential feature of this program was a "qualification" sticker that was to be attached to a written prescription for isotretinoin, which was to indicate adherence to certain program-mandated steps by prescribers and female patients. Prescribers were to read certain material about the teratogenic effects of isotretinoin and sign a letter attesting to their understanding of the measures to minimize fetal exposure to isotretinoin. Voluntary prescriber education was made available and encouraged.

Upon receipt of this letter by the manufacturer, the prescriber was eligible to receive qualification stickers. Qualification of female

patients involved multiple steps. The first step consisted of education about the teratogenic effects of isotretinoin, signing a consent form indicating understanding of the risks associated with the use of isotretinoin during pregnancy, and documentation of an initial negative serum or urine pregnancy test. In the second step, prescribers counseled sexually active women to select and use simultaneously two forms of effective contraception control, from a list of acceptable primary and secondary methods outlined in the SMART program, for one month prior to initiation of isotretinoin treatment, during treatment, and for one month after discontinuation of treatment. The third step was a confirmatory negative pregnancy test within seven days before the actual start of treatment. When each of these steps had been met, the patient was qualified, and was to present a written prescription with a qualification sticker to the pharmacist, who was to dispense isotretinoin only if the qualification sticker was present. The supply was limited to 30 days, and was to be accompanied by a Medication Guide. Before additional isotretinoin could be dispensed, women were again to qualify by having a negative serum or urine pregnancy test.

Prior to implementing SMART, the manufacturer agreed to evaluate the program's effectiveness during the first year [28]. A Pharmacy Compliance Survey found that, after the third month of the program, compliance with the requirement for a "qualification" sticker was generally high, above 99% for urban pharmacies and above 90% for rural pharmacies. The proportion of stickers that contained information on patient sex and qualification date was similarly high. A voluntary patient survey, which enrolled 21–26% of patients during the first four quarter-years of SMART, revealed that 9% of women reported signing no consent form, 81% indicated they received a Medication Guide, and 90% reported receiving a qualification sticker on their prescription. Among women aged 15–45 of child-bearing potential, 91% reported at least one pregnancy test and 66% reported two pregnancy tests prior to the initiation of treatment.

In further analyses, FDA staff examined the relationship of a qualification sticker to pregnancy testing and use of birth control measures. For the pregnancy test analysis, across 4400 prescriptions, a qualification sticker was present for 4300 and not present for 100. The frequency of pregnancy testing when a sticker was present was 91%; the corresponding frequency when a sticker was not present was 90%. For the birth control analysis, across 1788 prescriptions, a qualification sticker was present for 1715 and not present for 73. The frequency of reported birth control use testing when a sticker was present was 97%; the corresponding frequency when a sticker was not present was 96%.

The qualification sticker in the SMART program was, in some ways, designed to be a surrogate marker for important conditions of safe use of isotretinoin. The analysis shows that despite reasonably high compliance with the placement of a qualification sticker on a prescription, this measure yielded information no different from the lack of a sticker with regard to two important conditions of safe use: the undergoing of pretreatment pregnancy tests and the use of acceptable methods of birth control.

These findings indicate that process measures that are a surrogate for clinical events need to be validated. The results of the evaluation of the SMART program led to the development of iPLEDGE®, a single, shared, restricted distribution program that includes all isotretinoin products. iPLEDGE requires the participation and enrollment of prescribers, patients, pharmacies, and wholesalers. Unlike SMART, iPLEDGE links the dispensing of isotretinoin to the documentation of negative pregnancy tests, prescriber confirmation that contraceptive counseling has occurred, prescriber and patient identification of contraceptive methods chosen, and demonstration of patient comprehension of isotretinoin risk and measures intended to mitigate risk. When all elements have been confirmed,

iPLEDGE provides a "risk management authorization" to the pharmacist. While it is not known if the total number of fetal exposures to isotretinoin has decreased under the iPLEDGE program, there is greater certainty that patient counseling and pregnancy testing are being conducted, and that patients are made aware of the risks and agree to appropriate measures to prevent pregnancy during treatment [29].

Another role for pharmacoepidemiology is in the area of assessing risk communication. The assessment of communication is a broad endeavor, and can involve many disciplines and approaches. A survey of the evidence base for the factors that can contribute to improved content and format of patient-oriented prescription drug labeling identified randomized clinical trials, surveys, questionnaires, interviews, and other methods used to assess readability and understanding, though it noted that little evidence existed linking label design or content to measurable health outcomes [30].

To assess the relationship of various communication strategies to health outcomes, Shrank and colleagues took advantage of a deliberate effort by one large pharmacy chain to improve its patient labeling [31]. They then used administrative claims data from one insurance carrier in two states in the US to look at various health outcomes for patients to whom outpatient medicines for one of nine chronic conditions were dispensed. Because these data contained detailed information on the specific pharmacy at which the medicines were dispensed, they could examine the impact of the new labeling strategy, which was linked to one specific pharmacy chain, on health outcomes. Health outcomes of interest included outpatient, emergency department, and inpatient health services use. The sample included 23 745 users of the pharmacy which introduced the newly designed labeling, and 162 369 matched patients who used other pharmacies.

The study found that the introduction of the modified labeling was not associated with a significant change in the rates of outpatient health services use (event rate ratio: 0.53, 95% confidence interval [CI]: 0.15–1.86) or inpatient and emergency department care (event rate ratio: 0.88, 95% CI: 0.62–1.24) among users of pharmacies that incorporated the modified labeling compared to users of pharmacies that did not incorporate the new labeling. However, the 95% confidence intervals include clinically important event ratios, which suggest that insufficient power, and not failure of the intervention, may account for the lack of a statistically significant finding. The authors noted the challenges in developing health literacy interventions that can have a measurable impact on health outcomes.

Currently Available Solutions

Regulatory Framework in the US

It is important to distinguish the broad strategies used to manage the risks of medicines from the specific legislative initiatives that are often associated with risk management. Specifically, the latter are generally a subset of the former.

The Food and Drug Administration Amendments Act (FDAAA) of 2007 created section 505-1 of the Federal Food, Drug, and Cosmetic Act (FDCA), which authorizes the FDA to require a risk evaluation and mitigation strategy or REMS for certain drugs if it determines that a REMS is necessary to ensure that the benefits of the drug outweigh its risks [32]. A REMS is a required risk management plan that utilizes tools beyond routine labeling to ensure that the benefits of a drug outweigh its risks. The FDA can require manufacturers to develop and comply with the REMS if specific statutory criteria are met. These provisions became effective in 2008. The REMS authorities apply to prescription products approved under New Drug Applications (NDAs) and Abbreviated New Drug Applications (ANDAs), as well as products approved under Biologics License Applications (BLAs).

Prior to the initial approval of an application, the FDA offices responsible for review of the

medicinal product and for postapproval safety review determine whether a REMS is needed to ensure that the benefits of the drug outweigh its risks. In the postapproval phase, the FDA may determine that a REMS is needed if it becomes aware of new safety information after the drug was approved, and determines that a REMS is necessary to ensure that the benefits of the drug outweigh its risks. New safety information may be derived from a clinical trial or study, adverse event reports, published literature, or other scientific data deemed appropriate by the FDA about a serious risk or unexpected serious risk associated with the use of the drug. This may include information based on a new analysis of existing data or an assessment of the effectiveness of an approved REMS. The FDA makes decisions about requiring a REMS as part of a benefit–risk determination for a drug after an evaluation that includes consideration of certain statutory factors (listed in Table 24.1) [33].

All REMS for NDAs and BLAs must include a timetable for assessment of the REMS and may include the following additional elements:

- A Medication Guide (MG) or a patient package insert (PPI)
- A communication plan
- Certain packaging and safe disposal technologies for drugs that pose a serious risk of abuse or overdose
- Elements to assure safe use (ETASU)
- An implementation system

A Medication Guide provides FDA-approved patient-focused labeling, and may be required as part of a REMS to inform patients about serious risks associated with the product; it may also be used to provide patients with information necessary for the safe use of the product. A communication plan consists of FDA-approved materials used to aid the implementation of the REMS and/or inform healthcare providers about serious risks of a product. FDA may require certain packaging or safe disposal systems be made available for opioids and other drugs that pose a serious risk of abuse or overdose if the FDA determines that such packaging may mitigate such risks [34]. Elements to assure safe use (listed in Table 24.2) are required if they are necessary to mitigate a specific serious risk listed in the labeling of a product, thus enabling access for patients to drugs that would otherwise not be approved. The FDA may also require an implementation system for REMS with certain ETASU. An implementation system requires the application holder to take reasonable steps to monitor, evaluate, and improve implementation of ETASU by healthcare providers and other participants.

The minimal timetable for assessment of a REMS includes assessments by 18 months, by 3 years, and in the seventh-year post-REMS

Table 24.1 Factors the US Food and Drug Administration must consider when determining the need for a risk evaluation and mitigation strategy.

Estimated size of the population likely to use the drug involved
Seriousness of the disease or condition that is to be treated with the drug
Expected benefit of the drug with respect to such disease or condition
Expected or actual duration of treatment with the drug
Seriousness of any known or potential adverse events that may be related to the drug and the background incidence of such events in the population likely to use the drug
Whether the drug is a new molecular entity

Source: Federal Food, Drug and Cosmetic Act, section 505-1(a)(1).

Table 24.2 Risk evaluation and mitigation strategies in the US: elements to assure safe use.

A) Healthcare providers who prescribe the drug have particular training or experience or are specially certified
B) Pharmacies, practitioners, or healthcare settings that dispense the drug are specially certified
C) The drug be dispensed to patients only in certain healthcare settings, such as hospitals
D) The drug be dispensed to patients with evidence or other documentation of safe use conditions, such as laboratory test results
E) Each patient using the drug be subject to certain monitoring
F) Each patient using the drug be enrolled in a registry

approval. The FDA may require more frequent assessments that may be specified in the REMS.

Regulatory Framework in the EU

The requirement for risk management in the EU is specifically included in legislation. The term "medicinal product" is also defined in the legislation and includes both chemical and biologic medicines.

Article 6 of Regulation (EC) No 726/2004 as amended and Article 8 of Directive 2001/83/EC as amended lay down the requirements for the documents to be included in an application for the authorization of a medicinal product for human use. A description of the pharmacovigilance system is developed by the manufacturer for a marketing authorization in the format of a pharmacovigilance system master file (PSMF); the legal requirement is to maintain and make available upon request the PSMF (Directive 2010/84/EU). It is a requirement of the marketing authorization application that summary information about the pharmacovigilance system is submitted to the competent authorities; this summary includes information on the location of the PSMF.

The manufacturer is also responsible for developing and maintaining product-specific risk management systems. The terms "pharmacovigilance systems" and "risk management systems" mentioned in the legislation may cause confusion. A pharmacovigilance system refers to the measures that a company puts in place to meet the requirements in the legislation for pharmacovigilance, designed to monitor the safety of authorized medicinal products and detect any change to their benefit/risk balance. These requirements include the need to have within the company an "appropriately qualified person responsible for pharmacovigilance." This person must reside within the EU, Norway, Iceland, or Liechtenstein, and is known as the qualified person responsible for pharmacovigilance (EU QPPV). The pharmacovigilance activities that they and the company are responsible for can be summarized briefly as:

- Setting up a system to ensure that all reports of suspected adverse reactions are collected, collated, and accessible.
- Preparing and submitting reports to the authorities of both individual adverse reactions and periodic safety update reports, as specified in the legislation and guidance.
- Providing the authorities with any requested or any other information that relates to the benefits or risks of the medicinal product, including drug utilization data.

The means whereby this is achieved is known as the pharmacovigilance system. A pharmacovigilance system is therefore company specific and would include the adverse reaction database, the EU QPPV, and the various processes, standard operating procedures (SOPs), and so on, by which an individual company ensures compliance with pharmacovigilance legislation. The requirements for the description of the pharmacovigilance system are described in Module II – Pharmacovigilance

system master file of the Guideline on good pharmacovigilance practices.

Whereas the pharmacovigilance system applies to the people and processes in a whole company, a risk management system is usually substance specific, or, if the manufacturer has authorizations for more than one product containing the same active substance, the risk management system will be substance specific. It describes the important risks and missing safety information pertaining to a particular product; how they will be investigated and characterized further; how new risks will be identified; and the risk minimization activities which will be put in place to prevent or mitigate them.

All marketing authorization applications are required to include a description of the risk management system in the form of the Risk Management Plan, submitted for assessment. The guidance on the format and content of the EU RMP is provided in the Guideline on good pharmacovigilance practices Module V – Risk management systems, and the Guidance on the format of the risk management plan in the EU.

The aim of an RMP is to document the risk management system considered necessary to identify, characterize, and minimize a medicinal product's important risks. As knowledge regarding a medicinal product's safety profile increases over time, so will the RMP change.

The RMP structure requirements are described in EU legislation, Commission Implementing Regulation (EU) No 520/2012. The three main parts of the RMP mirror the essential activities in risk management:

- Part II – Safety specification, aimed at the identification of safety concerns for the product (i.e., important identified risks, important potential risks, and missing information).
- Part III – Pharmacovigilance plan (including postauthorization safety studies), describing the plan to further characterize the safety concerns of the product.
- Part V – Risk minimization measures (including evaluation of the effectiveness of risk minimization activities), describing the plan to prevent, minimize, and manage the important risks of the product.

The content requirements for the RMP are risk proportionate. For example, the RMP Part II – Safety specification of a medicinal product containing a new active substance will include more information than one of a generic or hybrid product, as the uncertainty is greater at the approval of the first product containing a new active substance. However, the list of safety concerns is determined by the risks associated with the substance or the specifics of each product (e.g., particular formulation). Similarly, the postmarketing requirements for pharmacovigilance and risk minimization activities reflect the safety profile of products, and for common risks equal requirements apply.

Routine Risk Minimization

EU GVP Module V defines routine risk minimization as those activities which apply to every medicinal product and lists all the available tools. These "routine" risk minimization activities are as follows:

- Product information:
  - Summary of Product Characteristics (SmPC), targeted at HCPs, including routine risk communication messages and routine risk minimization activities recommending specific clinical measures to address the risk.
  - Patient Information Leaflet (PIL), targeted at patients/caregivers.
- Labeling (the immediate and outer packaging of the medicine) and pack design [35].
- Pack size, ensuring that patients see an HCP after the use of the doses in the pack.
- Legal status of a medicine (i.e., whether subject to medical prescription or not subject to medical prescription).

Medicines subject to medical prescription may have a further limitation by being categorized as being on special or restricted prescription.

These further categories are defined in Article 71 of Directive 2001/83/EC as amended. Some Member States have within their national legislation the ability to specify further the use of a medicine, but this is not common to all EU countries. For example, in the UK, a medicine that is not subject to medical prescription can be classified as being available only when a pharmacist is present or as suitable for sale without a pharmacist.

A medicine within the "restricted" medicine category will have the details of the restriction in the SmPC, and will be:

- reserved for treatments which can only be followed in a hospital environment, because of its pharmaceutical characteristics or novelty or in the interests of public health;
- used in the treatment of conditions which must be diagnosed in a hospital environment or in institutions with adequate diagnostic facilities, although administration and follow-up may be carried out elsewhere;
- intended for outpatients, but its use may produce very serious adverse reactions, requiring a prescription to be drawn up as required by a specialist and special supervision throughout the treatment.

All these routine risk minimization activities are part of the authorization for a medicine and, for centrally authorized medicines, are contained within the Annexes to the Commission Decision, translated into all EU languages (all translations are at http://ec.europa.eu/health/documents/community-register/html/reg_hum_act.htm?sort=a). They are thus legally binding on the manufacturer.

Additional risk minimization activities

Centrally authorized medicines may have additional risk minimization measures specified as part of the marketing authorization. Article 9 (4)(c) of Regulation (EC) No 726/2004 requires the CHMP to attach to the scientific opinion it gives to the European Commission "details of any recommended conditions or restrictions with regard to the safe and effective use of the medicinal product." These recommendations will be adopted by the European Commission and form part of the legally binding conditions of the Marketing Authorization. In exceptional cases, the European Commission will also adopt a decision related to Article 127 (a) of Directive 2001/83/EC, directed to the Member States, describing the responsibilities of national competent authorities in ensuring that the additional risk minimization measures are implemented in the Member States in accordance with defined key elements.

The legislation refers to recommended conditions or restrictions with regard to the safe and effective use of the medicinal product. This permits any measure deemed necessary by the PRAC and the CHMP (and the European Commission) to be a legally binding condition of the marketing authorization with which the manufacturer must comply.

Each condition will usually state what must be achieved, but how this will be done remains flexible. For example, the conditions of the Marketing Authorization may specify that the manufacturer should set up controlled distribution. Because of the differences in the way healthcare is delivered in each of the Member States, there are at least four different ways in practice in which distribution is controlled across the EU. Specifying the end rather than the means allows for this flexibility.

The conditions may stipulate that certain information is provided to physicians, patients, or both. Typically, they will state what the information must contain, but the format it is presented in, how it is provided, and the particular phrasing of the information are usually left flexible. An exception to this was the risk minimization activities related to 5-aminolevulinic acid hydrochloride. These required that the product only be used by "experienced neurosurgeons conversant with surgery of malignant gliomas and in-depth knowledge of functional

brain anatomy who have completed a training course in fluorescence-guided surgery." The conditions of the Marketing Authorization required the manufacturer, in agreement with the competent authorities in the Member States, to implement training courses prior to launch of the product. The conditions included considerable details on exactly what should be included in the training course, the qualifications and experience needed to become a trainer, and the minimum requirements for a training center. Because the Commission Decision also required the Member States to ensure that these conditions were implemented in their territory, this meant that they had to put in place measures to restrict the use of the product to appropriately trained neurosurgeons. Since not all Member States had centers involved in clinical trials, training centers did not exist initially in all countries. Consequently, training of neurosurgeons from those countries in the particular techniques necessary to use the product safely would need to take place in another Member State. This external training would also need to be continued until sufficient expertise had been developed to enable the specific requirements for trainers and training centers to be met in each country. This case illustrates the fact that very stringent conditions can be set for risk minimization while still allowing flexibility in how it is achieved.

The ability to set conditions and restrictions does not apply to medicines only at the time of authorization. If during the life cycle of a medicine it becomes apparent that additional risk minimization activities are necessary, then these can be made conditions of the Marketing Authorization. In the same way, if it becomes apparent that the risks in real-world usage are not as great as estimated at the time of authorization or when the additional minimization activities are incorporated in routine clinical practice and are well adhered to, it is possible to remove conditions or restrictions. A critical review milestone is the five-year renewal, when an active review of the suitability of risk minimization activities is performed by the manufacturer and PRAC, and changes to the conditions for the safe and effective use of the product are proposed as needed.

Risk Management Example in the US: Alemtuzumab

As mentioned previously in this chapter, the FDA can require a REMS at the initial approval of a medicinal product if it is determined that such a strategy is necessary to ensure that the benefits of a drug outweigh its risks, or postapproval if the FDA becomes aware of new safety information following approval of the product and determines that a REMS is necessary to ensure the benefits outweigh the risks.

Alemtuzumab (with the brand name Lemtrada) is a CD52-directed cytolytic monoclonal antibody indicated for the treatment of patients with relapsing forms of multiple sclerosis (MS). It depletes T and B lymphocytes via binding to the cell surface antigen CD52, and it is believed that any effects in MS are mediated through this action. Alemtuzumab was originally approved (with the brand name Campath) in 2001 for the treatment of patients with B-cell chronic lymphocytic leukemia (B-CLL) without a formal risk management plan. However, the manufacturer removed alemtuzumab (as Campath) from the commercial market prior to its approval as Lemtrada for the treatment of MS.

Alemtuzumab for the treatment of MS has a unique dosing and administration schedule of two treatment courses. The first treatment course is administered via intravenous infusion on five consecutive days, and the second course is administered on three consecutive days, 12 months later. Subsequent treatment courses may be administered, as needed, at least 12 months after the last dose of any prior treatment course [36]. Besides its more immediate effects, infusion-associated reactions (IAR) occurring during the infusion and 24 hours thereafter, alemtuzumab is associated

with longer-term effects that can occur 1–5 years after administration. Secondary autoimmune diseases are the most important adverse events associated with alemtuzumab therapy, predominantly affecting the thyroid, kidneys, and thrombocytic function in approximately 30–40% of patients taking the product [37]. Serious and life-threatening stroke has been reported within 5 days of alemtuzumab administration.

Because of the risks associated with alemtuzumab, its approved US label states that "the use of Lemtrada should generally be reserved for patients who have had an inadequate response to two or more drugs indicated for the treatment of MS." It was also approved in the US with a REMS. The specific goals of the alemtuzumab REMS are provided in Table 24.3. This REMS includes several components to address the short- and long-term risks associated with its use [38].

Only healthcare providers certified in the REMS program are able to prescribe alemtuzumab. Certification includes an educational component that instructs prescribers about the autoimmune risks associated with alemtuzumab, including the risk of idiopathic thrombocytopenia purpura as well as other cytopenias, glomerular nephropathies, thyroid disorders, stroke, and malignancies; how to recognize the clinical presentation of these adverse events; and how to monitor for these events. Prescribers also agree to monitor patients periodically for at least 48 months following the final alemtuzumab infusion.

Alemtuzmab can only be administered by certified healthcare facilities that have on-site access to equipment and personnel who are trained and capable of managing infusion-related reactions, including anaphylaxis and cardiac and respiratory emergencies. Patients are premedicated with high doses of corticosteroids, and possibly antihistamines and/or antipyretics. They are monitored during the entire infusion and for a minimum of two hours following the infusion, or longer if clinically indicated.

Patients who are considered candidates for treatment with alemtuzumab must be enrolled by their provider in the program and counseled about the risks associated with the drug. The initial enrollment form captures baseline patient information, including baseline laboratory data. Prescribers are required to complete a patient status form every 6 months for about 4 years

Table 24.3 Goals of the Alemtuzumab risk evaluation and mitigation strategy (REMS).

The goal of the LEMTRADA REMS is to mitigate the risks of autoimmune conditions, infusion reactions, stroke, and malignancies associated with LEMTRADA by:

1) Helping to ensure informed decisions about the safe use of LEMTRADA by:
   - Informing patients about the serious risks of autoimmune conditions, infusion reactions, and malignancies with LEMTRADA and the need for baseline and periodic monitoring; and
   - Informing healthcare providers about the serious risks of autoimmune conditions, infusion reactions, stroke, and malignancies with LEMTRADA, the need to counsel patients, and the need for baseline and periodic monitoring.
2) Helping to ensure the safe use of LEMTRADA by:
   - Ensuring that only certified prescribers prescribe LEMTRADA;
   - Ensuring that LEMTRADA is dispensed only in certain healthcare settings, by certified pharmacies, and certified infusion sites, which have on-site access to equipment and personnel trained to manage infusion reactions; and
   - Ensuring that only enrolled and authorized patients receive LEMTRADA;
   - Ensuring that certified prescribers submit documentation of periodic monitoring of patients who receive LEMTRADA to identify autoimmune conditions and malignancies.

after the final dose for each patient to capture adverse events of interest. The purpose of this is to further characterize the long-term safety of alemtuzmab.

The final component of the alemtuzumab REMS is an implementation system, which describes how operational elements and responsibilities specified in the REMS will be implemented by the manufacturer. The manufacturer is also responsible for conducting an assessment of whether the alemtuzumab REMS is meeting its risk mitigation goals. Assessments are required every 6 months from the date of approval of the REMS for 1 year, and annually thereafter. The assessment plan includes primarily process indicators, including outreach efforts by the manufacturer; the numbers of certified prescribers and infusion centers; results of assessments of the knowledge of prescribers, other healthcare providers, and patients about the risks and required safe use conditions; deviations from program requirements, for example administering alemtuzumab to patients who have not been enrolled in the program; information regarding any unintended consequences such as unintended delays in treatment; and an evaluation of whether appropriate patient monitoring has occurred, including reports of adverse events of interest.

The alemtuzumab REMS includes features of a modern pharmaceutical risk management program. First, the goal of this risk mitigation strategy is not prevention of the serious adverse events associated with alemtuzumab, but rather the program was instituted to ensure that the benefits of the drug outweigh its risks. To accomplish this, the FDA required that a rigorous safety program be implemented to mitigate the severity of the adverse events (i.e., improving outcomes in patients who may experience an infusion-related reaction) and early detection of serious autoimmune disorders so that patients can be appropriately managed.

Risk Management Example in the EU: Bupropion/Naltrexone (Mysimba)

Bupropion/naltrexone (with the brand name Mysimba and referred to as Mysimba throughout) was authorized in the EU in March 2015. It is a medicine used together with diet and exercise to treat obesity, which is defined as a BMI (body-mass index, a measure of weight relative to height) of 30 or above; it can also be given to very overweight patients who have weight-related complications.

The main safety and tolerability concerns identified with Mysimba were related to central nervous system and gastrointestinal adverse events, and uncertainties with regard to cardiovascular outcomes in the longer term. The manufacturer submitted an EU-RMP which included a risk minimization plan.

The CHMP decided that there was a need for both additional pharmacovigilance activities and risk minimization activities.

Additional pharmacovigilance activities for Mysimba

Apart from routine pharmacovigilance (i.e., a spontaneous reporting system), the manufacturer agreed to request the results of two Phase IV randomized clinical trials to evaluate the effect of Mysimba on the occurrence of major adverse cardiovascular events in overweight and obese subjects with high cardiovascular risk. Also, a drug utilization study and a physician survey were requested to evaluate how Mysimba is used in real-world medical practice because of the potential for off-label use.

Risk minimization activities: Mysimba

The most important safety concerns for Mysimba are seizures, suicidality in patients with depression, and off-label use. The main risk minimization strategy was to prevent patients with an increased risk of these adverse drug reactions from being prescribed Mysimba.

This translates into risk minimization activities to ensure the following:

- Mysimba is used within the SmPC indication.
- Patients with contraindications are not prescribed Mysimba.
- Physicians understand which patients (without contraindications) are likely to have additional risk factors for safety concerns and may need additional monitoring/counseling.
- The benefit/risk balance is positive at the individual patient level.

To reinforce the indication and warning and precautions in the SmPC and prevent off-label use, a physician prescribing checklist was proposed to guide physicians in prescribing appropriately. The checklist reminded the physician not to prescribe Mysimba in the presence of:

- Uncontrolled hypertension
- Current seizure disorder or a history of seizures or known central nervous system tumor
- Current or previous diagnosis of bulimia or anorexia nervosa
- Currently dependent on chronic opioids or opiate agonists (e.g., methadone), or patients in acute opiate withdrawal
- Undergoing acute alcohol or benzodiazepine withdrawal
- Concomitant treatment containing bupropion or naltrexone
- History of bipolar disorder
- Receiving concomitant administration of monoamine oxidase inhibitors
- End-stage renal failure or severe renal impairment

Also the checklist contained information to carefully evaluate the benefits and risk of treatment in the presence of the following conditions:

- Mild or moderate renal impairment
- Controlled hypertension
- Angina or recent history of myocardial infarction
- History of mania
- Suicidal ideation
- Depression
- Risk factors for seizures

In postmarketing, based on a review of the clinical trials and postmarketing reports of serious and nonserious cases of hepatotoxicity, there was evidence to suggest a possible causal relationship between hepatotoxicity and the use of Mysimba. Nonserious cases were reported to result in an elevation of liver enzymes. In addition, drug-induced liver injury (DILI) was described in clinical trials.

Therefore, in view of the data presented, it was considered that changes to the product information of all medicinal products containing the combination product naltrexone/bupropion were warranted, although there was no need to change the additional risk minimization in place until the results of the drug utilization and physician survey were provided.

The Future

Managing the risk of medicinal products is an evolving area involving multiple stakeholders in the complex medication use system. In this section we describe possible areas for future refinements of the current risk mitigation systems that are in place.

One critical area for future development is to continue to improve the way risk mitigation activities are being implemented. Many of the risk mitigation tools have relied in whole or in part on communicating a risk associated with a medicinal product to increase stakeholders' awareness and knowledge. The goal is that awareness of a particular risk will impart knowledge and influence prescribing practices of the medicinal product or how practitioners will monitor patients once treatment with the product has begun. The communication can be in the form of a one-time letter or ongoing communication to practitioners, a formal training program

that practitioners must undertake in order to prescribe the medicinal product, or an agreement by the practitioner that they will undertake certain conditions of safe use (e.g., to perform laboratory testing on a prespecified periodic basis). Communication is necessary, but delivery may be more effective if done in real time rather than weeks or months prior to prescribing the medicinal product.

Risk management plans are designed to work within a complex medication use system. The complex systems were developed before the advent of contemporary risk management planning efforts. A current challenge for risk management systems is that they be developed in ways that can integrate with minimal difficulty into the current medication use systems and in a manner that is least burdensome to healthcare providers. Risk mitigation strategies that require documentation of safe use conditions need refinement. A future challenge is to develop a quality systems approach to implementing this type of risk mitigation strategy in a manner that is seamless for practitioners and within the scope of their usual clinical practice. The design of this type of mitigation strategy can be challenging, because the medication use process is complex. Furthermore, the medication use process differs across various healthcare settings, which makes it additionally challenging to implement mitigation strategies with the same goals across the various settings. Evaluation of its impact will also be challenging and difficult to answer, and will require the integration of many disciplines, including pharmacoepidemiology.

Another area for future refinement is to continue to gather evidence of the impact of various risk mitigation strategies, particularly on safety or health outcomes. Measurement of the impact is important, because it allows policymakers and other stakeholders to determine if the goals of the strategy are being met. Much of the evidence collected to date has been on process indicators such as whether particular safety messages have reached the intended stakeholder, whether it imparted the knowledge necessary to use the medicinal product safely, and whether that knowledge resulted in a change in the clinical practice of the practitioner (i.e., whether it resulted in the desired behavior by the stakeholder). Disciplines including social science and health service research have made significant progress in advancing our understanding of those types of outcomes. As noted earlier, the most important outcome measures to assess are the specific health outcomes of interest. If process outcomes and behavioral outcomes are met, but there is no impact on health outcomes or the impact on health outcomes is unknown, risk management strategies may need to be reconsidered. The optimal way to measure the impact of risk management strategies on safety or health outcomes remains a challenge, and is an area in which pharmacoepidemiology plays a crucial role.

Pharmacoepidemiology is integral to the measurement of specific health outcomes. The challenges for this field include developing models to relate risk management strategies to health outcomes, as well as ways to identify the contribution of individual components of the strategy to the overall outcome. Evaluations of the risk mitigation strategy should include an assessment of any negative consequences to implementing a risk management strategy. For example, if restricted distribution is put in place for a certain medicine that requires documentation that a laboratory test was conducted prior to dispensing the medicine to the patient, does this strategy, because of the real or perceived burdens associated with its implementation, result in patients not receiving the medicine even if it is the most appropriate medicine for that patient? This assessment should be followed by an evaluation of the impact of the risk mitigation strategy on stakeholders, including prescribers, pharmacists, and patients, to ensure the strategy improves the safe use of the product, but does so in the most efficient manner possible.

As risk management planning is evolving in multiple countries and regions, there is considerable interest in international harmonization of these efforts. At this time, there are many challenges that must be overcome if harmonization is to become a reality. First, the diversity of healthcare systems and medication use systems from one country to the next limits the degree to which identical, or even similar, individual risk mitigation plans can be put in place across several countries. Second, because of the differences in risk mitigation systems that can be put in place across countries, it would be challenging to develop a common risk management plan that manufacturers could submit to all regulatory authorities. The differences in risk management activities across countries and regions, however, create a natural opportunity for stakeholders to determine the relative impact of different approaches to risk management.

It is now common to analyze large and complex electronic healthcare databases – created as part of regular business operations or routine clinical care – to assess the safety and effectiveness of medical products. Pharmacoepidemiologic studies have traditionally analyzed information available in single databases. However, single-database studies may not be sufficient to answer certain clinical questions, especially when the exposure or outcome is rare, when the goal is to study the treatment effect in specific subgroups, or when the objective is to identify a sufficiently large number of exposed patients within a relatively short time window (e.g., during the early months following the approval of a new medical product).

Thanks to the increase in the number of data sources, and the improvement in the quality of and ease of access to these data sources, multidatabase studies are now feasible and ubiquitous in pharmacoepidemiologic research. There are several ways to conduct multidatabase studies. An intuitive approach is to pool the databases or the derived analytic datasets centrally for analysis. However, centralized pooling of databases that contain detailed individual-level data is not always possible for several reasons, including concerns about patient privacy, data security, unauthorized uses of data, and potential disclosures of sensitive institutional or business information. A distributed approach, in which databases are not combined centrally but rather stored in different physical locations under the direct control of the participating sites, is becoming increasingly preferred.

In this chapter, we describe the design, development, implementation, strengths, and challenges of distributed data networks (DDNs). We begin with a brief description of select DDNs in pharmacoepidemiology. We then discuss the types of research questions that DDNs are designed to address. We examine the methodologic and data issues unique to DDNs, and progress that has been accomplished to address these issues. We conclude with a discussion about some of the future directions for DDNs.

Here we first define three key terms that are central to the chapter:

- *Distributed data network*: two or more data sources stored in different physical locations

Pharmacoepidemiology, Sixth Edition. Edited by Brian L. Strom, Stephen E. Kimmel and Sean Hennessy.

under the direct control of the participating data partners.
- *Common data model (CDM)*: a data model that generally includes a set of standardized data files and variables, adopted by all data sources participating in a DDN.
- *Common protocol*: a study protocol that typically includes detailed description of key design and analytic parameters of the study, implemented by all data sources participating in a DDN study.

Examples of Distributed Data Networks in Pharmacoepidemiology

DDNs have been in existence for more than 20 years. Drawing on more than two decades of experience, the DDNs today are more sustainable, efficient, and diverse. This section briefly describes a number of DDNs designed to conduct pharmacoepidemiologic research, medical product safety surveillance, or comparative effectiveness research using electronic health data collected as part of routine healthcare delivery. Table 25.1 provides a summary of their key characteristics.

Asian Pharmacoepidemiology Network (AsPEN)

Established in 2008, AsPEN is a multinational research network formed to provide a mechanism to support the conduct of pharmacoepidemiologic research and to facilitate more rapid identification and validation of emerging safety issues among the Asia-Pacific countries [1,8]. AsPEN is a collaboration of 8 countries involving 12 databases formalized as a Special Interest Group of the International Society for Pharmacoepidemiology. It has piloted a number of approaches to conduct distributed studies including a common protocol, a standard analytic program [9–12], and translation to a CDM developed by the Observational Medical Outcomes Partnership (OMOP; see later) [13].

Canadian Network for Observational Drug Effect Studies (CNODES)

CNODES is a distributed network of Canadian research teams designed to provide evidence to Canadian stakeholders, in particular Health Canada, on drug safety in the Canadian context [2]. It is one of four collaborating centers supported by the Drug Safety and Effectiveness Network (DSEN) of the Canadian Institutes of Health Research. Queries from stakeholders are prioritized by DSEN head office and sent to the CNODES coordinating center. CNODES teams conduct analyses of a distributed network of Canadian and international databases, and report both to stakeholders and via published literature.

Health Care Systems Research Network (HCSRN)

Established in 1994, HCSRN (formerly known as the Health Maintenance Organization Research Network, HMORN) is a consortium of 18 integrated delivery systems and health plans designed to facilitate multidatabase collaborative research [3]. Compared to other DDNs, HCSRN is unique because it is not created to address specific clinical or research questions. Instead, it is "multipurpose" and supports a wide range of research and surveillance activities. HCSRN is the foundation on which several large-scale collaborative projects are built and maintained, including the Vaccine Safety Datalink (VSD; more later) [14], the Cancer Research Network [15], the Mental Health Research Network [16], and the Cardiovascular Research Network [17]. HCSRN is often considered one of the best examples of a sustained DDN [3]. Its distributed network architecture and CDM (known as the Virtual Data

Warehouse) [18] have been adopted by other DDNs, such as the Sentinel system (see later).

National Patient-Centered Clinical Research Network (PCORnet)

Launched in 2013, PCORnet is a network of networks that includes 13 Clinical Data Research Networks, 20 People-Powered Research Networks, 2 Health Plan Research Networks, and a coordinating center in the US [4]. The Clinical Data Research Networks are primarily comprised of healthcare delivery systems, the Health Plan Research Networks are shepherded by two national insurers, and the People-Powered Research Networks are mainly led by patient and caregiver organizations. PCORnet is designed to support both randomized trials and observational studies. It currently includes electronic health record (EHR) or administrative claims data from more than 100 million individuals and has access to over 40 million patients who could be recruited into pragmatic clinical trials.

Pharmacoepidemiologic Research on Outcomes of Therapeutics by a European Consortium (PROTECT)

Initiated in 2009 and ended in 2015, PROTECT was a joint undertaking by the European Union (EU) and pharmaceutical industry as part of the Innovative Medicines Initiative [5]. Its 35 partners, including academics, regulators, small and medium enterprises, and member companies of the European Federation of Pharmaceuticals Industries and Associations, were coordinated by the European Medicines Agency. The overall objective of PROTECT was to address limitations of current methods in the field of pharmacoepidemiology and pharmacovigilance. As part of this work, a network of electronic healthcare databases was established to conduct multicountry, multidatabase, drug safety studies. Currently, several former public partners of PROTECT are continuing their collaboration with additional public partners in the European Research Network for Pharmacoepidemiology and Pharmacovigilance, allowing access to a broad variety of datasets (general practice, hospital pharmacy/laboratory, pharmacy, hospitalization, claims, questionnaires, and biological samples) covering six EU countries (Spain, UK, Italy, the Netherlands, Denmark, and France) and records from approximately 100 million active patients to address various research questions.

Sentinel System

The Sentinel system is funded by the US Food and Drug Administration (FDA) as a national medical product surveillance system mandated by the US Congress in the FDA Amendments Act of 2007 [6,19,20]. Initiated as a pilot program called Mini-Sentinel in 2009 [21], the system includes a distributed network of 18 data partners that provide access to administrative claims and EHR information from over 290 million cumulative patient identifiers. A feature of Sentinel is its ability to conduct rapid descriptive and inferential analysis using preprogrammed, pretested, and customizable analytic tools [22–25]. These analytic tools and other Sentinel-related materials (e.g., protocols, reports, data model) are all available in the public domain.

Vaccine Safety Datalink (VSD)

Funded by the US Centers for Disease Control and Prevention since 1990, VSD monitors the safety of vaccines using EHR databases from a network of nine delivery systems and health plans [7,14,26,27]. While VSD initially used a centralized data model in which the data partners submitted de-identified analytic datasets for centralized analysis, it switched to a more sustainable DDN model in 2001 [28]. A unique feature of VSD is its ability to provide near

real-time surveillance of vaccine safety. Researchers apply study design and statistical methods appropriate for sequential surveillance to analyze weekly updated data. The analysis takes into account data lag and incompleteness due to frequent refreshes of the data [29,30].

Others

OMOP was a partnership between the FDA and the Pharmaceutical Research and Manufacturers of America established to inform the appropriate use of electronic healthcare databases for studying the effects of medical products [13]. In achieving that goal, OMOP initiated a series of experiments to investigate the feasibility and validity of conducting fully automated assessments of medical product safety [31,32]. The initiative also created a CDM and a suite of CDM-compatible analytic tools. The OMOP experiment was completed in 2013, but much of its collaborative work continues within Observational Health Data Sciences and Informatics (OHDSI) [33].

The "Exploring and Understanding Adverse Drug Reactions by integrative mining of clinical records and biomedical knowledge" (EU-ADR) project was launched in 2008 with the aim to leverage information from various EHR databases in Europe to produce a computerized integrated system for the early detection of drug safety signals [34]. The same approach and some of the same databases were used in study-specific networks, including the Safety of Non-steroidal Anti-inflammatory Drugs (SOS) [35], Arrhythmogenic Potential of Drugs (ARITMO) [26], Safety Evaluation of Adverse Reactions in Diabetes (SAFEGUARD) [37], Global Research in Paediatrics (GRIP) [38], and Accelerated Development of Vaccine Benefit-risk Collaboration in Europe (ADVANCE) [39] projects. Apart from EU-ADR, these collaboratives have included several of the same EU datasets and developed study-specific CDMs.

Clinical Problems to Be Addressed by Pharmacoepidemiologic Research

As with multidatabase studies that analyze centrally pooled information, DDN studies support analyses that cannot typically be done with one data source. Examples include assessments of rare exposures, rare outcomes, treatment effect heterogeneity in specific subpopulations, and surveillance of newly approved medical products (Table 25.2).

Assessment of Rare Exposures

Examples of rare exposures include, but are not limited to, drugs used to treat orphan diseases, defined as conditions that affect fewer than 200 000 individuals (US definition) or 5 in 10 000 individuals (EU definition). DDNs allow studies of drugs indicated for orphan diseases [59,60]. For example, several People-Powered Research Networks within PCORnet, such as the Phelan-McDermid Syndrome Data Network [61], are leveraging patient-generated information and the electronic health data within Clinical Data Research Networks to generate evidence about disease progression and treatments for these conditions.

Assessment of Rare Outcomes

An example of rare outcomes is Guillain-Barré syndrome, which occurs in 1–2 per 100 000 person-years [62]. An adequately powered study to examine the association between a vaccine and Guillain-Barré syndrome requires information from millions of individuals from multiple databases. For example, to assess the risk of Guillain-Barré syndrome following receipt of a quadrivalent human papillomavirus vaccine, a VSD study used six databases to identify males and females aged 9–26 years who received the vaccine from 2006 to 2015 [58]. One confirmed case of Guillain-Barré syndrome within 42 days

Table 25.2 Select examples of studies conducted within distributed data networks.

Network	Select studies
AsPEN	• Antipsychotic use and risk of acute hyperglycemia [9] • Thiazolidinedione use and risk of heart failure across ethnic groups [11] • Cardiac safety of methylphenidate among pediatric patients with ADHD [40]
CNODES	• Statin use and risk of acute kidney injury [41] • Incretin-based drug use and risk of heart failure [42] • Occurrence of pregnancy during isotretinoin therapy [43]
HCSRN	• Lipid-lowering drug use and risk of rhabdomyolysis [44] • Prenatal antidepressant exposure and risks of congenital malformations [45] • ADHD medication exposure and risk of serious cardiovascular events [46]
PCORnet	• Aspirin dosing and secondary prevention of atherosclerotic cardiovascular disease [47] • Antibiotic use and weight outcomes in children [48] • Long-term benefits and risks of bariatric procedures [49]
PROTECT	• Antibiotic use and risk of acute liver injury [50] • Antidepressant use and risk of hip fracture [51] • Antiepileptic drug use and risk of suicidality [52]
Sentinel	• Antihyperglycemic use and risk of acute myocardial infarction [53] • Dabigatran use and risks of bleeding and cardiovascular events [54] • Rotavirus vaccination and risk of intussusception [55]
VSD	• Thimerosal exposure and risks of neuropsychological outcomes [56] • Safety of H1N1 and seasonal influenza vaccines [57] • Quadrivalent human papillomavirus vaccination and risk of Guillain-Barré syndrome [58]

ADHD, Attention-deficit hyperactivity disorder; AsPEN, Asian Pharmacoepidemiology Network; CNODES, Canadian Network for Observational Drug Effect Studies; HCSRN, Health Care Systems Research Network; PCORnet, National Patient-Centered Clinical Research Network; PROTECT, Pharmacoepidemiological Research on Outcomes of Therapeutics by a European Consortium; VSD, Vaccine Safety Datalink.

following vaccination was confirmed among over 2.7 million vaccinees.

Assessment of Treatment Effect Heterogeneity

Certain treatments may have different effectiveness or safety profiles in patients with specific characteristics. Combining information from multiple databases allows researchers to have enough sample sizes in subsets of populations (e.g., children, the elderly, individuals with a history of heart failure). Results from studies of databases that cover demographically and geographically diverse populations also provide better generalizability. For example, AsPEN conducted a study to determine whether the risk of edema or heart failure associated with thiazolidinediones was different between Caucasian and Asian populations, potentially due to differences in the prevalence of metabolizing enzymes in these ethnic groups [11]. In another example, a Sentinel study examined the associations between antihyperglycemic treatments and risk of hospitalized heart failure among diabetes patients with and without a history of cardiovascular disease [63]. The European Research Network for Pharmacoepidemiology and Pharmacovigilance

is currently investigating the risk of major bleeding associated with direct oral anticoagulants in targeted clinical and demographic subgroups for which variations in plasma concentrations might affect the safety of the products [64].

Postmarket Surveillance of Newly Approved Medical Products

An increasingly common scenario that warrants the use of multiple databases is postmarket surveillance of the safety of newly approved medical products. The goal is to monitor new medical products as postmarket experiences of their use accrue in routine clinical practice. The number of users in a single database is usually low in the early postapproval phase, so multiple databases are required to support an informative analysis. Prospective, sequential analysis of cumulating data can be addressed by appropriate statistical techniques [65–67]. For example, the Sentinel system has leveraged its DDN to complete prospective postmarket surveillance of two newly approved medical products and select health outcomes. One assessed the association between saxagliptin (an oral antihyperglycemic agent) and acute myocardial infarction following the approval of the drug in 2009 [53]. The other examined the associations between rivaroxaban and ischemic stroke, intracranial hemorrhage, and major gastrointestinal bleeding after the oral anticoagulation drug was approved in 2011 [68].

Methodologic Problems to Be Addressed by Pharmacoepidemiologic Research

Pooling of individual-level data, often in a format that is stripped of direct identifiers, had traditionally been the default approach used in multidatabase analyses. Sharing of de-identified individual-level data is generally feasible in the presence of proper governance, appropriate data use or sharing agreements, and established collaborative relationships [69]. However, concerns about patient privacy and confidentiality, unauthorized uses of transferred data, and unintended disclosures of sensitive corporate or institutional information have made data sharing increasingly more challenging in practice, specifically in newly formed collaborations or projects that perform a large number of studies [70–72]. Contractual agreements between health plans and some of their members may further restrict sharing of individual-level information with other entities for secondary purposes such as research.

A DDN architecture addresses some of the concerns associated with pooling of individual-level data [70–72]. A typical DDN generally has the following features:

- There is one or more coordinating center(s).
- Data partners maintain physical control of their data.
- Data partners have the ability to review and approve each data request.
- Data partners have the ability to review the output before sharing it with the requester.
- Data partners can opt out of any data request at any time.

These features offer data partners more autonomy in multidatabase studies. They allow data partners to evaluate their ability or willingness to share their data with the requester at various steps of the request. More importantly, a DDN approach keeps the data close to the individuals who know the data best. The data partners can advise on the appropriate use of the data and help investigate data anomalies and interpret findings.

Challenges in Distributed Data Networks

DDNs also come with challenges, some of which are common across all multidatabase studies and others unique to the distributed environment.

There could be heterogeneity in data quality, data completeness, coding system, and patient population. Neither a centralized nor a distributed system is immune to these issues, but they can be more difficult to identify or diagnose in a distributed environment. Compared to single-database studies, multidatabase studies often involve additional administrative and governance issues, such as the need for multicenter ethics review and data-sharing agreements. These issues may sometimes (but not always) be more resource intensive in DDNs than a centralized system, depending on the type of analysis and information shared. There may be a need for more frequent communications between the coordinating center and participating sites in DDNs, which can create delays. In multinational DDNs, the participating data sources may have different languages, different availability of medical products, wider variation in clinical practice and drug utilization, and different responses to medical products due to ethnic or genetic variations. The conduct of the statistical analysis is generally more complicated in DDNs, because individuals responsible for the analysis do not have full access to the source data from all the participating sites. Although DDNs increase overall sample size, the larger sample size does not necessarily help improve control for confounding, since confounding control typically occurs separately within each site.

Currently Available Solutions

To facilitate the conduct of studies, existing DDNs organize themselves differently based on their resources, needs, expertise, and data infrastructure. On one end of the spectrum are DDNs that employ a common protocol and a CDM approach. At the other end of the spectrum are DDNs that have neither a common protocol nor a CDM. There are also DDNs that adopt a common protocol approach without a CDM. These options lie on a continuum and do not represent all the possible scenarios. For example, a DDN can develop a CDM for some of its data partners but not the others. Each of these options has its unique strengths and limitations (Table 25.3). However, some offer clear advantages over the others in many scenarios. In particular, a DDN that has neither a CDM nor a common protocol approach is typically less efficient than the other systems. Table 25.1 summarizes the approaches employed by some of the DDNs.

Common Data Model, with or without a Common Protocol

Some DDNs have all participating data partners convert their source data into standardized data formats, often known as a CDM. The CDM specifies a uniform data file structure and data element naming conventions and definitions across all databases. There are several CDMs in use, including for Sentinel [72], PCORnet [73], HCSRN [18], and OMOP [74]. The first versions of the Sentinel and OMOP CDMs were modeled in part on the HCSRN CDM, and the Sentinel CDM served as the backbone of the PCORnet CDM. CNODES has implemented the Sentinel CDM in four databases, is working to implement it network-wide, and has initiated queries using the CDM.

There is a general misconception that a CDM is a "lowest common denominator" approach, which reduces the data elements in a DDN to only variables common across all databases. In reality, data partners with more information can populate additional tables or variables for use in specific studies. For example, both the HCSRN and Sentinel CDMs allow data partners with clinical information from EHRs to populate additional tables on vital signs and laboratory test results [18,72].

However, certain information may be lost during the standardization process. This may occur when the data elements are available in multiple coding systems and researchers attempt to map across these systems. For example, US databases primarily use the International

Table 25.3 Strengths and limitations of various structures of distributed data networks.

Common data model	**Yes**	**Yes**	**No**	**No**
Common protocol	**Yes**	**No**	**Yes**	**No**
Upfront data infrastructure investment	Substantial	Substantial	Minimal	Minimal
Site-specific statistical programming effort	Minimal to moderate	Minimal to moderate	Moderate to substantial	Moderate to substantial
Ability to develop preparameterized, reusable tools	Yes	Yes	Limited	Limited
Ability to assess database heterogeneity	Yes	Yes	Yes	Yes

Classification of Diseases, 9th or 10th Revision, Clinical Modification (ICD-9-CM or ICD-10-CM) coding systems to record diagnoses, while the general practice databases in the UK document diagnoses using Read codes. It is possible to map and standardize these coding systems, but doing so may lead to some information loss or misclassification. In the presence of multiple coding systems, it is still possible to develop a CDM while preserving the fidelity or granularity of the source information for use in actual studies. In the diagnosis example earlier, the CDM will have a variable that contains the specific diagnosis codes (G30z.00 or 410.00) and an additional variable that indicates the code type (Read or ICD-9-CM). DDN studies that analyze against the CDM can then use the two variables together to define the study parameters. In the presence of multiple coding systems, input from researchers and others familiar with the data is required, either during the mapping process or when conducting a study.

DDNs with a CDM almost always conduct their studies with a common protocol (more later). Analyzing CDM-backed databases with a common protocol allows study-specific data checking, management, and analysis to be done via identical computer programs that can be developed and beta-tested by a smaller group of individuals. This helps reduce programming burden at sites, minimizes opportunities for errors across participating sites, and ensures consistent analysis across databases. However, the centrally developed computer programs have to accommodate differences in computing environments (e.g., different operating systems, software versions) to allow successful execution across all participating sites. In addition, a coding error that occurs in a centrally developed program will have an impact on all sites.

On the rare occasions that a common protocol is not developed in the presence of a CDM, the data partners presumably would have more flexibility in answering the study question. This would allow certain data partners that have more data elements in the CDM to include them in their analysis. However, it is worth noting that a common protocol can be developed in a way that also allows database-specific analysis, for example through a semi data-adaptive approach like high-dimensional propensity score analysis, in which the propensity score is built individually in each database using available information rather than using a common set of variables [23].

Common Protocol, with or without a Common Data Model

In a common protocol approach, a protocol is developed, often collaboratively among participating sites, for implementation across the DDN. As already discussed, employing a common protocol approach in the presence of a CDM generally allows the study to be conducted more efficiently, as programming burden is limited to one site rather than having each site develop *de novo* code. In the absence of a CDM, the common protocol is generally less prescriptive, to allow data partners to define the measurement of exposure, outcome, covariates, and other study parameters based on the information available in their databases. For example, in a study of rivaroxaban, the protocol will specify the exposure of interest, but each data source will identify rivaroxaban exposure based on its coding system (e.g., National Drug Codes or Anatomical Therapeutic Chemical Classification System).

As individuals who are most familiar with the data are actively involved in the implementation of the protocol, the study can accommodate the differences in coding practices, data quality and completeness, and other idiosyncratic issues associated with each database. The disadvantage of this approach is that it can lead to variations in the interpretation of the protocol, which may artificially inflate the heterogeneity across sites or affect the robustness of results. In addition, each site is required to have adequate

programming resources to conduct its own analysis. Coordination across the DDN during the study can be intensive in order to resolve any discrepancies and to ensure consistent interpretation of the analysis plan. However, this can be accomplished by using a detailed statistical analysis plan and a phased analysis, in which, for example, analyses are reviewed at various stages in the process (e.g., after baseline tables are populated, after propensity scores are estimated). Protocol refinements and modifications, as well as site-specific amendments (should initial analyses uncover differences in prescription patterns across sites), can help eliminate or explain discrepancies between sites. Some DDNs employ a blinding procedure to mask the results from participating data sources to facilitate more objective assessment of heterogeneity across sites. These processes to improve consistency require substantial time investment by analytic personnel. The common protocol approach can be particularly onerous for DDNs that do not share a common language or coding system across data partners.

The Necessity of Having a Common Data Model

Creating a CDM is a substantial undertaking. It requires considerable upfront investment on data infrastructure, in particular the extraction, transformation, and loading of the source data to a CDM. Additionally, the ongoing maintenance of the CDM can be burdensome, particularly as new versions of the CDM are needed, which can occur when there are new analytic requirements or changes in certain data elements. Each site must also routinely convert its new data into the CDM. It is generally easier to create a CDM for databases that contain the same type of information and coding system (e.g., claims data coded in the ICD-10-CM system). Developing a CDM for disparate data sources (e.g., claims databases and EHR databases) or databases with different coding systems is more challenging, but is possible through the use of mapping algorithms. However, as discussed earlier, there may be information loss or misclassification if mapping is required.

In general, it will be worthwhile to develop a CDM if the DDN is designed to conduct multiple studies. It may also be useful to convert the source data into a specific CDM to leverage available software or tools that are compatible with the CDM. For example, Sentinel, PCORnet, and OHDSI have developed a suite of analytic tools that can be executed within databases that use their CDMs. From the scientific validity perspective, the amount of data management, quality assurance, and harmonization for a given multidatabase study is similar regardless of the data network architecture. The CDM approach spends more resources upfront on data harmonization and quality assurance, so that downstream studies can be done more efficiently. However, the cost of establishing and maintaining the CDM is the same for 1 study as it is for 100 studies. The CDM achieves an economy of scale when the number of studies supported by the CDM is sufficiently large. In principle, the marginal cost of conducting a study is lower in DDNs with a CDM than in DDNs without a CDM when the number of studies is large.

A key consideration in developing a CDM is how much, if any, preprocessing of the information should be done upfront, and how much should be handled when conducting the study. Preserving the fidelity and granularity of the source information, as briefly discussed already, allows researchers of specific studies to determine the most appropriate study parameters. The extra time to execute the study, due to the additional deliberation, is generally worthwhile. Preprocessing the information upstream via mapping or creating specific constructs or concepts helps expedite the implementation of specific studies downstream, but may restrict researchers' ability to develop study parameters tailored to the studies. The approach taken by a given DDN depends on its missions, objectives,

and preferences. For example, the Sentinel system does minimal preprocessing of the data upfront, which allows the system to tailor its analysis to the FDA's regulatory questions. The OMOP CDM involves a significant amount of preprocessing, which allows researchers to streamline the conduct of their analysis using predefined variables and parameters. The pros and cons of these approaches, as well as their comparative performance, have been covered in the literature [75–78].

Methodological Advances

The defining feature of DDNs is that the data are stored locally under the direct control of participating data partners, and ideally only minimal necessary information is shared in each analysis. Traditionally, it had been necessary or preferred to share de-identified individual-level datasets for centralized analysis. With this approach, the participating sites send the analysis center an individual-level analytic dataset with distinct covariate information necessary for the analysis, yielding what is essentially a single centralized dataset after pooling. The confounders can be incorporated into the analysis through matching, stratification, restriction, regression, or weighting, and the data can be considered all together or stratified by contributing site [79,80]. Confounder summary scores (discussed shortly) can be estimated after centralizing the data. Although this approach offers the most analytic flexibility, it requires the most granular information among all the analytic options.

Recent methodological advances have expanded the data-sharing and analytic options, some of which require less granular information to perform the same type of analysis afforded by pooled individual-level data [81–85]. As a result, these newer methods may be preferred because they are more privacy protecting. Another feature of these new methods is that most or all the analyses will need to be specified *a priori*, or additional data requests may be required to obtain the additional information needed for *ad hoc* analyses. Although these are often seen as the limitations of these newer methods, they can also be considered strengths, because there is better transparency in the analysis. They help ensure clear delineation between prespecified and *ad hoc* analyses, and minimize opportunities for conducting unspecified analyses and selective reporting of results.

Individual-Level Confounder Summary Score-Based Methods

Confounder summary scores, such as propensity scores [86,87] and disease risk scores [88,89], are widely used in pharmacoepidemiologic research. If estimated correctly, these summary scores contain sufficient information to account for the confounding effects of the covariates used to estimate them. These data dimension reduction techniques have some appealing features useful for DDNs. Specifically, they obscure the information from a large number of covariates into scalar measures that are much less identifiable. Instead of requesting an individual-level dataset with information on individual covariates, one can replace these covariates with the summary scores [82,90,91]. In its simplest form, the dataset will only include variables indicating the treatment, outcome, follow-up (for time-to-event analysis), and confounder summary score. Other variables needed for the analysis, such as age or age categories if one wishes to perform age-stratified analysis, can also be requested. Conventional approaches to handling confounders, including matching, stratification, restriction, regression, and weighting, can then be done with the pooled, less granular, individual-level datasets.

This approach can perform essentially all the prespecified analyses afforded by the approach that shares individual confounder information, but it may not be able to accommodate all *ad hoc* analyses. For example, if sex is included in the estimation of the confounder summary score but is not requested separately, one will not be

able to perform a secondary, sex-stratified analysis without going back to the sites to request additional sex information.

The confounder summary scores should ideally be estimated and adjusted within each database, not just for practical reasons but also to ensure validity. For example, propensity scores are a function of the prevalence of the exposure in the population in which the scores are estimated. The prevalence of the exposure may vary across databases due to differences in formulary, regional prescribing pattern, and patient characteristics. Having site-specific propensity score models also allows the effect of a given covariate (e.g., age) on the probability of receiving the treatment of interest to vary by site. Researchers should account for site or database in the analysis by either including it as a stratification variable or performing within-site matching or stratification. As already discussed, data-adaptive approaches like the high-dimensional propensity score method [23] readily allow the analysis to be more tailored to the data availability at each participating site.

In contrast, the influence of risk factors on the outcome is generally more stable across databases, even if the outcome incidence varies by site. For example, the relation between age and heart failure, conditional on all other risk factors, should be similar across data sources. Therefore, it may be possible to combine disease risk scores, another commonly used confounder summary score that models and summarizes the associations between potential confounders and outcome risk, across sites. Additional research is needed to evaluate this issue.

Confounder Summary Score-Based Methods

It is possible to combine confounder summary score-based methods with other analytic techniques to further reduce the granularity of information shared. One can perform matching and stratification at the sites, and then only request the aggregate-level matched or stratified data to return to the analysis center [82,91]. In a matched analysis, if each site matches in the same fixed ratio, the only information needed for the analysis will be the total exposed and unexposed persons or person-times, and the number of exposed and unexposed outcomes. In a stratified analysis, participating sites send to the analysis center the total exposed and unexposed persons or person-times, and the number of exposed and unexposed outcomes within each stratum. Alternatively, one can structure the datasets into a risk set format at the sites and request risk set-based summary-level information for centralized analysis [82–84,92]. Results from the risk set-based approach have been shown to be statistically equivalent to results from the pooled individual-level stratified Cox regression model [83,92]. As with other methods, subgroup and sensitivity analyses will need to be prespecified so that appropriate summary-level information can be generated at the sites and shared for centralized analysis. As before, care should be taken with subgroup analyses to avoid small cells and potential identification risks. These methods protect against patient identification to an extent, but are not foolproof. If, for example, a rare disease or exposure is of interest, and prespecified analyses involve substantial stratification, some cells of the summary tables may be small enough to violate data partners' privacy regulations.

Meta-analysis of Database-Specific Results

An alternative to pooling individual-level data in a central repository is the commonly used approach of pooling site-specific effect estimates using meta-analytic techniques. In this approach, each site performs its own analysis, and the effect estimates and their variances (or other information needed to calculate database-specific weights) are provided to a central location and combined via meta-analysis [83,84,93–95]. The site-specific estimates can be obtained from matching, stratification, restriction, outcome modeling, or weighting, with or without confounder summary scores. This has

been shown to produce similar pooled effect estimates when compared with individual-level data analysis [90,96,97]. Although all data-sharing methods, including those discussed in this section, can in principle inspect treatment effect heterogeneity across databases, meta-analysis does that in the most obvious way, because database-specific effect estimates are shared and used in the pooled analysis. Each subgroup or sensitivity analysis requires all sites to perform each analysis internally, and then transfer the effect estimates to the lead team. Smaller sites may not be able to perform certain analyses, although sometimes using confounder summary scores to obtain site-specific effect estimate may help.

Distributed regression

The basic idea of distributed regression is for each data source to process its own individual-level data and share with the analysis center only summary statistics (e.g., sums of squares and cross-products matrix), such that the analysis center can either calculate the effect estimates or, if an iterative process is needed, update the parameter estimates and send them back to each data source to further update the summary statistics [98–101]. The iterative process continues until either a specified convergence criterion is met and the final parameter estimates are calculated, or the maximum number of iterations is reached. In other words, distributed regression conducts the same numeric algorithm with only centrally combined summary statistics as standard regression with pooled individual-level data. Although distributed regression is appealing in theory, it is relatively cumbersome to implement in practice, particularly for regression models that require multiple iterations. There are ongoing efforts to improve the practicality of distributed regression in existing DDNs [102–105].

Encryption

When applied in pharmacoepidemiology, encryption or hashing techniques are generally used to obscure potentially identifiable information while allowing valid database linkages [106,107]. In principle, it is possible to use these techniques to process the de-identified analytic dataset at the site before the encrypted data, along with the decryption method, are shared centrally for analysis. There have been some efforts in combining homomorphic encryption techniques with distributed regression [103,108], but using encryption to obscure potentially identifiable individual-level data is still quite theoretical and has not been widely implemented in practice.

The Future

More Sustainable and Efficient

DDNs, regardless of their actual configuration, typically require significant upfront investment. An architecture with a CDM is costly and time consuming to set up and maintain; however, efficiency benefits may be realized if the infrastructure is used for multiple studies. Some DDNs may achieve "economies of scale" and be able to conduct additional studies more efficiently and at a marginal cost compared to doing these studies as a series of "one-offs" [3,109]. DDNs without a CDM require infrastructure and initial investment to develop replicable and systematic processes. With more sustained funding support from regulatory agencies and other stakeholders, existing and future DDNs will have the much-needed stable foundation to grow, expand, and mature. This will be particularly important for some DDNs that are currently not supported by a single regulatory authority, such as AsPEN, and the various EU networks like PROTECT and EU-ADR. Even for funded DDNs, it can be argued that the infrastructure should be made available to other stakeholders with proper governance in place. The Sentinel system is an example of how this can be possible. Although the surveillance system was originally created by the FDA to meet its regulatory mandate, the agency envisioned the infrastructure eventually becoming a national resource for evidence generation [19]. Through the Innovation in Medical

Evidence Development and Surveillance initiative, non-FDA funders, including life science companies, can now access the same data sources and analytic tools used in Sentinel to conduct their own studies [110].

Broader Scope

With few exceptions, most DDNs were initially created for specific purposes (e.g., medical product safety surveillance). However, the scientific and technical infrastructure of many DDNs has the potential to address a wider range of topics, including comparative effectiveness research, patient-centered outcomes research, public health surveillance, and quality improvement. In addition to facilitating observational studies that analyze secondary data sources, some DDNs also support intervention studies. For example, PCORnet is conducting a pragmatic trial within participating health systems to examine aspirin dosing and secondary prevention of atherosclerotic cardiovascular disease [47]. Another pragmatic trial is underway in Sentinel to investigate the effect of direct mailings to patients and providers on initiation of anticoagulation therapy among eligible, treatment-naive patients [111]. These trials leverage the existing electronic healthcare databases of participating delivery systems or health plans to identify eligible patients and collect follow-up data, which allow the trials to be conducted more efficiently in real-world clinical settings compared to conventional randomized controlled trials.

More Diverse and Complementary Data Sources

Most DDNs are "horizontally partitioned," meaning that each database in the network contains information from different patients. Information is increasingly and routinely collected in various databases, for instance administrative claims databases, EHRs, disease or product registries, and data warehouses that contain information collected from wearables, mobile devices, or social media. In the future, we will likely see more DDNs that include disparate databases that include various data elements from the same individuals. These methods will require continued methodologic development to account for variation in data quality and completeness across data sources. Missing data and potential selection bias that arises from restricting the analysis to only patients appearing in multiple databases will require special attention.

More Robust and Secure Analysis

Continued methodologic advancement, both in developing cutting-edge analytic methods and in refining existing methods, will offer more analytic options that allow researchers to perform sophisticated statistical analysis while offering sufficient protection for patient confidentiality and data security. Existing methods already allow researchers to perform multivariable-adjusted outcome regression analysis and confounder summary-based analysis without sharing individual-level data for one-time exposures and one-time outcomes [82–84]. As DDNs mature, additional methodologic developments are likely to become available, including analysis of time-varying exposures, time-varying or repeated outcomes, missing data, and multilevel data.

Greater Transparency and Reproducibility

The DDN structure often requires researchers to prespecify the study design and analysis plan in advance, because they may not have direct access to all the data. For DDNs that employ a CDM, the analytic code will be pretested to ensure successful execution across the participating data partners. For DDNs that use a common protocol approach, the protocol will also need to be developed in advance. These data models, protocols, analytic code, and results should be made publicly available whenever

possible to improve transparency and encourage reproducibility [112]. Several DDNs, such as Sentinel and CNODES, are already adopting this policy, which has allowed other researchers to replicate the analyses [113,114]. OHDSI also makes its analytic tools publicly available.

Better Interoperability and Coordination across Networks

A possible future is one that has a national or international infrastructure that supports multiple DDNs. A healthcare delivery system or health plan can participate in multiple networks, each created for different purposes (e.g., medical product safety surveillance, comparative effectiveness research, pragmatic trials, public health surveillance). Each network will have its own governance and coordination. The networks can share the infrastructure, analytic tools, lessons learned, and software development and improvement. Regulators and decision-makers may also choose to collaborate on questions or work with multiple networks on specific queries.

Comparative Effectiveness Research in the US

Clinical and scientific communities have a long-standing desire to use scientific evidence to optimize clinical decisions for patients. While randomized controlled trials (RCTs) and meta-analyses of RCTs are generally considered to constitute the highest level of evidence, they have also been criticized for several aspects inherent to their design: comparison to placebo rather than alternative treatment; nonrepresentativeness of patient populations that tend to exclude older and multimorbid adults and children; controlled settings that differ from real-world care settings; relatively short follow-up; frequent use of surrogate endpoints rather than hard endpoints such as clinical events or death; and insufficient sample size to assess subgroup effects. Efforts to produce evidence that overcomes these limitations and is directly applicable to real-world patients as well as making clinical care more rational have been referred to at different times as *outcomes research*, *effectiveness research*, *evidence-based research*, *health technology assessment*, and, most recently, *comparative effectiveness research* (CER) [1]. To reduce the perception that the main agenda behind the push for CER is cost containment for healthcare, at least one government agency has begun relabeling CER as *patient-centered health research* [2].

CER is not a new concept, but has existed for the last several decades under various labels, and its popularity in the US had risen in response to several government initiatives. Earlier government initiatives for CER in the US were attempted first by the Congressional Office of Technology Assessment (established in 1972), then by the National Center for Health Care Technology (1978–1982), and then by the Agency for Health Care Policy and Research (established in 1989 and later renamed the Agency for Healthcare Research and Quality, AHRQ) [3]. The most recent impetus for CER came from the 2009 American Recovery and Reinvestment Act (ARRA Stimulus), with an appropriation of $1.1 billion "to study the comparative effectiveness of healthcare treatments" [4].

Furthermore, in 2010, the Patient Protection and Affordable Care Act (PPACA) authorized

Pharmacoepidemiology, Sixth Edition. Edited by Brian L. Strom, Stephen E. Kimmel and Sean Hennessy.

the establishment of the Patient-Centered Outcomes Research Institute (PCORI) to carry out CER and improve its quality and relevance [5]. PPACA established new requirements for the Department of Health and Human Services (HHS) to disseminate findings from federally funded CER, including findings published by PCORI, and to coordinate with relevant federal health programs to build data capacity for this research. To fund CER activities, PPACA established the Patient-Centered Outcomes Research Trust Fund (PCORTF), from which PCORI and HHS are expected to receive an estimated $4 billion from fiscal years 2010 through 2019. As of November 2017, PCORI had disbursed more than $2 billion for approximately 600 CER-related projects [6].

CER in Europe and Other Countries

Europe

In recent years a number of European Union (EU) countries have introduced so-called health technology assessments (HTA). HTA includes not only assessment of clinical effectiveness, but cost-effectiveness as well [7]. Publicly funded healthcare systems are the main healthcare providers in a number of EU countries, and these systems are under substantial financial pressure to make the best use of available resources. Assessing cost-effectiveness as part of HTA is therefore critical in the evaluation of health technology.

The National Institute for Health and Care Excellence (NICE) in England and Wales, created in 1999, represents one model for using CER primarily to inform policy and practice, but also to develop research recommendations [8]. Since April 2013, NICE has gained new responsibilities for providing guidance to those working in social care. Accordingly, NICE guidance documents are used by the National Health Service (NHS), local government, employers, volunteer groups, and others involved in delivering care or promoting wellbeing [9]. NICE guidance takes several forms, including NICE guidelines, technology appraisals guidance, medical technologies, and diagnostics guidance, as described shortly.

NICE guidelines make evidence-based recommendations on a wide range of topics, from preventing and managing specific conditions, improving health, and managing medicines in different settings, to providing social care to adults and children and planning broader services and interventions to improve the health of communities. These guidelines aim to promote integrated care where appropriate. NICE has provided a substantial number of evidence-based guidelines for clinical practice [10], though not without controversy and challenge [11].

Technology appraisals guidance assesses the clinical and cost-effectiveness of health technologies, such as new pharmaceutical and biopharmaceutical products, but also procedures, devices, and diagnostic agents. For example, recent guidance recommends ixazomib with lenalidomide and dexamethasone for use within the Cancer Drugs Fund (a central funding source for cancer drugs in England) as an option for treating multiple myeloma in adults only if patients have already had two or three lines of therapy [12]. Technology appraisals guidance is intended to ensure that all NHS patients have equitable access to the most clinically and cost-effective treatments that are viable.

Medical technologies and diagnostics guidance helps to ensure that the NHS is able to adopt clinically and cost-effective technologies rapidly and consistently. For example, Neuropad is a technology that aims to detect preclinical diabetic peripheral neuropathy. However, its use is not supported by evidence [13]. Interventional procedures guidance provides recommendations on whether interventional procedures are effective and safe enough for use in the NHS. For example, NICE recently

recommended that intravesical microwave hyperthermia and chemotherapy for non-muscle-invasive bladder cancer be used only with special arrangements for clinical governance, consent, and audit or research [14].

For their evaluations, NICE's advisory committees use objective evidence provided by academic institutions in the UK, such as the Royal College of Physicians, under contract with NICE to perform evidence syntheses and to conduct small-scale studies entailing primary data collection [8]. The explicit use of cost-effectiveness data to evaluate and choose among medical interventions is viewed in the UK "as a tool to ensure fair shares for all in a resource-limited system," according to Chalkidou and Walley [8].

A six-country comparison by Sorenson [15] and a similar three-country comparison by Evans [16] illustrate the considerable efforts extended by European governments to incorporate CER into health policy decisions and the different approaches used for organizing these efforts. In France (the National Authority for Health – Haute Autorité de Santé or HAS [17]), Germany (the Institute for Quality and Efficiency in Healthcare – Institut für Qualität und Wirtschaftlichkeit im Gesundheitswesen or IQWiG [18]), and the Netherlands (Commissie Farmaceutische Hulp or CHF, Committee for Pharmaceutical Aid), the entities responsible for CER, act in an advisory role to the government, making recommendations on reimbursements and pricing. This is in contrast with the UK (NICE), Denmark (Reimbursement Committee of the Danish Medicines Agency or DKMA), and Sweden (Dental and Pharmaceutical Benefits Board or TLV), where the CER entities have regulatory authority and are directly responsible for prioritizing reimbursements for drug and devices [15,16]. Cost-effectiveness data are formally incorporated in evaluations and recommendations about coverage and pricing by most CER entities (UK, Germany, the Netherlands, and Sweden) [15].

Another five-country comparison by Levy *et al.* [19] that also includes Canada and Australia (the Pharmaceutical Benefits Advisory Committee, or PBAS [20]) noted that in each of the countries surveyed, the health technology evaluation committees (conceptually comparable to CER) retain their independence regarding decisions about which technologies are included in the formulary, despite receiving government funding. Members of these committees are primarily health professionals, with only Canada, Australia, and Scotland also including public representatives, and only Scotland permitting industry representation as well [19].

Other Countries

Healthcare systems and their financing mechanisms outside Western Europe and North America are very diverse, and it is impossible to comprehensively discuss the applications (or potential applications) of CER in all countries. According to Bloomberg Health Care Efficiency, Hong Kong was ranked the most efficient healthcare system in the world in 2017 and 2018 [21]. Hong Kong has a universal, publicly funded healthcare system which does not formally apply CER in decision-making. In parallel, Hong Kong also has a very well-developed private healthcare system, funded by insurance and patient out-of-pocket payments. The two sectors complement each other, in that the private sector is the major provider of primary healthcare, while the public sector is the predominant provider of secondary and tertiary healthcare services. About 70% of outpatient consultations are provided by the private sector, while over 90% of inpatient services (in terms of the number of bed-days) are provided by public hospitals. This system presents substantial difficulties for effectiveness research, as the two sectors cannot use the same CER for evaluation. At present, neither the public nor the private sector has adopted formal assessment of CER for evaluation of treatment. This raises important

questions regarding what factors beyond CER play significant roles in the efficiency of the healthcare system.

African countries in general are facing significant issues in healthcare financing and are struggling to provide sufficient publicly funded healthcare services. In South Africa, the National Department of Health includes a series of explicit references to HTA in a white paper setting out the government's 10-year vision for high-quality universal healthcare coverage. A dedicated taskforce has been set up to consider HTA and other tools in order to design high-quality, affordable packages of health services [22].

Patel *et al.* describe the healthcare and government environment and the use (and potential use) of CER to control healthcare expenditures in China, India, and South Korea [23]. This report demonstrates the diversity of the healthcare systems and potential uses of CER in these three countries. CER will clearly be of increasing importance to aid government agencies in healthcare resource allocation. While the use of CER by government agencies has been well established for a substantial period outside the US, much of the recent activity is occurring within the US, and that will be the primary focus of this chapter.

Efficacy vs. Effectiveness

A study of *treatment efficacy* investigates whether a drug *has the ability to* bring about a given intended effect in ideal (controlled) settings. For example, a drug efficacy study would be centered on the question: "In an ideal world, with perfect adherence, no interactions with other drugs or other diseases, etc., *could* the drug achieve its intended effects?" In contrast, a study of *treatment effectiveness* investigates whether, in real-world patients and settings, a treatment *in fact* achieves its desired effect. For example, a drug given in a controlled setting may be shown to reduce glucose levels in younger patients having no major co-morbidities, but it might not achieve good glucose control in older patients with heart failure if it causes even mild water retention that leads to nonadherence or premature discontinuation. To answer questions about effectiveness, studies need to include representative real-world patients and assess effectiveness in real-world care settings.

Definitions, Key Components, and Goals of CER

CER seeks to assist stakeholders, for example patients, clinicians, insurers, the medical products industry, and policymakers to make informed decisions to improve healthcare at both individual and population levels. Several definitions of CER have been proposed by US government and nongovernment organizations and are summarized in Table 26.1. In Europe, the term CER is not commonly used, but HTA describes similar though not identical research. Several definitions of HTA are also provided in Table 26.1. HTA as defined by the UK National Institute for Health Research (NIHR) is actually broader than CER, since it formally includes cost-effectiveness evaluation, whereas CER generally does not.

For CER to assist in clinical decision-making, it must include three key components: (i) evidence synthesis (identifying and summarizing already existing data addressing a question); (ii) evidence generation (creating new data addressing a question); and (iii) evidence dissemination (distributing the available data with the goal of informing healthcare decision-making). In other words, for some decisions, existing evidence from individual studies may be controversial or insufficient to support specific clinical decisions. In such cases, the evidence must be synthesized (evidence synthesis), which may then provide a sufficient basis to support the decision or identify knowledge gaps to guide

Table 26.1 Definitions of comparative effectiveness research and health technology assessment proposed by US and other government and nongovernment organizations.

Agency/report	Definition
Comparative effectiveness research (CER)	
US Congressional Budget Office report, December 2007 [24]	"A rigorous evaluation of the impact of different options that are available for treating a given medical condition for a particular set of patients. Such a study may compare similar treatments, such as competing drugs, or it may analyze very different approaches, such as surgery and drug therapy."
Institute of Medicine report [25]	"The generation and synthesis of evidence that compares the benefits and harms of alternative methods to prevent, diagnose, treat, and monitor a clinical condition or to improve the delivery of care. The purpose of CER is to assist patients, clinicians, purchasers, policy makers, and the public to make informed decisions that will improve health care at both the individual and population levels."
US Federal Coordinating Council [26]	"CER is the conduct and synthesis of research comparing the benefits and harms of different interventions and strategies to prevent, diagnose, treat and monitor health conditions in 'real world' settings. The purpose of this research is to improve health outcomes by developing and disseminating evidence-based information to patients, clinicians, and other decision-makers, responding to their expressed needs, about which interventions are most effective for which patients under specific circumstances."
Patient-Centered Outcomes Research Institute [27]	"CER is a field of research designed to compare the effectiveness of two or more interventions or approaches to health care, examining their risks and benefits. CER findings assist clinicians, patients and other stakeholders in making informed decisions that improve health care for both individuals and populations. The direct comparison of two or more interventions distinguishes CER from studies explor[ing] outcomes related to one intervention alone. CER can not only validate a particular intervention but also identify which of available treatments best meet the needs of a given population."
Health technology assessment (HTA)	
National Institute for Health Research, UK [7]	"HTA research is undertaken when evidence exists to show that a technology can be effective. The purpose of an HTA study is to establish the clinical and cost-effectiveness for the NHS in comparison with the current best alternative(s). A study may also investigate uncertainty around a technology's place in the existing care pathway. 'Technologies' in this context mean any method used to promote health; prevent and treat disease; and improve rehabilitation or long-term care. They are not confined to new drugs and include any intervention used in the treatment, prevention or diagnosis of disease."
European Commission [28]	"HTA measures the added value of a new health technology compared to existing ones. Examples of health technologies include medicinal products, medical equipment, diagnostic and treatment methods, rehabilitation, and prevention methods."
International Network of Agencies for Health Technology Assessment (INAHTA) [29]	"HTA is the systematic evaluation of the properties and effects of a health technology, addressing the direct and intended effects of this technology, as well as its indirect and unintended consequences, and aimed mainly at informing decision making regarding health technologies. HTA is conducted by interdisciplinary groups that use explicit analytical frameworks drawing on a variety of methods."

further evidence generation. For some decisions faced by patients, clinicians, insurers, and policymakers, there may be insufficient evidence from individual studies to inform the decision. In these cases, new CER studies must be conducted to generate evidence (evidence generation). Generated or synthesized evidence must be disseminated for decision-makers of healthcare and CER to make informed decisions. It is also important to note that CER may assess both benefit and harms. Therefore, traditional pharmacoepidemiologic studies assessing the safety (harms) of medications in postmarket settings fall under the umbrella of CER.

The most important gaps in the current knowledge base about treatment interventions are lack of information about how a treatment works in actual clinical practice in contrast to the artificial settings of clinical trials, lack of information about the comparative effectiveness of treatment options, and lack of information about how variation in patient characteristics affects treatment effectiveness [30]. CER has the potential to fill important evidence gaps associated with the limitations of a predominantly RCT-driven drug and device approval pathway. The RCT pathway speaks to efficacy rather than effectiveness, because (i) placebo is often used rather than an active comparator agent; (ii) RCT study populations are not representative of the medication users post-approval (i.e., RCTs tend to exclude older and multimorbid adults and children); and (iii) the controlled settings used in clinical development programs often differ substantially from real-world care settings (e.g., they use short follow-up and surrogate endpoints).

In summary, the goals of CER are (i) to inform decisions on interventions or approaches to health care in real-world settings with regard to their intended and unintended outcomes that are relevant to patients; (ii) to put new technology into proper perspective in relation to older technology; and (iii) to identify patients who are more or less likely to respond to some interventions than others [31]. As a result, CER is expected to increase the use of more effective clinical options and decrease the use of less effective treatments [1,32–34]. Another consequence of achieving these goals could be a reduction in healthcare costs through avoidance of treatments that do not work or are less effective than alternatives.

CER and Pharmacoepidemiology

The concept of CER is in fact very familiar to pharmacoepidemiologists. Classic pharmacoepidemiologic studies that assess postmarket safety of medications constitute CER as defined earlier. Also, soon after the field of pharmacoepidemiology emerged in response to the need to study drug safety after marketing of medications, pharmacoepidemiologists recognized the need for postmarketing "efficacy" assessment (now defined as "effectiveness") and debated the challenges of assessing "intended" effects or benefits [35–37]. Despite the concern that non-experimental studies may not be useful in studying the intended effects of drugs, Strom *et al.* showed that of the 100 most recently approved drugs with 131 potential drug uses, only 28% would require experimental designs [38]. In the field of pharmacoepidemiology, we developed a research framework for experimental and non-experimental studies, knowledge of study designs, data sources, and analytic strategies, and faced various new methodologic challenges when studying unintended and intended effects in real-world patients. As described in the previous section, CER became a popular concept and a well-funded field as a result of the most recent government initiative in 2008 and the subsequent establishment of PCORI. The majority of CER has dealt with the effectiveness of medications, surgical procedures, and

medical devices, which is another reason why the field is of great relevance and interest to pharmacoepidemiologists.

In the context of pharmacoepidemiology and especially in the drug development process, CER covers the tail end of the pathway that begins with bench research (characterized by preclinical research to qualify for Phase I regulatory approval), moving to bedside research (characterized by proof of concept and efficacy research to qualify for Phase II regulatory approval), and ending with population research (characterized by clinical efficacy to qualify for Phase III regulatory approval and Phase IV clinical safety and effectiveness in postmarket settings), and finally research on the effect of policies (characterized by postmarketing surveillance and pharmacoeconomic research). A schematic illustration of this process is presented in Figure 26.1. In one sense, the full scope of CER is much broader than pharmacoepidemiology, as CER covers a range of clinical modalities for prevention, diagnosis, and treatment (drugs, medical devices, procedures, behavioral and other complex social interventions, as well as health delivery systems and policies) [39]. It also covers strategies for implementation. In another sense, however, CER is narrower than pharmacoepidemiology, not only because it covers the tail end of the pharmacoepidemiology spectrum (Figure 26.1), but also because it emphasizes "head-to-head" comparisons of the safety and benefits of treatments and diagnostic strategies to identify "best-in-class" treatments in the real world [40], whereas pharmacoepidemiology can compare users to nonusers or to alternative treatments.

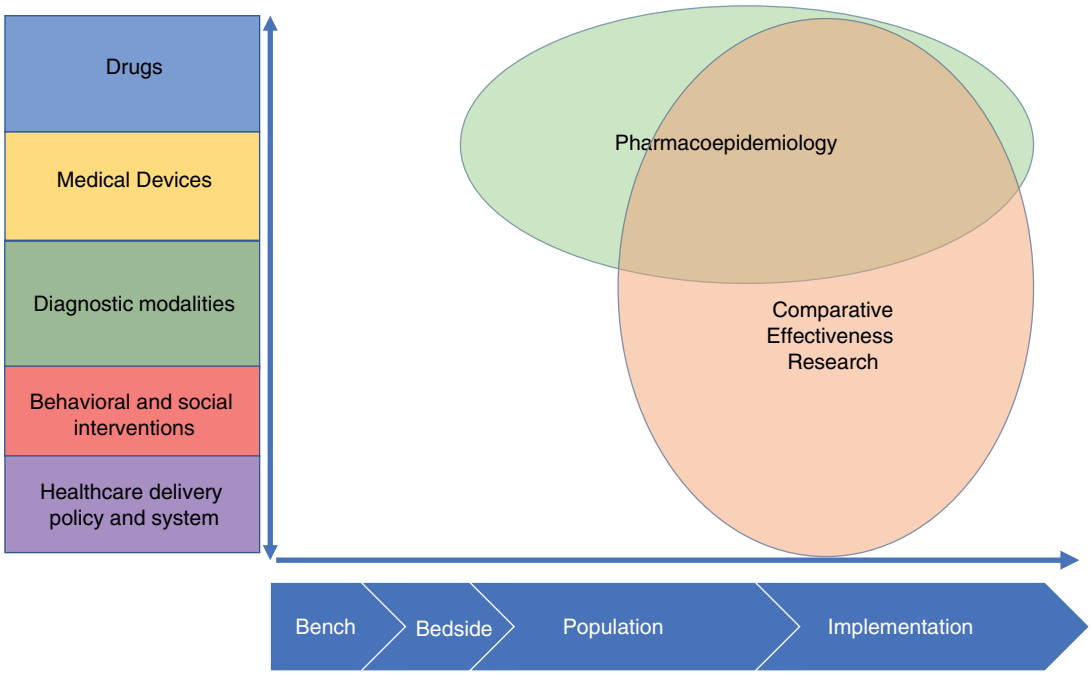

Figure 26.1 Schematic representation of overlap between pharmacoepidemiology and comparative effectiveness research.

Clinical Problems to Be Addressed by Pharmacoepidemiologic Research

Scope of CER

CER is broad in scope and addresses the continuum of medical and surgical interventions, including drugs, biologics, devices, medical procedures, technologies, behavioral interventions, prevention strategies, talk therapies, diagnostics, complex social interventions, and health delivery systems [25,41]. In addition, as characterized by Lauer and Collins [42], CER should utilize an array of technologies that enable quality and efficient healthcare delivery, and should account for the wide range of infrastructure of integrated healthcare systems. CER also encompasses beneficial and adverse effects as well as economic implications. It focuses attention not only on knowledge creation, but also on strategies for implementation. This broad scope can only be addressed by a diverse research portfolio that employs multiple study designs and analytic techniques (randomized trials, observational studies, and meta-analyses), as well as diverse data from primary data collection, preexisting data, and hybrid approaches linking different data sources [32,42].

Key Attributes of CER

The key attributes of CER that are embedded explicitly or implicitly in the aforementioned definitions and goals are as follows:

- It studies effectiveness in real-world patients and settings.
- It directly compares alternative methods to prevent, diagnose, treat, and monitor clinical conditions (rarely comparing alternatives to placebo, as "doing nothing" is often not a real-world clinical decision).
- It involves stakeholders, including patients and caregivers, in the research process.
- It uses clinically relevant and patient-centered outcomes.
- It assesses subgroups and different care settings in which differential effects may be observed (so that the evidence is more applicable to individual patients and is useful in various clinical settings).

Key attributes and related goals of CER studies are presented in Table 26.2.

The first attribute (inclusion of real-world patients and settings) is necessary to increase the direct applicability of the evidence generated from CER. Traditional efficacy trials are typically conducted by investigators affiliated with tertiary care hospitals. In contrast, CER should include data from patients and physicians from a wide range of care settings. The vision for CER is that it will provide opportunities for community hospitals and practices to become involved [43].

In real-world clinical practice, clinicians and patients need information to understand the comparative benefit or safety of two or more alternative treatments and to choose the best option. Therefore, "doing nothing" (placebo) is infrequently a viable alternative to treatment. However, traditional efficacy trials compare an intervention to nonintervention, for example treatment A to placebo, and are thus not informative on the comparative effect of different treatments. The goal of CER, as already mentioned, is to inform clinical or policy decisions *among alternative options*. Therefore, head-to-head comparison of alternative methods (including nonintervention if that is a legitimate option in clinical practice) is the second key attribute of CER. This attribute also addresses the goal of putting new technology into proper perspective in relation to older technology. The importance of comparing alternative healthcare options is highlighted by the 2007 Institute of Medicine (IOM) report [44], which points out that "the rate with which new interventions are introduced into the medical marketplace is

Table 26.2 Attributes and corresponding goals of comparative effectiveness research studies.

Desired/necessary attributes	Corresponding CER goals
Real-world patients and settings	To inform decisions on interventions or approaches to healthcare in real-world settings with regard to their intended and unintended outcomes that are relevant to patients.
Head-to-head comparison of various treatment/diagnostic/ implementation strategies	To inform decisions on interventions or approaches to healthcare in real-world settings with regard to their intended and unintended outcomes that are relevant to patients. To put new technology into proper perspective versus older technology.
Inclusion of all stakeholders of healthcare (including patients/ caregivers) in the research process	To inform decisions on interventions or approaches to healthcare in real-world settings with regard to their intended and unintended outcomes that are relevant to patients.
Use clinically relevant and patient-centered outcomes	To inform decisions on interventions or approaches to healthcare in real-world settings with regard to their intended and unintended outcomes that are relevant to patients.
Assess heterogeneity of effects by patient variability, including phenotype and genotypes	To identify patients who are more or less likely to respond to some interventions than others.

currently outpacing the rate at which information is generated on their effectiveness and circumstances of best use" [3], and that "less than half of all medical care is based on or supported by adequate evidence about its effectiveness" [44]. In addition, wide variation in practice [45–49] as well as geographic variations in the utilization of certain treatments and procedures [50–55] suggest a lack of "sufficient evidence to determine which approach is most appropriate" [44].

The third key attribute invoked by the US CER initiatives is involving stakeholders, including patients and caregivers, in the research process [25,30,56]. As conceived in the IOM's recommendations for "a robust national CER enterprise" [25], this should involve a continuous process that considers and prioritizes topics for CER research and funding to address current knowledge gaps about diseases and conditions, and that consistently includes participation of patients, caregivers, and consumers to provide input regarding issues of public concern [25]. According to Slutsky *et al.* [30], priorities for CER must be based on input from all healthcare stakeholders, research and synthesis must apply to a wide range of healthcare services, and the results must be made accessible to multiple audiences. Stakeholders in healthcare are generally categorized as consumers (patients, caregivers, and the public), providers (clinicians), payers (health insurance programs and patients/ caregivers), policymakers, product makers (pharmaceutical industry), and researchers. A systematic review [57] assessing stakeholder engagement in CER and patient-centered outcomes research (PCOR) in published articles from 2003–2012 found that reports on stakeholder engagement were highly variable in content and quality. In this review, the most frequent engagement was with patients, engagement with clinicians was modestly frequent, and engagement with other groups was infrequent. Stakeholder engagement was more

common in the prioritization of CER than in its implementation and dissemination.

The fourth attribute of CER is that effectiveness and safety should be addressed using outcomes of interest and importance to patients and clinicians. This attribute also addresses the gap of traditional evidence based primarily on efficacy trials, many of which focused on surrogate outcomes instead of hard clinical outcomes or patient-reported outcomes [58] of most interest to patients and clinicians, such as quality of life or functional status.

Traditional efficacy trials typically report average effects and are usually underpowered to detect variability in patient responses. However, clinicians must make decisions about choices for patients whose profiles are similar to the average of study participants in the trials. Therefore, the fifth attribute of CER is exploration of heterogeneity to identify subgroups of patients who benefit more (or less) from a given intervention. While CER explores patient variability, it assesses treatment effects in subgroups that are not typically narrow enough to reflect differences in how individual patients respond to therapies [59]. Better practices are needed to evaluate treatment heterogeneity, accounting for more precise individual-level factors and preferences as well as genetic information, such as the conditional average treatment effect [59]. Developments in molecular biology and genomics will increasingly make it possible to assess genetic variation in individual responses to different treatment interventions, with the goal of individualized and predictive medicine [25] (see Chapter 30).

Methodologic Problems to Be Solved by Pharmacoepidemiologic Research

All three components of CER (evidence synthesis, evidence generation, and evidence dissemination) are relevant in the field of pharmacoepidemiology. This section will cover all three components but will focus most on evidence generation, as it is the core field in pharmacoepidemiology and its methods are directly relevant to CER.

Issues for Evidence Synthesis

Systematic Reviews and Meta-Analyses in CER

The synthesis of evidence features prominently in definitions of CER, and systematic reviews and meta-analyses are the central approaches in evidence synthesis. To clarify common terminology following the Cochrane Collaboration and Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) [60,61], a systematic review refers a collection of all empirical evidence that fits prespecified eligibility criteria to answer a specific research question. Meta-analysis is the use of statistical methods to summarize and combine the results of independent studies (see Chapter 36). Therefore, many systematic reviews contain meta-analyses, but not all. Systematic review and meta-analyses can be used to discover patterns among study results and to provide reproducible summaries of study findings. In CER, systematic reviews may provide direct answers to CER questions, or may elucidate the need for more evidence generation when the results from individual studies are contradictory or when the magnitude of the underlying risk is small. Also, systematic reviews have been used in combination with clinical guidelines as a framework to identify knowledge gaps and to set research priorities [62].

The strengths of meta-analyses are mitigated by several methodologic challenges. The methodologic issues of systematic reviews and meta-analyses described in Chapter 36 are also relevant in evidence synthesis in CER. Briefly, the results of a meta-analysis are often highly subject to decisions made by the investigator: which studies to include or exclude from a meta-analysis, which outcome endpoints to

consider, and how to pool studies that differ in design and methods. Simmonds *et al.* [63] identified several sources of disagreement among experts that can affect the summary findings of meta-analyses. In addition, any limitations of the original studies will influence conclusions from the analysis of the pooled studies. This can be problematic in meta-analyses of observational studies. Consequently, some researchers have argued that only randomized trials should be meta-analyzed [64–67] (further discussion about meta-analyzing observational studies is found later in this chapter). It has also been argued that the outputs of meta-analyses may not provide greater insights than the results of individual studies [63,68].

Another limitation is that reviewers of the same studies may reach different conclusions, because of varying expertise in the topic of the review or in the technical skill of performing meta-analyses [69], or because of differences in values and orientations held by different investigators. The value of meta-analyses may also be seriously limited by publication bias, which can take several forms [70]. Studies with statistically nonsignificant or negative results are less likely to be published, and studies with statistically significant results and with stronger treatment effects tend to be published with less delay than studies with nonsignificant results. In addition, findings in some areas of research, such as complementary and alternative medicine, are less likely to be published. The summary conclusions from pooled published results will thus tend to be biased because of this preferential selectivity [70]. Problems stemming from publication bias may be amplified in meta-analyses of observational data. In addition, meta-analyses commonly combine the summary statistics from individual studies, whereas stronger results could be produced by obtaining and aggregating individual patient data from the separate studies analyzed [63,71,72]. However, issues of access, privacy, and ownership of original data make it difficult for investigators to obtain individual-level data.

Meta-Analyses of Observational CER

Generated evidence for CER can take the form of either observational studies or clinical trials. Therefore, longstanding debates about meta-analysis of observational studies are particularly relevant to CER. While some commentators have argued that meta-analyses of randomized trials are preferred to meta-analyses of observational studies [64–67], meta-analyses of observational studies are as common as those of randomized trials [68,73]. Reviews and practice guidelines on meta-analyzing observational data [68,73,74] show some disagreement with regard to this message. Some common opinions distilled include:

- Observational studies are more diverse in their designs and populations.
- Publication bias may be more problematic in observational studies [75,76].
- Biases are more problematic in observational studies.
- Therefore potential biases in the original studies make the calculation of a single summary estimate of effect of exposure potentially misleading, creating more precise but equally spurious effect estimates.
- More is gained by carefully examining possible sources of heterogeneity between the results of different observational studies.
- Concerns related to methodology and interpretation make the clear and thorough reporting of meta-analyses of observational studies absolutely essential (one guide provides a draft checklist summarizing recommendations for reporting meta-analyses of observational studies [73]).

From the point of view of pharmacoepidemiology, *a priori* exclusion of observational studies from meta-analyses would constitute a major loss. In fact, in some circumstances, meta-analysis of observational studies may be the only option to quantitatively synthesize current evidence. For example, Man *et al.* investigated the long-term effectiveness of methylphenidate in

the reduction of physical injuries. Harm reduction is a very important clinical outcome for patients and the healthcare system due to the high personal and economic cost of injuries. No clinical trials for methylphenidate were sufficiently long or even measured this outcome; hence, meta-analysis of observational studies was the only available option [77]. A study by Kirtane *et al.* [78] provides an example of a comprehensive meta-analysis that included both RCTs and observational studies, but analyzed them separately because of the differences in these types of study designs. Regardless of which types of studies are included in a meta-analysis, we agree with the need for a careful and systematic examination and reporting of observational studies, and for using epidemiologists' and clinicians' judgments to reach decisions about whether meta-analyses should be performed, and, if so, what studies should be included.

The expertise and effort required to perform a well-conceived and credible meta-analysis are not trivial. The AHRQ and IOM have published recommended standards for performing and reporting systematic reviews [79,80]. Nevertheless, the conclusions obtained by a rigorous meta-analysis cannot be deemed to provide a lasting answer to a clinical question, because new information may continuously become available. Therefore, the meta-analysis will require regular updates to keep it relevant for clinical guidelines [81].

Issues for Evidence Generation

Observational (Nonexperimental) Studies in CER

Observational studies have an important place in CER. First, observational studies provide data on real-world patients in usual clinical practice, which is one of the required attributes of CER evidence. Second, observational studies can provide larger samples and/or longer follow-up more easily than experimental studies. These are features that will be needed, as CER compares two options head to head, and this type of comparison will result in smaller effect sizes than comparing one treatment to placebo [42,82–84]. To date, the majority of CER studies have been conducted using observational study designs. Observational study designs and the methodologic issues they raise [85] are directly applicable to CER. In this section, we will summarize methodologic issues of particular importance in observational CER.

Confounding by Indication

As mentioned earlier, observational CER studies of intended effects are more susceptible to confounding by indication than observational studies of unintended effects (e.g., studies evaluating adverse drug events). While confounding by indication is covered in greater detail in Chapter 43, this bias is especially prominent when studying beneficial effects of treatments. In clinical practice, if one assumes prescribers are rational, one would expect treated patients to differ from untreated patients, as the former have an indication for the treatment. To the extent that the indication is related to the outcome variable as well, the indication can function as a confounding variable. On the other hand, confounding by indication for the treatment is less of a problem when a study is focused on unintended drug effects (side effects), regardless of whether those effects are harmful or beneficial. In this situation, the indication for treatment is less likely to be related to the outcome variable under study. However, this is sometimes not the case for studies of intended beneficial effects, which are the focus of many CER studies.

Confounding by indication (for the treatment) may also appear to be less of a problem when making comparisons between therapeutic alternatives for the same condition, since both study groups have the indication for treatment. However, nonrandomized studies comparing therapeutic alternatives are not necessarily free from confounding by indication, because the

true indication for a given treatment is often more subtle than the regulator-approved indication. For example, patients prescribed an angiotensin-converting enzyme (ACE) inhibitor as initial treatment for hypertension are likely to be different from those prescribed a thiazide diuretic for the same condition, as the former are more likely to have diabetes with nephropathy, myocardial infarction, and heart failure, whereas the latter being are more likely to have uncomplicated hypertension. As a second example, patients prescribed a combination of methotrexate and tumor necrosis factor alpha inhibitor as initial treatment for rheumatoid arthritis are likely to have more severe and active disease than those prescribed methotrexate monotherapy. Unless the choice between treatment alternatives is effectively random given measured variables, confounding by indication remains an issue in comparative studies. Disease severity is often associated with the outcomes of interests in studies assessing intended effects of treatment (e.g., improvements in rheumatoid arthritis symptoms or disease activity in the second example). Therefore, inability or limited ability to control for disease severity will results in bias (confounding by severity). The subtler examples of confounding by indication in the aforementioned scenarios are directly pertinent in CER, as these are exactly the types of questions CER addresses (comparing alternative options head to head). Furthermore, CER studies generally aim to detect differences that are likely to be smaller than in studies comparing exposed subjects to unexposed subjects. Accordingly, subtle instances of confounding by indication or confounding by severity can be especially problematic in CER.

Considerable effort has been undertaken to develop more effective methods for control of confounding in studies based primarily on administrative data (see also Chapters 12 and 43). Common approaches include propensity score-based methods, disease risk score-based methods, doubly robust methods, and instrumental variable analyses. These methods may, under certain conditions, provide better control of confounding than standard multivariable adjustment. However, it is important to keep in mind that most of these approaches (including propensity score but not instrumental variable analysis) are dependent on identifying and measuring those variables that are the true predictors of therapeutic choice in the databases.

For example, we conducted a study assessing the comparative effectiveness of carotid stenting versus carotid endarterectomy in older patients with carotid stenosis. Substantial confounding by indication would be suspected in this study, as carotid stenting is indicated and reimbursed only for patients with high surgical risks due to age, anatomic characteristics of carotid stenosis, or other cardiovascular or noncardiovascular co-morbidities (which are the predictors of worse prognosis). In this study, we demonstrated that propensity score-based methods (including high-dimensional propensity score methods [86]) using only claims data are insufficient to control for confounding by indication, and additional clinical information from vascular registries was necessary to achieve adequate control of confounding [87]. While these approaches provide sufficient confounding control in certain situations, they are generally not sufficient unless important variables related to the indication for treatment are available in the data [88]. Instrumental variables are promising alternatives if a valid instrument can be found for the clinical question. However, finding valid instruments in pharmacoepidemiology is extremely difficult – some would say impossible [89]. Design-based approaches such as restriction [90,91] and use of active comparators [92] may work in certain situations, and self-controlled methods can sometimes help to control time-invariant confounders [93], but it must be kept in mind that such approaches are directly linked to how the research question is defined. Accordingly, investigators must ensure

that the research question and the design are consistent and as intended. Much more work is needed in these areas to advance the field of CER.

Healthy User/Candidate Bias

Healthy user effect or bias has been observed among users of some medications, especially preventive medications such as hormone replacement therapies, statins, and certain antihypertensive medications [94–99]. For example, cardiovascular event reduction is consistently smaller in clinical trials compared with observational studies of antihypertensive medications [100,101], which suggests healthy user bias plays a role in observational studies of these preventive therapies. In CER comparing medical devices or interventions to a pharmacologic treatment, the healthy user effect (or more precisely for interventions, the healthy candidate effect) will be a major concern, as interventions typically pose short-term risks in exchange for long-term benefits, and patients at high risk of complications or deemed too sick to benefit are thus less likely to be selected for interventions. The healthy candidate effect is one of the biggest threats to validity in CER when comparing different treatment modalities. For example, we previously demonstrated the existence of healthy candidate bias in older heart failure patients who received implantable cardioverter-defibrillators (ICDs) versus those on medical therapies only by showing that patients with implanted ICDs had drastically better outcomes that were very unlikely to be attributed to the effects of ICDs (e.g., nursing home admissions, hip fracture, and short-term mortality) [102]. This highlights the utility of including falsification outcomes in observational studies.

Healthy user or candidate bias is thought of as a mix of confounding and selection bias. It arises when users of certain medications or candidates for invasive interventions have better outcomes due to factors other than effects of the treatment. While the factors associated with healthy user/candidate bias are not fully understood, many factors suggested to be responsible for healthy user/candidate effects are typically unmeasured in most databases. These include healthier lifestyles (healthy diets, regular exercise, and being less prone to using tobacco or alcohol) [99,103], higher socioeconomic status, better adherence to screenings and other preventive therapies [96], better physical [104] and cognitive function, less frailty [105], better social support, and stronger willingness to live. The effect size of healthy user/candidate bias can be quite substantial and is often as strong or stronger than the effect of the treatment itself [94–97,106]. Most importantly, healthy user bias may be refractory to analytic solutions unless prevented by thoughtful study design (e.g., self-controlled) and/or availability of extensive data on lifestyle and behavioral factors, thus resulting in inflation of the apparent benefits of preventive and other medications or invasive interventions.

Data Sources, Record Linkage, and Multidatabase Studies

As noted by the IOM report [25], CER studies should rely on multiple types of data sources, including primary data sources (medical and pharmacy records, electronic medical records, and *de novo* data generated through clinical trials or observational studies) and secondary data sources (administrative claims and clinical registries). Most CER studies to date have used the same data resources described in Chapters 12–14 of this book. As in usual pharmacoepidemiology practice, the data sources should be selected based on the study question and to maximize the internal and external validity of the results. To overcome the biases mentioned as well as others, including misclassification bias and selection bias, linking multiple data sources through record linkage can be a powerful tool, as it enriches the information for the given study subjects. Also, multidatabase studies within or across countries can potentially

enhance observational CER studies by enlarging the sample size for statistical power, assessment of effect heterogeneity, and improving generalizability. The methods, applications, and challenges of record linkage and multidatabase studies are described in other chapters.

A distinction must be made between data or record linkage (linking multiple data sources to enrich information) and multidatabase studies (using multiple databases for mostly nonoverlapping individuals). These two approaches are often confused, but each has a distinct goal. Data linkage is conducted in order to enrich information using a record linkage method, a computer-based technique to identify and link records from different databases that refer to the same entity or individual [107]. The data required for impactful and valid CER studies may be spread across two or more databases. Linking records across databases can transform ordinary individual datasets into powerful new platforms from which to perform timely and valid CER. For example, linkages between administrative claims databases and clinical or device registries can add longitudinal follow-up to registry data and add clinical details to administrative data. In addition to answering clinical questions, data linkage can also be used to address various methodologic issues in CER. For example, a linked database can be used to study data quality (e.g., by assessing agreement between two sources of the same data) and to validate claims-based endpoint ascertainment algorithms (e.g., by comparing a claims-based variable to a clinical gold standard) [108]. In addition to facilitating observational CER, record linkage can improve randomized trial evidence by linking patients in the trial to complementary data. For example, linking patients in a trial to Medicare claims can be a relatively inexpensive and effective way to extend the follow-up period of a clinical research study. Data linkage combining two or more data sources has enabled the conduct of more observational CER and/or more valid observational CER that would not be possible using a single data source [106,109–111]. Recent development of data linkage in Scandinavian countries has provided exciting opportunities to evaluate effectiveness beyond medical care. For example, Lichtenstein *et al*. linked the use of attention deficit hyperactivity disorder (ADHD) medication with criminal justice system records. They found that among patients with ADHD, rates of criminality were lower during periods when they were receiving ADHD medication. These findings raise the possibility that the use of medication reduces the risk of criminality among patients with ADHD [112].

The challenges of data linkage are both methodologic and ethical. Methodologic challenges include unavailability of linkage variables to researchers, especially unique identifiers such as names or social security numbers, incompleteness or inaccuracy of linkage variables due to poor data quality, nonoverlap or relatively small overlap of populations covered in each database, general misconceptions about linkage methods (especially probabilistic linkage methods), and understanding when to use what linkage method [113,114]. When unique identifiers of subjects are not available, at least for certain databases and populations (e.g., linking inpatient or outpatient claims data to clinical registry data for patients with heart failure, device implantations or surgeries, rheumatoid arthritis, and atrial fibrillation) [115,116], it is possible to conduct record linkage with high accuracy using multiple nonunique identifiers [115,116]. The primary ethical challenges of data linkage are ensuring patient privacy, which can be achieved by removing or limiting access to patient identifiers for research use including record linkage. However, this can make the linkage more difficult and sometimes impossible.

In our recent study of patients in a US-based online community, most reported that they were comfortable with researchers accessing their de-identified data for research purposes. Our study indicated that patient comfort levels

may be improved by better communication and transparency around specific research goals and how they may be beneficial to patient communities. In addition to mitigating re-identification risk, developing and improving methods to link databases through use of multiple nonunique identifiers may also improve patient comfort with secondary use of health data for research [117]. In a survey commissioned by the Wellcome Trust (a UK medical charity), 53% of respondents in the UK indicated that they would be happy for their data to be used by commercial organizations if it was for research purposes. Interestingly, over 60% of respondents indicated they would prefer that commercial research organizations have access to health data than that society miss out on the benefits these companies could potentially create. One of the most significant findings from the survey is that respondents considered academic researchers, charities, and organizations working in partnership with the public sector to be the most acceptable users of health data [118]. Patients' understanding and perceptions of the use of health data are still evolving, and it is important to continue to maintain communication and transparency regarding the use of health data for research.

In the last 10–15 years, networks of national and multinational database studies relevant to CER have been established in the US, Canada, Europe, and Asia [119–124]. Multidatabase study networks have been used to conduct observational CER or to provide a platform for CER trials [125]. The advantages of multidatabase studies in CER are that they capture diverse patient populations and/or increase the number of patients to detect relatively small effect sizes that can be expected in head-to-head comparisons and to assess the heterogeneity of effects. In multidatabase studies, data linkage methods are not necessary, as their intention is usually to bring databases together for nonoverlapping populations. However, structure, governance, and methods to manage and conduct a study using data from multiple sites and to synthesize results are needed. The structure, governance, and methods have to meet data management policies and data safety and privacy standards that may be unique to each database and can vary substantially, especially in international contexts [126,127].

Many networks employ a distributed network approach with a common data model (CDM), where the ownership and management of the database are left with individual data partners participating in the network. This approach is often preferred, as it mitigates most of the ethical and political issues with data privacy, governance, and ownership. In this model, each database is converted using a CDM so that its structure and coding are fully standardized. Multiple CDMs have been developed and modified to date [122,128–130]. To conduct analyses, researchers create a single statistical program that can be run against any database in the network with minimum or no modification. Another common approach is a distributed network with a common protocol rather than a CDM. The Canadian Network for Observational Drug Effect Studies (CNODES) operates using this approach, which eliminates the need to convert data from each site to a CDM [123]. In a distributed network with a CDM, a standardized coding language and format are needed to permit identical computerized queries to be submitted and executed across data resources, as well as standardized formats for returning responses from different databases [128,131,132].

In any approach for conducting multidatabase studies, understanding and dealing with variability in results across databases are especially challenging, particularly when the data come from different countries or diverse geographic regions/populations with differing healthcare systems, policies, and patient and clinician behaviors [126]. When large or unexpected variability in the results from each database is observed, researchers must first exclude the

possibility that the observed variability is due to technical issues arising from mapping codes or converting to a CDM, and/or from biases that are unique to each database (e.g., poor data quality, existence of and/or lack of understanding of unique features or idiosyncrasies in the data). When this possibility has been excluded, considerations must still be given as to when it is appropriate to combine results from different databases. This is especially important in CER, as understanding heterogeneity of effects is a major attribute of CER, and combining results that exhibit significant variability is not desired. The methodologic issues involved in combining results for meta-analyses discussed earlier are directly applicable to multidatabase studies as well, since it is generally not possible to analyze patient-level data to synthesize the results from each database, due to concerns about data security and privacy and/or restrictions of policies for data access and use.

Common challenges for data linkage and multidatabase studies include (i) logistical problems in accessing data sources, including issues of ownership of data, infrastructure, governance, data security, and data privacy (see also Chapters 12–14); and (ii) the required familiarity with the logical organization and content of disparate databases, including features or quirks in the data that are unique to each database. Needless to say, the aforementioned methodologic issues in observational CER (e.g., confounding by indication) can also affect the conduct and validity of results in linked database or multidatabase studies.

Experimental Studies

As already discussed, the goals of CER are to fill gaps in evidence that is traditionally and heavily based on premarketing RCTs. Observational studies leveraging existing data sources or primary data collection can be used as a valid and more cost-efficient approach for CER when available data include the necessary fields, and/or when researchers employ design-based or analytic methods to overcome potential biases. However, there are situations where bias is intractable and randomized trial designs are needed to obtain valid results. Large simple trials such as pragmatic trials or cluster randomized trials can determine the effects of an intervention under the usual conditions in which it will be applied, and therefore can assess real-world treatment effectiveness [133]. For clinical trials to be used in CER, researchers must focus on using trial designs that are flexible, adaptive, pragmatic, practical, and efficient, in contrast to traditional randomized, blinded, placebo-controlled clinical trials [134–137] (see also Chapter 32 for a discussion of large simple trials).

Briefly, pragmatic clinical trials are intended to overcome the limitations of traditional RCTs in order to answer CER questions. Pragmatic trials include real-world patients such as those with co-morbid conditions and those from diverse demographic backgrounds [138], and providers from community settings instead of only tertiary settings. In pragmatic CER trials, comparator treatments should be those in use in clinical practice (rather than placebo controls), outcomes should be those that matter to patients and clinicians rather than investigators or drug companies, and variations in patient responses to the treatment (treatment heterogeneity) should be explored [134,137,139].

One example of a pragmatic trial for CER is the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT) [140], a $120 million NIH-funded trial comparing three antihypertensive medications and evaluating more than 42 000 patients in 600 clinics and centers in the US, Canada, Puerto Rico, and the US Virgin Islands [141]. A more recent example of a pragmatic trial for CER is the Ziprasidone Observational Study of Cardiac Outcomes (ZODIAC) study, which compared ziprasidone and olanzapine for their risk of nonsuicide mortality [142,143]. This large randomized pragmatic trial included

approximately 18 000 patients in 18 countries and cost $85 million.

As in observational CER studies, using clinical trial designs for CER presents its own challenges. First, demonstrating clinically meaningful effect sizes is often challenging for several reasons: (i) the liberal inclusion criteria needed to assure generalizability of the study groups, although this increased heterogeneity can decrease the probability of detecting a given treatment effect as statistically significant, requiring an even larger sample size [134]; (ii) head-to-head comparison of commonly used clinical strategies; and (iii) modern medical interventions showing less dramatic benefits. The effect sizes seen even in placebo-controlled trials have been decreasing over time, and this pattern is considered to stem from the increasing rarity of discoveries of transformational medical interventions [144]. To detect a relatively small effect size and evaluate long-term and clinically relevant outcomes including hard endpoints, larger samples make CER trials more expensive [145]. The emphasis on usual care settings and the less-controlled nature of the trials lead to problems that are well known in observational studies. For example, loss to follow-up and/or nonadherence over time can introduce bias [135]. The lack of blinding in pragmatic trials creates the potential for biased observations and a threat to internal validity [134]. Another similar limitation of this type of trial results from the flexible treatment protocols that are preferred, as they are closer to what happens in real-world settings. Specifically, pragmatic trials involve the participation of community providers in their usual practice. Accordingly, providers can vary the treatment process, dose, and regimen given to different patients, depending on differing responses to therapy over time. This flexibility permits assessment of the outcomes of the composite treatment, but not of particular components within the treatment process [135].

As shown in the earlier examples of CER, the high cost of pragmatic trials is a major obstacle. However, conducting a simple randomized trial in usual clinical care conditions using routinely collected data, what are called "electronic point-of-care trials," could minimize the cost burden [146]. Attempts to conduct such trials with information technology (IT) tools to facilitate timely and efficient point of care (POC) recruitment have been reported by UK researchers using the General Practice Research Database® (GPRD®) [146,147]. In the US, researchers at Veterans Affairs (VA) hospitals have a head start taking advantage of the VA's sophisticated electronic health records (EHR) system [148]. The UK experience showed that the recruitment of clinicians and patients was a major challenge: the investigators observed that the number of interested clinicians/practices dropped substantially with each stage of the governance process, including site contracts, local approval forms, web-based good clinical practice, and protocol training [146]. A successful implementation of electronic POC trials will require three conditions at minimum: (i) a well-connected community with a network of practices and patients; (ii) data and IT infrastructure that enables patient recruitments at POC and captures clinically important outcomes; and (iii) readiness of clinicians and patients to accept "randomization" in routine clinical practice when there was equipoise among therapeutic options. A recent review article described attempts to conduct POC trials and integrate comparative effectiveness trials into patient care, illustrating challenges and limitations specific to POC trials [149]. Obviously, use of EHR poses limitations on the questions that can be addressed, processes that can be implemented, and outcomes that can be assessed.

Choosing the Right Methods: Experimental vs. Observational CER

There are inherent limitations in both experimental and observational designs, as discussed in the previous sections. While an experimental design is generally accepted and considered to

yield higher internal validity than observational CER, one must carefully examine how either of these types of studies are conducted in order to assess validity (both internal and external), interpret results, and draw meaningful conclusions. Several considerations can guide the decision of which study design to use for CER. First, some interventions cannot be investigated with clinical trials because of ethical considerations, even though such trials may otherwise be preferred scientifically. Second, it is not practical to employ pragmatic trials for most CER research questions due to their prohibitively high cost. Thus, observational studies using the techniques of nonexperimental pharmacoepidemiology will continue to play a role in CER, because some questions cannot be answered in clinical trials or because observational studies provide a cost-effective approach (when they can provide results with high internal validity).

Finally, there are some research questions that cannot be answered in observational CER due to intractable biases that severely compromise the internal validity of the results. Questions related to bias are not binary (existence or nonexistence of bias) but rather quantitative (degree of bias), and researchers must consider all potential biases and their quantitative impacts on the results before conducting observational CER studies. As one of the goals of CER is to produce results that are applicable and generalizable to real-world patients and practices, attempts to achieve higher generalizability may compromise features that are favorable to internal validity [84]. Nonetheless, results from CER studies that have significant bias and therefore have poor internal validity cannot be generalized. Once observational CER studies are completed, when intractable and significant biases are suspected in the results, researchers must provide a fair and honest assessment of study validity and must attempt to publish the results including this assessment in order for the research community to learn from their experiences.

Published Guides for CER Studies for Evidence Generation

Standards for performing and reporting observational studies have been provided by several professional associations [150–152]. While these guides are not specific to CER, they are relevant and directly applicable to observational CER. In addition, several other guides specifically targeting observational CER have been published through initiatives of AHRQ, PCORI, other governments, and professional societies (e.g., International Society of Pharmacoepidemiology [ISPE], International Society of Pharmacoeconomics and Outcomes Research [ISPOR], American Heart Association [AHA]) [151–160].

A recent systematic review of these CER-related guidance documents assessed shared expectations for quality CER [161]. The review identified nine documents with over 300 recommendations for designing and conducting CER. The most frequently shared recommendations included transparency and adaptation for relevant stakeholders in the interpretation and dissemination of results. Other frequently shared CER methods recommendations included developing an *a priori* study design and operational definitions that allow for replication (n=8 documents); focusing on areas with gaps in current clinical knowledge that are relevant to decision-makers (n=7); assessment and discussion of validity of measures, instruments, and data (n=7); and clinically meaningful and objectively measured outcomes, including benefits and harms (n=7). Additional commonly shared recommendations included assessment for and strategies to minimize bias (n=6 documents), confounding (n=6), and heterogeneity (n=4). Pragmatism in the design of experimental CER trials has been widely discussed [139,162–177], and there are proposed tools to assess pragmatism in clinical trials that researchers and clinicians can use when designing or evaluating pragmatic trials, especially for CER [178–181].

Issues for Evidence Dissemination

The ultimate goal of CER to improve clinical care will not be achieved without successful dissemination and adaptation of CER evidence. Evidence dissemination has several distinct goals. One goal involves identifying priority topics, comprehensively identifying available information on these topics, and developing objective interpretations of the information [182] (for example, as provided by Cochrane Collaboration reviews [183]). The output from this research then becomes the source information for dissemination to clinicians, patients, and policymakers. This goal will be achieved through expanding efforts on systematic reviews and studies using novel research designs (see earlier discussion), focusing on the priority research areas that were identified by the IOM as having knowledge gaps.

Another goal involves knowledge translation; namely, using research findings as the basis for drafting clinical guidelines. Achieving this goal will require qualified review panels that have scientific and clinical expertise in the content areas of the topics for which guidelines are developed, and who can develop clinical practice guidelines. Ideally, clinical guidelines should also be both comprehensive for general patient care and specific for particular patient circumstances – a very demanding specification. Furthermore, to remain relevant, guidelines need to be updated periodically to incorporate new information about existing interventions and new treatments. The IOM recently proposed standards for developing trustworthy clinical practice guidelines [184].

A third goal involves knowledge exchange and utilization, achieved by the actual distribution of information and the education of clinicians, patients, and policymakers about current knowledge and best practices. This goal may be attained by more intensive use of technology and/or social interventions. Examples of such tools include computerized physician order entry (CPOE) systems, supplemented by computerized clinical decision support systems (CDSSs) that incorporate electronic reminders to comply with guidelines (e.g., reminders to perform screening tests or to order other tests or treatments, reminders to avoid co-prescribing interacting drugs, etc.). Other strategies for achieving knowledge exchange and knowledge utilization will require educating clinicians and patients about what treatments work best [2,26,185]. These efforts should include monitoring to ensure that information is integrated into the normal workflow and decision processes of clinicians and patients.

A final goal involves monitoring and assessment of whether these efforts translate into actual good practice and, if not, to identify which means of dissemination have a greater chance to create an impact. However, recent history suggests that scientific evidence is often slow to change clinical practice. For example, despite harms associated with overdiagnosis of prostate cancer with prostate-specific antigen screening [186], the test is widely utilized in general practice [187]. Also, after the aforementioned multimillion-dollar ALLHAT pragmatic trial showed that thiazide diuretics are more effective than ACE inhibitors or calcium channel blockers for patients with hypertension, no significant changes in practice were observed [188]. Timbie *et al.* [189] reviewed CER studies conducted in the 2000s, including the ALLHAT trial, and identified five root causes underlying the failure of many CE studies to alter patient care:

- Financial incentives, such as fee-for-service payment, that may go against the adoption of new CER evidence.
- Ambiguity or concerns about the validity of CER study results.
- Common cognitive biases, including confirmation bias [189], pro-intervention bias [190], and pro-technology bias [191] in the interpretation of new CER information.

- Failure of research to address the needs of end users of CER evidence (clinicians, patients, policymakers).
- Limited use of decision support tools by patients and clinicians.

The authors offered several suggestions that align with the four dissemination goals already described. In addition, they suggested that in developing guidelines based on CER evidence, adapting the standards proposed by IOM (one of which was that guideline development groups be "multidisciplinary and balanced" [192]) may overcome several of the root causes mentioned, such as ambiguity of CER results and cognitive bias in interpreting the evidence. Finally, the authors proposed that aligning the incentives of clinicians and patients by changing payment and insurance models may facilitate the adoption of CER evidence in clinical practice. However, a recent systematic review found that pay-for-performance programs in healthcare were associated with improved processes, but not patient outcomes [193].

Dissemination of CER evidence is a legal mandate of PCORI [194,195]. The federal AHRQ works to disseminate findings from patient-centered outcomes research funded by PCORI, as well as government agencies and other sources. PCORI's release of new evidence from the funded studies begins with translating all research findings into understandable summaries with the help of the Patient-Centered Outcomes Research Translation Center. PCORI funds support not only engagement activities and infrastructure development, but also research to bring findings from completed studies into practice in real-world settings, and to compare approaches to communicating and disseminating patient-centered outcomes research findings, as well as research on shared decision-making [194]. PCORI recently announced a dissemination initiative (Eugene Washington PCORI Engagement Awards) through which it was planning to award $20.5 million in fiscal year 2018. Between fiscal years 2011 and 2017, AHRQ committed about $260 million for the dissemination and implementation of CER findings.

CER and Cost-Effectiveness Analyses

The primary goal of CER is to inform decisions that lead to better care, not necessarily cheaper care [196]. This could result in abandoning expensive technologies that are no better than less expensive options. However, it could also result in paying for a more expensive technology because the evidence shows it is superior [33,196,197]. The relevance of including cost-effectiveness analyses in CER investigations (see Chapter 34) is unquestionable. However, CER should not be used for cost-containment decisions [33,40,198], and the experts conducting CER studies should not be placed in the position of using their findings about treatment effectiveness to make recommendations about reimbursement. Nevertheless, well-performed CER inevitably should and will affect reimbursement decisions. In some cases, CER studies will find that the more expensive treatment is preferable. Yet, over time, CER should ultimately save money by preventing wasteful spending on treatments that are less effective, especially if dissemination is successful and CER evidence is adapted into clinical practice [196]. Ultimately, CER alone will not solve the US's healthcare spending problem ($3.3 trillion in 2016 – 17.9% of GDP – and $5.7 trillion projected in 2026 – 19.7% of GDP [199]).

Currently Available Solutions

In a review of recently published studies of the comparative effectiveness of existing (rather than new) medications, Hochman and McCormick [200] compared active therapies to each other (rather than to placebo comparators); compared medications to nonpharmacologic

interventions such as surgery or lifestyle interventions; compared different pharmacologic strategies for medication use; and compared different medication doses, durations, or formulations. They found that only one-third of studies evaluating medications qualified as comparative effectiveness research, and only a minority compared pharmacologic and nonpharmacologic therapies, emphasizing the need to expand the scope of CER. Another study reviewed clinical trials conducted in the US between 2007 and 2010 addressing priority CER topics identified by the IOM [201]. Among 1035 studies found on clinicaltrials.gov, 231 (22%) were comparative effectiveness (CE) studies. The most common interventions examined in CE studies were drugs (37%), behavioral interventions (29%), and procedures (16%).

These studies show what is observed in major medical journals or on clinicaltrials.gov during the period 2007–2010, but more recent data are not available. As described in the next section, the predominant source of funding for CER in the US thus far has been the federal government. Since PCORI was established in 2010, it has funded 596 CER projects (approximately $1.7 billion) [5]. These include CER studies, projects to examine CER methods, and projects to build infrastructure for CER and PCOR. The most frequent disease conditions for funded studies include mental/behavioral health (115 studies), cancer (84), neurologic disorders (74), cardiovascular diseases (69), and multiple chronic conditions (58). Most-studied populations of interest include racial/ethnic minorities (290), individuals of low socioeconomic status (194), women (145), older adults (134), and patients with multiple chronic conditions (110). Most of PCORI's research projects awarded through fiscal year 2017 are still underway; only 53 projects had been completed at the end of fiscal year 2017, but many are projected to be completed between 2018 and 2020.

The initial wave of funding came from the President's budget proposal for fiscal year 2011, with $286 million for patient-centered health research (the rebranded term for CER) through AHRQ. Much more substantial funding continued to come from the nongovernmental, nonprofit PCORI and its Patient-Centered Outcomes Research Trust Fund, established in 2010. As of January 2018, PCORI had brought a total investment of over $2 billion in projects meeting its congressional mandates, including funding for nearly 400 CER studies ($1.7 billion), as well as projects to improve the methods ($129 million) and infrastructure for CER, including the National Patient-Centered Clinical Research Network (PCORnet; $374 million). PCORI is projected to commit an additional $721 million for awards in fiscal years 2018 through 2021 [5]. From fiscal years 2011 through 2017, HHS including AHRQ committed approximately $448 million from the Trust Fund. Of this amount, HHS committed approximately $260 million (or 58%) to the dissemination and implementation of CER findings. HHS is projected to commit an additional $120 million for these activities in fiscal years 2018 through 2020 [5].

The EU does not have a central budget for healthcare expenditure. However, the European Commission has provided funding to conduct studies in European countries via its research budget (e.g., the CEPHOS-LINK Project [202]). In individual countries such as England, the NIHR has also provided funding for CER, particularly via the HTA Programme [7]. Examples from Asia include the Hong Kong Government's funding of CER via the Health and Medical Research Fund [203].

The Future

Funding

Thus far, the predominant source of funding for CER in the US has been the federal government, whereas much of the funding for clinical efficacy

research (i.e., RCTs) comes from industry sources. Recently, real-world evidence (RWE) has been gaining in popularity in the US, since the FDA's leadership published its opinion [204] and guidance document [205] on RWE, defining terminology and discussing its use in regulatory decision-making. RWE is defined by the FDA as "the clinical evidence regarding the usage and potential benefits or risks of a medical product derived from analysis of Real-World Data (RWD)" [206]. In the EU, according to the GetReal Glossary of Definitions of Common Terms [207], "RWE derives from the analysis and/or synthesis of RWD that can either be primary data collected in a manner which reflects how interventions would be used in routine clinical practice or secondary data derived from routinely collected data." There is substantial overlap between RWE and "evidence generation in CER," as RWE includes comparative evidence of the "potential benefits and risks of medical products."

With the emphasis on RWE among regulatory bodies in the US and Europe, there has been increasing interest in RWE/CER among producers of medical products. In this new CER/RWE environment where the results of RWE or CER studies can be used in regulatory decision-making, companies may invest resources in RWE/CER, thus allowing them to compete on the utility (e.g., comparative effectiveness) of their products rather than just on their marketing ability [196]. For example, two global pharmaceutical companies recently collaborated to invest in a set of RWD analyses, including CER studies, of direct oral anticoagulants [208,209]. As most head-to-head comparative randomized studies are already sponsored by industry [210], with the increasing demand for RWE in North America, Europe, and Asia, future comparative studies may be conducted using RWD to provide CER evidence for new medical products. In addition to the possibility of more funding from industry for CER, public funding agencies and charities in the US and Europe have supported and will continue to support nonpharmacologic trials and studies of off-patent medications, such as through the Better Medicines for Children Initiative [211].

Human Capital Development

As noted by the Federal Coordinating Council [26], training will be required for new researchers to apply the specialized methods of CER and to develop new CER methods [212]. Specialized skills are needed to perform both traditional RCTs and novel pragmatic trials. It should be noted that these are not necessarily new but specialized skills, as CER is not a novel concept. Specialized expertise is also needed to perform formal meta-analyses and nonexperimental studies, using either *ad hoc* data collection or existing databases, and to successfully access and link various databases and conduct multidatabase studies. Finally, the field needs individuals who are able to translate the findings into practice guidelines and for other dissemination channels. The emphasis of CER on community participation and inclusion will dictate that experts from many different fields and backgrounds will be required to communicate with each other, finding and developing a common language to permit productive interactions. Therefore, the research teams participating in CER will be composed of professionals from different disciplines and different settings, including pharmacoepidemiologists and practicing clinicians from specialties relevant to the given studies [40]. These teams will need to have the capacity to develop a shared understanding of basic scientific terminology and methods.

Accordingly, it is necessary to create and support training programs for researchers seeking careers in CER in order to develop capacity in the research community to conduct CER. In addition to preparing a cadre of researchers with expertise in CER methods, a critical mass of such researchers is required in order to undertake the large number of studies needed

to fill current knowledge gaps and to continuously update the knowledge inventory with systematic reviews. So far, PCORI has committed $30 million to workforce training awards for clinicians and researchers. For example, one of its career development programs, conducted in partnership with AHRQ, is designed to train clinician and research scientists to conduct patient-centered outcomes research and to actively engage stakeholders in efforts to improve the quality and safety of care [5]. AHRQ committed $94 million for efforts to train researchers on the conduct of CER [5] and plans to commit an additional $14 million by fiscal year 2020 for CER training. In Europe, the European Commission has provided funding for training in health and medical research including CER and pharmacoepidemiology in European countries (e.g., the Marie Skłodowska-Curie Fellowship [213]). In England, the NIHR has also provided funding for fellowships in health research including CER research, particularly through the NIHR Fellowship Programme [214]. In Asia, the Hong Kong Government funds health fellowships via the Health and Medical Research Fund [203].

CER and Clinical Practice

Though the research community continues to appear excited and energized, expectations must be tempered by several limits on what CER can realistically solve. It is unrealistic to expect that CER will address all therapeutic questions; healthcare is simply too complex. Sir William Osler, the Father of modern medicine, wrote, "The practice of medicine is an art, based on science" [215]. Even in the era of evidence-based medicine and CER, the practice of medicine is as much the application of art as the application of evidence. To reach an optimal decision in any given clinical situation, evidence must be applied to an individual patient who has her or his own values, preferences, life situations, and goals. Treating not only the disease but also the patient as a whole requires both understanding and application of the best evidence, as well as the skills and behaviors physicians bring to their own practice of the art of medicine [216]. Alternatively, if it were possible to base medical practice entirely on evidence, such evidence would consider not only complex pathophysiology, but also personal factors such as values, preferences, perceptions, and attitudes about risks, quality-of-life preferences, cost tradeoffs, as well as clinician–patient interactions. However, as the evidence underlying current medical practice consists of estimated averages from studied populations and is also not sufficiently complete, art comes into practice when subjective judgment is required. Therefore, even in situations where complete evidence-based information is available to guide clinical decisions, providers or patients may still opt for a decision based on personal choices that they value irrespective of the scientific evidence. As stated by Kerridge *et al.* [217]:

> Medical decision making draws upon a broad spectrum of knowledge – including scientific evidence, personal experience, personal biases and values, economic and political considerations, and philosophical principles (such as concern for justice). It is not always clear how practitioners integrate these factors into a final decision, but it seems unlikely that medicine can ever be entirely free of value judgments.

Overemphasis on scientific evidence can lead to therapeutic nihilism; that is, paralysis when such evidence is unavailable. Also, an overreliance on evidence-based guidelines can result in algorithmic care [218]. Ironically, this in turn may devalue individualized care, which is another goal and feature of CER. Subgroup analysis is the most commonly used approach for assessing heterogeneity in CER, but it has obvious limitations in providing sufficient evidence to "individualize" the care of each

patient. In the face of uncertainty, variation among reasonable but unproven options should be tolerated and even encouraged, as it will facilitate later evaluation. This runs contrary to the vision of a knowledge state that is sufficiently complete to guide all decisions about effective interventions at the individual patient level. We also need to be sure that the desire for scientific evidence does not paralyze medical practice when such evidence is absent. In such circumstances, the resulting variability in practice can provide the data that will underlie future CER studies.

As healthcare communities continue to embrace CER and demand better evidence to inform clinical decisions, CER will play an expanding role in healthcare research. It continues to establish its position as a central component of clinical research that is directly relevant to clinical practice and health policy; that is, CER is needed in order to practice the best evidence-based medicine and evidence-based policymaking. Nonetheless, creating sustainable funding sources, improving the quality of evidence generation and evidence dissemination through development of methods and better use of these methods, educating consumers about CER, and managing their expectation are ongoing challenges.

Recently our capability to harness computational power to collect, share, and analyze data has increased dramatically year on year. This has led to vast data sources potentially able to provide answers to questions relevant to pharmacoepidemiology. At the same time, there remains a need for method and tool development to extract reliable insights, rather than simply more information, distinguishing signals from the noise inherent in large volumes of data that are not collected with research as their primary purpose. Effective and reliable drug- and vaccine-related evidence generation is the goal in order to improve the public's health. Informatics and data-mining approaches are not intended to replace traditional pharmacoepidemiologic approaches, but rather to enhance the field by addressing questions of interest more efficiently, and being able to answer additional ones. This chapter sets out to provide an overview of how data mining and other informatics approaches are applied to the field of pharmacoepidemiology.

Data mining should be seen as exploratory data analysis for hypothesis generation, and as part of a knowledge discovery process [1]. It looks to uncover patterns or correlations in the dataset with no or limited presupposition, but almost invariably requires more rigorous testing of any emerging hypothesis, tailoring the subsequent testing to the issue at hand. As some researchers have put it, "data mining is asking a processing engine to show answers to questions we do not know how to ask" [2]. Often in pharmacoepidemiology "data mining" is used synonymously with quantitative signal detection, although naturally other forms of hypothesis generation of relevance to pharmacoepidemiology would also be in scope. As the sources of existing healthcare data and our capability to access and potentially analyze them increase, we strive to maximize the value of the data through developing more effective data mining and processes associated with it. Hence the recent emphasis on "Big Data" and "real-world evidence" and

Pharmacoepidemiology, Sixth Edition. Edited by Brian L. Strom, Stephen E. Kimmel and Sean Hennessy.

the supposed capability to generate more rapid insights from the increasing amount of diverse data available (see, for example, [3–6]). However, the wide range of different terminologies, dictionaries, and controlled vocabularies that are used as well as nonrandom variability in data capture due to different healthcare systems make linkage and analysis of multiple data sources challenging. In addition, there is an increasing amount of unstructured free-text/narrative data recorded, as well as repositories with biologic data, chemical structure, and pharmacogenomics information. However, data protection laws may make access to text and linkage between data sources more difficult in many regions. Informatics approaches, defined as "the study of the structure, algorithms, behaviour, and interactions of natural and artificial computational systems" [7], have obvious value for data mining, while they are also of relevance in the wider application of pharmacoepidemiologic approaches.

Signal detection, refinement, and evaluation describe three distinct secondary uses of data [8] that together form a signal management continuum (Figure 27.1). There is much discussion of definitions of signal-related terms and their relations as components of safety surveillance [9]. Other terms that are used include "signal strengthening" in place of "signal refinement," "signal validation" in place of "signal evaluation," and "signal substantiation," which incorporates an element of both refinement and evaluation, but has been applied using external data, such as protein information, to provide a pharmacologic mechanism for detected signals, often through semi-automated data linkage and analysis [6,10,11]. There is some inconsistency in the use of signal-related terms and further terminologic harmonization would be beneficial.

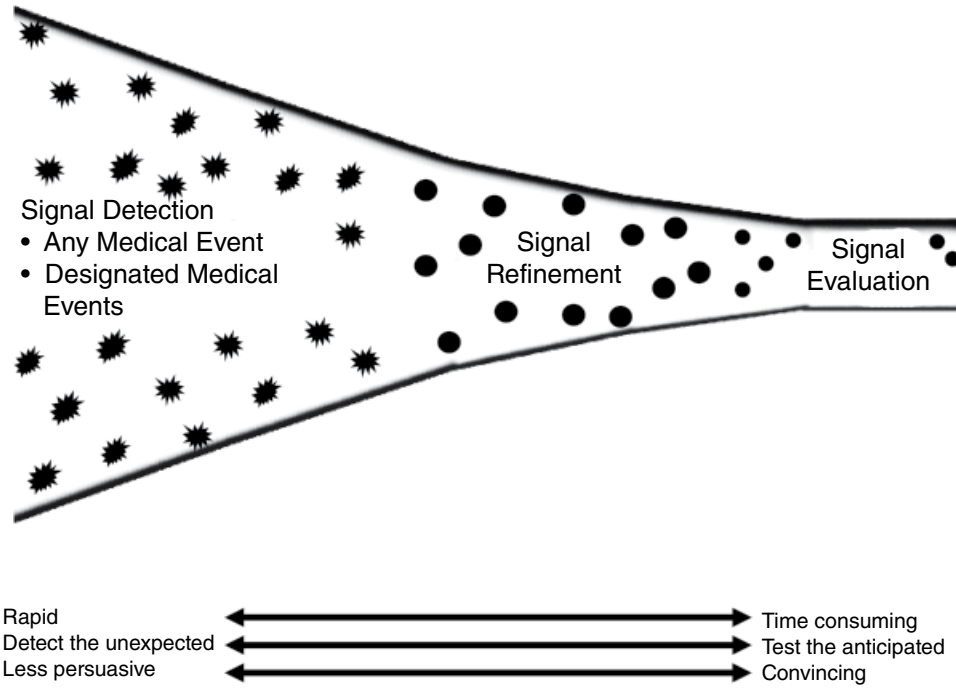

Figure 27.1 Signal stages after product approval and launch.

Clinical Problems to Be Addressed by Pharmacoepidemiologic Research

Signal Detection and Data Mining: Realistic Expectations

All medicines are licensed on the basis of a favorable benefit/risk balance. Routine activities are aimed at supporting the continual evaluation of the benefit/risk profile of medicines in the postmarketing setting. Specific aims include primarily detection of drug safety signals, and then quantification, characterization, and identification of predictors of known adverse drug reactions (ADRs).

The concept of a signal, from a drug or vaccine surveillance point of view, has evolved from its definition by the World Health Organization (WHO) as "reported information on a possible causal relationship between an adverse event (AE) and a drug, the relationship being unknown or incompletely documented previously. Usually more than a single report is required to generate a signal, depending upon the seriousness of the event and the quality of the information" [12], to a more comprehensive definition according to the Council for International Organizations of Medical Sciences (CIOMS): "information arising from one or multiple sources (including observations or experiments), which suggests a somehow new, potentially causal association between administration of a medicine and adverse event(s) that is of sufficient likelihood to justify verificatory action" [13].

In particular, this new definition highlights that a signal can be detected from multiple data sources. In a review of 25 drugs withdrawn from the market for safety reasons from 2000 to 2010 in the US or European Union (EU), the type of data that provided the basis for each withdrawal was examined [14]. The majority of safety-based withdrawals were rare events such as progressive multifocal leukoencephalopathy, Stevens–Johnson syndrome and cardiac arrhythmias, or AEs with delayed onset, such as myocardial infarction and liver toxicity. In almost 50% of the drug withdrawals, the authors' review [14] suggested that spontaneous reporting systems (SRSs, see Chapter 10) were the primary source of data in triggering regulatory action, thus confirming that SRSs remain the cornerstone of pharmacovigilance. In contrast, in two instances (8%) for two outcomes – cardiovascular events (including myocardial infarction and stroke) and liver toxicity/veno-occlusive disease – randomized clinical trials (RCTs) were the sole source of the safety information. For the remaining 48% of withdrawals, a combination of data from SRS, clinical trials, and/or observational studies contributed to the regulatory action.

Safety signal detection is both an iterative and a dynamic process, since emerging safety issues can be encountered over time after approval (e.g., progressive multifocal leukoencephalopathy associated with natalizumab). ADRs may have many different types of manifestation, underlying mechanisms, frequencies, latency, and predictors (see Chapter 3), which may require integrating and understanding evidence from all possibly relevant information sources on drug safety. Continued development of multimodal signal detection requires a deeper understanding of the data sources used and further research on methods to generate and synthesize signals [15].

Although RCTs are considered to be the most rigorous approach to determining a cause-and-effect relationship between an intervention (e.g., medication exposure) and an outcome, these trials are generally designed and powered to assess efficacy rather than safety end-points. The controlled nature of such trials, however, calls for a limited number of patients who may be at a lower baseline risk of ADRs than the population of all potential users of the drug, so the statistical power to detect ADRs will be low (see Chapter 4). In addition to limited study sample size, a relatively short observation period makes it difficult to detect ADRs that have long

latency [16,17]. Similar ADRs that occur in vulnerable subpopulations or when medications are in practice used suboptimally or in unusual combinations are also particularly important to detect once medicinal products are utilized in routine healthcare. While RCTs in the premarketing phase and SRSs in the postmarketing setting remain essential for drug safety surveillance, there are still gaps that may be filled by observational data derived from different sources. In particular, the role of mining data from healthcare databases for signal detection has been more extensively investigated in recent years [6]. Compared to clinical trial data, population-based healthcare databases such as electronic health records and claims databases (see Chapters 11–14) contain data from clinical practice about larger populations with longer follow-up periods, which may help in the detection of adverse reactions occurring after long-term exposure to medicines (e.g., cardiac valve disorders). Preliminary results [18,19] showed that these data sources might complement SRSs in routine pharmacovigilance in the postmarketing setting for detecting specifically signals concerning events occurring at relatively high frequency in the general population, as well as those that are multifactorial (e.g., myocardial infarction) and as such not commonly considered as a potentially drug-induced event, so unlikely to be reported to any SRS.

Ideal pharmacovigilance systems for signal detection should allow timely and accurate identification of new, potentially causal associations of drug(s) and AE(s) requiring further signal management, while minimizing false positive signals and optimizing use of human resources. Once detected, in general, a suspected signal has to be strengthened (or weakened) by adding other evidence on biologic substantiation and other key information on causality assessment, as done experimentally in the EU-ADR project (Figure 27.2) [10], and finally validated and fully characterized through formal pharmacoepidemiology studies. Because of the substantial effort required to evaluate signals, detecting these in systems with low precision (high false positive rates) would not be sustainable routinely. Ongoing efforts to develop quantitative methods, or other approaches that can provide at least some semi-automated triage, all with strong performance characteristics (positive and negative predictive values) in highlighting potential signals, remain critical. While improving signal detection is important, and is the focus of much of this chapter, our capability to effectively rule out spurious signals, and rapidly and effectively further analyse and better understand true emerging risks, through signal refinement and evaluation activities is equally critical, and is addressed in other chapters.

Disaster-Driven Pharmacovigilance

The traditional pharmacovigilance system mostly based on SRSs has been in place since the end of the 1960s as a reaction to the tragedy of thalidomide-induced limb defects. This system, despite its great potential, is far from optimal as a consequence of well-known SRS limitations such as underreporting, notoriety bias, and lack of denominators. It is therefore not surprising that serious ADRs leading ultimately to drug withdrawal are sometimes detected only with significant delay.

Electronic health record (EHR) data may be able to identify new risks for drugs associated with AEs that have high background incidence rates (such as acute myocardial infarction), as well as events that are not pharmacologically predictable and are less likely to be suspected as drug induced, thus less likely to be reported and therefore in spontaneous reporting systems. Historically, spontaneous reporting systems have been good at highlighting the unpredictable (at the time), for instance coughing with angiotensin-converting enzyme (ACE) inhibitors, heart rhythm disorders with terfenadine, or progressive multifocal leukoencephalopathy

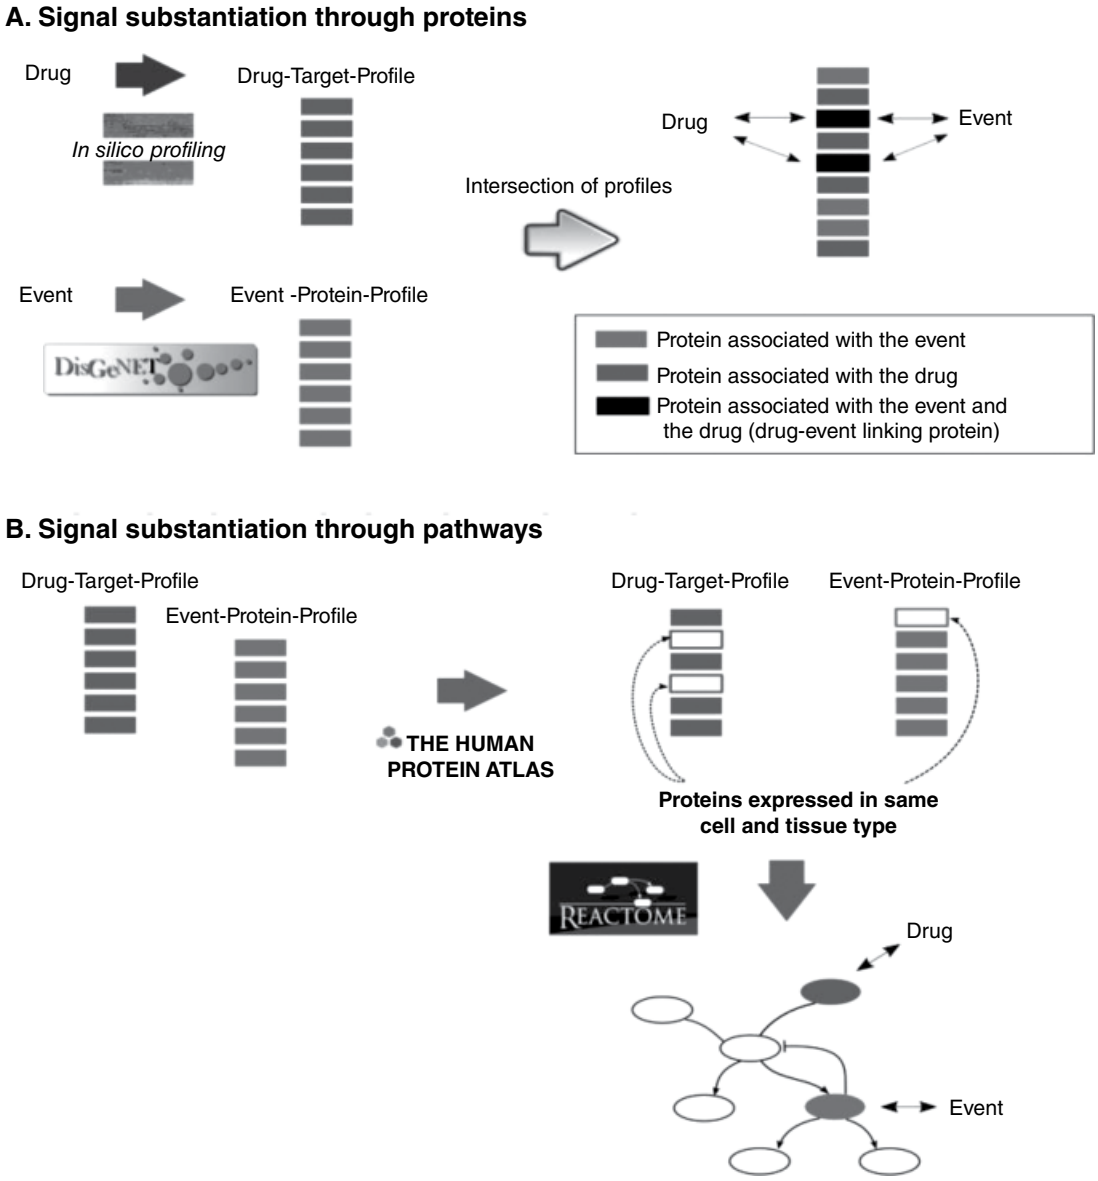

Figure 27.2 Example of a process for signal substantiation through proteins. *Source:* Bauer-Mehren A, van Mullingen EM, Avillach P, *et al*. Automatic filtering and substantiation of drug safety signals. *PLoS Comput Biol* 2012; **8**(4): e1002457.

(PML) and natalizumab and heart valve disorders with fenphen (the combination product of fenfluramine and phentermine). Data from EHRs provide denominators for the rate of occurrence as well as greater detail regarding possible confounding factors such as patient demographics, drug use, and utilization of healthcare services. These data may permit

epidemiologic evaluation of the benefit/risk profile of drugs (see Chapter 35). This process then puts safety issues in a broader perspective and fosters sound regulatory decisions, therefore providing a data source for moving from signal detection across signal refinement toward signal evaluation. This can lead to a more compelling rationale for further investigation than might sometimes be the case with signals from SRSs with limited clinical plausibility at the time.

The Example of Rofecoxib's Withdrawal from the Market and the Potential Role of Healthcare Databases

Several initiatives have been exploring the role of healthcare databases for drug safety signal detection and signal management. An example that has been studied in depth is the case of withdrawal from the market of rofecoxib due to increased risk of cardiovascular thrombotic events. Rofecoxib is a prescription cyclooxygenase (COX)-2 selective nonsteroidal anti-inflammatory drug (NSAID) previously indicated for relief of osteoarthritis signs and symptoms, management of acute pain in adults, and treatment of menstrual pain. The European Medicines Agency (EMA) and the United States Food and Drug Administration (FDA) provided approval for rofecoxib in 1999. In June 2000, the results of the Vioxx Gastrointestinal Outcome studies (VIGOR) trial were submitted to the FDA and demonstrated an increased risk of cardiovascular thrombotic events. This trial showed that patients who were given rofecoxib had four times as many myocardial infarctions as those who were given naproxen, which was attributed by the authors of the VIGOR trial at that time as due solely to the cardioprotective effect of naproxen. Subsequently, in September 2004, the Adenomatous Polyp Prevention on Vioxx (APPROVe) study showed increased risk of myocardial infarction and stroke with rofecoxib as compared to placebo after 18 months of treatment. The same month, the manufacturer withdrew rofecoxib from the market because of concerns about increased risk of heart attack and stroke associated with long-term, high-dosage use [20]. Thus, it took almost five years for rofecoxib to be withdrawn from the market after the first evidence of increased myocardial infarction risk was documented [21]. By the time of rofecoxib's withdrawal, more than 100 million prescriptions had been filled in the US, with tens of millions of these prescriptions being written for persons who had a low or very low risk of gastrointestinal complications of nonselective NSAIDs [20], which was the rationale for developing COX-2 selective NSAIDs. Using actual penetration of rofecoxib in the market, it was calculated that if the medical records of 100 million patients had been available for safety monitoring, the adverse cardiovascular effect would have been discovered in just three months [22]. In the context of the FDA's Sentinel initiative, a modular program was built that semi-automatically performs cohort identification, confounding adjustment, aggregation, and effect estimation across multiple databases, and application of a sequential alerting algorithm (see Chapter 25). In retrospective assessments, the system identified an increased risk of myocardial infarction with rofecoxib and an increased risk of rhabdomyolysis with cerivastatin years before these drugs were withdrawn from the market [23]. Similarly, the Exploring and Understanding Adverse Drug Reactions by integrative mining of clinical records and biomedical knowledge (EU-ADR) project, which built a European multidatabase network covering more than 30 million citizens, has shown that, had this data source been available at the time rofecoxib was still marketed, there could have been a faster withdrawal [18]. Although international SRSs did not play a significant role in detection and prioritization of this emerging signal, it is worth noting that the Dutch SRS did identify this as a potential signal [24].

What are the lessons to be learned from this story? First, suggestions to replace spontaneous reporting by other systems are illogical and not supported by the evidence provided by the rofecoxib case, as signals of rofecoxib-associated

cardiotoxicity from both clinical trial and Dutch SRS were detected; secondly, it is what happens after the first signal of an ADR has been found that should be the major focus of concern. In this case there was a considerable delay from the initial signal to regulatory action [24]. Availability of a large amount of EHR data represents an additional data source for signal refinement, as well as for signal evaluation, thus potentially contributing to accelerating the process of signal management. Nevertheless, as discussed shortly, while healthcare databases on their own or combined in networks are used for signal refinement, as discussed in Chapter 25, they may also help enhance signal detection capability.

As another example, in recent years safety data from the US Vaccine Adverse Event Reporting System (VAERS) and the Vaccine Safety Datalink suggested that more venous thromboembolism (VTE) cases were observed than expected after vaccination with quadrivalent human papillomavirus vaccine (HPV4; Gardasil®), but data were inconclusive [25,26]. The Sentinel initiative rapidly evaluated the risk of VTE in more than 650 000 females aged 9 through 26 years of age, totalling more than 1.4 million doses of Gardasil evaluated, and found no evidence of an increased risk for VTE after Gardasil vaccination, reporting a relative risk estimate (95% confidence interval) from both unrestricted analyses, for all doses, with a 28-day risk interval of 0.7 (0.3–1.4) [27].

Methodologic Problems to Be Solved by Pharmacoepidemiologic Research

Data Mining and Causality

The fundamental problem for much of pharmacoepidemiology is that of inferring causality. For much data mining outside of pharmacovigilance, there is no need to assess causality: association is enough. This can be true even for public health purposes in some circumstances. For example, let us assume that there is no biologic or pharmacologic effect of isotretinoin on the likelihood of a patient's taking a suicidal action. However, there may well be an association resulting from other conditions the patient has, which result in their being prescribed isotretinoin. From a public health perspective, it would be good for the prescribing health professional to be aware of the isotretinoin–suicide association, even if it is not causal. That is, when prescribing isotretinoin, the characteristics of the patient and the circumstances in which it is prescribed are associated with suicidal events, and attention should be paid to caring for the patient with this in mind. With data mining in the sphere of economics or politics, the association between previous purchases and other factors like age would be enough to make the targeting of an advertisement to an individual very productive, in that the individual is more likely than others to respond to that particular advertisement, without any requirement to take other factors into account that may be the causal elements. A similar effect is seen in response to encouraging donations or going out to vote for a particular candidate; no inferences about what is causal are necessary.

Finding associations is a reasonable first step toward the assessment of causality. Associations that are stronger may be believed to be good candidates for both being causal and of public health importance. However, Ioannidis has argued, persuasively, that almost all of Bradford Hill's considerations (not "criteria," as Ioannidis and others have misquoted) for causality have limitations, and maintains that *strength* of association is almost the exact opposite of a good indicator – "when large effects are seen, they are mostly transient and almost always represent biases and errors" [28]. Ioannidis's assessment is largely based on randomized trials, but those are where evidence for causality is likely to be good. He notes that this applies to adverse effects as well as benefits, but has not assessed it

in relation to data mining. That said, it seems likely the same arguments could apply.

Many of the large associations, whether seen in pharmacovigilance, randomized trials, or genome studies, are based on small numbers of exposed cases. Therefore, careful attention to lower limits of confidence intervals may help with considering the magnitude of association. In data mining for pharmacovigilance, it is often the case that cut-offs for signals are based on lower limits of confidence Intervals, and this should probably be a principle in data mining more generally. It may even be argued that it is sensible to use 99%, 99.5%, or even more extreme confidence limits to account for multiplicity [29]. This may lead to too many type II statistical errors, but the problem with method validation in pharmacovigilance is that many of the labeled "true positive" associations could well be false positives themselves, so what is assumed to be a "gold standard" is in fact an "iron pyrites standard" (iron pyrites is known as "fool's gold"!). In addition, Bayesian shrinkage estimates also reduce the large effects seen with small sample sizes. The "shrinkage" can be illustrated using a comparison of an observed count of the numbers of an AE compared with the expected count for that event. The expected count in pharmacovigilance may be derived from a database of spontaneous reports, or from a comparison group in a trial or a pharmacoepidemiologic study. Most measures of association are based on the ratio of the observed (o) with the expected (e) count. A shrinkage estimate will add a constant, usually 0.5, to both the observed and the expected count, and recompute their ratio. If the observed count is, say, 2 and the expected is only 0.1, then o/e = 2/0.1 = 20. This ratio (close to a risk ratio or an odds ratio) is quite extreme, but using (o+0.5)/(e+0.5) gives 2.5/0.6 = 4.2. This is a much less extreme value and the appropriate lower confidence interval will also be much lower. Values are "shrunk" toward the null value of 1. For a more extensive treatment of shrinkage for signal detection, see [30]. The ranking of potential signals must take these considerations into account, so that large (relative) effects with very small observed numbers of cases do not dominate. At the very least, the usual cut-off criteria utilize lower bounds of confidence (or in Bayesian systems, credible) intervals.

There is an extensive literature on how potential signals are highlighted and investigated as part of sophisticated auditable systems for signal management [31–33]. Such management systems include alternative approaches for highlighting emerging signals from spontaneous reports and other sources; this is beyond the scope of this chapter, but suffice it to say that quantitative signal detection plays a core role as the spontaneous reporting repositories increase in size. The whole process is in contrast to *data dredging*, where a search is made for one or a few statistically significant findings, without reporting that such a search has been made and without taking into account the problems of multiple testing. With data mining, it is explicit that many possible associations are found, and further processes will be carried out to find those that are likely to be causal. The wider knowledge discovery process for using data mining as a component of a signal management system has been treated extensively in the pharmacovigilance literature, for example [34, 35].

The "COMPARE" project of Ben Goldacre and colleagues [36] has established that many investigators change the outcome variable specified in the protocol (presumably to get a desirable answer), and this has been found by many others, in the context of both trials [37] and systematic reviews [38]. With transparent methods of data mining, the output should not be treated as if it were a confirmed hypothesis. This is at least partly because bias and confounding are especially challenging for data mining and signal detection. In epidemiologic studies where specific hypotheses are tested, it is possible to consider biases and confounding relating to a specific drug/AE combination. In data mining it

is much more difficult to deal with biases or confounding in a general way. At the very least it can require massive computing power to be able to carry out, for example, high-dimensional propensity score methods, calculating a new score for every one of possibly many thousands of drug/event pairs, and then using a regression method to look at each association.

Hence data mining, which finds associations that may or may not be causal, can nevertheless be useful in some contexts, provided the associations are not taken as providing sufficient evidence on their own of causal effects [39]. Also, methods for association detection can be used to provide ranking for further triage, as well as more granular hypotheses that can be prioritized for future hypothesis-testing studies and helping to refine hypothesis definitions. There is a necessarily iterative element, in that generated or tested hypotheses may stimulate the need for further exploratory analysis, and the process will continue. This broad conceptual use of data mining/signal detection makes rigorous assessment of performance and value challenging. Despite this openness, the credibility and value of data mining and exploratory data analysis (EDA) are supported by clear process and audit trails for the use of such techniques, as exhibited for example in signal detection in SRS as part of overall signal management plans [31].

Using Replication and Transparency to Improve Reliability

Ioannidis has argued that replication is an important component of improving the quality of published findings [40]. This also applies when data mining. In this case, the combining of results across different settings and databases helps to distinguish genuine causal effects from spurious associations. Replication can occur both between different independent groups studying the same question(s) and also within a single group or collaboration. If data mining is to be done across different groups, then a great deal more transparency is required. The Sentinel initiative has an excellent record of doing this, making code lists and software readily available, as does the group called Observational Health Data Sciences and Informatics (OHDSI, pronounced "Odyssey") and its predecessor, the Observational Medical Outcomes Partnership (OMOP). OHDSI includes among its objectives "Reproducibility: Accurate, reproducible, and well-calibrated evidence is necessary for health improvement." This can be a deliberate choice and is open to other investigators to follow its example, although there are many challenges with trying to ensure reproducibility and transparency.

However, the transparency did allow Gruber *et al.* [41] to examine a particular result from the OMOP analyses that they felt was anomalous. The resources required to reexamine more than one such result were noted to be considerable. This anomalous result, a finding of upper gastrointestinal bleeding associated with benzodiazepines, was studied in detail. The conclusion was that the association was largely restricted to the first day of a prescription and unlikely to be a causal finding – "driven by an excess of procedures on the first day of treatment." This seems entirely sensible as an explanation, since benzodiazepines are given prior to endoscopy. Gruber *et al.* conclude: "It is likely that all surveillance programs will need tailored designs that reflect pharmacologic and clinical knowledge." To some degree, this misses the point: if each possible association requires an individual design, it suggests that surveillance is impossible across more than a limited range of issues. What is clear is that, as stated earlier, taking an association that is flagged up by a system as if it were a confirmatory study is a mistake. Further work is required, as in the processes of signal detection leading to confirmation (or not) through signal evaluation. It may be more sensible to ensure that the window during which a possible risk may appear should not generally include the day of a prescription.

Guidelines like the International Society for Pharmacoepidemiology–International Society for Pharmacoeconomics and Outcomes Research (ISPE-ISPOR) guidance on reporting of healthcare database studies [42] and the guideline for the REporting of studies Conducted using Observational Routinely collected Data (RECORD) statement [43] from the "Enhancing the QUAlity and Transparency Of health Research" (EQUATOR) network (http://www.equator-network.org), which includes the CONsolidated Standards Of Reporting Trials (CONSORT) guidelines, may help with this.

Problems of Exploratory and Confirmatory Analyses

Data mining in surveillance of medicines and similar fields is exploratory in nature, as already noted, and generally takes place in one or a few databases. When confirmation of "signals" or other hypotheses that are generated is sought, then it is not generally sensible to carry this out in the same dataset. It is not good enough simply to divide a single dataset (randomly) into training and test sets. A random split will nearly always ensure that the test set will replicate the biases in the training set. It only deals with sampling variability, and provides some limited protection when the model used in the data mining has included factors that are there just because of chance variation. The test set will not reflect the chance factors, but will reproduce the biases. This is why many predictive models developed in one context do not function as well as expected when they are applied in different data. Nonrandom splitting (e.g., by region) may be possible, but totally independent data are required for proper validation.

In practice, however, with the finite, even if large, number of observational databases in total, many will be unsuitable (in terms of variables recorded, data access, and power) to answer some questions. For example, for some questions smoking and lifestyle factors may be vital to address confounding and the number of appropriate independent databases available may be very limited. Frequently there are different studies including both exploratory and confirmatory analyses, which are commonly conducted in the same or overlapping databases. It is not clear that totally independent analyses can be carried out in the same databases, but reanalysis by independent groups may come to different conclusions, showing that there is more than sampling uncertainty (captured in a confidence interval) in the findings. Walker [44] has suggested that it is possible to use the same database and employs the term "orthogonality" to describe assessing other hypotheses related to a primary discovery, which nevertheless add to or subtract from the evidence for causality of the primary discovery. He uses an example of intussusception following a rotavirus vaccine (the primary hypothesis, found by "data mining") and utilizing the same data to see if the vaccine is associated with reports of other conditions that have the same pathology. While Walker argues that this is evidence for causality, Gould [45] disagrees, stating that "hypothesis-generating and test data from the same data source generally cannot be considered 'independent,'" and arguing that the evidence for causality may not be strengthened at all by this approach if there is unmeasured or unanalyzed confounding. Confounding by indication can also apply across related pathologies. Whatever the view, it is important to be clear that overinterpreting concordance with previous findings as if it were as convincing as two completely independent studies is likely to be mistaken. Using the "orthogonal" hypothesis may serve to strengthen evidence, but will rarely be sufficient to confirm a causal relationship.

Fortunately, databases themselves often have a relatively rapid turnover of included patients (e.g., US claims databases), so there can be a reduction in some of the dependence when conducting studies in the same datasets with different time periods. Clear transparency of

exactly how outcomes, exposures, and confounding variables are measured, classified, and utilized in a statistical model is necessary. As always in science, findings need to be related to previous relevant findings to ensure appropriate interpretation by the reader of a single study publication. When exploratory and confirmatory analyses are executed on the same drug safety issue in the same database, it will be important to know what data influenced the design of the confirmatory study and how, and the extent to which the authors (or readers) believe this influenced the results.

The phrase "signal refinement" may be applied to a process akin to Walker's orthogonal approach, in that outcomes related to the primary hypothesis will also be examined. Similarly, looking at whether other related exposures (perhaps the same drug class) have the same effect and whether the pattern with time is consistent contribute importantly to the evaluation. This process of signal refinement or rapid cycle analyses [46] looks more like full studies, and often leads to a full hypothesis testing confirmatory study. In Walker's example [44], having found an association with intussusception, the search for similar associations with gastrointestinal hemorrhage, intestinal obstruction, gastroenteritis, and abdominal pain makes such an exploratory search begin to look like a more formal study. They are exploratory in mindset but with a clear hypothesis on the table. Although the approach is more common now, it has been used previously in the literature, for example by Behrens [47] as a "rough confirmatory analysis." As the boundary between EDA and confirmatory data analysis (CDA) becomes blurred, it will be important that transparent processes are in place to ensure appropriate credible inferences are made from analyses.

A challenge of particular importance in data mining and hypothesis generation is the necessity of rapidity – and the delays in data capture in data sources and their availability for secondary data analysis for pharmacoepidemiology can be a key rate limiter. Developing capabilities for analysis as data, and confidence in its accuracy, accrue will be very important, and clearly the balance between availability and ensuring robust quality is a natural tension. Transparency around process and near real-time quality control of the raw data to the extent possible is required, together with the capability to update analyses over time as needed.

Currently Available Solutions

Data Mining in Spontaneous Reports

The history of routine data mining in pharmacoepidemiology began with the analysis of spontaneous reports of suspected adverse drug reactions [48–51]. It was initially very simple, based only on knowledge from a database of suspected drugs and AEs reported with them. For every combination of drug (classified as drug substance) and AE (classified at, usually, preferred term level according to a hierarchical terminology), it produced a measure of association (disproportionality), then used a cut-off for that measure to classify whether this combination results in a "signal of disproportionality" or not (and subsequent clinical review, leading some of these to be "signals of suspected causality"). The core concepts had been proposed in fact many years previously, though the computing technology had not been applied to every possible combination in a database [52]. Specifically, measures of disproportionality use a two-by-two contingency table for each drug–event pair and look for unexpectedly frequent reporting of the combination compared to the count expected based on general reporting of the drug and the AE if they were independent. The four most commonly used metrics – that is, information component (IC), empirical Bayes geometric mean (EBGM), proportional reporting ratio (PRR), and reporting odds ratio

(ROR) – are all based on this core contingency table [35]. Despite the inherent limitations and oversimplification of the complexities of spontaneous reporting, these metrics have been found to have robust performance characteristics in practice, in the sense that the precision and recall estimates from many independent method evaluations are concordant in suggesting they provide helpful assessments of the data (see, e.g., [53,54]). Thus, they are now widely considered sufficiently strong to justify the usefulness of such approaches as routine surveillance tools for signal detection by regulators and industry [35].

Data mining has looked to include other factors available for individual reports – age, gender of patients, year of reporting, and country in which it was reported [55] – which would modify the metric used. Approaches such as lasso shrinkage regression, a Bayesian approach applicable for regression across the often huge numbers of explanatory variables needed for hypothesis generation, can be used to analyze all possible medicinal products and combinations thereof with a given AE as predictor variable [56]. In contrast to traditional regression approaches, lasso shrinkage regression addresses problems with lack of convergence, prohibitive computational complexity, and unstable parameter estimates that can occur with large numbers of predictor variables. This regression approach does not simply look at a single drug–AE combination, but considers what concomitant medication appears on an individual report. So, if two drugs are reported together, it attempts to obtain the separate effect of each. In practice, this added complexity of algorithm and its implementation do not necessarily lead to more effective signal detection, and care is required with implementation [57]. There are other features on such reports that might be utilized in quantitative analysis, for instance previous medical history, concomitant drugs, weight and height, and time since drug initiation. Usually adding features can improve causality assessment in individual cases, as there is more information to consider in the clinical review; however, where the data are frequently missing (and this is nonrandom), it is not guaranteed that consideration of such features in the quantitative screening leads to gains [55,57].

What has been clear in the past is that there are other issues than simply the counts of reports that should determine whether a signal exists or not [35,58]. It has also been shown that each of the systems basically behaves very similarly (that is hardly surprising when they are based on the same fundamental data), and by choice of the cut-off point for a metric can produce very similar results [50]. What is relatively unusual in terms of pharmacoepidemiologic applications is that all the methods applied to spontaneous reports have considered all possible drugs (with thousands of drug substances) and all possible medical terms (again, many thousands of terms). Some methods were initially applied to a narrow selections of drugs or terms, such as two early publications that conducted disproportionality analyses of specific drug–event issues in cefaclor and serum sickness-like symptoms, and hypoglycemia and ACE inhibitors [59,60]. However, to be useful to regulators and those who use the databases of reports, having a system that can consider every possible combination of drug and AE has been important. Research continues to further optimize, from a statistical point of view, quantitative screening approaches in SRS, combined with more work to integrate the medical aspects into signal management systems [61–72].

Data Mining in Healthcare Databases and Distributed Database Networks

A new strand of research looks to use a different source for signal detection: the utilization of healthcare databases, either medical claims data or electronic health records. These databases have been employed for formal pharmacoepidemiologic studies for many years, but using them

for scanning for a huge number of possible associations is more recent. In these databases the variety of data items is several orders of magnitude greater than with spontaneous reports, and data are clearly collected for a very different purpose than signal detection, so there is very rarely any recorded clinical suspicion of adverse drug reactions. Systematic collection on diagnostic and procedural events prior to exposure, in contrast to spontaneous report, presents a significant potential benefit for signal detection. Signal detection and data mining have been tested in both individual databases and also across networks of multiple healthcare databases. The performance of the whole systems for detecting signals of ADRs have not as yet been as great a step forward as many of us anticipated they would be, in that there is no clear emergence of signals that are being detected earlier in healthcare databases than spontaneous reports, and high false positive rates can still occur [19,73,74].

No single observational data source provides a comprehensive view of all encounters a patient accumulates while receiving healthcare, and therefore none can be sufficient to meet all expected outcome analysis needs. This explains the need for assessing and analyzing multiple data sources concurrently. For some research in pharmacoepidemiology, a common data model (CDM) has been used, which is a standardized database model that aims to standardize terminologies of medical events and procedures, and data structures, to facilitate analyses across data sources. This can help with analyzing data across databases and even across countries, but has the disadvantage of necessarily not making full use of all original data and therefore potentially relevant covariates available in some, but not all, databases. The rapidity at which CDM-based analyses can be conducted is particularly advantageous for signal detection/data-mining activities. The alternative is to have optimal designs in a series of studies in different databases, but with enough commonality in the outcome being studied to allow for meta-analysis to provide greater understanding and precision in the answers. Causality may still be difficult to assess [75], but taking a wide picture may still allow for causal conclusions to be reached in some circumstances.

The (in)famous example of hormone therapy (HRT) is instructive. In spite of observational studies suggesting prevention of coronary heart disease (CHD), regulators generally did not allow prevention of CHD as a labeled indication, but did have sufficient belief in the observational studies to include in product information the harms of breast cancer (BC) and VTE. The later randomized trials did not find benefit for CHD, but instead possible harm and did find harms of BC (for combined HRT) and VTE [76]. The lessons of this should be borne in mind when using data mining in observational data [77]. If data mining is seen as a signal detection process, then the failure to eliminate noncausal associations may not be a major problem, provided that the false positive rate is not so high as to overwhelm the systems for evaluation. However, there can be a temptation for regulators to rely on the associations to amend product information, and it clearly would result in better performance for detecting real effects if noncausal associations can be reduced as far as possible.

One issue that has not been well discussed is whether answers from different data sources should automatically be analyzed simply by adding up the numbers across all studies, ignoring the study source ("crude pooling"), or reported separately and combined using formal meta-analysis techniques. It is well known that, even with randomized trials, crude pooling of data can lead to misleading estimates [78]. Since it is misleading with randomized data, it certainly suggests that crude pooling of results should be avoided. Even if there is no difference between the crude pooling and a meta-analysis, the opportunity to test whether results are similar across data sources is important. Whether there is consistency or not in the estimates of

the effect of the drug from different sources can help decide whether an effect is real or not. The consequence is that it is possible that, even with a CDM, using data mining across multiple databases could lead to spurious associations or a failure to find real associations, as occurred in Xu *et al.*'s study, where discordant results were obtained across the OMOP CDM and Mini-Sentinel CDMs and their associated CDM specific analytics tool implementations, all run on the same database [79].

Much of the work done in health records has not attempted to screen for every possible drug and every possible AE, but has focused on a single or a limited number of drug(s) and AE(s), although this is changing. Scaling up the numbers to consider all possible drugs and AEs is not simply computationally challenging, but even with a low false positive rate can mean an unacceptably high absolute number of signals to examine.

As well as initiatives in Europe and the US, testing of methods of signal detection or data mining is occurring internationally, including, for example, in the Korean national insurance claims database, HIRA [80]. A range of methods for signal detection in healthcare databases have been examined or implemented, including measures of disproportionality as used for spontaneous reports [81], but also several other methods [82–84]. Two methods have received considerable attention, because rather than focusing on trying to generate an individual point estimate for cut-off/filtering/ranking drug–event pairs as potential emerging signals, they concentrate on visualizing how events have occurred relative to the date of a given exposure across an entire database, and therefore leverage more of the data in the record. These two methods are the chronograph, which plots IC values for each drug–outcome event stratified by the month of recording of the outcome/diagnosis before/after a given exposure, and secondly the Longitudinal Evaluation of Observational Profiles of Adverse events Related to Drugs (LEOPARD). For the chronograph, the visualization allows one to find interesting patterns at any time relative to exposure [85,86], and heuristics based on comparison of multiple potential exposed and nonexposed windows have been developed [87]. Similarly, LEOPARD is a method that can be used to attempt to automatically discard false drug–event associations caused when a drug was initiated in response to the underlying disease under investigation or misclassification of the dates of the AEs, by comparing prior event prescription rates to postevent prescription rates [88]. Similar to the chronograph, LEOPARD can generate a single test statistic, or a visualization that can be used for more qualitative information on the relationship between drug and event. Initiatives exploring EHR-based signal detection systems are intended to complement, not replace, existing drug safety surveillance systems.

Data Mining in Other Emerging Data Sources

Social Media

One of the more recent data streams that has become available for interrogation for postmarketing drug evaluation is "social media" or "digital media" – both terms used interchangeably as umbrella terms for many distinct data types [89], such as social media blogging-type sites (e.g., Facebook, Twitter), disease/product-specific discussion forums, patient engagement program data, web search logs (e.g., Google, Bing), and consumer reporting of AEs. The data on the internet are available for analysis through a variety of means. Companies and academic groups "web scrape" the internet to generate anonymized datasets for analysis; secondly, some algorithms and software solutions look to analyze data on the internet directly; and lastly social media companies that host content that users upload to the social media platforms often provide de-identified datasets for analysis, and are welcoming collaborations with external

partners to analyze the large datasets that are produced. All of these diverse data sources may be anticipated to bring different strengths and limitations in the context of signal detection.

Much research is emerging on the potential application of surveillance to social media data, but it is nascent. Examples of analyses of social media data include efforts to compare concordance to quantitative outputs from spontaneous reporting systems, such as the paper by Freifeld *et al.* [90]. They looked at the concordance between AEs suspected based on Twitter posts and US spontaneous reporting, and found a strong Spearman rank correlation. The authors concluded: "Despite the public availability of these data, their appropriate role in pharmacovigilance has not been established." They also suggested that denominator-based pharmacoepidemiologic methods needed to establish baselines and thresholds for "proto AE output" gleaned from social media. Another example is White *et al.* [91], who conducted a comparison of search log outputs and an external reference set of established drug–AE pairs. The authors reported higher accuracy in identifying the OMOP "gold-standard" reference set of known drug–event pairs, compared to that achieved using the US spontaneous reports.

Another example of analysis of social media data is Pierce *et al.* [92]. In this study, 935 246 posts were harvested from Facebook and Twitter over 5 years, and an automated classifier identified 98 252 proto-AEs. The authors focused on searching for proto-AEs that resembled 10 preselected drug–event pairs considered "positive controls" as they were recent FDA postmarketing safety signals, and 6 "negative controls" by randomly pairing each product that appeared in the set of positive controls with one event that appeared in the set of positive controls. A mere 13 posts mapped to the true positive controls across the entire set of posts A, and these were selected for causality assessment of product–event pairs, the clinical assessment revealing that the 13 posts had sufficient information to warrant further investigation for 2 of the 10 possible product–event associations: dronedarone–vasculitis and Banana Boat sunscreen–skin burns. In further analysis, for one of the two product–event pairs judged by the authors as worthy of further investigation, the first report occurred in social media prior to signal detection from the US spontaneous report database, whereas the other case occurred earlier in the spontaneous reporting system. By contrast, no product–event association posts were found among the negative controls. Overall, the literature clearly does not, at this time, articulate a case for replacing traditional spontaneous reporting with social media screening, and in fact remains inconclusive regarding the supplementary value of such activity for signal detection compared to more traditional approaches.

In social media analysis one talks about "annotation"; that is, social media observations with reliable explanatory or commentary notes, which in the case of pharmacovigilance would look to articulate explicitly the chance that a social media observation represented a suspected ADR. Sarker *et al.* in their review [93] made clear that publicly available social media (annotated with relevant medical or drug identification) data were scarce, making study/methods comparisons particularly difficult. This then limits determination of the performance characteristics of social media data analysis. Hence, the extent to which social media are able to accurately highlight emerging safety issues, while minimizing both false positive and false negative findings, is unclear. Many studies on social media have focused on data extraction rather than the novel contribution of such data. Much of the performance evaluation has concentrated on correlation of social media analysis outputs with spontaneous reports, where of course a key question is what the novel contribution of such data stream analysis might be.

Another example of ongoing research is that coming out of the EU Innovative Medicines

Initiative (IMI) "WEB-RADR" project. The project is developing a mobile app for patients and healthcare professionals to report suspected ADRs to national EU regulators, and investigating the potential for publicly available social media data for identifying drug safety issues. Although this project has seemingly made progress in showing the effectiveness of using mobile phones for reporting suspected ADRs [94], the ability so far for identifying any new AE signals more effectively than spontaneous reports and other traditional data sources seems more questionable [95]. Thus, the promise of this new data source for safety surveillance has not yet been fully realized.

Medical literature

While considerable attention has been given to mining social media records, one area possibly unique to drug safety is mining the medical literature for possible identification of ADRs. Manually searching the literature to find reports or other information on possible ADRs or adverse events following immunization (AEFI) is generally time and resource consuming. To overcome this limitation, an interesting semi-automatic approach has been described by Botsis *et al*. [96], who searched for reports of rotavirus vaccines and intussusception. They used text-mining approaches to extract medical terms for primary and secondary diagnoses, cause of death, and plain symptoms from the free text in published abstracts, and then linked them to standard MedDRA codes for further analysis. Various techniques have been developed to automate knowledge extraction for providing appropriate information [97]. The MEDLINE database from the National Library of Medicine (NLM) is a leading source of scientific information. Extracting articles related to ADRs from MEDLINE using a medical subject headings (MeSH) approach has been successfully applied in several projects [32,98,99]. Most success so far has been for signal refinement of signals detected by other methods. As an example, one study [100] aimed to automate the search of publications concerning ADRs by defining the queries used to search MEDLINE and determining the required threshold for the number of extracted publications to confirm the drug–event association in the literature. The MeSH "descriptor records" and "supplementary concept records" thesaurus was used, utilizing the subheadings "chemically induced" and "adverse effects" with the "pharmacological action" knowledge. Employing a threshold of three or more extracted publications, the automated search method had a sensitivity of 90% and a specificity of 100% [100].

Longstanding Biomedical Computing Methods Emerging in Pharmacoepidemiology

Biomedical ontologies with logical classification hierarchies have emerged and played important roles in biomedical knowledge management and data integration, as compared to controlled vocabulary resources. Specifically, a biomedical ontology is a human- and computer-interpretable set of terms and semantic relations that represent all entities in a specific biomedical domain and how these terms relate to each other. A biomedical ontology is automatically computer interpretable, since the ontology is generated using a standard computer-understandable language such as the Web Ontology Language (OWL; https://www.w3.org/OWL/) [101]. As an example, the Ontology of Adverse Events (OAE) is a recent biomedical ontology designed to represent without ambiguity various AEs observed after medical interventions, including drug administration [102]. Compared to controlled vocabulary terminologies such as the Medical Dictionary for Regulatory Activities (MedDRA) and the WHO's Adverse Reaction Terminology (WHO-ART), OAE has many advantages, such as the inclusion of textual definitions for terms and references, logical axioms, and a clearly defined and widely accepted

hierarchical structure [101,102]. Instead of defining an adverse event as shown in MedDRA and WHO-ART, OAE defines an AE as a pathologic process that occurs after a medical intervention and has an unintended outcome of a symptom, a sign, or a further pathologic process (e.g., acute infection). Such an OAE definition semantically links the AE with the medical intervention (e.g., drug administration), patient records, adverse health outcome, and temporal relation between the medical intervention and health outcome [101]. Emerging studies [103–105] suggest that OAE may provide more robust hierarchical structure definitions than MedDRA in terms of AE classification.

Natural language processing (NLP) of unstructured data is a field of computer science, artificial intelligence, and computational linguistics concerned with the interactions between computers and human (natural) languages, and, in particular, with programming computers to fruitfully process large sections of natural-language text to extract information. It is emerging as a tool to leverage underutilized data sources that can improve pharmacovigilance, including the objective of adverse drug event detection and assessment by automatically extracting both the drugs and the potential adverse effects [106]. Research has also looked to uncover information stored in electronic medical record clinical narratives, from which summary information can be shared for research, but not the full narrative. Such an approach was, for example, used in a proof-of-concept study to provide knowledge that acute liver disease (ALD) detection could be identified earlier when an NLP-uncovered clinical narrative was combined with the structured information on ALD [107].

Chemical structure activity and wider systems biology thinking also hold potential. ADRs vary widely in mechanism, severity, and populations affected, making ADR prediction and identification important public health concerns. Systems pharmacology [108], an emerging interdisciplinary field combining network and chemical biology, provides important tools to uncover and understand ADRs and may mitigate some of the drawbacks of traditional data systems such as spontaneous reporting systems. In particular, network analysis allows researchers to integrate heterogeneous data sources and quantify the interactions between biologic and chemical entities. Recent work in this area has combined chemical, biologic, and large-scale observational health data to predict ADRs in both individual patients and global populations [108]. Drugs can act on multiple protein targets, some of which can be unrelated by traditional molecular metrics, and thousands of proteins have been implicated in adverse side effects. Some ADRs are caused by modulation of a drug's primary target, and others result from nonspecific interactions of multiple reactive metabolites. In many cases, however, ADRs are caused by unintended activity at off-targets. Recent informatics methods have been tested to systematically evaluate – on a large scale – new targets to the ADRs of those drugs for which they are the primary or well-known off-targets, creating a drug–target–ADR network [109]. Examples of attempts to include chemical structure and receptor activity relationships in pharmacovigilance have been published [110–112]. In a recently published study [11], the authors investigated the mechanisms underlying the known association of antipsychotic drugs and pneumonia. First, hypothesized mechanisms underlying antipsychotic-related pneumonia were identified through a systematic literature review; thereafter, by mining public repositories of drug targets and drug safety data these mechanisms were confirmed, and other novel antipsychotic drug targets were identified though mapping biologic pathways that could link antipsychotic drug targets and off-targets to pneumonia. In general, innovative approaches for biologic substantiation of drug–AE associations may strengthen evidence on drug safety profiles and help to tailor pharmacologic therapies to patient risk factors.

The Future

Signal detection is a critical component of pharmacoepidemiology. Historically, there has been a near complete reliance on spontaneous reporting systems for signal detection [35]. While these systems have evolved, quantitative signal detection now plays an essential role in signal detection. One wonders if we are a reaching a tipping point, where signal detection in other data streams will be an important routine complement to spontaneous reporting. If this occurs, how will spontaneous reporting evolve?

As part of postmarketing surveillance, regulatory agencies and other institutions have created and maintain large collections of suspected ADR reports. However, confounding factors such as concomitant medications, patient demographics, patient medical histories, and reasons for prescribing a drug often are uncharacterized in spontaneous reporting systems. These omissions can limit the use of quantitative signal detection methods, not to mention the lack of a denominator to allow routine accurate estimation of reporting rates [113]. Improving mechanisms to detect ADRs is a key element in strengthening postmarketing drug safety surveillance. Most signal detection relies on a single information source; methods based on jointly analyzing multiple information sources are an interesting line of research [15].

Indeed, in the future, in the same way as there will be potential consideration of new mobile data (mdata) and device data streams in pharmacoepidemiology, more work will be needed to better consider how to conduct analyses and inferential implications of analyses across multiple data streams. The dangers of getting wrong answers when pooling data across trials or databases seem to be even greater when trying to utilize data from social media with spontaneous reports. It would seem sensible to report them separately, rather than to treat them as a single source of data. When they are concordant, this strengthens the evidence for (but does not prove) a causal association. When they are discordant, this weakens the argument, and investigation of possible reasons for discordance, if evident, may provide additional insight. With these two streams (social media and spontaneous reports), concordance is likely to be greater between them in comparison to EHRs, as there is at least a suspicion of a linkage between drug and AE.

The growth in approaches to developing and implementing common data models portends an increasing availability of high-quality real-world clinical data in support of research. Building on these efforts will allow a future whereby significant portions of the world population may be able to share their data for research.

Spontaneous reporting systems and clinical observations will remain essential for postmarketing drug safety evaluation and in particular signal detection, despite the known limitations. On the other hand, vast amounts of observational data, mostly healthcare databases as part of distributed networks, offer opportunities for better pharmacovigilance surveillance in the future. Use of distributed database networks for rapid drug safety signal substantiation has been consolidating thanks to the relevant contribution of Sentinel and other worldwide initiatives. In Europe, several initiatives through multiple database networks have been conducted with the aim of exploring drug safety issues, despite the substantial efforts that are required to integrate information coming from different European healthcare databases with different underlying healthcare systems, languages, coding systems, and types of collected information (Table 27.1). Use of this source to complement SRSs for signal detection concerning events which are unlikely to be reported is promising, while optimal methods which may minimize substantially the risk of spurious signal detection have not yet been developed. SRSs currently remain the best source for looking at all possible drug–AE combinations, and we do not yet see such a universal approach being implemented effectively using EHR or similar systems. Their

Table 27.1 Harmonization process for the identification of medical events in eight European healthcare databases: the experience from the EU-ADR project.

Table	Fields	Aarhus	ARS	HSD	IPCI	PEDIANET	PHARMO	QRESEARCH	UNIMIB
HOSP	**Main diagnosis**	ICD10	ICD9CM				IC09CM		ICD9CM

role is going to be in the second and subsequent stages of evaluation of signals, or in looking at a range of possible signals in a limited area.

In general, we need to consider healthcare databases for providing postmarketing evidence in situations where the RCT-premarketing evidence is limited. Such is the case for high-cost, innovative medicines with fast-track approval due to a lack of alternative, orphan drugs, or drugs in pediatrics and pregnancy. For example, a healthcare database may provide a substantial contribution in the context of emerging signal detection issues related to biosimilars and biologic reference products, which are expected to be an increasingly discussed topic due to a growing number of biosimilars being marketed worldwide [114].

We live in an increasingly connected world where there is more data accumulated that may have direct or indirect impacts on pharmacoepidemiology. Informatics approaches to help us access, structure, and link data sources to enhance pharmacoepidemiology strategies will become ever more important. There is clearly more work to do in the future that might help in the next generation of new, robust pharmacoepidemiologic strategies. Near real-time clinical help systems allowing interactive healthcare patient support through trusted third parties would be valuable for enriched data collection, assuming privacy and trust concerns can be appropriately addressed. Furthermore, it will be important and interesting to increasingly examine how to leverage such data for pharmacoepidemiology and support their development. More signal substantiation using informatics across other datasets will also be important to examine. Ensuring appropriate, robust generation of evidence and its communication (including explicit communication assumptions and anticipated uncertainty) through transparent approaches will be critical as more and more evidence generation occurs increasingly rapidly. To conclude, we anticipate great advances internationally in the use of data-mining and informatics approaches to inform pharmacoepidemiology, which will act as a complement and serve only to enforce the vital role of more traditional pharmacoepidemiologic approaches in ensuring the safe and appropriate use of medicines.

Pharmacoepidemiologic Research on Drugs of Abuse

Jana McAninch, Alex Secora, Cynthia Kornegay, and Judy Staffa

Division of Epidemiology, Office of Surveillance and Epidemiology, Center for Drug Evaluation and Research, US Food and Drug Administration, Silver Spring, MD, USA

Although pharmaceutical drug abuse is not a new phenomenon, there has been an explosion of interest and research in this area in recent years, largely due to the unprecedented crisis of opioid abuse, addiction, and overdose in the US [1], and to a lesser extent in other developed countries. Beginning in the 1990s, a dramatic rise in prescription opioid overdoses paralleled increases in the prescribing of these drugs in the US, particularly for chronic noncancer pain [2]. The urgency around the opioid epidemic has generated a need to identify and understand emerging trends, identify populations and geographic areas at greatest risk, develop evidence-based interventions, and evaluate the impact of those interventions. There is a need to understand not only the scope and patterns of the problem at the population level, but also individual-level risk factors and the role of pharmaceutical products in substance use disorders and drug overdoses.

From a regulatory standpoint, there is a need to understand misuse, abuse, and related risks associated with specific pharmaceutical products. Related adverse clinical outcomes – including addiction, overdose, and death – may involve not only the pharmaceutical drug of interest, but also other drugs, including illicit street drugs and counterfeit drugs. The US Food and Drug Administration (FDA) has identified five outcomes – misuse, abuse, addiction, overdose, and death – as issues necessitating both postmarketing safety studies and risk evaluation and mitigation strategies (REMS) for opioid analgesics. Although terminology and outcome definitions vary, the FDA has used the following definitions for "abuse" and "misuse":

> Abuse is defined as the intentional, nontherapeutic use of a drug product or substance, even once, to achieve a desirable psychological or physiological effect. Abuse is not the same as misuse, which refers to the intentional therapeutic use of a drug product in an inappropriate way and specifically excludes the definition of abuse. [3]

In some other contexts, for example in the National Survey on Drug Use and Health [4], the terms "misuse" and "nonmedical use" are used more broadly to refer to any use of a drug other than as directed by a healthcare provider. Terminology around drug addiction also varies, and has evolved, particularly with the release of the *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition (DSM-V). The DSM-V

Pharmacoepidemiology, Sixth Edition. Edited by Brian L. Strom, Stephen E. Kimmel and Sean Hennessy.

contains revised diagnostic categories and criteria for substance use disorders [5]. Currently approved opioid analgesic labeling describes "addiction" as:

> A cluster of behavioral, cognitive, and physiological phenomena that develop after repeated substance use and include: a strong desire to take the drug, difficulties in controlling its use, persisting in its use despite harmful consequences, a higher priority given to drug use than to other activities and obligations, increased tolerance, and sometimes a physical withdrawal … Abuse and addiction are separate and distinct from physical dependence and tolerance. [6]

Pharmaceutical drug overdose may be broadly defined as the accidental or intentional use of a drug in an amount higher than is indicated; however, in practice, overdose is often used synonymously with the constellation of adverse effects associated with supratherapeutic use for a particular drug class. These include, for example, severe respiratory and central nervous system (CNS) depression, and, in the case of opioid overdose, possibly death. For simplicity, throughout this chapter we will sometimes use the general term "abuse" to refer to abuse and these related outcomes.

Although many fundamental principles of pharmacoepidemiology apply to the study of pharmaceutical drug abuse, there are also unique challenges and approaches, which are outlined in this chapter. Some of these challenges arise due to the diversion of drugs with abuse potential from the intended patient to others, making complete exposure difficult to ascertain; these individuals are then also at risk for adverse outcomes (Figure 28.1). Outcomes in this area can be difficult to measure, as they often relate to covert behaviors, lack clear definitions, and are not fully captured in traditional healthcare data systems. Therefore, a "mosaic" approach is frequently employed, where multiple studies using a variety of data sources and methods are qualitatively synthesized to answer an abuse-related research or regulatory question.

Finally, the landscape of controlled substance prescribing and substance abuse is ever-changing,

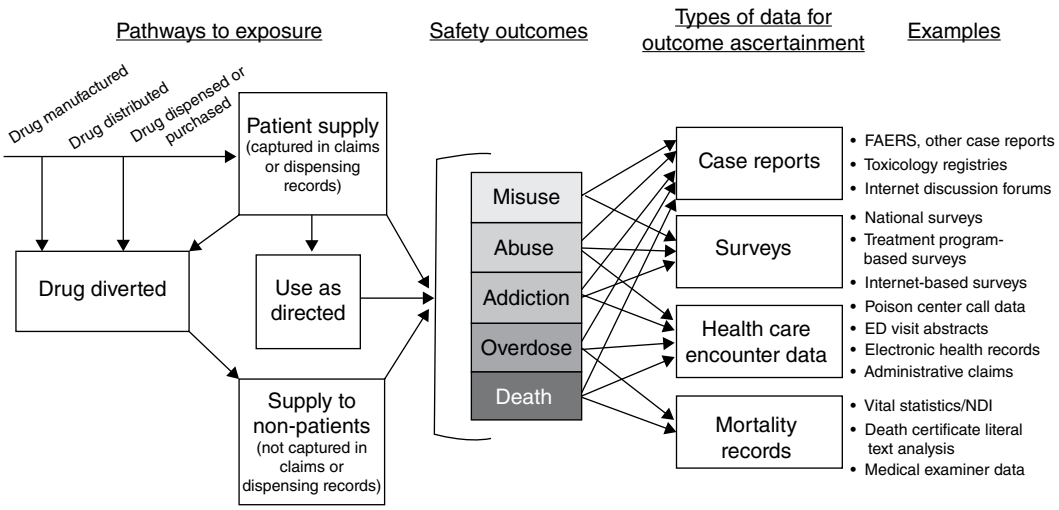

Figure 28.1 Ascertaining exposure and outcomes in studies of pharmaceutical drug abuse. ED, emergency department; FAERS, Food and Drug Administration Adverse Event Reporting System; NDI, National Death Index.

with myriad interventions being implemented at federal, state, and local levels, and with pharmaceutical and illicit drug abuse patterns intersecting in complicated ways that are often difficult to fully characterize. Opioids represent the focus of much of the current research in this rapidly evolving field and are the focus of most of this chapter. Many of the methodologic questions around studying opioid abuse apply to other drugs with abuse potential as well. Prescription stimulants, anxiolytics, sedative/hypnotics, and other drugs with CNS activity have safety concerns related to misuse, abuse, and addiction.

Clinical Problems to Be Addressed by Pharmacoepidemiologic Research

The types of clinical problems that need to be addressed by pharmacoepidemiologic research in this area can be grouped into three broad categories:

- *Signal detection*: to determine whether a drug is being abused in the community, and to understand the associated clinical consequences.
- *Descriptive quantitative assessment*: to determine the scope, demographic and geographic patterns, and trends in use, abuse, and related morbidity and mortality for a drug, class, or drug combination, or to quantify the risk of abuse and related outcomes associated with a drug or class, among those dispensed the drug(s).
- *Analytic studies*: to determine the relative risk of abuse and related outcomes using analytic epidemiologic study designs with comparator groups; for example, to evaluate risk factors for abuse and related adverse outcomes, or the effectiveness of an intervention designed to reduce abuse.

One pharmacologic concept that may take on different connotations when studying drugs of abuse is that of type A and type B reactions. Type A reactions refer to adverse reactions that are the result of an exaggerated but otherwise usual pharmacologic effect of the drug. Type A reactions tend to be common, dose related, predictable, and historically considered to be less serious. Type B reactions refer to aberrant effects, which tend to be uncommon, not related to dose, unpredictable, and potentially more serious. For example, opioid-associated respiratory depression could be categorized as a type A reaction, as it is a predictable dose-related effect that can be managed by reducing the opioid dose. However, in contrast to many type A reactions with other drugs, opioid-associated respiratory depression is frequently life threatening or fatal, and often occurs in association with abuse. The more idiosyncratic type B reactions can also arise in cases of abuse, for example due to the intravenous injection of excipients contained in a product formulation indicated only for oral use. Whereas detecting previously unknown type B reactions represents the major focus of many pharmacoepidemiologic studies, type A reactions – such as opioid overdose – are a primary public health concern and a target of research for drugs with abuse potential.

Signal Detection

The abuse potential of a new drug product with CNS activity is evaluated prior to approval and market introduction based on established criteria that determine scheduling per the Controlled Substance Act (CSA) [7,8]. However, premarket assessments cannot always accurately predict abuse in the community, where sociocultural and economic forces become manifest. Therefore, epidemiologic data are sometimes used to examine whether a drug is being abused in the postapproval setting, and to identify associated adverse clinical consequences. Abuse signals can also help identify potential risk factors or high-risk populations.

Quantitative Descriptive Assessment

As in other areas of drug safety evaluation, quantitative assessment of an established signal may be needed. Such an assessment may seek to quantify the risk of abuse and related outcomes among those exposed to a drug, to better understand the progression from therapeutic use to addiction, or to conduct ongoing surveillance to understand the scope, patterns, and trends in abuse of a drug product in the population. Measuring and tracking drug-involved mortality form one of the central responsibilities of public health, particularly amid the national opioid crisis; however, the complexity of attributing deaths to specific drugs and the variability in death certificate documentation present significant challenges [9].

Some of the assumptions of classic pharmacoepidemiologic studies may not be met when studying abuse and related adverse effects of pharmaceutical products, and modifications to study approaches and designs are often needed. For example, one of the basic principles of studying drug safety issues associated with prescription drugs is that patients use the drugs prescribed to them, and that the date of a dispensed medication approximates the start of the exposure period. However, in the case of drugs with abuse potential, the individual prescribed the drug may give or sell it to others, and may use additional drugs obtained from sources other than their own prescribed medication (i.e., diversion). Therefore, adverse outcomes associated with exposure to a drug can occur in individuals other than those to whom the drugs were prescribed and dispensed. In addition, because drug abuse is generally a covert activity, abuse-related outcomes may not come to medical attention, and can be difficult to measure using traditional pharmacoepidemiologic sources such as administrative insurance claims and electronic medical record data. Many serious social, legal, psychiatric, and physical adverse effects can also occur and yet not be documented in medical records or claims.

Analytic Studies

Finally, there are questions that require analytic study designs, including comparator groups and formal hypothesis testing. Clinical and policy questions often arise regarding risk factors for adverse outcomes such as addiction and overdose. For example, risk factors may include patient characteristics or co-morbidities, drug dose, or concomitant use of other drugs. Another common study question is whether specific interventions – for example, mandatory use of state prescription drug monitoring programs (PDMPs), prescribing guidelines, REMS (see Chapter 24), and opioid formulations with properties designed to deter abuse – are effective in mitigating abuse and related adverse outcomes. To answer these questions, studies may formally compare rates of abuse and related outcomes across drug products or classes, geographic subgroups, or time periods. A wide variety of data – including data not routinely used in pharmacoepidemiology – are used for these types of investigations; however, all have substantial limitations and challenges, as discussed in the next section. The design and interpretation of analytic studies in this area require a thorough understanding of the strengths and limitations of the underlying data and methods, particularly when attempting to make causal inferences.

Methodologic Problems to Be Solved by Pharmacoepidemiologic Research

Despite some overlap, the areas of inquiry described – signal detection, descriptive quantitative assessment, and epidemiologic studies involving comparator groups and formal hypothesis testing – generally require different types of data and methods. As the study questions become more quantitative and analytic, investigations require more systematic and rigorous data collection and statistical methods.

Again, many of the methodologic problems encountered in this subject area are not unique, but some challenges are relatively specific to the study of pharmaceutical drug abuse and related safety outcomes. Both drug abuse patterns and the data systems available to study them vary widely across countries. This chapter will primarily discuss US examples; however, the types of data and methods covered may be relevant for studies in other countries as well.

Data Sources

Signal Detection

Several data sources may be of value for identifying and characterizing postmarket abuse signals for pharmaceutical products. The FDA's Adverse Event Reporting System (FAERS, see Chapter 10) regularly receives reports describing abuse of approved drug products, intentional use via unintended routes of administration, manipulation of the product for the purposes of abuse, and adverse effects associated with these behaviors. Published case reports, case series, and media reports may also play a role in abuse signal detection for marketed drugs. Spontaneous reporting data in this area share many limitations common to evaluation of other safety signals. For example, reports do not always contain enough detail to properly evaluate an event as being abuse related, and many factors can influence whether an event will be reported. Because misuse and abuse are typically covert behaviors, adverse events associated with these behaviors may be even less likely to be reported or brought to medical attention, exacerbating underascertainment of these events in spontaneous reporting systems. Medical toxicology case registries, such as the Toxicology Investigators Consortium (ToxIC) [10], may provide more detailed clinical information and have value for abuse-related signal detection as well.

An emerging source of abuse signal detection is internet-based recreational drug use message boards, discussion forums, social media, and other web-based portals, where individuals discuss their experiences with abusing various pharmaceutical products and other drugs, often comparing preferred routes of abuse and methods for product tampering to increase availability of the active pharmaceutical ingredient. Several proprietary web monitoring programs collect and analyze these types of data [11,12]. In another online data source, individuals anonymously report prices they paid or heard were paid for various drugs [13]. Reports from law enforcement that a drug is being diverted or sold on the street may also serve as a signal that a drug is being abused [14]. Anecdotal reports from sentinel cohorts of known substance abusers (e.g., those using syringe exchange services) may also be useful in elucidating emerging trends in pharmaceutical abuse. As with traditional spontaneous reporting data, these data generally do not support quantitative estimation of abuse or comparison of abuse liability across products or time periods.

Quantitative Descriptive Assessment and Analytic Studies

Quantitative assessments of abuse-related risk, and the scope, pattern, and trends in abuse-related adverse outcomes, require more robust data collection systems, ideally using validated measures and probability sampling methods. Hypothesis testing studies use many of the same data sources, but require even greater attention to data limitations, potential bias, and measured and unmeasured confounding to facilitate causal inferences. Some of the data described in the previous section may provide contextual or supporting information for these types of investigations.

Nationally representative surveys, for example the National Survey on Drug Use and Health (NSDUH) [4] and Monitoring the Future (MTF) [15], can play an important role in both descriptive and analytic (i.e., hypothesis-testing) studies. NSDUH captures information on self-reported

drug-taking behaviors, including the nonmedical use of pharmaceuticals, in the general US population, while MTF focuses on drug-taking behaviors in secondary school students and young adults. National surveys are valuable for studying broad trends in the misuse of pharmaceutical products with known abuse potential; however, the lack of product- and formulation-specific information presents a substantial limitation in the utility of these data for estimating the misuse and abuse of specific drug products. Smaller surveys may target specific populations and drug classes – for example, surveys of college students to study misuse and abuse of stimulant drugs used to treat attention deficit disorder [16] – but the generalizability of these findings is limited. An emerging approach to substance abuse research is the use of "opt-in" internet survey panels, where a survey administration company recruits individuals to join an online panel from which participants may opt to complete various surveys. Internet panel surveys have cost advantages over traditional in-person, school-based, and telephone-based surveys, and they can be more easily tailored to examine specific products or questions [17,18]. However, these surveys do not use probability sampling techniques, and further work is needed to understand the underlying population represented, the selection forces operating, and how these might be changing over time given the rapid evolution of internet and social media use. Another method is to recruit enriched populations through web-based drug abuse discussion forums, by inviting visitors to these websites to complete online surveys exploring specific drug abuse-related questions. The relative ease of modifying these internet-based questionnaires is an obvious advantage, but rigorous questionnaire development and validation are still needed to ensure high-quality data.

Several existing surveillance systems collect information from individuals being assessed for, or who are entering, substance use disorder treatment. One of these is the Treatment Episode Data Set (TEDS). TEDS is an admission-based system that collects and aggregates information on demographic and substance use disorder characteristics among those admitted to substance use disorder treatment facilities that report to state administrative data systems [19]. Similar to national surveys of the general population, however, product- and formulation-specific information is generally not available. Several proprietary surveillance programs in the US collect more detailed data from people entering or being assessed for treatment, including self-reported recent abuse of specific pharmaceutical products and illicit drugs [20,21]. The primary strengths of these proprietary surveillance programs are their comprehensiveness with respect to specific products and behaviors, including route of abuse. The enriched nature of these study populations also improves the precision of abuse estimates for products with lower utilization. However, all of these data systems are limited, in that participant selection and outcome ascertainment depend on an individual seeking or being referred to treatment, and numerous factors (e.g., judicial referral policies and availability of and funding for treatment) affect the probability that an individual who is abusing is included in the sample. Furthermore, the nonrepresentative and dynamic nature of these samples can bias between-drug comparisons, and changes in the distribution of participating assessment and treatment sites over time can bias time-dependent analyses, such as pre–post comparisons and trends, as sites drop in and out of the surveillance networks [22,23]. Finally, all surveys are subject to the misclassification inherent to self-reported data, particularly with respect to respondents' ability to correctly identify specific products and formulations that they have abused. The extent of such misclassification and the degree to which it may be differential – for example, depending on how long a product has been on the market or the manner or order in which it is presented in a survey – are largely unknown and represent important areas for further research.

Call data from poison control centers (PCCs) and data extracted from emergency department (ED) visit records can play a role in understanding the scope, trends, and patterns of pharmaceutical drug abuse and related adverse outcomes, and these data are often used in comparative analytic evaluations as well. PCC data include reports of drug and other substance exposures and consequent adverse effects, based on calls from exposed individuals or someone caring for them, including health professionals [24]. PCC data have several strengths for studying the abuse of pharmaceutical products, including the capture of meaningful abuse-related outcomes, recording of drug exposure at the most detailed level possible based on the information provided, national or near-national geographic coverage, and ability to analyze in near real time. An important limitation of these data is that an unknown proportion of abuse-related events result in a call to a PCC, and it is unclear which factors might influence whether a call is made. Furthermore, these factors might vary over time or across drugs, making interpretation of direct drug–drug comparisons and time trends difficult. In addition, the ability to distinguish specific product brands and formulations (e.g., immediate versus extended release) is limited. Finally, out-of-hospital deaths are unlikely to be captured in PCC data, a critical limitation for potent opioids and other drugs with the potential for rapidly fatal overdose. Some research suggests that trends in the number of opioid-related deaths in PCC data correlate with trends in national mortality data [25,26], but more work is needed in this area to better understand the fraction of poisoning and overdose deaths likely to be captured in PCC data, and whether this varies across drugs or drug classes, with other case characteristics, or over calendar time.

As with PCC call data, data captured in ED visit records provide information not only about abuse behaviors, but also about morbidity and burden to the healthcare system. Again, the completeness and accuracy of these data depend on the completeness and accuracy of the medical records themselves. Currently available national ED surveillance systems are limited in the US. Data collection ended in 2011 for the Drug Abuse Warning Network (DAWN), in which data on drug-involved ED visits were manually abstracted from a probability sample of hospitals [27]. The National Electronic Injury Surveillance System: Cooperative Adverse Drug Events Surveillance System (NEISS-CADES) surveillance network, operated by the Centers for Disease Control and Prevention in collaboration with the Consumer Product Safety Commission, uses similar methods to capture ED cases and generate national estimates for ED visits related to adverse drug events. In 2016, NEISS-CADES began including cases related to drug abuse, withdrawal, or attempted self-harm. The Nationwide Emergency Department Sample (NEDS) is a surveillance system managed by the Agency for Healthcare Research and Quality (AHRQ) [28]. NEDS can be used to generate national estimates of hospital-based ED visits based on ICD-9-CM and ICD-10-CM diagnosis and external cause-of-injury codes; however, information on the involvement of specific drug products is generally not available, and drug molecule/class involvement information is limited by the International Classification of Diseases (ICD) coding system.

Electronic health records and administrative claims data have been used to assess the prevalence of misuse and abuse – or aberrant behaviors suggestive of misuse or abuse – among patients using opioids [29]. Various efforts have been made to create algorithms identifying opioid misuse and abuse using electronic healthcare data; however, both conceptual and operational outcome definitions vary widely [30], and the lack of a true gold standard complicates the evaluation of algorithm performance [31]. Administrative insurance claims may include diagnosis codes and treatment claims for substance use disorder (SUD);

however, identifying these outcomes in claims requires (i) a patient's interaction with the medical system; (ii) a practitioner's recognition and documentation; and (iii) submission of a claim for insurance reimbursement. One or more of these requirements is likely lacking in a high proportion of substance use disorder cases. Drug overdose may be ascertained in claims if medical treatment is sought; however, algorithms need to be sufficiently validated in the data source being used, particularly if they are being used in formal hypothesis-testing studies. Also, due to the high potential for out-of-hospital death, data must include or be linked to a reliable source of mortality data, such as the National Death Index (NDI) [32]. Despite their limitations, if linked to death data claims data may be useful in evaluating patient- and drug-related risk factors for overdose, for example demographic characteristics, co-morbidities, and concomitant use of other drugs. However, socioeconomic, psychological, and legal factors may play particularly strong roles as confounders of associations between drug exposure and abuse-related adverse outcomes, factors not typically captured well in claims data. Claims-based studies are further limited in this area, since pharmaceutical drug abuse and associated adverse outcomes often occur in those who obtain the drugs from a source (e.g., friend, family member, dealer) other than their own prescription, and, as is the case with other pharmaceuticals, self-paid dispensings and over-the-counter (OTC) products are generally not captured.

Vital statistics systems provide information on drug-involved mortality, including deaths that involve pharmaceutical products. These are primarily employed in descriptive analyses, but are sometimes used to evaluate interventions [33] or compare overdose risk across drugs [34]. In the US, the National Vital Statistics System (NVSS) Multiple Cause of Death data files contain national mortality and population data based on death certificates for US residents. Each death certificate contains a single underlying cause of death, up to 20 multiple causes, and demographic data. These data have several important limitations. First, involved drugs are grouped into broader categories based on the ICD-10 Injury Mortality Diagnosis Matrix [35]. Second, documentation of specific drugs on death certificates is entirely dependent on the certifier (e.g., medical examiner or coroner), and death investigation practices and documentation of involved drugs vary widely based on resources, training, location, workload, and other factors. A newly available mortality data resource is the Drug-Induced Mortality database, which links NVSS files to literal text information from death certificates to identify mentions of specific drugs [36], allowing for a more granular analysis of specific drugs involved in deaths, if they are noted [37]. Finally, medical examiner and coroner records, in comparison with death certificates, may be more timely and contain more detail on drug overdose deaths. These data are sometimes made available to researchers through agreements with individual state health departments, and efforts are underway to make these data more available nationally [38].

Data gathered from law enforcement and other agencies on drug diversion cases can be used to identify pharmaceutical products found outside of controlled distribution channels [14], and databases containing information on chemical analyses of drugs seized by law enforcement are another source for monitoring drug trafficking [39]. Diversion information is important for monitoring emerging trends to guide policy, public health, and enforcement activities. It can also provide context and aid in interpreting results of other studies in this area. However, drug diversion data are not direct measures of abuse or related clinical outcomes, but rather measures of law enforcement activity. It is unclear how funding or local law enforcement priorities may influence the number of identified drug diversion cases, the drugs on which investigators focus their efforts, and how these factors may vary over time.

Drug utilization data – from state PDMPs and other retail dispensing and administrative claims databases – are widely available and often analyzed to understand controlled substance prescribing and use patterns, including use in different age groups and geographic regions, changes over time, and concomitant use of multiple classes of controlled substances (e.g., opioids and benzodiazepines). These data are sometimes employed, either with or without linkage to additional data, to try to identify misuse, abuse, or diversion by identifying dispensing patterns suggestive of "doctor/pharmacy shopping," discussed further in the analytic methods section. While these analyses may identify some patients at elevated risk of misuse, abuse, addiction, and/or diversion, their ability to discriminate therapeutic from nontherapeutic use is a subject of ongoing research. Therefore, while "doctor/pharmacy shopping" data may have some value, they should not be interpreted as a proxy outcome measure for abuse.

Analytic Methods

Signal Detection

Methods for abuse signal detection are similar to those used to examine other safety signals, with the case series being the predominant study design. Quantitative approaches, such as Bayesian data-mining algorithms and disproportionate reporting rate analyses (see Chapter 27), can also be used for abuse-related adverse events in spontaneous adverse event reporting systems. These types of analyses have recently been conducted for gabapentinoid abuse in European data systems [40–42]. Calculating more traditional reporting rates for an abuse-related adverse event – using a population-based utilization estimate as the denominator – is also possible, but relies heavily on untestable assumptions.

Web monitoring programs typically employ a mixed quantitative and qualitative approach to studying the abuse of specific products, for example categorizing and quantifying discussion forum postings as positive, negative, or neutral experiences, or identifying posts that discuss recipes for tampering with a product for abuse purposes [43,44]. These types of analyses can be valuable for signal detection and generating hypotheses for formal studies, but they have limited utility for quantifying abuse or making comparisons across drugs or time periods. The use of websites is constantly evolving and the quality of information is highly variable.

Quantitative Descriptive Assessment

Quantitative assessment requires careful consideration of sample representativeness and appropriate denominators. Data from PCCs, ED records, surveys, vital statistics mortality databases, and other types of population data are generally normalized using one or more different denominators, depending on the study question. The first type of denominator is derived from the total study population (e.g., the number surveyed within a given time period) or the population of the study coverage area (e.g., a population covered by participating PCCs or treatment program sites). Estimates using population-based denominators are useful for understanding the scope and public health burden of abuse for different drugs in a population. The large, nationally representative surveys use survey weights to generate national prevalence estimates. Therefore, repeat cross-sectional estimates can be employed to conduct ecologic time-series assessments, often employing trend analysis methods such as time-series regression analysis or Joinpoint regression [45]. Surveys using convenience samples generally cannot be utilized to generate national abuse prevalence estimates, and they present challenges in evaluating trends over time due to nonrandom changes in the study population distribution.

Like other safety outcomes, the frequency of abuse and related outcomes depends in part on the extent to which a drug is prescribed.

Therefore, the second type of denominator incorporates some measure of drug utilization to account for dissimilar or changing levels of prescribed availability. The measure of prescribed availability used (e.g., unique recipients of drug, prescriptions dispensed, tablets dispensed, total morphine milligram equivalents dispensed) can dramatically affect the relative magnitude of the abuse estimates for different drugs [46,47]. Again, the most appropriate metric depends on the question being asked. For example, when comparing abuse rates for drugs with widely varying numbers of tablets per prescription (e.g., immediate-release opioids), the total number of tablets dispensed may be the best denominator, as each tablet can be viewed as an opportunity for diversion and abuse. One might also wish to examine differential abuse rates of different opioid active moieties (e.g., hydrocodone, oxycodone, tramadol), accounting for the different analgesic potencies and dosage strengths available. In this case, the most useful denominator might be total morphine milligram equivalents dispensed. As with population denominators, the appropriate coverage area for utilization denominators can be difficult to define in studies using nonrepresentative convenience samples.

Finally, using some subset of the study population as the denominator can also generate meaningful measures of abuse behaviors. For example, the number of individuals surveyed who report *any* use of a drug (therapeutic or nontherapeutic) may serve as a denominator, allowing estimation of the proportion of those who have *used* a particular drug who also have *abused* it in a given time period. Or, one might estimate the proportion of individuals abusing a particular drug who report doing so through specific routes such as chewing, snorting, or injecting. This type of analysis is sometimes referred to as a drug's "route-of-abuse profile."

Cohort studies can provide valuable descriptive data as well, for example linking electronic healthcare data to death certificate data in a retrospective cohort design to study rates of fatal and nonfatal overdose among patients receiving chronic opioid therapy [48]. Event rates associated with exposure time can be calculated for the overall cohort and in patient subgroups. Defining exposure periods can be challenging due to the poorly understood assumptions regarding the amount of dispensed opioid, the intended and recorded days' supply, and actual patient use. As in other pharmacoepidemiologic studies, these analyses are ideally conducted in incident user cohorts. If available, validated codes or code-based claims algorithms should be used (e.g., for overdose), with portability assessment in the database being used for the study, and linkage to a source of data that captures out-of-hospital overdose deaths. Otherwise, validation should be conducted using medical records, although the lack of a true gold standard for some abuse-related outcomes can complicate these efforts. When evaluating trends over time, the effect of the transition from ICD-9 to ICD-10 must also be carefully considered [49]. Prospective cohort studies using a mix of administrative claims and in-person assessments are also possible, where dispensing claims data can be used to identify eligible patients. In these mixed-methods studies, baseline and follow-up evaluations of misuse, abuse, and addiction can be conducted using validated self- or clinician-administered instruments [50]. A limitation of these studies is that they are designed to evaluate the risk of, and risk factors for, abuse-related adverse outcomes among persons dispensed these drugs, and not in those who obtain the drugs from another source.

As noted in the previous section, drug utilization data alone are sometimes used to try to understand and compare abuse of prescription drugs in the postmarket setting. When concurrent use of two or more drug classes raises concerns about increased risks of abuse, addiction, or overdose (e.g., opioid analgesic combined with benzodiazepines), concomitancy analyses

can be conducted in drug utilization databases to understand the extent and characteristics of this potentially problematic concomitant use. "Doctor/pharmacy shopping" analyses typically use a large retail dispensing database or PDMP to create classification schemes that incorporate the number of different prescribers and pharmacies identified in overlapping or nonoverlapping controlled substance prescription dispensings [51,52]. However, these metrics have not been validated sufficiently to determine how well they distinguish between abuse-related behaviors and other drivers for these dispensing patterns that are unrelated to abuse. Research is ongoing to better understand these "doctor/pharmacy shopping" measures and the degree to which they might be useful in discriminating between therapeutic use and abuse- or addiction-related behavior [53]. Although these types of analyses can be useful descriptive and hypothesis-generating exercises, drug utilization analyses without linked outcome data are generally not appropriate for the formal assessment of abuse, as many factors unrelated to abuse may contribute to aberrant-looking drug prescribing or dispensing patterns.

Analytic Studies

More complex pharmacoepidemiologic methods are generally necessary when the objective of a study is to formally assess risk factors for abuse-related outcomes [54], or to compare abuse risk across products or time periods, for example to understand the effect of an intervention designed to reduce the risk of abuse and related adverse outcomes. As risk is a longitudinal concept, cohort studies are, in theory, ideally suited to answering these types of questions. For relatively rarer outcomes, such as fatal overdose, case–control designs may have some utility as well. Prospective cohort studies may improve ascertainment of behavioral outcomes, such as misuse and abuse, that are not captured well in claims or other electronic healthcare data. However, these may often be infeasible due to the challenges in recruiting and retaining appropriate study populations and the long follow-up that may be necessary to observe outcomes such as addiction. Designing longitudinal studies is complicated by the aforementioned challenges related to both exposure and outcome ascertainment. In addition, confounders and effect modifiers of the drug exposure–abuse–overdose causal pathway for opioids and other drugs have not been fully characterized, and are topics in need of empiric research. Selection of comparators and use of statistical applications such as propensity score matching, as well as inverse probability of treatment weighting, are all topics for further methodologic work in this area. The use of historical time periods as comparison groups (e.g., comparing the risk of overdose associated with a product before and after an intervention) is complicated by the evolving landscape of abuse trends in general, as well as insurance access and inclusion of higher- and lower-risk individuals.

When cohort studies are not feasible or warranted for a given study question, other study designs and types of data (e.g., from PCCs, ED records, and surveys) are often employed for comparative evaluation of the risk of abuse and related outcomes across multiple products. The limitations of each of these types of data must be carefully considered in the design, analysis, and interpretation of studies. Sensitivity analyses are often necessary to explore the potential effect of untestable assumptions, particularly around missing data, differential and nondifferential misclassification, and sampling bias, particularly in nonprobability samples. When appropriate for the question being posed, the prescribed availability of the drugs under study (e.g., prescriptions or tablets dispensed) may be accounted for either as an offset or as a predictor variable in statistical models. Evaluation of new market entrants and drugs with persistently small prescription volume is particularly challenging, due to low levels of population

exposure and small event counts in most abuse surveillance systems [55].

When evaluating interventions, isolating the effect of a specific intervention from the effects of other interventions and secular trends – confounders by calendar time – is a particularly challenging endeavor, especially in the case of opioid analgesics, and it is important to consider other factors that can affect prescribing and abuse trends. Examples include changes in formularies and insurance coverage policies, provider education initiatives and practice guidelines, increasing use of PDMPs, law enforcement operations to reduce inappropriate prescribing and dispensing (e.g., "pill mill" crackdowns), and the availability and cost of alternative drugs of abuse, including illicit drugs. In some instances, comparator products expected to be similarly affected by these external forces are used to control for the effects of these confounders; however, additional strategies may sometimes be warranted, for example adjusting for geographic differences in the implementation of important concurrent interventions. In most cases, one or more comparators are selected to approximate the counterfactual [56], using them to approximate the expected abuse trends and patterns in the absence of an intervention (e.g., formulation of an opioid product with abuse-deterrent properties).

When studying changes in outcomes before and after a reformulation of a drug or other intervention using a pre–post design, comparators are often incorporated into models using a drug-by-time interaction to conduct difference-in-difference analyses. One approach is to compare the mean rate or prevalence of abuse between a specified pre-period and post-period, and then to compare the magnitude of any observed change to that of a comparator; however, these analyses do not fully take into consideration preexisting secular trends, either for the drug of interest or for the comparator. Particularly in situations where baseline use and abuse rates are not stable, interrupted time-series analyses (e.g., segmented or piecewise linear regression) can be used. The latter approach is generally preferable, but is not feasible without an adequate sample size and a sufficient number of data points in each time period. These analyses also have their own set of assumptions, for example about linearity and the lack of concurrent interventions. Multiple comparators are often used because no single comparator is ideal, given inherent differences in baseline characteristics such as abuse rates and patterns. The use of multiple comparators complicates hypothesis testing and overall interpretation of findings, however. Composite comparators (multiple drugs grouped together) are sometimes used, but these may include drugs that vary widely in market share and utilization and abuse trends, further complicating interpretation. In some instances, it may be useful to include both "positive" and "negative" controls; for example, a drug known to have a high risk of abuse or expected to be greatly affected by an intervention, and another with no or low abuse potential or not expected to be affected by an intervention.

Interpretation

The interpretation of abuse-related findings depends on the study question, the source of data, and the methods used to analyze them. A review of spontaneous or anecdotal reports of abuse or abuse-related adverse outcomes may be adequate to establish a safety signal, but would not be an appropriate basis for quantifying differential risk between one product and another. Descriptive analyses of population data – for example from national surveys, ED visit data, or death certificates – are important for guiding public health and law enforcement policy, resource allocation, drug regulation, and design of interventions. Understanding the data and their limitations is critical to proper interpretation of study findings, for instance avoiding conflation of utilization and abuse trends, and

accounting for jurisdictional variation in the documentation of specific drugs in fatal drug overdoses [57].

When interpreting the results of hypothesis-testing studies, the goal is generally causal inference, determining, for example, the causal role of opioid analgesic dose in overdose risk, or the effect of an abuse-deterrent formulation on the likelihood of a drug being insufflated or injected. Often, a mosaic of different types of data and study populations must be qualitatively synthesized to make a causal inference. Fundamental epidemiologic principles such as the Bradford Hill causality criteria [58] can be helpful in this endeavor. Particularly important elements in this area are temporality, strength of association, consistency of findings across multiple populations and study designs, coherence with experimental data, specificity of effect, and consideration of alternative explanations. Ultimately, the interpretation may be a largely qualitative determination, or include a range of possible effect estimates that take into consideration both random and systematic errors and effect modifiers.

Finally, the unit of analysis and the potential for ecological fallacy must be considered. In particular, one must exercise great caution when drawing inferences about individual-level risk from ecologic analyses. For example, a study may show a decline in the prevalence of nonoral abuse of a product within a given population after that product was reformulated with properties designed to deter intranasal and injection abuse. Although a change in the prevalence of a specific drug's abuse by more dangerous routes in the community may be an important finding, one cannot directly infer that individuals exposed to the drug have a reduced risk of abusing the drug through these routes. Similarly, correlations in trends for different drug classes – for example, prescription opioid overdose deaths plateauing as heroin death rates rise [59–61] – are important for generating hypotheses, but do not provide direct evidence of individuals transitioning from one drug to another. Addressing this issue directly would require a longitudinal study analyzed at the individual level.

Currently Available Solutions

Despite their many challenges, pharmacoepidemiologic investigations and advances in methodology have contributed to answering many important clinical, public health, and regulatory questions involving pharmaceutical drug abuse and related adverse outcomes. Some examples include the three major types of questions addressed by research in this area.

Signal Detection

Pharmacoepidemiologic data have been used to determine whether a currently marketed drug is being abused in the community, and to identify important clinical adverse consequences of this behavior. A recent example was the regulatory action involving the OTC antidiarrheal drug loperamide. Loperamide is a peripherally acting opioid agonist that does not have significant CNS effects when used at recommended doses, and has been available without a prescription in the US for about 30 years. However, FAERS reports and multiple published case reports began to emerge in recent years, identifying serious cardiac arrhythmias associated with loperamide ingestion at many times the maximum recommended dose, typically among individuals attempting to self-treat opioid withdrawal symptoms or attain a euphoric effect [62]. These reports were accompanied by a published analysis of an internet discussion forum describing misuse and abuse of high doses of loperamide, as well as the reasons and subjective experiences that individuals reported [63]. This analysis noted a recent sharp increase in internet postings related to the misuse and abuse of loperamide, as well as mentions of

concomitant use of other medications in an attempt to facilitate the CNS penetration. Finally, rates of loperamide intentional exposure calls to PCCs in the US also increased markedly [64]. Based on this body of evidence, in June 2016 the FDA issued a Drug Safety Communication warning that taking higher than recommended doses of loperamide in the context of abuse or misuse of the product, or otherwise, can cause serious cardiac problems that can lead to death. In addition, the FDA required labeling changes for loperamide products to alert healthcare providers and consumers to these risks [65].

Descriptive Quantitative Assessment

Descriptive analyses of population data on drug misuse, abuse, addiction, and overdose are widely used for public health surveillance [2]. They are also used to inform decisions on drug scheduling and other regulations intended to minimize these risks. In October 2014, based on the FDA's review of the available epidemiologic and other scientific data, the Drug Enforcement Administration rescheduled hydrocodone combination products from Schedule III to the more restrictive Schedule II of the CSA. The FDA's review of the available epidemiologic data included analyses of ED visit data from the now defunct DAWN system, survey data from NSDUH and MTF, and selected state medical examiner data on drug-involved mortality. The review found that, after adjustment for prescription volume, the abuse prevalence of hydrocodone combination products appeared to be lower than that of Schedule II comparator products. However, both use *and* abuse were found to be widespread, and, from a public health standpoint, the products were determined to pose a significant absolute risk to the community [66]. Therefore, the decision to recommend the more restrictive scheduling was based largely on analyses using population-based (rather than utilization-based) denominators, which suggested a large public health burden associated with these products.

Descriptive Quantitative Assessment and Analytic Studies

Sometimes, descriptive and analytic pharmacoepidemiologic investigations are used together to guide public health or regulatory actions. A recent example is the issuance of a boxed warning – also commonly referred to as a "black box warning," which appears on a prescription drug's label and is designed to call attention to serious or life-threatening risks – describing the serious risks and death associated with concomitant use of opioids and benzodiazepines and other CNS depressants [67]. This regulatory decision relied on studies suggesting both increasing trends in concomitant prescribing, misuse, and overdoses involving opioids and benzodiazepines together, as well as an elevated risk of fatal overdose associated with concomitant use of these two drug classes. One descriptive study examined concomitant use patterns of opioid analgesics and benzodiazepines using a proprietary source of retail pharmacy dispensing data (IMS Health®). Investigators observed that despite multiple published clinical guidelines advising against co-prescribing of opioid analgesics and benzodiazepines, the proportion of opioid analgesic recipients receiving an overlapping benzodiazepine prescription increased by 41% between 2002 and 2014. They also found that a majority of these overlapping prescriptions were written by the same prescriber [68]. Another descriptive study used DAWN to analyze ED visits due to nonmedical use of both prescription opioid analgesics and benzodiazepines, and the NVSS Multiple Cause of Death file to analyze overdose deaths involving both opioid analgesics and benzodiazepines. Between 2004 and 2011, rates of both nonmedical use-related ED visits and fatal overdoses involving both drug classes

increased sharply, and the proportion of overdose deaths due to prescription opioid analgesics that also involved benzodiazepines rose from 18% to 31% [69]. Two analytic epidemiologic studies published in the medical literature suggested an increased risk of fatal overdose in patients dispensed both opioid analgesics and benzodiazepines. First, a cohort study linking North Carolina medical examiner data and state prescription drug monitoring program dispensing data found that rates of overdose death among patients co-dispensed opioid analgesics and benzodiazepines were 10 times higher than those among patients dispensed opioid analgesics alone [70]. Although the ability to control for confounding is limited in this type of study, the magnitude of effect suggested an elevated risk of death with this drug combination. Second, a case–cohort study examined Veterans Health Administration data from 2004 to 2009 and found that the risk of death from drug overdose significantly increased among patients with concomitant opioid analgesic and benzodiazepine prescriptions compared to patients taking opioid analgesics without receipt of a benzodiazepine, after controlling for both baseline and time-varying confounders [71]. In summary, a variety of pharmacoepidemiologic studies, both descriptive and analytic, were used to characterize a growing public health problem in this area and support new warnings on product labels.

Researchers, public health practitioners, policymakers, and regulators frequently use epidemiologic data to evaluate the impact of interventions intended to increase the safety of controlled substances. Much of this work in recent years has focused on opioid analgesics, for example evaluating the impact of interventions such as PDMPs [72], implementation of opioid analgesic prescribing guidelines [73], and pain clinic regulation [33]. Other subjects of interest are the assessment of opioid analgesic REMS and the effectiveness of abuse-deterrent opioid analgesic formulations. As already described, this is one of the most challenging areas of pharmaceutical drug abuse pharmacoepidemiology. The use of multiple different study designs, data sources, denominators, and comparators, as well as sensitivity analyses, can help to evaluate assumptions that are difficult to test empirically; for example, misclassification of products in self-reported data, sampling bias, the best approximation of the counterfactual, or the relationship between the prescribed availability of a drug and the likelihood of abuse in a population.

A recent example where this approach was useful was the evaluation of postmarketing data for reformulated Opana® ER (oxymorphone extended-release) [74], which ultimately resulted in removal of this product from the market [75]. Opana ER was an opioid product initially approved by the FDA in 2006. In 2012, a reformulated version was introduced with a proprietary polyethylene oxide–containing matrix designed to make the drug more difficult to crush into a powder or dissolve in solution for abuse via nonoral routes. In 2017, the FDA convened an advisory committee meeting to discuss the postmarketing safety data on the reformulated product. Key to this evaluation were epidemiologic data collected from individuals entering or being assessed for substance use disorder treatment within the National Addictions Vigilance Intervention and Prevention Program (NAVIPPRO®) Addiction Severity Index-Multimedia Version (ASI-MV®) surveillance network. These data suggested that after Opana ER was reformulated, the predominant route of abuse shifted from the intranasal to the more dangerous injection route. However, substantial changes also occurred in the geographic distribution of the sites participating in the NAVIPPRO network and in the distribution of treatment settings in which individuals were being assessed. These changes resulted in a shift in the study population toward sites, specifically in Tennessee, where both Opana ER abuse and more severe substance use disorders and injection drug use

were highly prevalent. Sensitivity analyses were used to explore this potential bias, restricting the sample to sites contributing data in every quarter of the study period, as well as stratifying analyses by site location within and outside Tennessee. The shift in the route of abuse profile for Opana ER was consistently observed in all of these analyses. PCC call data also indicated a shift in the route of abuse profile of Opana ER, although both the PCC and treatment center survey data were limited by difficulties distinguishing between brand and generic versions and original and reformulated versions of a product, a critical distinction because only the branded product was reformulated. The potential for differential misclassification across these products limited the ability to make inferences about changes in population- and utilization-based abuse rates over time. Therefore, changes in route of abuse patterns over time in the subgroup reporting abuse of Opana ER became a critical piece of information, as product misclassification is less likely to bias change estimates away from the null for these conditional probabilities.

The Opana ER example also illustrates how multiple studies, each with limitations, can be qualitatively synthesized using fundamental epidemiologic principles, including Hill's criteria, to make a determination regarding the effect of an intervention. The marked shift from intranasal to injection abuse of Opana ER corresponded temporally with initial marketing of the reformulated product, and a shift of similar magnitude was not observed for any other opioid comparator analyzed. The shift in the route of abuse was observed in multiple epidemiologic data sources and populations, and was coherent with other types of data, including premarket experimental abuse liability data. The patterns seen in the epidemiologic data were also consistent with spontaneous and anecdotal reports. A FAERS case series indicated that prior to Opana ER's reformulation, the vast majority of reported cases of nonoral abuse described the intranasal route, whereas after the reformulation, cases of intravenous abuse began to emerge. The review of FAERS reports also identified an association between intravenous use of reformulated Opana ER and a rare hemolytic microangiopathy. Finally, investigation of an unprecedented HIV outbreak in rural Indiana indicated that Opana ER abuse via injection was virtually universal among those newly infected with HIV, and that users reported switching from the intranasal to the injection route after the drug was reformulated. Interviews with drug users in the community indicated that the hardening and gelling properties of reformulated Opana ER were driving users to increase the volume of solvent and to share pills and "cooking" equipment, resulting in increased injections and opportunities for transmission of blood-borne infections [76]. In summary, although each individual study and source of postmarketing data had limitations, synthesis of all the information using fundamental principles of causal inference led to a determination that the benefits of reformulated Opana ER as an opioid analgesic option no longer outweighed the risks associated with abuse of this product.

The Future

The opioid crisis has elevated the urgency of pharmacoepidemiologic research on drugs of abuse; however, data and methods developed to improve research on opioid analgesics are valuable for studying abuse of other pharmaceuticals as well. Robust surveillance systems and systematic data linkages are needed to support these investigations, and efforts are underway to develop such data systems at the national and state levels. Although no single data source or method is ever expected to be sufficient to address all questions about drug abuse, the most useful data systems and methods to support

future pharmacoepidemiologic research in this area would feature several characteristics:

- Identification of specific products, formulations, and routes of abuse, with the ability to evolve in response to changes in the pharmaceutical market.
- Rigorous development and validation of survey instruments and coded algorithms, using innovative methods to minimize misclassification.
- Use of probability sampling methods when feasible. Where infeasible (e.g., when using emerging approaches such as internet/mobile phone surveys), conducting external validation studies to ensure that results can be applied to a well-defined target population that is stable over time.

Further empiric research is needed to identify and appropriately adjust for individual- and community-level confounding and to better characterize the relationship between prescription volume and abuse rates, in order to understand the degree to which prescribing is driven by the demand of those intending to abuse or divert the drug. More studies using longitudinal designs are also needed to understand the progression from therapeutic use of pharmaceutical products to abuse, addiction, and related harms, and where we can intervene to prevent these outcomes.

Finally, the opioid crisis has highlighted the intertwined nature of pharmaceutical and illicit drug abuse. This interconnection emphasizes the sociocultural and economic forces driving drug abuse, and has spurred interest in methods that fall outside of traditional pharmacoepidemiology but are well established in the broader field of substance abuse research. These often include more qualitative and mixed-methods approaches that may enhance our understanding of patterns observed in the epidemiologic data.

The evaluation of reports of suspected adverse drug reactions in the clinical setting or in a clinical trial is a judgment about whether – and the degree to which – any reported event is, in fact, causally associated with one or more suspected drug(s). In reality, a particular event either *is* or *is not* associated with a particular product. However, our current tools almost never allow a definitive determination. Accordingly, a number of approaches to the assessment of the probability of a causal drug–event association have evolved and are utilized in determining the possibility that a drug contributed to an event. This chapter will discuss the evolution of these efforts and several of the current approaches and uses. It will then review the evolving regulatory changes on this topic, including a brief consideration of the evaluation of single events in the clinical trial setting. The focus of this chapter is on causal assessment of individual events and differs from the approach to assessing general causality as discussed in Chapter 3.

Understanding Potential Causal Relationships Supports Clinical and Regulatory Evaluations and Actions

Figure 29.1 illustrates the basic clinical problem to be addressed: An adverse event occurs within the milieu of a number of possible causal factors. That event either occurred independently or was partially or totally linked to one or more of the potential causative agents. The assessor's task is to determine the degree to which the occurrence of the event is linked to one particular suspected causal agent – a drug or other medical product.

This task is similar to evaluating causality in chronic disease epidemiology, as discussed below. However, in disease epidemiology, causality relates to events in populations and to the assessments of those events in one or more population studies. In medical products

Pharmacoepidemiology, Sixth Edition. Edited by Brian L. Strom, Stephen E. Kimmel and Sean Hennessy.

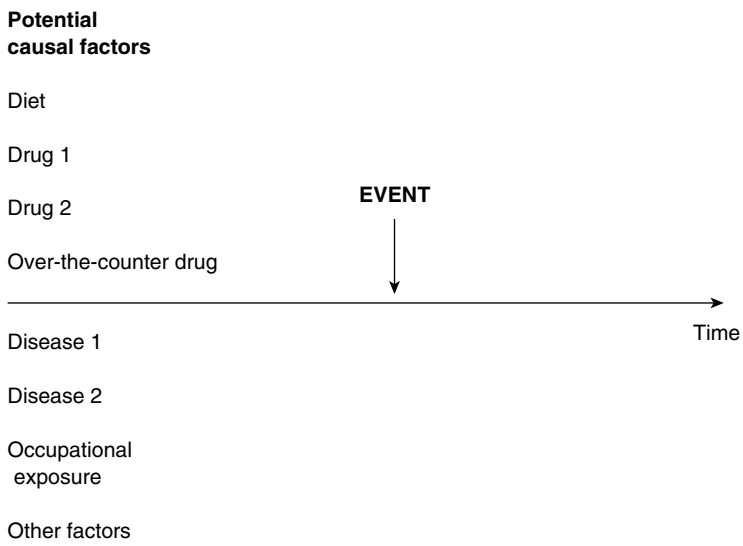

Figure 29.1 Diagram depicting the dilemma for determining causation of an event in a clinical setting. In reality, a drug either did or did not cause or contribute to an event. However, given the multiple factors associated with the event, the actual truth can seldom be ascertained. Instead, some expression of probability that the drug was associated with the event is made. The method by which this expression is determined is the primary concern of those in adverse reaction causality research.

epidemiology, assessing causality from individual case reports of suspected adverse reactions to a medical product represents a different, equally complex challenge due to multiple factors.

Observations of medical events and resulting reports are often *biased*: A reporter reports because he/she suspects a causal relationship between the product and the event. Thus, alternative causes can be overlooked or ignored and few or no data are collected that might support the alternative(s).

Data are frequently *incomplete*, often omitting details on:

- reason for use
- age, gender
- product exposure including dose, actual dose ingested, duration of use, prior exposure
- route of administration
- concomitant medical products
- patient medical history
- details of the adverse event including onset, characteristics, time course, and outcome
- baseline laboratory data and other important clinical factors (because the suspicion is usually retrospective and the desired data are often not available when the report is made)
- whether the event stopped when the product was withdrawn (dechallenge)
- whether the event returned when the product was resumed (rechallenge)
- outcome of the event
- follow-up information.

Case reports from clinical trials and hospital settings tend to be more complete than reports submitted in the postmarketing setting.

Adverse reactions can be acute, subacute, or chronic, can be reversible or not (e.g., death and birth defects), can be rare or common, and can be pathologically unique or identical to known common diseases. Therefore, the challenge has been to define general data elements and criteria for assessing causality that will apply to *most* types of suspected adverse reactions. For example, for irreversible events such as birth defects or death, data on dechallenge (what occurs when a drug is discontinued) and rechallenge (what occurs when a drug is reintroduced) are irrelevant.

Since the assessor must make, at the very least, an implicit judgment of causality, and since evaluations of case reports are an important part of postmarketing surveillance, methods

were devised in an attempt to develop a coherent, consistent, and reliable way to assess the degree, if any, of a causal relationship between exposures and events.

Assessment of a potential causal relationship is closely linked to the reason for making that particular causality assessment, and the impact of that judgment. If the causality assessment is perceived to have little impact on future actions relating to either a patient in a clinical setting or to product labeling in the regulatory environment, it might logically be less rigorous. Conversely, if continuation of a clinical trial or continued approval of a drug hinges upon the assessment, the reliability of the method becomes more critical. The need for consistent and reliable methods of causality determination [1] has become more important with greater focus on the entire subject of adverse drug reactions, the introduction of concepts of causality assessment into more drug regulatory language, and product liability.

Moreover, worldwide and country/region-specific regulations all require reporting of events in clinical trials and in the postmarketing period. This chapter will discuss the US and European requirements briefly as well as the French method.

Historical Perspectives

Development of Concepts of Causality for Adverse Reactions

The development of thinking about the causality of adverse drug reactions evolved in two disciplines: epidemiology and the study of individual case reports of adverse reactions. Consideration of both is important.

In the 1950s, epidemiologists grappled with the issue of disease causality. Yerushalmy and Palmer [2] developed a set of proposed criteria for causality related to the association of exposures with events. They drew upon the Bradford Hill causality criteria (described in more detail in Chapter 3) as well as the Koch–Henle postulates for establishing causation for infectious diseases. After considerable deliberation with other epidemiologists, Yerushalmy and Palmer's method was refined into the following five criteria to determine the causal nature of an association.

1) Consistency
2) Strength
3) Specificity
4) Temporal relationship
5) Coherence, or biological plausibility [3]

While actively discussed and criticized [4], these criteria continue to be generally used in chronic disease epidemiology. They are most appropriately applied to population-based data rather than in evaluating individual cases or groups of cases from poorly defined populations. However, sometimes when large numbers of cases are considered, possibly along with population-based data on an adverse event, Yerushalmy and Palmer's criteria are invoked. For example, they form the basis for the World Health Organization's (WHO) evaluation of collective data on vaccine adverse effects by the Global Advisory Committee on Vaccine Safety of the Immunization Safety Priority Project [4]. Shakir and Layton cited these criteria as useful for considering the overall data, including spontaneous reports, on an adverse event [5]. Although seldom explicitly noted, the reasoning behind Yerushalmy and Palmer's criteria appeared at about the same time as thinking about the causal assessment of individual reports of suspected adverse drug reactions.

In the past, and occasionally currently, association between a drug and a reported adverse event was typically assumed if there were a number of similar reports [6]. Considerations of pharmacologic plausibility, dose–response, and timing factors were sometimes implicit but seldom explicit. More recently, this tendency has been supplanted by more specific methods,

proposed and in use since the 1980s, which will be detailed later in this chapter.

One of the most widely used tools is known as either "global introspection" or "unstructured clinical judgment." In it, more perplexing single or multiple suspected drug–event associations get referred to one or more experts. The experts collect all the facts relevant to the problem, compile them, and make *unstructured judgments* to assess the potential relationship. The answer is usually expressed in terms of a qualitative probability scale: "definite"; "probable"; "possible"; "doubtful"; or "unrelated" [7].

The recognized subjective nature of global introspection as an approach prompted the development of more structured methods of causality assessment. Irey, in examining the details of cases of suspected adverse reactions at the US Armed Forces Institute of Pathology in the 1960s, clearly demonstrated the discrepancy between cases initially reported as drug associated and those smaller number of cases found by careful detailed examination to likely *be* drug associated [8,9]. Shortly thereafter, clinical pharmacologists Karch and Lasagna also recognized the inadequacy of expert "global" evaluations of adverse reactions and developed an algorithm to segment the evaluation of a case into several components [10]. These two groups of investigators identified very similar basic data elements that they felt were necessary for a more standardized assessment.

- The timing of the event relative to the exposure.
- The presence or absence of other factors which might also cause the event.
- Dechallenge.
- Rechallenge.
- Other data supporting an association, for example, previous cases.

These criteria are specifically related to the special characteristics of suspected adverse drug reactions. They apply to causality assessments using either a single case or a group of cases from an ill-defined exposed population. Thus, it was thought that there was only a partial correspondence to the Bradford Hill criteria for chronic disease epidemiology; but in fact, the temporal relationship does also apply. Furthermore, in assessing the causality of either a single report or a series of cases outside an epidemiological context, there is no way to evaluate the consistency, strength or specificity of the association. The exception would be some rare, drug-associated disorders where the event in fact was uniquely and specifically (due to a defined pharmacologic or biologic mechanism) associated with a drug. For example, some patients treated with sulindac developed renal stones containing sulindac crystals.

Further, Aronson and Hauben proposed four types of adverse reactions reports where "attribution to the drug is either irrefutable or demonstrable to a high level of confidence" [11].

1) Deposition of the drug or metabolite in extracellular or intracellular tissue.
2) A very specific anatomic location or pattern of injury, such as injection site edema or inflammation.
3) Direct tissue injury or physiologic dysfunction that can be proven by physicochemical testing, such as esophageal injury with bisphosphonates.
4) Infection resulting from administration of an infectious agent, such as in bacterially contaminated injections.

Following the introduction of these assessment methods, several other approaches were developed [12–20], either as algorithms, decision tables or, in at least one case, as a diagrammatic method [19,20]. Many of these were reviewed and summarized in monographs from conferences held in the early 1980s on the causality of adverse drug reactions – two in Morges, Switzerland [21], and another in Crystal City, Virginia [22]. Most of these methods shared the basic elements originally suggested by Irey and Karch and Lasagna, but some added numerous

other details useful for the evaluation of special cases, such as injection site reactions or *in vitro* verification [18]. Some included extensive scoring systems linked to relatively extensive algorithms, such as the approach published by Kramer *et al.* [12]. Selected methods from Kramer *et al.* are discussed in detail in the next section of this chapter.

The Morges conferences [21], the 1983 Crystal City conference [22], and a 1983 Paris meeting [23] were all convened to compare a number of these approaches and to consider whether a single "gold standard" method might be developed that could represent an international consensus to be used by regulators and pharmaceutical sponsors alike. An international study group, the Active Permanent Workshop of Imputologists (APWI) ("imputology" is the French term for causality assessment), was initiated at Morges and continued into the 1990s [24–26]. Although a consensus method was not developed, a theoretical statistician, Dr David Lane, an invited outside observer at the Crystal City conference, provided an appraisal of the deliberations [27]. His critique and subsequent participation in the Paris conference and APWI resulted in the development of a new approach for assessing causality based on the Bayes probability theorem [28]. This approach considered the probability of an event occurring in the presence of a drug relative to its probability of occurring in the absence of the drug, considering all details of the case [29–32]. Although applied elsewhere in medicine, the Bayesian method had not been applied to suspected adverse effects analyses. A discussion of its application follows in the next section.

After this flurry of activity in the mid-1980s, there was more limited activity in adverse event causality, primarily marked by efforts in France in the mid-1990s. Causality assessment is a regulatory requirement in French reporting. This resulted in further elaboration of the Bayesian method by Bégaud and colleagues in Bordeaux [33] and development of a further scoring method, RUCAM, by Bénichou and Danan [34–36].

Although a standard method has not been adopted since this time, causality assessment by varying methods has diffused into other regulatory requirements in the European Union (EU), Canada, and the US, into the requirement for publication of reports in at least one journal (*Annals of Pharmacotherapy*), and, sporadically, into analyses of both clinical trial data and spontaneous reports, as described below.

Actual and Potential Uses of Causality Assessment

Despite the proliferation of methods and the great interest in adverse effects of drugs, the actual use of causality assessment methods for decision making has been infrequent; it may increase as interest in various methods of analysis of adverse events burgeons, and as old tools are adapted to new technology [37]. However, causality assessment has been required in France for many years [38] and has been formally considered in a European Community Directive [39]. This has resulted in a general consensus on the causality terms used by the EU member states [440–42]. Further, in 1994, a formal method of causality assessment for reports of vaccine-associated adverse events was instituted by Health Canada's Vaccine Safety Surveillance Section, Division of Immunization, Laboratory Center for Disease Control, conducted by the Advisory Committee on Causality Assessment [43,44].

In fact, standard assessments of causality could be useful in a variety of settings, from the clinical trials activities in drug development by the pharmaceutical manufacturer, to evaluation and monitoring of postmarketing spontaneous reports by both sponsors and regulators, to the clinical setting, where suspected adverse reactions should be a common component of the differential diagnosis, and even possibly to the courtroom and the newsroom [1].

Pharmaceutical Manufacturers

Manufacturers of biopharmaceuticals must view causality assessment for events associated with their products from the standpoints of both regulatory requirements and product liability.

The appearance of US Food and Drug Administration (FDA) regulations and draft guidances for reporting adverse events in clinical trials that are "reasonably" associated with a drug [45,46] indicates a growing need to describe the basis for defining an association that began within this setting. In September 2010, the FDA published a Draft Guidance for safety reporting in clinical trials that updated the current requirements in some respects [47]. In March 2003, the FDA proposed broadening the definition of causality to "a causal association cannot be ruled out." However, after careful consideration of the many public comments that expressed concern over what was deemed a very broad definition, in the final regulation the FDA agreed to maintain the former requirement that an event must be "reasonably associated" for it to warrant reporting [47].

Until these regulations took effect in 2011, US biopharmaceutical manufacturers did not need to consider causality assessments of adverse events in clinical trials for regulatory purposes. Regulations covering postmarketing event monitoring in the US required reporting of *all* events associated with the drug "whether or not thought to be associated with the drug" [47]. Current US FDA regulations require causality assessment for determination of reporting certain types of clinical events in clinical trials and in the Investigational New Drug (IND) regulations (21 CFR §312.22) [47], reporting of serious, unexpected events associated with use of a drug where there is a "reasonable possibility" that the events may have been caused by the drug is required. The regulations also include a disclaimer that such a report does not constitute an admission that the drug caused the event. No causality criteria or a suggested method of assessment are provided; however, they do imply that such methods might be useful.

In postmarketing regulations that became effective on June 30, 2006, the FDA modified its standard for including postmarketing safety information on the labeling [48]. The current regulatory standard for addition of an event to the product label Warnings section currently states: "The labeling must be revised to include a warning about a clinically significant hazard as soon as there is reasonable evidence of a causal association with a drug; a causal relationship need not have been definitely established" (21 CFR 201.57(c)(6)).

Outside the US, the requirements for manufacturers to consider causality varied from country to country. With promulgation of EU directives on pharmacovigilance and related EU activities, an increase in regulatory harmonization activities, and the expanded globalization of biopharmaceuticals, there are more similarities in regulatory approaches than differences. Many regulatory agencies have requested or implied some type of evaluation to minimize the number of nonspecific events reported [36]. Given this environment, particularly in a growing international milieu, manufacturers have been actively interested in this area. In fact, several of the specific methods for causality assessment have been published by investigators based in the biopharmaceutical industry [49–52].

The impact of the United Kingdom's exit from the EU in 2019 is as yet unknown. It is comforting to know that in September 2017, the UK government published a paper setting its objectives for continued scientific cooperation and collaboration with the EU, and the field of biopharmaceuticals is considered particularly important. The EMA announced in November 2017 that the new location of the organization will be in Amsterdam.

Causality definitely is an issue for pharmaceutical manufacturers in the arena of product

liability, especially in the US (see Chapter 9). In 1984, Freilich considered many aspects of this [53], concluding that a company must have a rigorous process for the review of any adverse event reports and "make causality assessments on an ongoing basis" for product liability purposes. This is necessary to comply with the duty to warn, which he summarized as follows: "Information must be given of any risks of death or serious harm, no matter how rare, as well as information concerning side effects where there is a substantial probability of their occurrence, no matter how mild." Others in the legal arena dealing in product liability have considered causality issues and the notion of the "substantial factor" test for contributing to causation [54,55]. A substantial factor is one that by itself may possibly have caused a plaintiff's injury, but that may not be the only factor involved in the injury.

Drug Regulator

Causality assessment of spontaneously reported postmarketing adverse reactions by drug regulators has varied considerably. Most countries' drug regulators have some method of approaching causality, but this has been most well defined in France, Australia, and certain other countries [49,56,57].

In France, owing in part to the considerable original work on and interest in adverse reaction causality by a regulator, J. Dangoumau, and his colleagues, all reports of suspected reactions must be evaluated by the "French method" [58]. This combines symptom and chronologic criteria relating to the individual case to give a "Global Intrinsic Score" and then adds bibliographic data relating to information on other cases and the known pharmacology and adverse effects of the drug from standardized sources to give an "Extrinsic Score" [14,58]. This method, still mandatory in France, was updated in 2011 by an *ad hoc* working group including regulators and members of pharmaceutical companies. It now provides a seven-degree score, considers the degree of completeness of data in the case, and differentiates between *expected* and *unexpected* adverse reactions [59,60].

In the US, no formal method for evaluating all reports was used until a simple algorithm was developed in the early 1980s, based on the Irey and Karch and Lasagna work [16,17]. This simple, basic method considered the timing, de- and rechallenge, and confounding factors criteria. It specifically *excluded* examining literature reports when considering the strength of the association. It was reasoned that, in many cases, the FDA would be in the position of receiving the first reports of an association. The primary use of the assessment by the FDA was administrative, as the causality assessment was a mechanism for identifying the best documented cases – those with a "probable" or "highly probable" association. The causality judgment was specifically deleted from publicly available files, which consistently carry the caveat "a causal relationship need not have been definitely established."

Use of the FDA algorithm ended in 1986, but the caveat stating that no cause–effect relationship could be derived on all released adverse event information remains. The FDA does not now use formal causality assessment on a routine basis (see Chapters 8 and 10). Instead, it posts quarterly reports of "Potential Signals of Serious Risks/New Safety Information Identified from the FDA Adverse Event Reporting System (FAERS)," which continues to state that inclusion on this list "does not mean that FDA has determined that the drug has the risk" [61].

In 2016, Bailey *et al*. reviewed the different reporting systems in use worldwide for drug regulatory purposes [62]. They identified 11 international and 97 national-level reporting systems. They found "substantial variability" in the data fields reported, limiting data comparability between systems. However, they were concerned that existing forms focused more on regulatory needs (e.g., drug lot numbers) and recommended developing a form that would

better support clinical care needs. Notably, they identified which countries requested data on such items as rechallenge and dechallenge to allow causality assessment, and called for consensus on data elements used.

Publishers of Reports of Adverse Reactions

The medical literature containing case reports of suspected adverse reactions has largely avoided the issue of causality, although there are many published series of cases reports that apply the Naranjo scoring method [13]. In fact, the *Annals of Pharmacotherapy* now requires that this method (or another validated and appropriate scale) be applied and reported in all case reports published. The majority of single case reports, letters to the editor, or short publications do not provide an explicit judgment using any of the published algorithms. More importantly, despite several meetings and publications, many published reports do not provide information on confounding drug therapy or medical conditions – data elements considered essential for considering causality by experts. This issue was recognized as one of several problems relating to the publication of adverse reactions in the literature and was discussed extensively in 1981 and 1983 at the conferences in Morges, Switzerland. Editors of several medical publications were present and discussed the quality of information in reported cases. The participants developed a list of the types of information desirable for published reports, including data permitting the reader to assess independently the likelihood of the association [63,64]. They concluded that publication of case reports should require the five elements of causality: timing, the nature of the reaction, discontinuation, reintroduction, and alternate causes based on prior history.

The need for publication requirements was underscored in 1990 when Haramburu and her colleagues compared the value of 500 published reports with 500 spontaneous reports with respect to the availability of information needed in most standard causality assessments [65]. Although analysis suggested that the published reports contained significantly more information, the tabulation of these reports indicated very sparse data on both alternate causes/other diseases and other drugs in *both* types of reports. Nonetheless, even years later, few journals appear to require specific types of information for publication of spontaneous reports. This prompted another formal effort in 2004 by the International Society of Pharmacoepidemiology to address this issue. An international working group, looking at the broader need for higher quality publications of suspected adverse reactions to biopharmaceuticals, published recommendations for publications of suspected adverse reactions that were published simultaneously in two major journals focusing on drug safety, *Pharmacoepidemiology & Drug Safety* and *Drug Safety* [66–68]. Subsequently, the recommendations have been adopted by some other journals, including *Annals of Pharmacotherapy* and *Thérapie*.

Methodologic Problems to be Addressed by Pharmacoepidemiologic Research

The goal is to find one or more methods that are reliable, consistent, accurate, and useful for assessing the likelihood of association between an adverse event and a medical product. This problem is compounded by the nature of biopharmaceutical-associated adverse events. They vary in frequency, manifestation, timing relative to exposure, and mechanism. They mimic almost the entire range of human pathology, as well as adding unique new pathologies (e.g., kidney stones consisting of sulindac drug crystals and the oculomucocutaneous syndrome caused by practolol). In addition, biopharmaceutical-associated events are always nested within other pathologies associated with the indication for

the drug. Since drugs are used to produce a beneficial effect, known or expected adverse events are sometimes reluctantly accepted within the clinical risk/benefit equation. However, unknown or unexpected events are inconsistently recognized and/or described. Seldom are the desired baseline and other detailed laboratory measurements or past medical history obtained.

The nature of this task, and its context, has generated two divergent philosophies. One discounts the value or importance of causality assessment of individual reactions, deferring judgment to the results of formal epidemiologic studies or clinical trials [69]. The other contends that evaluation of single reports can help determine at least some degree of association – useful or even critical information when considering ending drug development or a clinical trial or a drug withdrawal [70]. The latter view spurred the evolution of causal evaluation from expert global introspection to structured algorithms and to elaborate probabilistic approaches, as described previously. Further, because of the nature of drug and biologic-associated effects, particularly rare and serious effects, the question has been raised whether epidemiologists need to consider using algorithms or probabilistic methods for case evaluations in formal studies and in clinical trials, since the small numbers available may not be amenable to standard statistical analysis [71].

Currently Available Solutions

There are now a variety of methods for causality assessment of spontaneous reports. Four basic types will be described, chosen as illustrative examples and because they have been widely described in various publications. Agbabiaka and colleagues in a 2008 review concluded that "there is still no method universally accepted for causality assessment of ADRs" [72], as pointed out much earlier by Koch-Weser *et al.* [73]. Khan *et al.* agreed in 2016 [74].

Unstructured Clinical Judgment/Global Introspection

Probably the most common approach to causality assessment is unstructured clinical judgment. An expert is asked to review the clinical information available and to make a judgment as to the likelihood that the adverse event resulted from drug exposure. However, it has been amply demonstrated that global introspection does not work well, for several reasons [7,74].

First, cognitive psychologists have shown that the ability of the human brain to make unaided assessments of uncertainty in complicated situations is poor, especially when assessing the probability of cause and effect, precisely the task of causality assessment [72]. This has been clearly demonstrated for the evaluation of suspected adverse reactions. Several studies have used "expert" clinical pharmacologists to review suspected reactions. Comparing their individual evaluations, these studies documented the extent of their disagreement and illustrated thereby how unreliable global introspection is as a causality assessment method [14–16,69,70,72,73].

Second, global introspection is uncalibrated. One assessor's "possible" might mean the same as another assessor's "probable." This has been well demonstrated in a study of one pharmaceutical company's spontaneous report reviewers, who used both verbal and numerical scales [19]. These and other shortcomings of global introspection as a causality assessment method for adverse reactions are discussed in detail by Lane, Hutchinson, and Kramer, among many others [7,27,72,75–79].

Despite these concerns, global introspection for evaluation of adverse events continues to be used. Most notably, the Uppsala Sweden WHO Centre for Drug Monitoring, which collects the spontaneous reports from national centers

worldwide, has published causality criteria ranging from "certain" to "unassessable/unclassifiable" that essentially represent six levels of global introspection, though they generally incorporate consideration of the more standard criteria for causality [80]. The Portuguese central pharmacovigilance unit (Nucleo de Farmacovigilancia do Centro) utilizes this WHO global introspection (GI) method, in part based upon a comparison of results from evaluation of 200 cases by algorithm methods and the WHO GI method. They found a relatively moderate to high degree of correspondence of judgments for the reactions more likely associated [81].

Algorithm/Criterial Method with Verbal Judgments

The subsequent attempts to address the limitations of global introspection have resulted in the proliferation of methodologic approaches [72,73]. Methods range from simple flowcharts posing 10 or fewer questions to lengthy questionnaires containing up to 84 items. They share a common basic structure essentially based on the original work by Karch and Lasagna [10] and Irey [8,9]– the timing of the adverse event in relation to administration of the drug, alternative etiological candidates, previous recognition of the event as a possible adverse reaction to the drug, the response when dechallenged, and rechallenged. Information relevant to each factor is elicited by a series of questions, the answers to which are restricted to "yes/no" (and for some methods, "don't know").

The advantage of algorithms compared to global introspection [70,76] is improvement in the consistency of ratings among reviewers. Since the consideration of each case is segmented into its components (e.g., timing, confounding diseases, etc.), it allows for a better understanding of areas of disagreement. However, global introspection is still required on the separate elements of the algorithms or decision tables. In some cases, "yes or no" answers are required where a more quantitative estimate of uncertainty would be more appropriate. For example, the reviewer might have to consider whether the appearance of jaundice within one week represented a sufficient duration of drug exposure to be consistent with a drug–event association. Even adherents of some of the methods agree that their procedures for converting answers into probability ratings are arbitrary.

Previously, the FDA used an algorithm based on the Irey and Karch and Lasagna concepts [16]. It inquired sequentially about temporal sequence, dechallenge, rechallenge, and concomitant diseases which might have caused the event. It was tailored for rapid use by professionals with varied backgrounds for the administrative purpose of finding well-documented cases for regulatory signal evaluation. It was also considered useful and easily remembered by clinicians in initial differential diagnosis of a clinical event. However, this very simple approach is less useful for irreversible drug effects (e.g., death, birth defects), since dechallenge and rechallenge are impossible. To address this, an alternate algorithm for fatal outcome events was developed by Turner in the aftermath of the FDA algorithm [17]. Algorithms/decision trees are used by some drug regulatory agencies, such as that of Australia [56].

Algorithms Requiring Scoring of Individual Judgments

Many algorithms permit quantitative judgments by requiring scoring. The answers to the algorithms' questions are converted into a score for each factor, the factor scores are summed, and this overall score is converted into a value on a quantitative probability scale. These

judgments range from the extensive, multiple question method of Venulet [18], which has now been translated for computer use, to the relatively simpler French method [14,60]. The method developed by Kramer *et al*. [12] received considerable review and is representative of the scored methods. Although it was presented in algorithm format with multiple steps, it can also be represented in tabular format.

One of the more practical methods of this type was developed by Naranjo *et al*. [13]. This method has been adopted in a number of clinical settings and by at least one publisher (*Annals of Pharmacotherapy*) and is shown in Figure 29.2 [13]. The RUCAM method was developed in 1994 by Bénichou and Danan [36]. Like the Naranjo method, this has six criteria with three or four levels of scoring for each criterion to derive an overall score. RUCAM has been applied in evaluation of adverse events in HIV clinical trials [82].

CAUSALITY ASSESSMENT
NARANJO SCORED ALGORITHM

QUESTION	ANSWER			SCORE
	Yes	No	Unknown	
Previous reports?	+1	0	0	_____
Event after drug?	+2	−1	0	_____
Event abates on drug removal?	+1	0	0	_____
+ Rechallenge?	+2	−1	0	_____
Alternative causes?	−1	+2	0	_____
Reaction with placebo?	−1	+1	0	_____
Drug blood level toxic?	+1	0	0	_____
Reaction dose-related?	+1	0	0	_____
Past history of similar event?	+1	0	0	_____
ADR confirmed objectively?	+1	0	0	_____
Total Score				

Figure 29.2 A critical scored algorithm illustrated by the method of Naranjo et al. in wide use. This particular method uses some of the basic data elements as well as more details of the history and characteristics of the case, and a score is designated for the response to each question. Source: Reproduced from Naranjo *et al*. [13] with permission of John Wiley & Sons.

These quantitative methods have found applications in a number of settings, ranging from evaluations of suspected adverse reactions by hospital committees (US hospitals are now required by the Joint Commission on Accreditation of Health Care Organizations (JCAHO) to have programs of adverse reaction surveillance) to use by some regulatory authorities, as in France. They are also used, although sometimes only in a research context, by some pharmaceutical manufacturers [21,49]. The specific manner in which they are used has not been well described in the literature.

A newer tool is the Liverpool Adverse Drug Reaction Causality Assessment Tool [83]. The Liverpool tool is a flowchart developed by a team of seven researchers involved in the Adverse Drug Reactions in Children project [84]. They assessed 40 pediatric suspected ADRs with their own methodology (ADRIC Study 1 [85]) and using Naranjo. They then compared the results obtained and carefully examined cases for which assessments differed by more than one degree. This comparison led them to develop a modified version of Naranjo, called the Liverpool ADR Causality Assessment Tool (LCAT), in 2011.

The authors believe that this method may be somewhat cumbersome for practitioners [86]. In 2015, the developers adapted a mobile app for the LCAT and its easy availability may make the Liverpool tool a widely used causality assessment tool [37].

Probabilistic Methods

Recognition of the various methodologic challenges set the stage for the development of an alternative approach: The Bayesian probability approach to assessment of causality (Figure 29.3). This method provided an opportunity for a different perspective on causality assessment, but its difficulty (due to the requirement to use all available information) raised

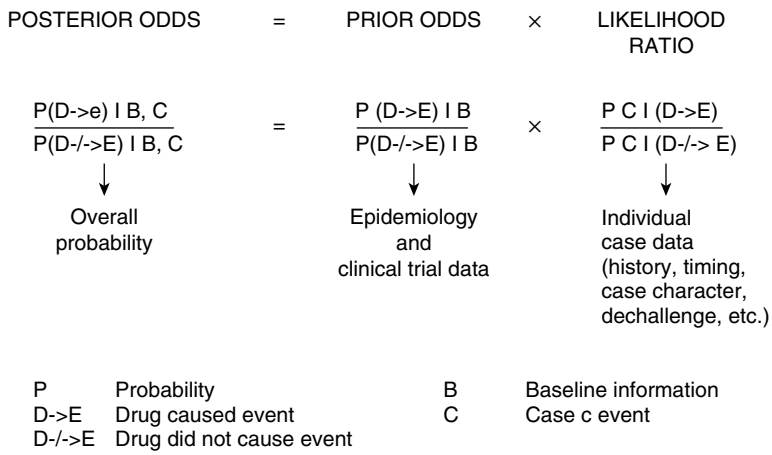

Figure 29.3 The basic equations for the Bayesian analysis of suspected drug-associated events. These provide a structured yet flexible and explicit approach to estimating the probability that an event is associated with one, or more, drugs, as described in the text and extensive literature dating from Auriche [52], Lane *et al*. [28] and others. Since the prior probability estimate is dependent on explicit data from clinical trials and epidemiologic studies, this approach can provide a framework for specific event-related questions in these studies [29].

some new issues about causality assessment of adverse reactions. It also brought adverse reaction evaluation into a larger discussion of the value of applying Bayesian and probabilistic approaches to the analysis of medical and scientific data [3].

First published as a method for adverse reaction assessment by Auriche [52], who participated with Lane and others in a working group within the APWI organization, the Bayesian method was first presented in extensive form in a workshop in 1985 [28]. Several examples were published in a monograph and subsequently in early papers [31,32]. The methods were incorporated into automated versions by both Naranjo and Hutchinson, the latter developing a model using an expert system [87,88]. Naranjo and colleagues implemented a practical spreadsheet/automated version called BARDI (Bayesian Adverse Reaction Diagnostic Instrument) and applied it to a number of practical adverse event problems [70,87,89].

The Bayesian method assesses the probability of an event occurring in the presence of a drug, relative to the probability of that event occurring in the absence of the drug, as illustrated in Figure 29.3. Estimation of this overall probability, the "posterior probability," is based on two components.

- What is known prior to the event, the "prior probability" which is based on clinical trial and epidemiologic data.
- What the likelihoods are, or are not, for the drug to cause the components of the specific case, including its history, timing, characteristics, dechallenge and its timing components, rechallenge, and any other relevant factors.

Application of the Bayesian method requires knowledge of the clinical event, its epidemiology, and relatively specific information about the event's characteristics and kinetics over time. Examples have been published for several types of events, including Stevens–Johnson syndrome, renal toxicity, lithium dermatitis, ampicillin-associated colitis, agranulocytosis, Guillain-Barré syndrome, and pancreatitis [29,78,89,90].

Thus far, this approach appears to be useful for analysis of the perplexing first events in new drug clinical trials, serious spontaneous adverse reaction reports, and possibly rare events discovered in both case–control and cohort pharmacoepidemiologic studies, when standard methods of statistical analysis will not provide sufficient clues as to causality because of inadequate sample size.

Due to automation, the Bayesian method can now be performed rapidly, but the major impediment to is more general application is the frequent lack of information required for robust analyses of events. There are often limited data on the incidence of most events and their occurrence in the presence and absence of most drugs (the required information for the prior probability). There are even fewer data available on the historical risk factors, time course, and specific characteristics of the drug-associated conditions, as opposed to the naturally occurring conditions. However, with the current proliferation of epidemiologic studies, particularly in the areas of natural history of disease as well as of drug-associated diseases such as Stevens–Johnson syndrome, this information is becoming more readily available. So, although this lack of information is sometimes a limitation, it represents both an important challenge and a framework for structuring further understanding.

Bénichou and collaborators have delved further into a mapping process of reactions by type in an attempt to begin classifications of specific drug-associated disease, using acute liver disease as one model that incorporates qualitative clinical definitions of the disease into the judgment [91,92].

For this reason, and with the increasing availability of more epidemiologic data, there are several advantages of using the Bayesian method for analysis of suspected drug-associated events.

- All judgments must be explicit and quantified, permitting better explanations of the degree of uncertainty about each component of information. Further, this approach makes maximum use of the available information and follows the basic rule of not discarding information.
- Since each component is analyzed separately, a sensitivity analysis of each information component can estimate its overall contribution to the final posterior odds or probability estimate. This, in turn, can be used to determine which information is pivotal. For example, if a 10-fold difference in the estimate of the timing does not materially modify the overall posterior odds estimate, further efforts to determine the "best" estimate would not be worthwhile.
- Because of the multistep approach to a judgment, combined with lack of the prejudged weighting present in most other methods, this approach resists the tendency to achieve a result expected on an *a priori* global judgment. This is quite important in evaluating events with multiple possible causes.
- This approach can provide an extensive summary of the information needed and areas needing further research and data compilation.

Thus, the Bayesian approach ultimately provides a "map" to define the information most critical for understanding drug-induced disease and will help formulate the most critical questions to be researched. As disease natural histories and drug-induced diseases are now being described in large population databases, it is essential to link these two types of analyses.

Another useful application of the Bayesian method, combined with the Poisson method for estimating the probability of rare events in populations [33] developed by Bégaud and colleagues, was described by Zapater *et al.* [93]. They demonstrated the feasibility of utilizing both clinical trial and population data to estimate the posterior probabilities of association in complex cases of ticlopidine-associated hepatitis.

More recently, a method based upon the logistic model and directly providing a probability for drug causation ranging between 0 and 1 has been proposed [94]. This method, also proposed in an automated version, preserves some of the basic principles of conditional probabilities; it notably provides a neutral assessment of 0.5 when no information is usable, while conserving the ease of use of classic algorithms. The assessments of seven criteria are combined, the relative weight of each criterion having been calibrated by taking consensual judgment of five experts on a random sample of case reports as gold standard. An improved version was published in 2012 [95].

Comparison Among the Different Methods for Causality Assessment

Several efforts have been made to evaluate and compare methods. The 1983 conference in Crystal City involved the application of several of them to a standardized case, illustrating a considerable lack of concordance for some methods [23].

A much more elegant and detailed evaluation of six representative algorithmic methods was carried out in 1986 by Péré *et al*. [96], who identified standard evaluation criteria and carried out an evaluation of 1134 adverse reactions using the various methods. Significantly, they found only moderate agreement between all pairs, and considerable disagreements on weightings of three of the major criteria – timing, dechallenge, and alternate etiologies – which tends to underline the lack of complete information on the events and their characteristics. More recent attempts to quantify agreements on different methods, including global introspection, have been published by Kramer and Macedo *et al.* [77–79,81].

Given the current state of affairs, where a number of published methods exist, the choice of a method for use in evaluating individual adverse effects will likely be determined by a number of practical factors.

- *How the evaluation will be used*. This refers to both its short-term use (e.g., a rating suggesting more than possible association may be needed to result in a "signal") and long-term use (e.g., will a single highly probable case in a file, not otherwise acted upon, be a source of liability for the evaluator?).
- *The importance of the accuracy of the judgment.* If this evaluation will affect a specific clinical outcome, the continuation of a clinical trial, or the continued marketing of a drug, the accuracy of the judgment may be critical. Conversely, if little hinges upon the judgment, cruder estimates and methods, recognized as such, may suffice.
- *The number of causality evaluations to be made.* The decision on method to use must also be weighed against the time required to make judgments – a concern especially for regulatory agencies and manufacturers where the need for accurate judgments is pitted against the volume of reports. One approach is suggested by the FDA's method of identifying high-priority problems according to their newness and seriousness (see Chapter 8).
- *The accrued value of thorough evaluations*. In some circumstances, the careful, rigorous evaluation of certain categories of drug-associated events will facilitate the more accurate evaluation of subsequent, related events. For example, if a drug under development is anticipated to cause hepatic events, detailed evaluations of hepatic events induced by other drugs may allow more satisfactory causality evaluation of reports received on the new drug [91]. In some cases this results from data collection being focused to a much greater degree, as was initiated in France by Bénichou *et al*., where special reporting forms

using disease-specific criteria for events were developed [91,92]. Zapater *et al.* demonstrated the advantages of these forms in assessing ticlopidine-associated hepatic toxicity, where the evaluation and sensitivity analysis not only clarified the estimated probabilities for the cases, but also suggested that more careful examinations of relative values of hepatic enzymes might further understanding of drug-associated hepatotoxicity [93].

- *Who will perform the evaluation?* Although no specific studies have been carried out to evaluate the interrater differences among differently trained professionals, it is likely that the body of information held by each reviewer will have considerable impact on any of the methods used, including the Bayesian method.

The Future

The field of adverse reaction causality assessment has many unresolved issues, both methodologic and practical, described in the preceding sections. Early on, there was hope for a consensus assessment method [21]. Despite repeated published expressions of need, no standard method has emerged. Several reasons can be suggested.

First, some individuals and institutions have committed to one or a few methods, often through choice of data collecting systems or software [18]. Second, *usability* appears to play a very real role in that choice. Although the Bayesian method was welcomed as the possible gold standard for adverse reaction causality, it was not embraced. Early on, it was difficult to use without automation but even since that barrier was lifted, the Bayesian is often too complex and time-consuming for practical application. The complex Kramer *et al*. algorithm [12] likewise discourages its use in some sectors in spite of improvements from automation, although this has not been documented. Third, concern about possible disagreement with global introspection determinations or algorithm scores has generated concern about potential legal liability [49], since there is no gold standard method.

All these factors suggest the need for considerable further work in several areas.

- Identify the purpose of the causality assessment to better determine the desired rigor, accuracy, and usability of the methods. There will probably always be needs for simpler and rougher methods when large quantities of reports are involved, as well as more complete and rigorous methods when the findings impact the regulatory future of the medical product or its development.
- Identify the critical elements needed for the evaluation of causality for different types of adverse reactions (e.g., hepatic, hematologic, skin etc.) so that this information may be collected at the time of reporting or publishing a spontaneous event. This need has long been recognized [14,23,96] and is being implemented in some centers (e.g., Bordeaux, France; University of Toronto; as well as many pharmaceutical companies) that collect adverse events. Further work in this area can have a major impact on the:
  - collection of better information on the different drug-associated events, using data collection instruments tailored to the event of interest
  - better definition of the dynamics and, ultimately, the pathophysiology and mechanisms of certain types of drug-induced conditions.

At present, with pursuit of the epidemiology and pathophysiology of drug-associated diseases by both individual centers (e.g., the efforts in drug-associated hepatic disease, including liver failure by Lee [97] and the US NIH) and the regulatory agencies, in particular the FDA (pursuing hepatic injury and

other drug-associated disorders such as Stevens–Johnson syndrome), it is likely that such research will support development of much more event-specific methods, such as the ALDEN method for Stevens–Johnson syndrome developed by the European SCAR registry [98].

- Gathering of data on critical elements of the specific adverse events in the course of both clinical trials and epidemiologic studies. Risk factor, history, timing, characteristics, and resolution patterns of adverse events should be described in these studies and incorporated into general data resources on the characteristics of medical events and diseases.
- Further work on automation of the causality evaluation process. Global introspection is still widely used because of the cumbersome nature of many of the more complete methods. Fortunately, several methods are now automated, including the French [96], the Venulet (J. Venulet, personal communication), the Bayesian BARDI [87], the Liverpool tool [20], and the logistic method [94]. Convenient access to the proper questions, arrayed in logical order, as well as background data on the state of information to date, has the potential for radically changing the state of adverse reaction causality evaluation.
- Consideration of new and different methods for assessment. Although future work will likely flow from currently available methods, other approaches have emerged. For example, as part of work on patient safety in the US (see also Chapter 41), "root cause analysis" has emerged to identify the important contributors to adverse events in clinical settings. It examines functional maps of possible contributing factors to identify a cause and determine methods of preventing it. Spath provided one illustration of this approach [99]. Another less generalizable approach described by investigators at the University of Toronto is the N-of-1 trial that evaluates the causality of adverse events in individuals, particularly those with multiple reactions to drugs [100]. Use of an assessment method that can lend itself to modern technology (mobile applications), such as the Liverpool tool, may supersede others simply because of its ease of access [20,37].

In conclusion, how best to assess causality of adverse reactions continues to represent a challenge. With increased understanding that causality assessment is necessary in the regulatory and drug development and testing processes, the need for consensus on one or more methods, depending on use, continues. Application of detailed causality assessment, particularly when viewed prospectively with collection of data in both pharmacovigilance centers and clinical studies, can ultimately contribute to the overall understanding of many drug-associated diseases.

Precision medicine has been defined by the National Institutes of Health (NIH) in the United States as an "approach to disease prevention and treatment based on people's individual differences in environment, genes and lifestyle." Genomic technologies are increasingly available and their use in clinical care has grown substantially over the last decade. As of July 10, 2018, there are over 54 852 tests for 11 233 conditions, 16 433 genes, and 507 laboratories according to the NIH's Genetic Testing Registry. There are different types and applications of genomic technologies. These include disease screening (in asymptomatic individuals, e.g., newborn screening and carrier screening), diagnosis (in symptomatic individuals, e.g., identifying genetic variants in children with suspected genetic disorders), prognostic (e.g., Lynch syndrome for increased risk for colorectal, endometrial, ovarian, and other cancers associated with mutations in mismatch-repair genes), risk assessment or susceptibility (e.g., *BRCA1/BRCA2* testing for hereditary breast and ovarian cancer), inform reproductive choices (prenatal and preimplantation testing), and pharmacogenetic (predict treatment response or adverse events, e.g., HLAB*1502 for risk of Stevens–Johnson syndrome and toxic epidermal necrolysis and to guide use of carbamazepine).

One of the most challenging aspects of precision medicine that involves pharmaceuticals is to understand why individuals and groups of individuals respond differently to a specific drug therapy, in terms of both beneficial and adverse effects. Reidenberg observes that, while the prescriber has basically two decisions to make while treating patients (i.e., choosing the right drug and choosing the right dose), interpreting the interindividual variability in outcomes of drug therapy includes a much wider spectrum of variables, including the patient's health profile, prognosis, disease severity, quality of drug prescribing and dispensing, adherence with prescribed drug regimen (see Chapter 38), and last but not least, the genetic profile of the patient [1].

The effects of genes and other biomarkers on drug response can be studied using molecular pharmacoepidemiology. This is the study of the manner in which molecular biomarkers alter the clinical effects of medications in populations. Just as the basic science of pharmacoepidemiology is epidemiology, applied to the

Pharmacoepidemiology, Sixth Edition. Edited by Brian L. Strom, Stephen E. Kimmel and Sean Hennessy.

content area of clinical pharmacology, the basic science of molecular pharmacoepidemiology is epidemiology in general and molecular epidemiology specifically, also applied to the content area of clinical pharmacology. Thus, many of the methods and techniques of epidemiology apply to molecular pharmacoepidemiologic studies. However, there are several features of molecular pharmacoepidemiology that are somewhat unique to the field, as discussed later in this chapter. Most of the discussion will focus on studies related to genes, but the methodologic considerations apply equally to studies of proteins (e.g., proteomics) and other biomarkers, such as the microbiome (the genes within the microbial cells, primarily bacteria in the gut, harbored within each person) and mRNA (messenger RNA that results from DNA transcription).

It has been suggested that, on average for each medication, about one out of three treated patients experiences beneficial effects, one out of three does not show the intended beneficial effects, 10% experience only side effects, and the rest of the patient population is nonadherent so that the response to the drug is difficult to assess [2]. Although this is just a crude estimate, it highlights the challenge of individualizing therapy in order to produce a maximal beneficial response and minimize adverse effects. Although it is clear that many factors can influence medication efficacy and adverse effects, including age, drug interactions, and medication adherence (see Chapter 2), genetics can clearly be an important contributor in the response of an individual to a medication. Genetic variability can account for a large proportion (e.g., some estimates range from 20% to 95% [3]) of variability in drug disposition and medication effects [3–7].

In addition to altering dosing requirements, genetics can influence response to therapy by altering drug targets or the pathophysiology of the disease states that drugs are used to treat [8–13].

Genetic Variability in Drug Response: Historical Perspective

Although molecular pharmacoepidemiology is a relatively new area of research, the idea that different individuals have different susceptibility to the effects of medications is not new. Since the advent of modern drugs soon after the Second World War, physicians, pharmacists, and patients have been confronted with interindividual variability in the effects of drug therapy. Some patients need higher than normal doses to achieve an optimum effect. In other patients, unwanted and adverse effects occur even in low doses, while some patients receive no apparent effect of the medication at all. History shows a number of cases where genetics or factors that may be correlated with genetic variability played a role in interpreting and predicting drug effects (Box 30.1).

One of the best-known "classic" examples of genetic variance in drug response is the metabolic defect caused by glucose-6-phosphate dehydrogenase (G6PD) deficiency [14]. This X-linked chromosome disorder is present in about 10% of African men, and occurs at low expressed frequencies in some Mediterranean peoples. In carriers of this deficiency, hemolytic reaction occurs after exposure to oxidant drugs such as antimalarials (e.g., chloroquine), but is also seen

Box 30.1 Some examples of "old" clinically relevant gene–drug interactions

Hemolysis in patients exposed to antimalarial therapy and G6PD deficiency [14]
Prolonged action of suxamethonium due to plasma cholinesterase polymorphism [15]
Neuropathy in patients exposed to isoniazid N-acetyltransferase polymorphism [16]
Inefficacy of codeine as analgesic in poor metabolizers (CYP2D6) [17]

in patients using drugs such as aspirin, probenecid, or vitamin K.

Another early stimulus for pharmacogenetic thinking was the observation that, in the 1 in 3500 white subjects who are homozygous for the gene encoding an atypical form of butyrylcholinesterase, the inability to sufficiently hydrolyze the muscle relaxant drug succinylcholine could lead to prolonged, drug-induced muscle paralysis resulting in severe, frequently fatal, apnea [15].

A third pharmacogenetic antecedent is the example of drug-induced neuropathy in patients with low activity levels of the metabolic enzyme N-acetyltransferase [16]. This enzyme plays an important role in Phase II pathways of drug metabolism, and variance of the activity of this enzyme may lead to dramatic and clinically relevant differences in the plasma concentrations of drugs such as isoniazid, hydralazine, and procainamide.

A final example is the metabolic variance caused by one of the many cytochrome P450 enzymes (CYP). Doctors treating patients with codeine as an analgesic have observed for decades that some patients do not respond at all to normal doses. These clinical observations were not well understood until it was discovered that a polymorphism of CYP2D6 (a subfamily of cytochrome P450) could result in suboptimal transformation of the inactive prodrug codeine into the active form, morphine [17]. The example of codeine points to inherited lack of efficacy. However, genetic polymorphisms of CYP2D6 also have consequences for drug safety, as discussed later in this chapter.

Definitions and Concepts

Genetic Variability

Building on the success of the various human genome initiatives, it is now estimated that there are approximately 25 000 regions of the human genome that are recognized as genes because they contain deoxyribonucleic acid (DNA) sequence elements including exons (sequences that encode proteins), introns (sequences between exons that do not directly encode amino acids), and regulatory regions (sequences that determine gene expression by regulating the transcription of DNA to RNA, and then the translation of RNA to protein). Some of these sequences have the ability to encode RNA (ribonucleic acid, the encoded messenger of a DNA sequence that mediates protein translation) and proteins (the amino acid sequence produced by the translation of RNA). In addition, we are learning a great deal about genomic regions that do not encode RNA or protein, but play important roles in gene expression and regulation such as epigenetics (changes in DNA expression that occur but are not related to the base order, such as DNA methylation). Moreover, changes in the DNA of microbial cells (the microbiome) can influence human response to medications.

Thanks to numerous human genome initiatives, we also have substantial information about interindividual variability in the human genome. The most common form of genomic variability is a single nucleotide polymorphism (SNP), which represents a substitution of one nucleotide (i.e., the basic building block of DNA, also referred to as a "base") for another, which is present in at least 1% of the population. Each person has inherited two copies of each allele (one from the paternal chromosome and one from the maternal chromosome). The term *allele* refers to the specific nucleotide at one point in the genome inherited from either the father or mother, and the combination of alleles in an individual is called a genotype. When the two alleles are identical (i.e., the same nucleotide sequence on both chromosomes), the genotype is referred to as "homozygous" and when the two alleles are different (i.e., different nucleotide sequences on each chromosome), the genotype is referred to as "heterozygous."

Approximately 10 million SNPs are thought to exist in the human genome, with an estimated two common missense (i.e., amino acid changing) variants per gene [18].

However, SNPs are not the only form of genetic variation that may be relevant to human traits and diseases. For example, copy number variants (CNV), sections of the genome that have repeats of base pairs, may also have a role in disease etiology [19]. DNA methylation, where methyl groups are added to DNA, thus changing the activity of DNA (which itself is regulated by genetics), and variability in the gut microbiome can also alter drug response [20–22].

Finally, we also recognize that the genome is not simply a linear nucleotide sequence, but that population genomic structure exists in which regions as large as 100 kilobases (a kilobase being a thousand nucleotides, or bases) in length-defined units remain intact over evolutionary time [23]. These regions define genomic block structures that may define haplotypes, which are sets of genetic variants that are transmitted as a unit across generations.

Thus, the complexity of genome structure and genetic variability that influences responses to medications provides unique challenges to molecular pharmacoepidemiology.

Pharmacogenetics and Pharmacogenomics

While the term *pharmacogenetics* is predominantly applied to the study of how genetic variability is responsible for differences in patients' responses to drug exposure, the term *pharmacogenomics*, as well as including studies of genetic variability on drug response, also encompasses approaches simultaneously considering data about thousands of genotypes, as well as responses in gene expression to existing medications [24,25]. Although the term *pharmacogenetics* is sometimes used synonymously with pharmacogenomics, the former usually refers to a candidate-gene approach as opposed to a genome-wide approach in pharmacogenomics (both discussed later in this chapter).

The Interface of Pharmacogenetics and Pharmacogenomics with Molecular Pharmacoepidemiology

Pharmacogenetic and pharmacogenomic studies usually are designed to examine intermediate endpoints between drugs and outcomes (such as drug levels, pharmacodynamic properties, or surrogate markers of drug effects) and often rely on detailed measurements of these surrogates in small groups of patients in highly controlled settings. Molecular pharmacoepidemiology focuses on the effects of genetics on clinical outcomes and uses larger observational and experimental methods to evaluate the effectiveness and safety of drug treatment in the population. Molecular pharmacoepidemiology uses similar methods to pharmacoepidemiology to answer questions related to the effects of genes on drug response. Thus, molecular pharmacoepidemiology answers questions related to:

- the population prevalence of SNPs and other genetic variants
- evaluating how these genetic variants alter disease outcomes
- assessing the impact of gene–drug and gene–gene interactions on drug response and disease risk
- evaluating the usefulness and impact of genetic tests in populations exposed, or to be exposed, to drugs (i.e., comparative effectiveness, see Chapter 26).

There are, however, some aspects of molecular pharmacoepidemiology that differ from the rest of pharmacoepidemiology. These include the need to understand the complex relationship between medication response and the vast number of potential molecular and genetic

influences on this response; a focus on interactions among these factors and interactions between genes and environment (including other medications) that raises issues of sample size and has led to interest in novel designs; and the need to parse out the most likely associations between genes and drug response from among the massive number of potentially important genes identified through bioinformatics (the science of developing and utilizing computer databases and algorithms to accelerate and enhance biological research).

As stated previously, the basic science of epidemiology underlies molecular pharmacoepidemiology just as it underlies all pharmacoepidemiology. What is different is the need for approaches that can deal with the vast number of potential genetic influences on outcomes; the possibility that "putative" genes associated with drug response may not be the actual causal genes, but rather a gene near or otherwise associated with the causal gene on the chromosome in the population studied (and that may not be similarly linked in other populations); the potential that multiple genes, each with a relatively small effect, work together to alter drug response; and the focus on complex interactions between and among genes, drugs, and environment. By discussing the potential approaches to these challenges in this chapter, it is hoped that both the similarities and differences between pharmacoepidemiology and molecular pharmacoepidemiology will be made clear.

Clinical Problems to be Addressed by Pharmacoepidemiologic Research

It is useful to conceptualize clinical problems in molecular pharmacoepidemiology by thinking about the mechanism by which genes can affect drug response.

The effect that a medication has on an individual can be affected at many points along the pathway of drug distribution and action. This includes absorption and distribution of medications to the site of action, interaction of the medication with its targets, metabolism of the drug, and drug excretion (see Chapter 2) [5,24–26]. These mechanisms can be categorized into three general routes by which genes can affect a drug response: pharmacokinetic, pharmacodynamic, and gene–drug interactions in the causal pathway of disease. These will be discussed in turn below.

Pharmacokinetic Gene–Drug Interactions

Genes may influence the pharmacokinetics of a drug by altering its metabolism, absorption, or distribution. As discussed previously, the fact that different individuals might metabolize medications differently has been well known for decades (see also Chapter 2). Metabolism of medications can either inactivate their effect or convert an inactive prodrug into a therapeutically active compound. Drugs can be metabolized either through Phase I reactions (oxidation, reduction, and hydrolysis) or Phase II (conjugation) reactions (e.g., methylation) [27]. The genes that are responsible for variable metabolism of medications are those that code for various enzyme systems, especially the cytochrome P450 enzymes.

The gene encoding CYP2D6 represents a good example of the various ways in which polymorphisms can alter drug response. Some of the genetic variants lead to low or no activity of the CYP2D6 enzyme whereas some individuals have multiple copies of the gene, leading to increased metabolism of drugs. A specific example is the clinically relevant association between polymorphism of CYP2D6 and the risk of antipsychotic-induced extrapyramidal syndromes, as measured by the need for antiparkinsonian medication. In a case–control study by Schillevoort *et al.*, patients using the CYP2D6-dependent antipsychotic drugs (e.g., haloperidol) who were poor metabolizers were

more than four times more likely to need antiparkinsonian medication than the extensive metabolizers (odds ratio 4.4; 95% confidence interval [CI] 1.1–17.7) [28]. An increased risk was not observed for patients using non-CYP2D6-dependent antipsychotic drugs (odds ratio 1.2; 95% CI 0.2–6.8). The decreased metabolic activity of CYP2D6 may also lead to lower drug efficacy, as illustrated previously for codeine, which is a prodrug that is metabolized to the active metabolite, morphine, by CYP2D6 [17,29]. It has been estimated that approximately 6–10% of Caucasians have variants that result in CYP2D6 genotypes that encode dysfunctional or inactive CYP2D6 enzyme, in whom codeine is an ineffective analgesic [9].

There is important interethnic variability of CYP2D6 alleles and phenotypes. An analysis of CYP2D6 allele-frequency data from >60 000 individuals suggests that diplotype frequencies predicting poor metabolism are highest among Europeans and the Ashkenazi Jewish population (about 5–6%) and lowest among East and South Central Asians, Oceanians, and Middle Easterns (<1% in each of these populations) [30]. In contrast, diplotype frequencies predicting ultrarapid metabolism were highest in Oceanians (21.2%), followed by Ashkenazi Jews and Middle Easterns (about 11% in each of these populations) and lowest in East Asians (1.4%).

Many drug–CYP2D6 genetic variant interactions have been reported based on experimental or epidemiologic associations. CYP2D6 is one of the most common pharmacogenomic markers included in drug labeling by the US Food and Drug Administration (FDA) and the European Medicines Agency (EMA). However, predicting clinical outcomes in daily practice based on CYP2D6 genetic data in a valid fashion remains complex, with probably an exception for optimizing breast cancer treatment with tamoxifen by assessing CYP2D6-metabolizing state before initiating therapy [31–33]. Drug–gene associations shown in one study cannot always be replicated in another [34]. Obviously, variance in drug response has many determinants and singling out only one genetic factor fails to account for the co-occurrence, interplay, and interactions of several other factors (e.g., disease severity, exposure variability over time, physiologic feedback mechanisms, testing bias), that are also of critical importance for molecular pharmacoepidemiology [35].

The genetic polymorphism of thiopurine methyltransferase (TPMT) in treating cancer patients is another example [10,36,37]. In its usual state, TPMT metabolizes thiopurine drugs, which would otherwise be toxic if not excreted. In approximately 86–97% of individuals, TPMT activity is high and allows normal drug excretion. In 3–14% activity is intermediate due to the presence of a heterozygous variant in the TPMT gene. In 0.03–0.56%, activity is so low (due to a homozygous variant in the TPMT gene) that patients using drugs such as azathioprine, mercaptopurine, or thioguanine accumulate excessive concentrations of the active thioguanine nucleotides, leading to severe hematologic toxicity. Thus, TPMT genotyping prior to treatment with these agents can be useful to avoid potential toxicities [38,39]. Alternatively, given the rarity of the homozygous variants, individuals who experience treatment-related toxicities may be genotyped for TPMT, and this may influence the course of further treatments.

In addition to metabolism, genes that alter the absorption and distribution of medications may also alter drug levels at tissue targets. These include, for example, genes that code for transporter proteins such as the ATP-binding cassette transporter proteins (ABCB, also known as the multidrug-resistance [MDR]-1 gene) [40], which has polymorphisms that have been associated with, for example, resistance to antiepileptic drugs [41]. It has been found that patients with drug-resistant epilepsy (approximately one of three patients with epilepsy is a nonresponder) are more likely to have the CC polymorphism of ABCB1, which is associated with increased

expression of this transporter drug-efflux protein (odds ratio 2.66; 95% CI 1.32–5.38) [41]. Of note, and consistent with the complexities of molecular pharmacoepidemiologic research noted later, the ABCB1 polymorphism falls within an extensive block of linkage disequilibrium (LD). LD is defined by a region in which multiple genetic variants (e.g., SNPs) are correlated with one another due to population and evolutionary genetic history. As a result, an SNP may be statistically associated with disease risk, but is also in LD with the true causative SNP. Therefore, the SNP under study may not itself be causal but simply linked to a true causal variant [41]. One of the major challenges in genetics research at this time is developing methods that can identify the true causal variant(s) that may reside in an LD block.

Pharmacodynamic Gene–Drug Interactions

Once a drug is absorbed and transported to its target site, its effect may be altered by differences in the response of drug targets. Therefore, polymorphisms in genes that code for drug targets may alter the response of an individual to a medication.

For example, polymorphisms of the beta-2-adrenergic receptor (beta-2-AR) might affect response to beta-agonists (e.g., albuterol) in asthma patients. In particular, the coding variants at position 16 within the beta-2-AR gene (beta-2-AR-16) have been suggested to determine patient response to albuterol treatment [11]. Israel *et al*. showed that the Arg-Arg genotype at beta-2-AR-16 was positively associated with clinical response to albuterol in patients who used this drug in an as-needed fashion [11]. However, patients with the same genotype showed a decrease in response after regular use of albuterol. The Gly-Gly genotype at beta-2-AR-16 was unaffected by regular use. This example shows that the clinical effects of genetic variants should be interpreted in the context of patterns of use of the drug regimen over time, in particular in cases where receptor kinetics (e.g., up- and downregulation of the receptor) play a critical role. However, later clinical and epidemiologic studies, directed at optimizing asthma treatment through beta-2-AR gene information, were not able to reconfirm the clinical relevance of the earlier findings, an example of type I error (discussed later in this chapter) frequently observed in common diseases [42].

Pharmacodynamic gene–drug interactions may also result in mixed responses in terms of intended and nonintended effects. For example, the treatment of patients with schizophrenia is still unsatisfactory because of the highly variable and frequently poor response profiles of antipsychotic drugs [43]. It is thought that dopamine receptors play an important role in both achieving the wanted therapeutic benefits and the occurrence of side effects (e.g., drug-induced tardive dyskinesia and parkinsonism) with these drugs. It appears as though there is a complex interplay between available antipsychotics and an array of dopamine D2, D3, and D4 receptor actions. This example of pharmacodynamic drug–gene interactions illustrates that therapeutic responses are unlikely to be associated with a single polymorphism, in particular when the same receptor panel is responsible for both therapeutic and adverse responses.

Thus, pharmacodynamic gene–drug interactions may also affect the risk of adverse reactions. Another example is a polymorphism in the gene coding for the bradykinin B2 receptor that has been associated with an increased risk of angiotensin converting enzyme (ACE) inhibitor-induced cough [44]. Cough is one of the most frequently seen adverse drug reactions (ADRs) in ACE therapy and very often a reason for discontinuation of therapy. The TT genotype and T allele of the human bradykinin B2 receptor gene were found to be significantly higher in subjects with cough [44]. However, similar to many other studies, replication of

these findings has been limited. Further research using genome-wide association studies (GWAS) has suggested that other SNPs are related to intolerance to ACE inhibitors, but again require replication [45].

Gene–Drug Interactions and the Causal Pathway of Disease

Along with altering the pharmacokinetic and pharmacodynamic properties of medications, genetic polymorphisms may also alter the disease state that is the target of drug therapy. As an example, hypertension is widely acknowledged to be a complex phenotype that involves many regulatory systems. These regulatory systems are associated with the responsiveness to different drug therapies. Medications that work by a particular mechanism, such as the increased sodium excretion of some antihypertensive medications, may have different effects depending on the susceptibility of the patient to the effects of the drug. One key polymorphism is in the alpha-adducin gene and its relation to treatment for hypertension. Cusi *et al*. found a significant association between the alpha-adducin locus (the site of the gene) and essential hypertension and greater sensitivity to changes in sodium balance among patients with the polymorphism of the gene [46]. These findings fueled various pharmacoepidemiologic studies to evaluate whether the alpha-adducin polymorphism may also be useful to identify hypertensive patients who can optimally benefit from diuretic treatment, but with rather inconsistent results regarding the impact of the drug–gene interaction on clinical outcomes [8,47].

Genetic variability in disease states also can be critical for tailoring drug therapy to patients with a specific genotype related to both the disease and drug response. One example is the humanized monoclonal antibody trastuzumab (Herceptin®), which is used for the treatment of metastatic breast cancer patients with overexpression of the HER2 oncogene. The HER2 protein is thought to be a unique target for trastuzumab therapy in patients with this genetically associated overexpression, occurring in 10–34% of females with breast cancer [12]. The case of trastuzumab, together with another anticancer drug, imatinib, which is especially effective in patients with Philadelphia chromosome-positive leukemias, has pioneered successful genetically targeted therapy [48]. The association of somatic mutations to drug response has received substantial interest. There are many targeted therapies now available that block the growth and spread of cancer by interfering with specific molecules involved in the growth, progression, and spread of cancer.

Genetic polymorphisms that alter disease states can also play a role in drug safety. For example, factor V Leiden mutation, present in about one out of 20 Caucasians, is considered an important genetic risk factor for deep vein thrombosis and embolism [49]. A relative risk of about 30 in factor V carriers and users of oral contraceptives compared to noncarriers and non-oral contraceptive users has been reported. This gene–drug interaction has also been linked to the differential thrombotic risk associated with third-generation oral contraceptives compared with second-generation oral contraceptives [13]. Despite this strong association, Vandenbroucke *et al*. have calculated that mass screening for factor V would result in denial of oral contraceptives for about 20 000 women positive for this mutation in order to prevent one death [50]. Therefore, these authors concluded that reviewing personal and family thrombosis history and, only if suitable, factor V testing before prescribing oral contraceptives is the recommended approach to avoid this adverse gene–drug interaction [50]. This highlights another important role of molecular pharmacoepidemiology: determining the utility and cost-effectiveness (see also Chapter 34) of genetic screening to guide drug therapy [51].

The Interplay of Various Mechanisms

It is useful to conceptualize how the effects of genetic polymorphisms at different stages of drug disposition and response might influence an individual's response to a medication. As an example, an individual may have a genotype that alters the metabolism of the drug, the receptor for the drug, or both [25]. Depending on the combination of these genotypes, the individual might have a different response in terms of both efficacy and toxicity (Table 30.1). In the simplified example in Table 30.1, there is one genetic variant that alters drug metabolism and one genetic variant that alters receptor response to a medication of interest. In this example, among those who are homozygous for the alleles that encode normal drug metabolism and normal receptor response, there is relatively high efficacy and low toxicity. However, among those who have a variant that reduces drug metabolism, efficacy at a standard dose could actually be greater (assuming a linear dose–response relationship within the possible drug levels of the medication) but toxicity could be increased (if dose related). Among those who have a variant that reduces receptor response, drug efficacy will be reduced while toxicity may not be different from those who carry genotypes that are not associated with impaired receptor response (assuming that toxicity is not related to the receptor responsible for efficacy). Among those who have variants for both genes, efficacy could be reduced because of the receptor variant (perhaps not as substantially as those with an isolated variant of the receptor gene because of the higher effective dose resulting from the metabolism gene variant), while toxicity could be increased because of the metabolism variant.

Some Examples of the Progression and Clinical Application of Molecular Pharmacoepidemiology

Medications with a narrow therapeutic ratio are good targets for the use of molecular pharmacoepidemiology to improve the use and application of medications. One example is warfarin. This example illustrates both the logical progression of pharmacogenetics through molecular pharmacoepidemiology and the complexity of moving pharmacogenetic data into practice. The enzyme primarily responsible for the metabolism of warfarin to its inactive form is the cytochrome P450 2C9 variant (CYP2C9) [52–54]. Pharmacogenetic studies identified polymorphisms in CYP2C9 that led to altered metabolism of warfarin [55,56].

Table 30.1 Hypothetical response to medications by genetic variants in metabolism and receptor genes.

		Drug response	
Gene affecting metabolism*	**Gene affecting receptor response***	**Efficacy**	**Toxicity**
Wild type	Wild type	70%	2%
Variant	Wild type	85%	20%
Wild type	Variant	20%	2%
Variant	Variant	35%	20%

Modified from Evans and McLeod [25].
*Wild type associated with normal metabolism or receptor response and variants associated with reduced metabolism or receptor response.

One of the first molecular pharmacoepidemiologic studies examining the clinical relevance of the CYP2C9 variants was a case–control study that reported that the odds ratio (OR) for a low warfarin dose requirement was 6.2 (95% CI 2.5, 15.6) among those having one or more CYP2C9 variant alleles compared with a control population with normal warfarin dose requirements [57]. The OR was elevated both in those with only one variant allele (i.e., heterozygotes: OR 2.7; 95% CI 1.2, 5.9) and in those with two variant alleles to an even greater extent (i.e., homozygotes: OR 7.8; 95% CI 1.9, 32.1). Patients on low doses of warfarin also were more likely to have difficulty with anticoagulation control during the first week of therapy and more likely to have bleeding complications, based on unadjusted analyses. A subsequent retrospective cohort study confirmed the lower dose requirement of patients with the genetic variant of CYP2C9, but did not examine clinical outcomes [58].

In order to address the clinically relevant question of bleeding, another retrospective cohort study was performed that demonstrated an increased risk of bleeding among patients followed in an anticoagulation clinic who had at least one variant of the CYP2C9 genotype [59]. The relatively small size of the study, retrospective nature, and selected population left unanswered the question of whether there is an independent effect of CYP2C9 variants on the risk of clinical outcomes throughout the course of anticoagulation therapy, whether specific variants or combinations of variants (e.g., heterozygotes with only one variant allele versus homozygotes with two variant alleles) have different effects, and whether knowing that a patient carries a variant can alter therapy in a way that can reduce risk.

A metaanalysis of studies examining the role of CYP2C9 in warfarin-treated patients demonstrated a significant association between CYP2C9 variants and bleeding risk [60]. Additional research clearly demonstrated that the vitamin K epoxide reductase complex 1 (VKORC-1) gene carries several variants that alter response to warfarin. Of note, most of the strongest associations with warfarin dose are among variants that are all in strong linkage disequilibrium with each other, particular in non-African American populations; thus, there is no benefit to dose prediction in these patients in genotyping more than just one SNP. Despite the presence of two genes with relatively strong associations with warfarin dosing, there is still about 50% of variability in warfarin dosing that is not explained by genetics or clinical factors, suggesting that other genetic factors may also influence the response to the medication [61]. However, despite much research, very few other SNPs have been identified that have a substantial effect on warfarin dosing, suggesting that perhaps many variants, including other variants in CYP2C9 and VKORC1 that may be more important in African-Americans, each with only a relatively small effect on dose, may be needed to add to our ability to predict warfarin response.

Eventually, clinical trials were performed to answer the important question of clinical utility: does altering warfarin dosing based on genotype affect outcomes? Following smaller, nondefinitive trials, three large-scale clinical trials of warfarin have been conducted. The first two had very different designs. The Clarification of Optimal Anticoagulation through Genetics (COAG) trial had greater control of dose titration in both study arms and used a comparison group that differed from the intervention group only in the absence of the use of genetics [62]. The EU-PACT UK trial used a formal dosing algorithm but left dose titration up to the discretion of practitioners who were not blinded to dose [63]. Perhaps most importantly, the comparison group was a usual care group and therefore did not incorporate a formal clinical-only (i.e., without genetics) initial dosing algorithm. In addition, while COAG enrolled about 27% African-Americans, EU-PACT UK enrolled only 1%. The two trials thus answered different

questions. COAG addressed whether adding genetics to clinical factors in a formal dosing algorithm can improve anticoagulation control relative to using a clinical-only algorithm under uniform dose titration methods and blinding of study subjects and practitioners. EU-PACT UK addressed whether a formal algorithm that used both genetic and clinical information improves anticoagulation relative to fixed-dose initiation where the dose titration method was left up to unblended clinicians. The COAG trial demonstrated no benefit of pharmacogenetic dosing on anticoagulation control overall, and worsening of anticoagulation control with pharmacogenetic dosing in African-Americans. The EU-PACT UK trial demonstrated improvement in anticoagulation control.

A third trial, the GIFT trial, examined pharmacogenetic dosing in orthopedic patients, compared with a clinical algorithm dosing arm [64]. This trial demonstrated benefit from pharmacogenetic dosing, but could not address the question of the effects of pharmacogenetics in African-Americans due to the enrollment of very few African-American patients.

Together, these trials demonstrate the need for, and benefit of, pharmacogenetic clinical trials testing different strategies in different patient populations.

Another pertinent example is in oncology. Cancer is an extremely heterogeneous disease with differences not only between cancer cells from different patients but also between cancer cells within a single patient. Every cancer patient exhibits a different genetic profile and the profile can change over time; thus, more patients will benefit if therapeutic options can be tailored to each individual, thus avoiding the "one size fits all" cancer treatment. Markers predicting response to anticancer drugs are mostly related to the fact that drug efficacy can be greatly influenced by alterations in drug targets and in related proteins present in tumor cells. Therefore, cancer-targeted therapies, directed to a specific cancer alteration, may only be indicated for the subgroup of patients with tumors carrying that molecular target. Examples include trastuzumab and imatinib mentioned earlier in the chapter.

To date, there is information about predictive biomarkers for many of the approved oncology drugs; the number of predictive biomarkers in cancer exceeds that in any other medical field. The US FDA currently includes over 300 pharmacogenetic labels, and a third of these are related to oncology. Most oncology-related markers indicate that drug use should be tailored to a subgroup of patients who have the targeted molecular alteration that predict drug efficacy (e.g., crizotinib for ALK rearrangements; bosutinib, omacetaxine, and ponatinib for BCR–ABL fusion protein; and dabrafenib, trametinib, and vemurafenib for mutated BRAF). The EMA also provides information regarding pharmacogenomic biomarkers in drug labels. In addition, several working groups, such as the PharmGKB (www.pharmgkb.org/view/drug-labels.do) and the National Comprehensive Cancer Centre (NCCN) Task Force, have published guidelines for the implementation of biomarkers in clinical practice to guide selection of drug treatments. Recommendations by several groups regarding the validity and utility of genetic tests for clinical practice are also available, for example by the Centers for Disease Control and Prevention (CDC) Office of Public Health Genomics (https://phgkb.cdc.gov/PHGKB/topicStartPage.action), which ranks genomic tests according to evidence level, and the Clinical Utility Gene Cards (CUGCs), which are disease-specific guidelines regarding the clinical utility of genetic testing authored by international experts (www.eurogentest.org/index.php?id=668).

It is now recognized that tumors have unique molecular compositions and can be subdivided accordingly. Each unique tumor type might be most sensitive to a specific drug combination. By identifying key driver mutations, specific drugs can be matched to the molecular targets

in the tumor and provide a "personalized" cancer treatment. While therapies for single targets are still common (e.g., trastuzumab targeting HER2 in treatment of breast cancer), use of therapies directed to multiple targets (e.g., sorafenib and sunitinib targeting the vascular endothelial growth factor receptor family [VEGF], platelet-derived growth factor receptor family [PDGFR], fms-like tyrosine kinase 3 [FLT-3] and stem cell factor receptor c-Kit in treatment of nonsmall cell lung cancer) are likely to increase to avoid relapses that occur frequently with targeted therapies. Precision oncology is enabled by technological advances. Next-generation sequencing technologies (described later in the chapter) can be applied to formalin-fixed paraffin-embedded tumor tissues (the samples routinely available in the clinic) to identify a large number of clinically relevant alterations in a timely and cost-effective manner and prospectively select cancer treatment.

It is important to note that novel treatment strategies can be based on a specific genetic characteristic regardless of the type or subtype of cancer. For instance, in 2017 the US FDA approved pembrolizumab for treatment of unresectable or metastatic solid tumors that have a biomarker, microsatellite instability-high (MSI-H) or mismatch repair deficient (dMMR), in adult and pediatric patients. This is the first drug approval based on a tumor's biomarker without regard to the tumor's original location.

Methodologic Problems to be Addressed by Pharmacoepidemiologic Research

As previously discussed, the basic science of molecular pharmacoepidemiology is the same basic science underlying pharmacoepidemiology. Therefore, the same methodologic problems of pharmacoepidemiology must be addressed in molecular pharmacoepidemiology. These problems include those of chance and statistical power, confounding, bias, and generalizability (see Chapters 3, 4, and 43).

However, the complex relationship between medication response and molecular and genetic factors generates some unique challenges in molecular pharmacoepidemiology. Many of these challenges derive from the large number of potential genetic variants that can modify the response to a single drug, the possibility that there is a small individual effect of any one of these genes, the low prevalence of many genetic variants, and the possibility that a presumptive gene–drug response relationship may be confounded by the racial and ethnic mixture of the population studied [65,66]. Thus, the methodologic challenges of molecular pharmacoepidemiology are closely related to issues of statistical interactions, type I and type II errors, and confounding.

First and foremost, however, molecular pharmacoepidemiologic studies rely on proper identification of putative genes. In addition, in all research of this type, use of appropriate laboratory methods, including the use of high-throughput genotyping technologies, is necessary. Similarly, appropriate quality control procedures must be considered to obtain meaningful data for research and clinical applications. Recent next-generation sequencing techniques have only highlighted further the need for, and complexity of, obtaining valid genotyping results. This section will focus on the methodologic challenges of studying interactions, minimizing type I and type II errors, and accounting for confounding, particularly by population admixture (defined below).

Interactions

Along with examining the direct effect of genes and other biomarkers on outcomes, molecular pharmacoepidemiologic studies must often be designed to examine effect modification between medication use and the genes or

biomarkers of interest. That is, the primary measure of interest is often the role of biomarker information on the effect of a medication. For purposes of simplicity, this discussion will use genetic variability as the measure of interest.

Effect modification is present if there is a difference in the effect of the medication depending on the presence or absence of the genetic variant. This difference can be either on the multiplicative or additive scale. On the multiplicative scale, interaction is present if the effect of the combination of the genotype and medication exposure relative to neither is greater than the product of the measure of effect of each (genotype alone or medication alone) relative to neither. On the additive scale, interaction is present if the effect of the combination of the genotype and medication exposure is greater than the sum of the measures of effect of each alone, again all relative to neither [67].

For studies examining a dichotomous medication exposure (e.g., medication use versus nonuse), a dichotomous genetic exposure (e.g., presence versus absence of a genetic variant), and a dichotomous outcome (e.g., myocardial infarction occurrence versus none), there are two ways to consider presenting and analyzing interactions [68]. The first is as a stratified analysis, comparing the effect of medication exposure versus nonexposure on the outcome in two strata: those with the genetic variant and those without (for example, see Table 30.2). The second is to present a 2 × 4 table (also shown in Table 30.2). In the first example (stratified analysis), one compares the effect of the medication among those with the genetic variant to the effect of the medication among those without the genetic variant. In the second example (the 2 × 4 table), the effect of each combination of exposure (i.e., with both genetic variant and medication; with genetic variant but without medication; with medication but without genetic variant) is determined relative to the lack of exposure to either. The advantage of the 2 × 4 table is that it presents separately the effect of the drug, the gene, and both relative to those without the genetic variant and without medication exposure. In addition, presentation of the data as a 2 × 4 table allows one to directly

Table 30.2 Two ways to present effect modification in molecular pharmacoepidemiologic studies using case–control study as a model.

Genotype	Medication	Cases	Controls	Odds ratio	Information provided
Stratified analysis					
+	+	a	b	ad/bc	Effect of medication vs no medication among those with the genotype
	-	c	d		
-	+	e	f	eh/fg	Effect of medication vs no medication among those without the genotype
	-	g	h		
2 × 4 table					
+	+	a	b	ah/bg = A	Joint genotype and medication vs neither
+	-	c	d	ch/dg = B	Genotype alone vs neither
-	+	e	f	eh/fg = C	Medication alone vs neither
-	-	g	h	Reference	Reference group

Modified from Khoury MJ, Little J, Burke W, eds. *Human Genome Epidemiology*. New York: Oxford University Press, 2004.

compute both multiplicative and additive interactions [68].

In the example given in Table 30.2, multiplicative interaction would be assessed by comparing the odds ratio for the combination of genotype and medication exposure to the product of the odds ratios for medication alone and genotype alone. Multiplicative interaction would be considered present if the odds ratios for the combination of medication and genotype (A in Table 30.2) was greater than the product of the odds ratios for either alone (B × C). Additive interaction would be considered present if the odds ratio for the combination of genotype and medication use (A) was greater than the sum of the odds ratios for medication use alone and genotype alone (B + C). The 2 × 4 table also allows the direct assessment of the number of subjects in each group along with the respective confidence interval for the measured effect in each of the groups, making it possible to directly observe the precision of the estimates in each of the groups and therefore better understand the power of the study. Furthermore, attributable fractions can be computed separately for each of the exposures alone and for the combination of exposures.

In general, we believe that presenting the data in both manners is optimal because it allows the reader to understand the effect of each of the exposures (2 × 4 table) as well as the effect of the medication in the presence or absence of the genotypic variant (stratified table).

Type I Error

The chance of type I error (concluding there is an association when in fact one does not exist) increases with the number of statistical tests performed on any one data set (see also Chapter 4) [69]. It is easy to appreciate the potential for type I error in a molecular pharmacoepidemiologic study that examines, simultaneously, the effects of multiple genetic factors, the effects of multiple nongenetic factors, and the interaction between and among these factors [69–71]. One of the reasons cited for nonreplication of study findings in molecular pharmacoepidemiology is type I error [42]. Limiting the number of associations examined to those of specific candidate genetic variants that are suspected of being associated with the outcome is one method to limit type I error in pharmacoepidemiology [72]. However, with increasing emphasis in molecular pharmacoepidemiologic studies on identifying all variants within a gene (and all variants within the genome) and examining multiple interactions, this method of limiting type I error is often not tenable [73]. Some other currently available solutions are discussed in the next section.

Type II Error

Because it has been hypothesized that much of the genetic variability leading to phenotypic expression of complex diseases results from the relatively small effects of many relatively low-prevalence genetic variants [74], the ability to detect a gene–response relationship is likely to require relatively large sample sizes to avoid type II error (concluding there is no association when in fact one does exist) (see also Chapter 4) [75]. The sample size requirements for studies that examine the direct effect of genes on medication response will be the same as the requirements for examining direct effects of individual risk factors on outcomes. With relatively low prevalences of polymorphisms and often low incidence of outcomes (particularly in studies of adverse drug reactions), large sample sizes are typically required to detect even modest associations. For such studies, the case–control design (see Chapter 3) has become a particularly favored approach for molecular pharmacoepidemiologic studies because of its ability to select participants based on the outcome of interest (and its ability to study the effects of multiple potential genotypes in the same study).

Studies designed to examine the interaction between a genetic polymorphism and a medication will require even larger sample sizes [76]. This is because such studies need to be powered to compare those with both the genetic polymorphism and the medication exposure with those who have neither. As an example, the previously mentioned case–control study of the alpha-adducin gene and diuretic therapy in patients with treated hypertension examined the effects of the genetic polymorphism, the diuretic therapy, and both in combination [8]. There were a total of 1038 participants in the study. When comparing the effect of diuretic use with no use and comparing the effect of the genetic variant with the nonvariant allele, all 1038 participants were available for comparison (Table 30.3). However, when examining the effect of diuretic therapy versus nonuse among those with the genetic variant, only 385 participants contributed to the analyses. Of note, this study presented the data for interaction in the two ways presented in Table 30.2.

In order to minimize false-negative findings, further efforts must be made to ensure adequate sample sizes for molecular pharmacoepidemiologic studies. Because of the complex nature of medication response, and the likelihood that at least several genes are responsible for the variability in drug response, studies designed to test for multiple gene–gene and gene–environment interactions (including other medications, environmental factors, adherence to medications, and clinical factors) will, similarly, require large sample sizes.

Confounding by Population Admixture

When there is evidence that baseline disease risks and genotype frequencies differ among ethnicities, the conditions for population stratification (i.e., population admixture or confounding by ethnicity) may be met [77]. Population admixture is simply a manifestation of confounding by ethnicity, which can occur if both baseline disease risks and genotype frequency vary across ethnicity.

For example, the African-American population represents admixture of at least three major continental ancestries (African, European, and Native American). Wacholder *et al.* demonstrated that the larger the number of ethnicities involved in an admixed population, the less

Table 30.3 Gene–exposure interaction analysis in a case–control study.

Diuretic use	Adducin variant	Cases	Controls	Odds ratio (OR) for stroke or myocardial infarction
0	0	A_{00} 103	B_{00} 248	1.0
0	1	A_{01} 85	B_{01} 131	1.56
1	0	A_{10} 94	B_{10} 208	1.09
1	1	A_{11} 41	B_{11} 128	0.77

Case control OR in variant carriers: $OR_{variant} = A_{11}B_{01}/A_{01}B_{11} = 41 \times 131/85x128 = 0.49$
Case control OR in wild-type carriers: $OR_{wild\text{-}type} = A_{10}B_{00}/A_{00}B_{10} = 94 \times 248/103 \times 208 = 1.09$
Synergy index = $OR_{variant}/OR_{wild\text{-}type} = 0.45$
Case-only OR = $A_{11}A_{00}/A_{10}A_{01} = 41 \times 103/94 \times 85 = 0.53$
Adapted from Psaty *et al.* [8].

likely that population stratification can be the explanation for biased associations [77]. Millikan [78] and Wang *et al*. [79] also reported that a minimal bias in point estimates is likely in African-American populations, suggesting that point estimates of association will not usually be influenced by population stratification in studies that involve African-American populations under most usual circumstances. Ardlie *et al*. used empirical data to show that carefully matched, moderate-sized case–control samples in African-American populations are unlikely to contain levels of population admixture that would result in significantly inflated numbers of false-positive associations [80]. They did observe the potential for population structure to exist in African-American populations, but this structure was eliminated by removing recent African or Caribbean immigrants, and limiting study samples to resident African-Americans. Furthermore, Cardon and Palmer argued that poor study design may be more important than population stratification in conferring bias to association studies [81].

Based on the literature evaluating the effects of confounding by ethnicity overall, and specifically in African-Americans, there is little empirical evidence that population stratification is a likely explanation for bias in point estimates or incorrect inferences [77]. Nonetheless, population admixture must be considered in designing and analyzing molecular pharmacoepidemiologic studies to ensure that adequate adjustment can be made for this potential confounder. New approaches to addressing population admixture are presented in the following section.

Currently Available Solutions

Identifying Additional Genetic Contributors to Drug Response

A great concern of the identification of low-penetrance alleles is that they have not yet been able to explain the majority of the estimated genetic contribution to disease etiology. Based on studies of families or phenotypic variability, most loci have been found to explain less than half (and at times as little as 1%) of the predicted heritability of many common traits [82]. This "missing heritability" of complex disease suggests that other classes of genetic variation may explain much of the genetic contribution to common disease.

There currently are two primary approaches for gene discovery: candidate gene association studies and genome-wide studies. In the former, genes are selected for study on the basis of their plausible biological relevance to drug response. While this allows for identification of variants with *a priori* biological plausibility, it is limited by our partial knowledge of which genetic variants may actually be responsible for variable drug effects. In the latter, DNA sequences are examined for associations with outcomes, initially irrespective of biological plausibility. The benefit of this approach is that it does not rely on our limited knowledge of genetics; the disadvantage is that the biological plausibility of the findings may then need to be confirmed.

One example is GWAS which rely on LD, defined above as the correlation between alleles at two loci. This approach uses DNA sequence variation (e.g., SNPs) found throughout the genome, and does not rely on *a priori* functional knowledge of gene function. Therefore, GWAS can be used to identify new candidate genes or regions, but relies on the potential for truly causative gene effects to be detected using genetic variants that may not have a functional effect. A number of factors influence the success of these studies. Appropriate epidemiologic study designs and adequate statistical power remain essential. Thorough characterization of LD is essential for replication of GWAS: the haplotype mapping (HapMap) consortium and other groups have shown that the extent of LD varies by ethnicity, which may affect the ability to replicate findings in subsequent studies [74]. Particularly informative SNPs that best

characterize a genomic region can be used to limit the amount of laboratory and analytical work in haplotype-based studies [83]. It has been hypothesized that studies that consider LD involving multiple SNPs in a genomic region (i.e., a haplotype) can increase power to detect associations by 15–50% compared with analyses involving only individual SNPs [84]. Finally, even if genome-wide scans may identify markers associated with the trait of interest, a challenge will be to identify the causative SNPs.

Newer, sequencing technologies have made it possible to study rarer genetic variants. While Sanger sequencing is still considered the gold standard in clinical testing, its limitations include low throughput and high cost. Broadly, next-generation sequencing (NGS) describes technologies that utilize clonally amplified or single-molecular templates that are then sequenced in a massively parallel fashion. The advance of NGS technologies has been enabled by innovation in sequencing chemistries, better imaging, microfabrication and information technology. In addition, bioinformatics tools for data analysis and management and sample preparation methods have rapidly evolved along with the sequencing technologies, translating to reductions in the amount of input materials required. In 2013, the US FDA approved marketing for the first time for a next-generation sequencer, Illumina's MiSeqDx, which allows the development and use of innumerable new genome-based tests.

Clearly, candidate gene and genome-wide approaches are not mutually exclusive. Both have the potential to identify important variants that may be clinically useful.

Interactions

Along with traditional case–control and cohort studies, the case-only study can be used for molecular pharmacoepidemiologic studies designed to examine interactions between genes and medications [85,86]. In this design, cases, representing those with the outcome or phenotype of interest, are selected for study, and the association between genetic variants and medication use is determined among these cases. Under the assumption that there is no association between the gene and medication exposure among those without the disease (i.e., controls), the odds ratio for the association between genetic variants and medication use in the cases is equivalent to the synergy index on a multiplicative scale for a case–control study [68]. (The synergy index is the odds ratio for medication use versus the outcome of interest in those with the variant alleles divided by the odds ratio for medication use versus the outcome in those without the variant alleles – see Table 30.3 footnote.) In other words, assuming that the use of the medication is unrelated to the genotype, the case-only study provides a valid measure of the interaction of the genotype and the medication on the risk of the outcome.

One strength of the case-only study design is that it eliminates the need to identify controls, which is often a major methodologic and logistical challenge in case–control studies. In addition, the case-only study can result in greater precision in estimating interactions compared with case–control analyses [85,86]. It also is possible to use the case-only approach to estimate interactions between genes and medications in large-scale registries of people with diseases or disease outcomes (e.g., cancer registries with genotypes and medication information available) [68].

One example of a case-only study is a study examining antihypertensive medication pharmacogenetics [87]. By using a large-scale clinical trial database derived from the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT), the authors examined cases of coronary heart disease and cases of heart failure outcomes and tested for gene-by-treatment effects among the cases. They

identified a potential interaction of a polymorphism within the ryanodine receptor 3 gene and heart failure outcomes.

There are several limitations of the case-only design [85]. As stated above, the design relies on the assumption of independence between exposure (medication use) and genotype. Although this assumption may be valid (in the absence of knowing genotype clinically, it may be reasonable to assume that the use of the medication is not related to patients' genotypes), it is certainly possible that, within observational studies, the genotype, by altering response to medications targeted at a specific disease or by altering the disease, could affect the medications being prescribed to patients. For example, the use of a particular antihypertensive medication may be related to prior success with other medications. Patients carrying genotypic variants that diminish the response to one class of antihypertensive medication may be more likely to be on other classes of antihypertensive medications. Thus, there would be an association between the genotype and the medication exposure. One way to minimize this possibility is to include only first-time prescriptions for hypertensive medications. Another method is to perform the case-only study within a randomized trial, where drug use is randomly assigned, as in the ALLHAT example provided above.

Another limitation of the case-only design is that it does not allow assessment of the independent effects of medication use or genotype on outcome. Further, the assessment of interaction can only be interpreted on a multiplicative scale.

Type I Error and Replication

Given concerns of type I error (along with other methodologic concerns such as uncontrolled confounding, publication bias, and linkage disequilibrium), a key issue in molecular epidemiology is the ability to replicate association study findings. Replication of association studies is required not only to identify biologically plausible causative associations, but also to conclude that a candidate gene has a meaningful etiologic effect. Lohmueller *et al.* observed that many associations are not replicated [42]. This lack of replication can be explained by false-positive reports (e.g., spurious associations), false-negative reports (e.g., studies that are insufficiently powerful to identify the association), or actual population differences (e.g., the true associations are different because of differences in genetic background, exposures, etc.). Given the perceived lack of consistency in association studies, what level of confidence can we have in associations reported to date?

Lohmueller *et al.* addressed these issues by undertaking a metaanalysis of 25 inconsistent associations and 301 "replication" studies (i.e., by ignoring the initial positive report) [42]. Most initial associations were not replicated, but an excess (20%) of replicated associations was seen, while only 5% were expected under the null hypothesis. This replication is not solely due to publication bias, since one would have to hypothesize that 40–80 negative studies were not reported rather than the average of 12 reported studies per association. Lohmueller *et al.* also concluded that it was unlikely that these replications represented false positives due to ethnic stratification. Different linkage disequilibrium patterns or other population patterns or population-specific modifiers (genes and/or environments) could also explain lack of replication, but this was unlikely to be a significant source of study inconsistency. The first positive reports also tended to be unreliable estimates for subsequently reported ORs [88], perhaps due to the "winner's curse" phenomenon which predicts that the initial positive report overestimates the "true" value [89]. Indeed, 23 of 25 associations studied showed evidence for a "winner's curse." An additional consequence of this phenomenon is

that replication studies may therefore require larger sample sizes since the actual effects being replicated may be smaller than suggested by the initial report.

Despite these limitations, these data indicate that associations are replicable more often than expected by chance, and may therefore represent truly causative effects on disease. Nonetheless, as illustrated by several examples in this chapter, replication is not guaranteed, and one cannot assume that an association from a single association is real.

In order to achieve believable, replicable association results, investigators must consider factors that influence the design, analysis, and interpretation of these studies. These include, as discussed above, adequate sample size, proper study design, and characterization of the study population, particularly when replication studies themselves are not comparable in terms of ethnicity or other confounding factors.

Data analytical methods can complement replication studies to address multiple testing and type I error, which are common problems in pharmacogenetics studies evaluating multiple SNPs, multiple exposures, and multiple interactions. Bonferroni correction is the most basic approach for adjusting multiple testing but is considered too conservative for tightly linked SNPs and may wipe out many small effects that one may actually expect (increased risk of type II errors). The false discovery rate (FDR) approach is less conservative for controlling for multiple analyses of the data. The FDR method estimates the expected proportion of false positives among associations that are declared significant, which is expressed as a q-value [90]. Under a Bayesian approach, there is no penalty for multiple testing because the prior probability of an association should not be affected by the tests that the investigator chooses to conduct. However, without strict standards, investigators might be tempted to cut corners or exaggerate the prior plausibility of a model that is supported *a posteriori* [91].

Type II Error

Reducing type II error essentially involves a logistical need to ensure adequate sample size (see also Chapter 4). One approach to increasing the sample size of molecular pharmacoepidemiologic studies is to perform large, multicenter collaborative studies. Another is to combine multiple, separately performed cohorts, sometimes referred to as metaepidemiologic studies. One example was the International Warfarin Pharmacogenetics Consortium (IWPC). This consortium of over 21 centers across nine countries combined data from multiple cohort studies in order to develop multiethnic dosing algorithms, attempt to identify uncommon SNPs associated with warfarin response, and perform GWAS [92]. By combining cohorts, the IWPC became the largest sample size of any warfarin pharmacogenetics studies.

Another potential solution to minimizing type II error is through metaanalysis, whereby smaller studies, which are individually not powered to detect specific associations (such as interactions), are combined in order to improve the ability to detect such associations (see Chapter 36). One particularly intriguing approach is the concept of prospective meta-analysis in which studies are planned or identified in advance of performing a metaanalysis so that important elements of study design complement each other across studies and important potential sources of bias that hamper the interpretation of retrospective metaanalyses can be avoided (see Chapter 36).

Adequate reporting of genetic association studies is important to allow assessment of their strengths and weaknesses. The STREGA statement (Strengthening the Reporting of Genetic Association studies) is an extension of the STROBE statement (Strengthening the Reporting

of Observational Studies in Epidemiology) that provides a checklist to help researchers and journals [93].

Population Admixture

As presented above, although population stratification is unlikely to be a significant source of bias in epidemiologic association studies, this assumes adequate adjustment for race. A number of analytical approaches exist to either circumvent problems imposed by population genetic structure or use this structure in gene identification [94,95]. The "structured association" approach identifies a set of individuals who are drawing their alleles from different background populations or ethnicities. This approach uses information about genotypes at loci that lie in regions other than the location of the gene of interest (i.e., "unlinked markers") to infer their ancestry (often referred to as ancestry informative markers) and learn about population structure. It further uses the data derived from these unlinked markers to adjust the association test statistic. By adjusting for these ancestry informative markers, one can adjust for differences in ancestry. The ALLHAT study, described above, performed such an adjustment using ancestry informative markers.

The Future

Without any doubt, scientific and clinical developments in biology and (bio)chemistry, particularly in the field of genomics and other biomarkers, have affected and will continue to affect the field of pharmacoepidemiology in a significant way. As discussed earlier in this chapter, translating biomarkers from the lab and experimental studies to clinical practice, and thereby to the study field of molecular pharmacoepidemiology, has been a difficult path.

We have addressed in this chapter several examples where the initial promising findings on drug–gene interactions to predict clinical drug responses could not be replicated in subsequent studies. For sure, the ability of genes and other biomarkers to improve patient care and outcomes will need to be tested in properly controlled studies, including randomized controlled trials. The positive and negative predictive value of carrying a genetic variant will be important determinants of the ability of the variant to improve outcomes. Those genetic variants with good test characteristics may still need to be evaluated in properly controlled trials. Such studies could examine several ways to incorporate genetic testing into clinical practice, including the use of genetic variants in dosing algorithms [96,97], in selection of a specific therapeutic class of drug to treat a disease [8], and in avoidance of using specific medications in those at high risk for adverse drug reactions [44]. These scientific advances are also finding their way into drug discovery and development in order to rationalize drug innovation and to identify good and poor responders, both in terms of efficacy and safety, to drug therapy in an earlier phase [98].

The cost-effectiveness of such approaches is also of great interest because the addition of genetic testing adds cost to clinical care (see also Chapter 34). Veenstra and colleagues have developed a set of criteria for evaluating the potential clinical and economic benefits of pharmacogenetic testing [99]. These criteria include the severity of the outcome avoided, the availability of other means to monitor drug response without the need for additional pharmacogenetics testing, the strength of the association between the genetic variants and clinically relevant outcomes, the availability of a rapid and relatively inexpensive assay, and the frequency of the variant alleles. In essence, these criteria could be applied to any new diagnostic test. Clearly, additional research will be needed to determine the cost-effectiveness of new biomarker and genetic tests as they are developed.

Next-generation sequencing will also require the development of novel approaches to data analyses. There are three levels of analysis that are conducted by NGS technologies: (i) targeted gene panels focus on a limited set of genes allowing for greater depth of coverage. The advantages include higher analytical sensitivity and specificity, and improved ability to interpret the results in a clinical context because only genes with an established role in the disease are sequenced; (ii) exome sequencing tests all coding regions of the human genome; and (iii) whole-genome sequencing analyzes the entire 3 billion bases of the genome. The targeted approach to genome sequencing is the more widespread clinical implementation of NGS technologies. This is because only some of the enormous amount of genetic information generated by exome or whole-genome sequencing can be interpreted and is actionable. Along with the bioinformatics challenges of managing and validating such large datasets, a significant amount of information will be novel and/or of unknown clinical importance.

A major area that requires further development is establishing the clinical utility of the identified markers/strategies for patients and healthcare systems. The level of evidence required to establish that a marker is clinically useful and should be introduced for routine use has been discussed extensively but consensus has not been reached.

Nevertheless, genetic and molecular studies are increasingly being incorporated in large clinical trials, which can lead to the identification of subgroups of patients with clear benefit from drugs, accelerating the discovery of effective therapies for selected populations. Another challenge to the implementation of genetic testing is the fact that pharmacogenetics knowledge is constantly being updated. Clinicians need to interpret the results of these tests in accordance with current understanding of the association between pharmacogenetic variation and drug effects.

What this all means for the future of pharmacoepidemiology is a challenging question. Genotype data will increasingly become available and will enrich pharmacoepidemiologic analysis. New methods (e.g., sequencing) will provide new opportunities, but also new challenges to analyzing pharmacoepidemiologic data. Further, although it is useful to characterize the three different pathways of how drug–gene interactions may occur, as was done in this chapter, this stratification is most likely an oversimplification of the large plethora of possible mechanisms of how drugs, genes, and patient outcomes are interrelated. All these may have consequences for how molecular pharmacoepidemiologic studies are designed, conducted, and analyzed. In addition, the more genotype testing is applied in clinical practice, the more drug exposure will be influenced by such tests, making genotype and drug exposure nonindependent factors.

Finally, just as for all research, the ethical, legal, and social implications of genetic testing must be considered and addressed [5,100–102] (see also Chapter 31). Pharmacogenetic testing raises issues of privacy concerns, access to healthcare services, and informed consent. For example, concern has been raised that the use of genetic testing could lead to targeting of therapies to only specific groups (ethnic or racial) of patients, ignoring others, and to loss of insurance coverage for certain groups of individuals [102]. There also is a concern that medicines will be developed only for the most common, commercially attractive, genotypes, leading to "orphan genotypes" [103,104]. Equally importantly, as more and more genetic data are collected on individuals as part of routine clinical care, the requirements and methods for returning unanticipated genetic results must be carefully determined and implemented.

All of these issues are challenges to overcome as we continue to reap the benefits of the tremendous strides made in determining the molecular basis of disease and drug response.

Bioethical Issues in Pharmacoepidemiologic Research

Laura E. Bothwell[1], Annika Richterich[2], and Jeremy A. Greene[3]

Because the bioethical issues involved in pharmacoepidemiologic research are closely related to changing patterns of drug usage and changing technologies of surveillance and data analysis, it is impossible to understand them without attention to historical and sociological perspectives. The field of pharmacoepidemiology emerged as a result of broader recent developments in medical therapeutics, concomitant with the expansion and refinement of the field of bioethics. Some key bioethical principles relevant to pharmacoepidemiologic research have remained significant over time; others have only gained attention in recent years. This chapter briefly introduces historical and sociological dimensions of pharmacoepidemiology from an international perspective, with an eye to commonalities and differences in national variations in ethical approaches to the field.

On the most common level, it is widely believed that pharmacoepidemiologic studies should create data that benefit public health, improve drug safety, and ensure efficacy. The protection of research subjects' rights and safety, their wellbeing, dignity, autonomy and privacy, as well as the reliability and robustness of generated data are relatively universal normative cornerstones of pharmacoepidemiology ethics. The same goes for the injunction that objectives and results of pharmacoepidemiologic research should be independent from economic and promotional interests of pharmaceutical companies or device manufacturers. Yet these principles are not simple to implement systematically at an international level. In this chapter, we explore the emergence and conduct of pharmacoepidemiologic research in three major global settings in which the field developed (North America, Europe, and East Asia) and some of the key challenges, tensions, and trends in historic and current international ethical policies relating to pharmacoepidemiology.

Pharmacoepidemiology, Sixth Edition. Edited by Brian L. Strom, Stephen E. Kimmel and Sean Hennessy.

Clinical Problems to be Addressed by Pharmacoepidemiologic Research

Emergence, Changing Methods, and Moral Stakes of Pharmacoepidemiology in 20th Century North America

In 1962, a series of epidemiological reports initiated by the German physician Widukind Lenz connected a recent increase in phocomelia, a birth defect which resulted in grossly visible limb deformities, with maternal use of the popular new antinausea medicine Contergan® (thalidomide) [1–4]. Images of thalidomide children became an international symbol of the ethical failure of the medical profession and the regulatory state to protect vulnerable populations from the harmful effects of widely marketed new drugs. Contergan had been extensively marketed to physicians and consumers alike, and its premarket testing and postmarket promotion had emphasized its remarkably *nontoxic* safety profile by available standards of clinical pharmacology [5,6]. As Lenz's work was read internationally, his careful use of the correlative techniques of infectious disease epidemiology within the terrain of prescription drug use documented not only the unseen dangers of newly marketed drugs but also the need for a new discipline of pharmaceutical epidemiology to scour observational data for therapeutic effects and adverse reactions that could clearly be associated with drug use in clinical practice [7,8].

The recognition that the risks of new drugs could be better understood when they were consumed by broad numbers of patients had been evident long before Lenz's epidemiology of thalidomide-associated phocomelia. Indeed, the history of federal drug regulation in the United States can be recounted as a succession of measures taken in response to dangers of drugs that became apparent after widespread consumption by the general public [9–11]. However, until the 1960s the Food and Drug Administration (FDA) had very limited authority in the postmarket regulation of drugs. The agency had neither direct means to control physician prescriptions nor resources to gather data on prescribing of newly marketed drugs. While the Committee on Pharmacy and Chemistry of the American Medical Association (AMA) nominally maintained more influence in both arenas, it depended entirely upon voluntary physician reports, and Committee members complained loudly that the system itself was doomed to failure; as one report noted, "physicians reported only a small fraction of all cases and the total number of patients receiving a drug was unknown" [12].

The 1962 Kefauver–Harris Amendments, passed largely on the strength of popular moral outrage over thalidomide, demanded that pharmaceutical manufacturers establish records and make reports to the FDA of "data relating to clinical experience and other data or information, received or otherwise obtained" [13] for all new drugs. By 1967, the agency had developed a protocol requiring manufacturers to seek and report any reported or published case reports related to putative side effects of their products. Any novel or unexpected adverse effect was to be reported to the agency within 15 days; other information "pertinent to the safety or effectiveness of the drug" was to be reported quarterly for the first year after approval, twice in the second year, and annually thereafter. Yet this kind of information could become actionable only after years of case reports, and then only if one of the relatively few FDA staffers took an active interest in pursuit of a specific question of drug harm.

The hospital became the center of early programs of pharmacoepidemiologic surveillance. By 1964, the FDA and AMA had built a surveillance program involving more than 600 hospitals, which became the focus of early pharmacoepidemiologic research by Johns Hopkins University's Leighton Cluff, Harvard University's Thomas

Chalmers, and Tufts University's Hershel Jick [14–18]. Yet the data were still only as good as the reporting physicians' records [19]. As Leighton Cluff noted, an early validation system of reporting efforts at the Johns Hopkins Hospital "proved completely unsatisfactory for detecting drug reactions …during recent daily intensive surveillance of one hospital service, four times as many reactions were detected than had been reported on the cards from the entire hospital" [19]. Would-be epidemiologists of adverse drug effects needed a way to circumvent the physician as reporting device and the digitization of data provided an appealing solution. Cluff's attempts at computerized drug monitoring involved the creation of three linked datasets for every drug received by every patient in a dedicated hospital ward [20]. D.J. Finney, another early theorist of computerized drug monitoring, expressed these data sets as a linked "P-D-E system," in which P(atient) population data would be systematically gathered within a set geographic or hospital catchment area, the D(rug) data would include records of all relevant prescriptions, and E(vent) collection would record all untoward reactions potentially attributable to the drugs prescribed [20].

Proponents of drug monitoring imagined a linked system of inpatient surveillance wards circling the globe, which could act as pharmacovigilance sensors, detecting early signals of possible drug harms and providing descriptive data regarding their frequency, severity, and relative strength of association. Finney predicted that surveillance would change pharmacoepidemiology from a reactive into a proactive field. Allowing that "much is due to Lenz for his discovery in 1961 [that thalidomide was associated with phocomelia]," he also boasted that "a *monitor* could have signaled a warning 1½–2 years earlier" [20]. Automated inpatient surveillance systems liberated pharmacoepidemiology from the "weak link" of the reporting physician [20]. With public and private support from the United States Public Health Service and the Pharmaceutical Manufacturers Association, Dennis Slone, Hershel Jick, and Ivan Borda demonstrated the feasibility of implementing an automated hospital-based drug monitor system in 1966 [21]. Based at the Lemuel Shattuck Hospital, the Boston Collaborative Drug Surveillance Program bypassed the physician by hiring a drug surveillance nurse "whose primary role is the acquisition of accurate data" [21,22]. The Boston team became a model for an automated drug surveillance program that functioned "largely independent of clinical judgment in establishing a connection between a drug and an adverse event" [23].

Early results showed that drug-related events were both more frequent and less severe than had previously been anticipated. More than one-third of patients on the Shattuck wards experienced at least one drug-associated adverse reaction during the first year of study [24]. By 1967, the Boston group had established a numerator/denominator approach for comparing drug usage between long-term and acute hospitals through a network of five hospitals in Boston [25]. By 1968, over 2500 patients had been entered and discharged from the surveillance system, with over 26 000 monitored drug exposures, representing more than 700 individual drugs [22]. Commonly prescribed drugs, such as digoxin and heparin, could be reported in detail, yielding novel information related to their clinical pharmacology and their interactions with other drugs [26–28]. The system enabled the observation of not only obvious drug reactions (such as a rash) but also other clinical events (such as heart attacks or kidney failure) that could only be associated with drugs by careful epidemiologic surveillance.

As the Boston Collaborative Drug Surveillance Program escalated its activities and exported its methods to other sites, these new data provoked a series of drug scandals that emphasized both the utility and the limitations of

the new forms of pharmacovigilance. Clioquinol, an antiinfective that had been in use since the 1930s, was found to be associated with subacute myelooptic neuropathy in 1970, over three decades after its initial introduction. An association between the synthetic estrogen diethylstilbestrol (DES) and a rare form of cervical clear cell adenoma was reported in 1971, with evidence of a 20-year latency period between use of the drug and detection of the cancer [29]. The beta-blocker practolol became the focus of a scandal after it was associated with a potentially fatal inflammation of the skin and soft tissues (oculomucocutaneous syndrome) some five years after its broad release on the British market. These examples simultaneously elucidated the scientific and ethical necessity for drug surveillance units and underscored the impossibility of inpatient surveillance systems to capture drug–disease associations in which three decades or more might pass between drug exposure and adverse events. As Jick warned, in a systematic proposal for the theory and design of the emerging field of pharmacoepidemiology, the ability to study "drug–illness relations" required distinct methods depending on the time course and prevalence of prescription-related adverse events. High-frequency events in high-prevalence diseases could be detected swiftly by case report, low-frequency events in high-prevalence diseases required careful active ongoing surveillance, and low-frequency events in low-prevalence diseases might simply never be adequately described [23]. Many early pharmacoepidemiologic researchers viewed scientific quality and ethics as complementary: more rigorous data collection of drug-related events carried ethical benefits by enhancing medical practitioners' capacity to "do no harm" to patients. As early pharmacoepidemiologic work also coincided with the development of bioethics as a field, critical principles of informed consent, external review of research protocols, and protection of patient privacy began to influence pharmacoepidemiologic investigators' thinking in the US and internationally.

To address the growing problems of drug safety, prescription surveillance needed to extend outwards: spatially, from the monitored wards of the hospital to the messier universe of outpatient care; temporally, from links visible in days or weeks of measurable hospital time to the longer stretches of months and years required to understand the impacts of chronic medication use; and thematically, from the isolated connection of drug and disease to the study of all steps of diagnosis, prescription, adherence, consumption, and presentation that might extend in between. In the United States, this project would find its boldest form in the Joint Commission on Prescription Drug Use, formed in response to a press conference held by Senator Edward Kennedy in November 1976, at which he announced that the new science of drug utilization studies had provided irrefutable evidence that prescription drugs were ill-used in American society [30]. Kennedy called for Congress to work with the medical profession and the pharmaceutical industry to sponsor a public–private body of expertise whose explicit purpose would be to establish a postmarket surveillance system for prescription drugs [31]. As the Commission would note in its final report, the purpose of systematic prescription surveillance was "not merely to learn 'something' about a drug but to glean information that is useful in improving the rational use of drugs" [31].

Conceived as a public–private venture, the Commission ran from 1976 until 1979 and issued its final report in the first month of 1980. The Commission worked to integrate the social, epidemiological, marketing, and policy interests in prescriptions as a source of data. Initially, the prospects for a harmonization of these four perspectives seemed auspicious. At the first meeting, Howard L. Binkley, Vice President for Research and Planning of the Pharmaceutical

Manufacturers Association, provided a description and critique of presently available sources of data on trends in the prescribing and dispensing of prescription drugs, with an emphasis on how market research data could be linked to broader systems of private and public claims and outcomes data [31]. Yet as the Commission assessed its findings by 1979, it became clear that although several datasets existed, no individual dataset contained enough information to deliver sufficient granularity to allow the full assessment of drug use in outpatient practice.

The Commission began to interview hybrid data sources that illustrated new links between the public and private nature of prescriber data sets. Fledgling HMOs such as Kaiser Permanente and the Group Health Cooperative of Puget Sound developed in-house proprietary databases that linked both prescription claims and outcomes data in the same place [31]. Exploratory work by Hershel Jick following the use of the blockbuster antiulcer drug Tagamet® (cimetidine) in Puget Sound pharmacies suggested that this approach could be quite promising [32]. Another hybrid form was introduced by Noel Munson, a spokesman from Prescription Card Services (PCS), a private prescription data company that acted as a "fiscal intermediary" for public payment groups like Medicare and Medicaid and other groups that paid for prescription drugs. But these individual companies (e.g., PCS) appeared to code their data according to their own proprietary software [31]. Even within the Medicaid system, the promise of effortless data linkage remained a dream in the late 1970s, complicated by wide state-by-state discrepancies in patterns of coding, storing, and retrieving prescription data [31].

If the 1980 publication of the Joint Commission report represented a high point of collaboration between market researchers, epidemiologists, policy reformers, and sociologists in imagining an early "big data" universe for therapeutic surveillance, it also represented a dream of collaborative work that would soon dissipate. Like many other grand designs for federally sponsored health programs conceived in the later 1970s and proposed in the early 1980s, its speculative structures would never materialize, its measures would be left unfunded, and subsequent calls for a center for postmarketing surveillance would be repeated, and unfunded, every few years for several decades. Only in the past decade, with the passage of the Food and Drug Administration Amendments Act of 2007 (FDAAA), would a substantial US public investment be made in the construction of a linked public prescription database for pharmacoepidemiologic research, with the creation of the FDA's new automated pharmacovigilance program, the Sentinel Initiative, which officially launched in 2016 (see Chapter 25).

European Pharmacoepidemiologic Trends and Ethics

In Europe, several nations with centralized national health systems like England and Sweden created prescription surveillance systems by the second half of the 20th century. Scandinavian countries in particular had long histories of centrally organized pharmacy records and more tightly controlled national formularies of allowable drugs [33]. Moreover, the World Health Organization had set up a regional European Drug Utilization Group in Oslo which held a prominent conference on the overprescribing of prescription drugs in 1969 [34] and then proceeded to develop methods of comparing utilization across drug classes and across national pharmacy standards [35]. Ironically, even in countries such as Sweden, much of the prescription data came from the private sector [33,36,37]. Still, pharmacoepidemiologic research in Europe continued to receive substantial public support throughout the 1970s, 1980s, and 1990s.

The founding of the European Medicines Agency (EMA) in 1995 was a crucial step toward a pan-European supervision of medicines. The

decentralized agency is critical to the European Medicines Regulatory Network (EMRN), partnering with the European Commission (EC) and national authorities of European Economic Area (EEA) member states (the Heads of Medicines Agencies [HMA] network). The EMRN's main objective is to achieve a consistent approach to medicines regulation across the EU. In collaboration with network partners, the EMA oversees the scientific evaluation, safety and efficacy monitoring of human (and veterinary) medicines in the EU. For most innovative medicines, including those for rare diseases, a central assessment and marketing authorization coordinated by the EMA is compulsory. In cases of human medicines, the EMA's Committee for Medicinal Products for Human Use (CHMP) carries out a scientific assessment, based on which the EC decides whether to grant marketing authorization. Once granted, such a centralized marketing authorization is valid across the EU. Predominantly, though, medicines in the EU are authorized by member states' national authorities.

Shared, key ethical requirements in European pharmacoepidemiologic research came to include beneficence, transparency, scientific independence, and integrity. Yet, inconsistent application and authorization procedures for clinical studies in European Union (EU) and European Economic Area (EEA) member states have long been criticized. This also applies to pharmacoepidemiology and pharmacovigilance. Especially for multinational, noninterventional studies (NIS), it has been lamented that "… a patchwork of regulations and codes of conduct have to be followed" [38].

Partly in response to some of these issues, since the early 2000s new EU regulations, directives, and guidelines have been introduced. These aim to facilitate ethical, effective pharmacoepidemiologic practices in and across different member states. Currently, crucial regulatory changes are under way that will affect pharmacoepidemiology and pharmacovigilance in the EU.

The EU pharmacovigilance legislation aims to minimize risks and harms posed by adverse drug reactions (ADRs). Its implementation is overseen by the EMA, EU member state authorities, and the European Commission (EC). Key legal documents for the pharmacovigilance legislation and pharmacoepidemiologic studies are EU Regulation No 1235/2010 and Directive 2010/84/EC [39]. In effect, the regulation outlines measures for safeguarding patients' safety and rights and asserts the crucial role of healthcare professionals in reporting ADRs. It moreover acknowledges the necessity to develop EU/EEA-wide "… harmonized guiding principles for, and regulatory supervision of, postauthorization safety studies that are requested by competent authorities and that are noninterventional, that are initiated, managed or financed by the marketing authorization holder" [39]. Among other deliverables, the regulation established the EudraVigilance database as a main platform for the obligatory reporting of ADRs by marketing authorization holders and respective national authorities.

In response to the benfluorex scandal, the legislation was amended in 2012. Servier Pharmaceuticals' Mediator® (benfluorex), marketed as an add-on for diabetes and hyperlipidemia, was under pharmacovigilance investigation in France since 1998. It was found that the drug caused cardiovascular complications in 2003. In response, Servier did not reapply for marketing authorization in Spain and Italy, effectively withdrawing the product from the market in those countries. However, benfluorex continued to be available and approved for diabetes treatment in France and other countries until 2009, when its authorization was fully revoked; its efficacy was found to be limited and it risked causing cardiac valvulopathy [40]. Subsequently, EU Regulation No 1027/2012 and Directive 2012/26/EC were published, amending the 2010 EU pharmacovigilance legislation. The amendments especially addressed the issue that safety measures for medicinal products

need to be implemented consistently and in a timely fashion in all member states where respective products were authorized.

The benfluorex scandal points to broader challenges regarding pharmacovigilance and pharmacoepidemiologic research in the EU: regulations and guidelines need to be applied across multiple states and to different actors, including national marketing authorization holders and applicants. While the legislation outlines fairly broad objectives, responsibilities, and issues, these are specified in concrete deliverables. One of these deliverables was the founding of the EMA Pharmacovigilance Risk Assessment Committee (PRAC) which monitors and assesses drug safety in the EU. Moreover, it initiated the development of the EMA's Good Pharmacovigilance Practices (GVP) guideline (described later in this chapter).

The European Network of Centres for Pharmacoepidemiology and Pharmacovigilance (ENCePP) was established in 2006 and is coordinated by the EMA. It is an expertise and resource network focused on pharmacoepidemiology and pharmacovigilance in Europe. It consists of partners that are public and not-for-profit organizations, including research and pharmacovigilance centers, university hospitals, healthcare database hosts, and electronic registry sponsors. For-profit organizations, such as contract research institutions, may only participate if they conduct pharmacoepidemiologic and/or pharmacovigilance studies commissioned by third parties. While pharmaceutical companies are not eligible for becoming ENCePP partners, the network provides relevant resources and allows for these companies to be involved in public document reviews.

The ENCePP offers crucial guideline documents for pharmacoepidemiology and pharmacovigilance: a Code of Conduct; the ENCePP Checklist for Study Protocols; and the ENCePP Guide on Methodological Standards in Pharmacoepidemiology. The Code lays down rules and principles aimed at ensuring transparency and scientific independence. While adherence to the Code is voluntary, it is required to receive the ENCePP Seal. Conditions for receiving the Seal are, among others, that a study is entered in the EU PAS Register and that it is of scientific and public health relevance, rather than mainly pursuing results which may promote certain medicinal products. The Checklist is meant to ensure that studies adhere to epidemiological principles, while also considering methodological transparency and the need for public outreach.

East Asian Pharmacoepidemiologic Trends and Ethics

East Asia has made major contributions as the field of pharmacoepidemiology has grown, producing a very robust body of pharmacoepidemiologic research that has expanded in recent decades. Researchers in South Korea, Japan, and Taiwan have linked into comprehensive data systems on insurance claims created through universal insurance coverage of these entire national populations. To help protect patient privacy, these databases have been made available for drug safety research only to researchers in nonprofit organizations who must apply and undergo ethical review [41].

The Korea Food and Drug Administration (KFDA) launched an adverse drug reaction (ADR) reporting system in 1988, although the reporting rate was initially very low. In 2004, the KFDA mandated that pharmacists and pharmaceutical companies report adverse drug reactions. The KFDA also established regional pharmacovigilance centers in university hospitals that now provide nearly complete coverage of the country. The KFDA funded a pharmacovigilance research network (PVNet) among these centers, and researchers in the network use their data for studying adverse events. The Korean national health insurance database also contains all information on insurance claims

made and prescriptions for approximately 50 million Koreans, and this has been used for pharmacovigilance [41].

In Japan, drug manufacturers are required to report adverse drug reactions to the Pharmaceuticals and Medical Devices Agency (PMDA). A partial adverse drug reaction dataset is available to researchers through the PMDA website. Healthcare professionals report adverse drug events to the Ministry of Health, Labor and Welfare. Japan made its national insurance claims database available for drug safety researchers in 2011. The database covers the entire population of 128 million and includes basic patient characteristics, drug prescription and dispensing, medical procedures, hospital admission, and annual health check data (for some patients) [41]. To protect patient privacy, Japan's national database is usually not available for purchase and may only be shared in some cooperative research projects [42]. The Japanese government has also created the Medical Information for Risk Assessment Initiative (MIHARI) to access data from different sources and create a central database with a common data format [43].

Taiwan requires mandatory reporting of serious adverse reactions by medical institutions, pharmacies, and drug and device companies, as well as obligatory safety reports for newly marketed drugs over a five-year surveillance period. In Taiwan, the National Adverse Drug Reactions Reporting System has been the primary source for postmarketing surveillance of adverse drug events. Taiwan's single-payer National Health Insurance (NHI) program was created in 1995 and covers more than 99% of the population. The NHI Research Database is thus a highly comprehensive dataset including basic patient data, care record and expenditure claims, and pharmaceutical reimbursements. There are also subject datasets available to researchers on topics such as traditional Chinese medicine, cancer, diabetes, dental, catastrophic illness, and psychiatric care. Patients and medical facilities are deidentified for pharmacoepidemiologic research use of the NHI Research Database [41]. To protect patient privacy, researchers using Taiwan's NHI Research Database also receive data for 10% or less of the population. Ethical policies for data privacy stipulate that no individual-level data can be shared with researchers from other countries [42].

China and other East Asian countries also have been creating national healthcare claims databases [44]. In China, the Shanghai Center for Adverse Drug Reaction Monitoring has operated a drug surveillance and evaluation system since 2001 that works with patient information from 10 Shanghai hospitals [43]. The Asian Pharmacoepidemiology Network (AsPEN) was recently established as a multinational research network for pharmacoepidemiological research that promotes international communication among academia, government, industry, and consumers. The network functions to promptly identify drug safety issues [44].

Pharmacoepidemiology ethics in East Asia are similar in many ways to those of Western countries, including features such as institutional ethical review and guiding principles such as beneficence, justice, autonomy, and data privacy. However, experts on East Asian bioethics also have recognized some distinctions. For example, scholars have contended that much East Asian bioethical thinking reflects value systems that emphasize the family and public interest ahead of the individual rights of the liberal subject that characterize much of Western bioethics. The family is often depicted as responsible for taking care of members who become sick, and medical decision making has often been family based. Some also have noted a plurality of ethical perspectives within East Asia, contending that a simple Eastern and Western bioethical dichotomy of communitarian versus individualistic values would be overly simplistic. Others have viewed bioethics as a Western entity, promoting the development of

Asian bioethics based more on the traditions, philosophies, religions, and perspectives of the region's cultures [45]. Future policies should consider these issues as core principles for pharmacoepidemiologic research ethics are discussed.

Methodologic Problems to be Solved by Pharmacoepidemiologic Research

More work remains to establish international ethical policy harmonization while also promoting practices that support cultural variation in ethical values. Yet, as pharmacoepidemiological practices developed in different national contexts that have been incorporated into increasingly globalized flows of pharmaceuticals and pharmaceutical-related information, a number of ethical principles and practices have been adopted widely across international settings in efforts to establish consistent pharmacoepidemiologic methodology.

The expansion of the field of pharmacoepidemiology has coincided with the establishment and institutionalization of the discipline of bioethics. Numerous critical ethical concepts took hold early in pharmacoepidemiology and have remained significant over time. For example, privacy of medical data is a historically consistent value guiding the ethics of global pharmacoepidemiologic research. Pharmacoepidemiologic research protocols and/or database designs also often have been subjected to review by institutional review boards as external review has become increasingly widespread for biomedical research since the second half of the 20th century, although there is variation in the nature of this review. For example, some pharmacoepidemiologic research has been reviewed by institutional or national ethics boards, as well as by privacy boards [46]. Some countries also do not require ethical review for deidentified datasets [47].

Informed Consent

Informed consent became increasingly valued as a critical standard of international research ethics following its establishment as a cornerstone of the 1964 Declaration of Helsinki, a ground-breaking statement of international human experimentation ethics [48]. However, the role of informed consent has been perceived differently in interventional versus noninterventional research studies. Many ethicists of international human subject research have argued that since pharmacoepidemiologic research involves relatively low risks to participants, patient consent is necessary only for studies that involve contact with patients/research subjects, such as for direct intervention or prospective gathering of information. There has been a broad acceptance among ethicists allowing researcher access to identifiable medical records for pharmacoepidemiologic research without explicit individual subject authorization [46]. Research has also found that public opinion has echoed the views of professional ethicists that pharmacoepidemiologists should be permitted to use identifiable patient records, without patient consent, to study drug safety as long as existing ethical guidelines and relevant laws are followed [49].

A number of nations, however, require explicit informed consent from each study participant, and there are also international variations in requirements for electronic consent versus hard copy written consent. Ethical regulatory disharmony causes differences in study conduct between countries and increases the cost of assembling multinational data. This poses challenges for conducting large international studies capable of detecting rare events. Additionally, requirements of explicit individual informed consent are problematic in that they can corrupt data by preventing a postmarketing pharmacoepidemiologic study from detecting fatal or serious events since people who have died are unable to provide informed consent [47].

Thus, it is unsurprising that ethicists weighing risks and benefits have tended to contend that individual consent is not essential for use of patient records in pharmacoepidemiologic research.

However, over time it has become normative that pharmacoepidemiologists also must meet certain requirements when conducting research in which participant consent is waived. These requirements often include that the use of protected health information involves no more than minimal risk to patients, the research could not be effectively conducted without access to the protected health information and/or the waiver of individual consent, the privacy risks to individuals are reasonable in relation to any value to the individuals of the knowledge expected to result from the study, there is a sound plan to protect patients from improper use or disclosure of their information, there is a plan to destroy identifiers at the earliest opportunity consistent with the research, and the data will not be shared with external parties to the research [46].

Recent attention has been given to waiver of patient informed consent to use data on substances of abuse or drugs that carry social stigma. Patient privacy is essential in these areas of research; however, requiring informed consent for each patient or allowing retraction of sensitive drug information from patient records leads to partial datasets that impede the ability of researchers to study the impact of these substances on patient health outcomes. The negative consequences of failing to collect sound pharmacoepidemiologic data on the health effects of these substances are likely worse than the relatively minimal risk associated with waiver of patient consent. However, in such circumstances, the highest precautions should be taken to protect patient privacy, such as deidentifying data through secure codes or potentially having extra ethics training requirements for all researchers using data on stigmatized or abused substances. (See Chapter 28 for further discussion of pharmacoepidemiology research on drugs of abuse.)

Ethics of Surveillance

Surveillance has long provoked public concern regarding privacy, confidentiality, and autonomy. This is relevant to postmarketing surveillance, since health information is seen as highly sensitive and personal. Thus, pharmacoepidemiologic researchers need to balance possible risks to a larger population against the harms concerning individuals, such as a possible infringement of privacy. While privacy is highly important to the ethics of pharmacoepidemiologic research, privacy is not an absolute value, nor does it seem to have been perceived as such in public health surveillance history. Rather, privacy is one of multiple values that are balanced in public health surveillance [50]. It has been argued that ensuring privacy is part of the broader value of protecting autonomy. Yet other key principles to be balanced in pharmacoepidemiologic research include beneficence to promote research that adds to the existing knowledge base of medicine to improve patient health and prevent mortality; nonmaleficence, or the prevention of patient harm; and justice, which manifests as the fair distribution of research burdens and benefits among people [51].

Risks of surveillance can be minimized through confidentiality and data anonymization. Such strategies are ethically imperative, since they safeguard individuals' rights, privacy, autonomy, and dignity. Applying the highest ethical standards and communicating with the public about potential criticism are also important for a positive public perception of pharmacoepidemiology.

While there have been some disagreements, international ethics policies have developed some common stances toward ethical review of drug surveillance. Certain pharmacoepidemiologic research tends to qualify as exempt from ethics board review or qualifies for expedited review by an ethics board chair or a designated member. For studies in which it is not possible for investigators to identify individual patients, ethics board review is often not required. For example, the US 45 Code of Federal Regulations 46.101

exempts from institutional review "research involving the collection or study of existing data, documents, records, pathological specimens, or diagnostic specimens, if these sources are publicly available or if the information is recorded by the investigator in such a manner that subjects cannot be identified, directly or through identifiers linked to the subjects" [52]. In many countries, research is also often eligible for expedited review if it poses no more than minimal risk to patients and involves a retrospective analysis of existing records. Still, ethics review policies vary internationally and by institutional practice, depending *inter alia* on respective national/state regulations, posing challenges for global collaborative studies [53]. This may lead to inconsistent risk–benefit assessments and variations in balancing subjects' protection (e.g., regarding safety and privacy) against public health interests.

The European Medicines Agency's guideline on Good Pharmacovigilance Practices (GVP) provides a useful differentiation between "active surveillance" and "passive surveillance." Active surveillance is defined as a continuous, systematic process of monitoring adverse events in a population. For example, a risk management system may be put in place which allows for the active surveillance of patients receiving a medicinal product. Another active surveillance option would be the monitoring of laboratory reports to detect adverse events. Active surveillance may be part of interventional or noninterventional studies (NIS). Passive surveillance, based on patients' spontaneous reporting, for example, is commonly seen as less effective, because it runs the risk of delivering less comprehensive data [54].

Ethical Benefits of Pharmacoepidemiologic Research for Data Integrity

From a broader ethical perspective, it is increasingly clear that the expansion of pharmacoepidemiological research can provide added benefits to drug research by detecting groups at risk for adverse events. Thus, the field can play an important role in reducing drug safety data inequalities. For example, expanding drug outcomes data for groups such as minorities or small/rare genetic subpopulations who may have treatment outcome variations that can only be identified and/or adequately quantified and measured through large postmarketing pharmacoepidemiologic studies may provide substantial benefits for members of these populations. There are also limited data on the efficacy and safety of drugs in children due to the fact that historically, children have often not been included in randomized controlled trials (RCTs). Pharmacoepidemiologic research helps to fill these research gaps [55]. However, it would be ethically problematic for pharmacoepidemiology to be relied on solely to provide missing data on children, minorities, or other subgroups in lieu of RCTs, particularly in cases when RCTs could produce more robust data.

Further, pharmacoepidemiologic studies are usually conducted after drug approval, and there is high variability in the frequency and design of postmarketing pharmacoepidemiologic research [56]. Such studies are not necessarily required, and so are not a consistently reliable source of information on drug outcomes among diverse demographic groups. Clinical trials are usually required for drug approval and are thus a mechanism for ensuring broader implementation of policies requiring the inclusion of diverse research subjects [48]. Ultimately, consistent with recurring concerns over ethical practices in pharmacoepidemiologic research in general, ethicists have noted that pharmacoepidemiology related to subpopulations would benefit from a more explicit legal ethical framework, particularly to clarify ethical requirements for data sharing [57].

Problems of Conflicts of Interest for Drug Industry Research

Academia–industry collaborations have become a critical area of concern for the ethics of pharmacoepidemiologic research, particularly in

recent decades as pharmaceutical profits have soared and the stakes have been raised for the outcomes of research on drug safety and efficacy. There is an inherent conflict of interest in research that is funded by drug companies to assess their own products. Academic settings in which researcher success and advancement depend on obtaining external funding also can exacerbate the ethical problems resulting from direct relationships between drug companies and the pharmacoepidemiologists evaluating their products. Investigators in such environments are under professional pressure to secure funding, and in a climate of heightened competition for public funding sources, an academician who establishes a positive working relationship with a pharmaceutical research sponsor may increase his/her chances of obtaining future funding from that sponsor.

This creates an incentive, whether subconscious or acknowledged, for researchers to conduct studies that sponsoring drug companies will find favorable. Indeed, studies have shown a trend toward more favorable efficacy results and conclusions for industry-sponsored drug research than research sponsored by other sources, finding a bias in industry-funded research that cannot be otherwise explained by standard assessments of risk of bias [58,59]. There are a number of feasible solutions to address the ethical conflicts of interest in industry-funded research.

Currently Available Solutions

Good Pharmacoepidemiology and Pharmacovigilance Practices

The International Society for Pharmacoepidemiology (ISPE) has created Guidelines for Good Pharmacoepidemiology Practice (GPP), which provide a model for key pharmacoepidemiologic research ethics policies. The guidelines recommend that researchers include a description of quality control procedures; plans for protecting human subjects; confidentiality provisions; ethical conditions under which a study would terminate; the use of Data Safety Monitoring Boards where appropriate; institutional review board and informed consent considerations in accordance with local laws; research study registration; and plans for disseminating study results [60]. However, ISPE GPP policies are nonbinding and therefore do not resolve concerns regarding national variations in ethical oversight and requirements by regulatory agencies for postmarketing pharmacoepidemiologic work [47].

European Union policies provide a useful example of transnational efforts at regulatory standardization of good pharmacovigilance practices. EU documents concerning biomedical research in general and pharmacoepidemiologic research commonly speak of two types of clinical studies, broadly speaking: interventional, that is, experimental, and noninterventional, sometimes called observational research. On the one hand, pharmacoepidemiologic research relies on noninterventional study designs such as case–control or cohort studies. On the other hand, interventional RCTs are an important element of postmarketing pharmacoepidemiology studies (see Chapter 32).

The EMA defines Good Pharmacovigilance Practices (GVP) as "a set of measures drawn up to facilitate the performance of the safety monitoring of medicines in the European Union" [54]. It includes chapters on pharmacovigilance processes as well as product- and population-specific considerations. For EU pharmacoepidemiologic postauthorization safety studies (PASS), module VIII is particularly relevant. PASS may be interventional or noninterventional. Although the module touches upon interventional studies too, emphasis is put on noninterventional PASS.

In accordance with the EU pharmacovigilance legislation, the GVP stipulates that the EMA needs to ensure that protocols and abstracts of PASS results are published. While the primary/

lead investigator is responsible for the information provided, the registration may be made by, for example, research center staff or representatives of pharmaceutical companies funding a study. Where possible, this should be done before the study commences. Practically, registration and publication are processed through the EU postauthorization study (PAS) register, hosted by the ENCePP [61]. As the ethics review procedure and requirements for respective committees depend on national legislation, information on individual application procedures is not included in the GVP. While there is no EU regulation or directive for NIS, interventional studies are covered in the Clinical Trials Regulation.

In the European Union, methodological, ethical, and legal requirements for pharmacoepidemiologic research hinge significantly on whether a study is categorized as a "clinical trial" or as "noninterventional/nonexperimental." Both categories are defined as "clinical studies" aimed at discovering or confirming the (adverse) effects of medicinal products [62]. For pharmacoepidemiologic studies involving clinical trials, the introduction of the EU Clinical Trials Regulation (CTR) No 536/2014 will be decisive [63].

The CTR was adopted on 16 April 2014 and entered into force on 16 June 2014. According to the EMA, it will come into application in late 2019, starting a transition period of three years [64]. It is meant to harmonize research practices and to ensure the highest methodological and ethical standards across all EU as well as EEA EFTA member states. To what extent it will deliver on these promises is under discussion [65,66]. The regulation replaces the Clinical Trials Directive 2001/20/EC which is said to have "… failed to achieve its goal of simplifying the scientific and ethical review of clinical trials in the EU" [67].

Moreover, the ENCePP had problematized the NIS definition given in the 2001 directive. The ENCePP raised the issue that the definition was not sufficiently specific and created uncertainty as to what counts as NIS or RCT. Pharmacoepidemiologic prospective case–control studies – like the IPPHS investigation of primary pulmonary hypertension (PPH) occurrence in association with anorectic agents – would classify as a clinical trial according to the 2001 directive. Its ambiguous NIS definition was thus criticized for impeding the conduct of pharmacoepidemiologic studies [68].

The ENCePP Guide on Methodological Standards in Pharmacoepidemiology (Revision 6, July 2017) lays down rules and principles for transparency and scientific independence. Chapter 9 of the Guide deals with ethical aspects of pharmacoepidemiology, focusing on patient and data protection (9.1) and scientific integrity and ethical conduct (9.2). It identifies key values based on documents such as the ADVANCE Code of Conduct for Collaborative Vaccine Studies, the GPP of the International Society for Pharmacoepidemiology, and the Good Epidemiology Practice (GEP) guidelines of the International Epidemiological Association. The Guide highlights that "principles of scientific integrity and ethical conduct are paramount in any medical research" and points out that the above-mentioned ENCePP code of conduct "… offers standards for scientific independence and transparency of research in pharmacoepidemiology and pharmacovigilance" [69]. In addition, it highlights core values, such as best science, strengthening public health, and improving transparency, as stressed by the ADVANCE Code of Conduct. It also emphasizes the need for ensuring scientific autonomy, beneficence, nonmaleficence and justice, according to the four general ethical principles defined in the GEP guidelines.

Protections Against Conflicts of Interest for Drug Industry-Sponsored Research

While industry-sponsored research creates real challenges for conflicts of interest, industry also has an interest in maintaining public trust in product integrity, as well as in compliance with

regulatory ethical and methodological requirements to obtain drug approval. Thus, there is some incentive for industry to address concerns about conflicts of interest. The Board of Directors of the International Society for Pharmacoepidemiology has published a set of principles for academia–industry collaboration that can be helpful in managing industry conflicts of interest. It includes the importance of transparent research agreements, open and complete disclosure of conflicts of interest, registration of research protocols in public sites such as the ENCePP registry or ClinicalTrials.gov, compliance with local laws, clarity on confidentiality of proprietary information while also ensuring reporting of all relevant and important information to regulators, the potential value of having a steering committee and/or an independent advisory committee to the research, and an obligation to disseminate and publish research findings of potential scientific or public health importance irrespective of results [70].

While all these principles are helpful in managing financial conflicts of interest, they do not eliminate the inherent problem of drug companies having a stake in the outcomes of research that they sponsor or the ethical concerns associated with the power dynamics of industry directly funding investigators as described above. To eliminate these underlying ethical problems, the direct relationships in which companies fund individual investigators to assess specific products would need to be severed. Alternative models that eliminate these ethical conflicts can be easily envisaged. For example, the British Drug Safety Research Unit (DSRU), an independent charity supported by the National Health Service, conducts publicly funded pharmacoepidemiologic research [43]. Still, the organization conducts a large amount of research funded by unconditional donations from pharmaceutical companies. However, the companies have no control on the conduct or the publication of studies conducted by the DSRU [71] which helps to mitigate the pressure of inherent conflicts of interest in industry-funded research.

Given that industry funding may lead to biased study results, a comprehensive solution could build from the DSRU model, for example by requiring sponsors of new drugs to contribute an unconditional fee to drug regulators that would fund pharmacoepidemiologic research. By making such contributions mandatory rather than voluntary, investigators could conduct studies without concern as to whether results may influence future industry donation decisions. In the US, for example, the expansion of the FDA's Prescription Drug User Fee could easily establish a fund for pharmacoepidemiologic research.

The Future

The ethical conduct of pharmacoepidemiologic studies is of crucial importance for subjects' safety, health, and wellbeing. Moreover, it is decisive for the public perception of pharmacoepidemiology. Research in this field is rooted in the moral obligation to preempt or at least minimize medicine-related harms and health hazards. Implementing highest ethical standards helps to avoid potential damage to the public image of the field and public trust in claims of pharmacoepidemiological research as a disinterested form of expert knowledge. Such damage may be related to research practices compromised by economic interests or misconduct of the pharmaceutical industry. Thus, scientific integrity, independence, and transparency will continue to be crucial for the ethics of pharmacoepidemiologic research.

Even in the recent past, regulatory amendments relevant to pharmacoepidemiology and pharmacovigilance were often triggered by scandals, although a dream to make pharmacoepidemiology a proactive rather than a reactive field can be traced back to the 1960s if not earlier. Adjusted, new, and emerging regulations and guidelines aim at promoting ethical

pharmacoepidemiologic research that effectively identifies and reports ADRs, thus allowing for timely responses. New policies must also be more thoroughly transnational and attentive to global variations in ethical beliefs. A main challenge is and will continue to be to translate inevitably general documents into practical instructions and relevant local practices.

In the future, national regulatory authorities, universities, and research centers will continue working to align requirements towards coherent pharmacoepidemiologic research ethics. It is to be expected that further regulatory efforts will be invested in streamlining requirements for ethics review boards and ethical guidelines for noninterventional studies, especially across the EU. Although recent regulations and directives in the EU hope to address several pressing issues, many of these are complicated anew by the UK's announced withdrawal from the EU. This has already triggered practical changes, such as the relocation of the European Medicines Agency from London to Amsterdam in March 2019. Moreover, legal uncertainties are increasing [72], as it has been disclosed by the UK Department for Exiting the European Union that the post-Brexit guidelines for clinical studies in the UK may deviate from EU legislation [73].

Transparency has been stressed as a key element for ensuring ethical pharmacoepidemiologic practices. Moreover, data sharing is pivotal for effective pharmacoepidemiology and pharmacovigilance. At the same time, researchers are required to safeguard subjects' privacy and dignity. Developments such as the open data movement on the one hand and regulations aimed at protecting individuals' privacy on the other hand put researchers in a difficult position. At an increasing rate, there is a tendency to require public accessibility of scientific results and even data. Simultaneously, privacy concerns and potential regulations may pose challenges for data (re-)use in pharmacoepidemiologic studies [74].

Heightened attention has already been paid to the environmental, polluting effects of pharmaceutical residues. Regulatory documents, such as the EU pharmacovigilance legislation, acknowledge that "the pollution of waters and soils with pharmaceutical residues is an emerging environmental problem" [39]. Research examining the adverse effects of pharmaceuticals on the environment has been labeled *pharmacoenvironmentology*. With its focus on the environmental impact of drugs given at therapeutic doses, it is considered part of pharmacovigilance [75]. Assuming that environmental issues will continue to be high on the political and scientific agendas, pharmacoepidemiologic expertise will be increasingly needed to assess medicines as pollutants. In this context, pharmacoepidemiologists will need to employ and expand their methodological repertoire for studies investigating medicines' adverse effects on the environment. This development might also imply an amplified need for novel, interdisciplinary research collaboration involving pharmacoepidemiologists.

Such collaboration is also characteristic for another emerging intersection, between pharmacoepidemiology, computer, and data science. Research at the intersection of digital services, big data, and public health is a potentially promising but precarious field. It has been demonstrated that emerging digital data sources like social networking sites can function as complementary resources for pharmacoepidemiology. The use of such data sources, often referred to as a type of big data, is atypical for pharmacoepidemiologic studies but may become more common in the future. Research drawing on big data may take place outside medical departments or hospitals, for example being conducted by data scientists. Big data and emerging data science approaches have created new possibilities for pharmacoepidemiologic research. For example, Freifeld *et al*. used data from the social networking site and microblogging service Twitter to monitor ADRs [76].

The term *big data* has become associated with various leaks and scandals. The UK Science and Technology Committee concluded in a 2015 report that data misuses and leaks have led to public skepticism concerning the use of big data [77]. Not only such negative connotations, but also scientific concerns regarding users' consent, autonomy, and privacy raise ethical questions about big data research. Pharmacoepidemiologic research involving big data requires careful ethical considerations for the individuals generating such data, for example users of social networking sites. Moreover, pharmacoepidemiologists need to consider the biases inherent to digital data sources: such bias can be caused by big data retrieved from populations that do not allow for generalizations. For instance, since individuals included in a digital data sample may represent only those using an expensive/innovative technical device or service, these users could be on average younger or above average in access to health-promoting resources [78]. In addition, the quality of such data may differ from other sources of data (e.g., medical records).

Research involving these alternative sources of data is subject to different laws and regulatory frameworks when conducted in different global settings. For the US, access to health-relevant information via social networking sites such as Facebook is at present legally possible, due to the lack of protection for health-relevant data retrieved outside the traditional healthcare and research system. With regard to medical privacy, the Electronic Frontier Foundation (EFF) points out that social networking sites and other online services compromise US citizens' control over their health data:

> The baseline law for health information is the Health Insurance Portability and Accountability Act (HIPAA). HIPAA offers some rights to patients, but it is severely limited because it only applies to an entity if it is what the law considers to be either a "covered entity" – namely: a health care provider, health plan, or health care clearinghouse – or a relevant business associate (BA). [79]

This also implies that content such as Facebook or Twitter data, despite their actual use as health indicators, are currently not protected under the HIPAA. Yet, although arguably unlikely, this may change in the future. In addition, scientists should not conflate legal with ethical requirements.

With regard to biomedical research, it has been pointed out that the ethical implications of big data research are, at least partly, uncharted territory. Additional ethical considerations for pharmacoepidemiologic research involving big data are thus needed. This applies to the autonomy of data subjects but also to new corporate stakeholders and public–private partnerships. The latter may not merely involve pharmaceutical companies or device manufacturers. Internet and technology corporations may also play a role and require ethical as well as legal oversight, since they control access to digital data that could further complement pharmacoepidemiology in the future.

The Use of Randomized Controlled Trials in Pharmacoepidemiology

Robert F. Reynolds[1], Samuel M. Lesko[2], Nicolle M. Gatto[1], Tjeerd P. van Staa[3], and Allen A. Mitchell[4]

[1] *Department of Epidemiology, Global Medical Value, Evidence and Outcomes, GlaxoSmithKline, Upper Providence, PA, USA*
[2] *Northeast Regional Cancer Institute, Scranton, PA, USA*
[3] *Health eResearch Centre, University of Manchester, Manchester, UK*
[4] *Slone Epidemiology Center at Boston University, Boston, MA, USA*

When properly conducted, randomized controlled trials (RCTs) are considered the gold standard for demonstrating the efficacy and safety of a medicine for regulatory approval. During the premarketing phases of drug development, RCTs typically involve highly selected subjects and in the aggregate include at most a few thousand patients. These studies are designed to be sufficiently large to provide evidence of a beneficial clinical effect and to exclude large increases in risk of common adverse clinical events. Premarketing trials are rarely large enough to detect small differences in the risk of common adverse events or to estimate reliably the risk of rare events, whether serious or trivial (see Chapters 1 and 4). Quantification of these potentially important rare risks requires large studies, which typically are conducted after a drug is marketed. Because of design complexity and costs, large controlled trials are not generally considered for the postmarketing safety evaluation of drugs.

Rather, observational designs are commonly used to evaluate the safety of medicines post approval. They may be the only means to study large populations under routine clinical conditions or to evaluate a medicine's association with rare events or long-latency outcomes. Observational studies are therefore a logical complement to preapproval safety data collected from RCTs, expanding the knowledge about a medicine's safety profile as it is used in larger and more diverse patient populations. It is now generally accepted that data on a drug's use among real-world populations strengthen its evaluation, whether through organized research efforts or voluntary reporting systems [1–4], and pharmacoepidemiologic studies as a condition of regulatory approval for new medicines have increased over the past 15 years [5,6].

Despite notable advances in observational methods for assessing medicine safety, findings from observational studies are frequently contested as the basis for regulatory and clinical decisions. One important reason is that epidemiologic studies of medication exposures and their effects have difficulty measuring and controlling for confounding in general, and confounding by indication for drug use (and/or severity of disease) specifically (see Chapter 33)

Pharmacoepidemiology, Sixth Edition. Edited by Brian L. Strom, Stephen E. Kimmel and Sean Hennessy.

[7–9]. Concerns about uncontrolled confounding are central to debates about the interpretation of observational study findings and have complicated the assessment of many potential medicine–adverse outcome associations [9–21].

Nonetheless, the options for investigating real-world safety, or the safety of a medicine as it is actually prescribed by physicians and used by patients once on the market, are limited [21]. Postapproval RCTs are ethically and logistically difficult to conduct, are not appropriate to address many safety issues (e.g., rare or longer-term outcomes), and are unlikely to provide information on the safety of medicines in real-world populations. Thus, studies that are observational and follow patients with minimal interference are often the only means by which to answer clinically meaningful questions about a marketed medicine's safety and to study patients in settings that generalize to real-world medicine use.

The ideal design for a postapproval safety study is one that minimizes the potential for bias yet is still relevant to real-world clinical practice. A design that in principle merges the ideal characteristics of the randomized controlled trial (randomization) with those of an observational epidemiology study (follow-up with minimal intervention) is the large simple trial (LST) [22–24]. LSTs are characterized by large sample sizes, often in the thousands; broad entry criteria consistent with the approved medication label; randomization based on equipoise, that is, neither physician or patient believes that one treatment option is superior; minimal data requirements such as a questionnaire or case report form usually collecting data in only a few pages with questions limited to key variables that are typically collected at routine clinical care visits; objectively measured endpoints (e.g., death, hospitalization); follow-up that minimizes interventions or interference with normal clinical practice; follow-up of all patients regardless of whether they discontinue randomized medication; and intent-to-treat (ITT) analysis examining the entire population of randomized subjects according to the treatment group to which they were initially randomized.

Although the LST design shares a key design component, randomization, with an RCT, it is distinguished by its intent to minimize interference with usual medical care. In the typical RCT, the intent is restriction and control to create experimental conditions at baseline and over the course of the study. In contrast, in the LST the intent is to create balance of baseline characteristics but to then follow patient outcomes using observational methods. Practically, this means that endpoint definition, physician and patient recruitment, drug delivery, data collection, allowance for treatment discontinuation, concomitant drug use, and patient and site monitoring in a LST are operationally different from that of a RCT. Recent studies referred to as pragmatic clinical trials (PCTs) typically fall somewhere in between these approaches, where the goal is to introduce one or more pragmatic elements into the design but with substantial protocol-required follow-up and testing outside usual care practice. We view the LST as a type of PCT, at the far end of a continuum of pragmatic randomized designs, where the goal of the LST is to adopt as many pragmatic elements as possible to mimic usual care practice while protecting study validity.

Most calls for the use of the LST design have, until recently, primarily focused on the need for studies of clinically important therapeutic or preventive effects of interventions to inform clinical and health policy decisions [23,24]. LSTs have been employed to study a range of real-world benefits, from interventions for the treatment and prevention of cardiovascular outcomes [25–29] to a comparison of antiretroviral treatment strategies for HIV-positive patients [30]. In the 1990s, two research groups (one of which included SL and AM) described its use for safety, each using a single LST they had completed as a case study to infer general lessons for future studies [31,32]. More recently,

the US Food and Drug Administration (FDA) [33] and the European Medicines Agency (EMA) [34] acknowledged the potential advantages for postmarketing safety evaluation due to its unique design characteristics.

Clinical Problems to be Addressed by Pharmacoepidemiologic Research

Pharmacoepidemiologic methods are classically used to quantify risks and benefits of medicines that could not be adequately evaluated in studies performed during the premarketing phase of drug testing. In this chapter, we focus on the role of LSTs for assessing the risks of medications; the same principles, however, are applicable to the postmarketing study of benefits.

As noted in the introduction, if there are questions about the safety of a drug after it has been licensed, large observational studies are typically used to satisfy the sample sizes needed to identify (or rule out) the relevant risks. The respective strengths and weaknesses of these designs are discussed elsewhere in this volume (see Chapter 3). Potential confounding is a major concern for virtually every observational study, and uncontrolled or incompletely controlled confounding can easily account for modest associations between a drug and an adverse clinical event. For example, in the relation between phenylpropanolamine and cerebrovascular disease, obesity increases both the likelihood of exposure to the drug and the risk of a cerebrovascular accident; thus, body weight must be controlled in any analysis of this association. The challenge to the pharmacoepidemiologist is to recognize those factors that represent potential confounders, validly measure them and then control for their effects. To do so requires that the relevant information be included in the data to be analyzed, but information on important confounding factors is frequently incomplete or unavailable. Surrogate variables are often used (e.g., years of education to reflect socioeconomic status) but these may be poor measures of the underlying confounding factor and their control therefore may not eliminate confounding.

In observational studies, weak associations deserve particular attention. Although there are important exceptions, the general view is that the stronger the association, the more likely it is that the observed relationship is causal. This is not to say that a weak association (e.g., a relative risk ≤1.5) can never be causal; rather, it is more difficult to be certain of it because such associations, even if statistically significant, can easily be an artifact of confounding. As an example, consider an analysis where socioeconomic status is a potential confounder and education is used as a surrogate for this factor. Because the relation between years of education completed (the surrogate) and socioeconomic status (the potential confounder) is, at best, imperfect, analyses controlling for years of education can only partially control for confounding. This leads to the familiar caveat in reports of observational studies, "…residual confounding may account for the observed association."

In pharmacoepidemiologic research, the phenomenon known as confounding by indication (also referred to as indication bias, channeling, confounding by severity, or contraindication bias) is a common methodologic problem (see also Chapters 33 and 43). According to Slone *et al.*, confounding by indication exists when "patients who receive different treatments … differ in their risk of adverse outcomes, independent of the treatment received" [35]. In general, confounding by indication occurs when an observed association between a drug and an outcome is due to the underlying illness (or its severity) and not to any effect of the drug. Put another way, confounding by indication occurs when the risk of an adverse event is related to the *indication* for medication use but not the

use of medication itself. As with any other form of confounding, one can, in theory, control for its effects if one can reliably measure the severity of the underlying illness. In practice, this is not easily done (see Chapters 33 and 43).

When confronted with the task of assessing the safety of a marketed drug product, the pharmacoepidemiologist must evaluate the specific hypothesis to be tested, estimate the magnitude of the hypothesized association, and determine whether confounding by indication is possible. If incomplete control of confounding is likely, it is important to recognize the limitations of observational research designs and consider conducting a randomized study design such as the LST. There is nothing inherent about a randomized design that precludes a pharmacoepidemiologist from designing and carrying it out. On the contrary, the special skills of a pharmacoepidemiologist can be very useful in performing large-scale randomized trials that use epidemiologic follow-up methods.

Methodologic Problems to be Solved by Pharmacoepidemiologic Research

Large simple trials may be the best solution when it is not possible to completely control confounding by means other than randomization. LSTs are really just very large randomized trials made simple by reducing data collection to the minimum needed to test only a single hypothesis (or at most a few hypotheses). Randomization of treatment assignment is the key feature of the design, which controls for confounding by known and unknown factors. The large study size provides the power needed to evaluate small risks, either absolute or relative. Table 32.1 highlights the design aspects that differentiate LSTs from RCTs.

How Simple is Simple?

Yusuf *et al*. have suggested that very large randomized studies of treatment-related mortality need collect only data concerning the vital status of participants at the conclusion of the study [22]. Because the question of drug safety frequently concerns outcomes less severe than mortality, these ultra-simple trials may not be sufficient. Hasford has suggested a somewhat less restrictive approach to data collection, in which "large trials with lean protocols" include only *relevant* baseline, follow-up, and outcome data [31]. Collecting far less data than is common in the usual RCT is the key feature of both approaches. With simplified protocols that take advantage of epidemiologic follow-up methods, very large trials can be conducted to test hypotheses that are relevant to clinical practice.

Concealed (Masking) Versus Known Treatment Assignment

Randomized controlled trials conceal treatment assignment to minimize detection bias and, in most cases, are only considered to be unbiased if all parties (patients, healthcare providers, and investigators) are unaware of the treatment assigned. Masking is particularly important when the outcome is subjective and/or investigators have views about the medications under study that may lead to differential testing, detection, and reporting of outcomes. Even in RCTs, however, concealing medications is not a panacea for unbiased outcome assessment. Masking has methodological limitations, ranging from investigators or patients guessing treatment allocation due to differential improvement in symptoms or outcomes to failures in the taste, texture or color of the random treatment assignments. In addition to the bias this may introduce for outcome assessment, it may also create selection bias if investigators are able to predict the likelihood of an upcoming treatment allocation. For this reason, RCT investigators use

Table 32.1 Typical design characteristics of a large simple trial (LST) compared to those of a randomized controlled trial (RCT).

Design characteristic	LST	RCT
Randomization	Yes	Yes
Medicine assignment	Concealed if feasible, assignment may be known, dose adjustment permitted	Concealed
Sample size	Larger (thousands)	Smaller (hundreds)
Inclusion criteria	Broad (e.g., per approved medicine label)	Narrow (e.g., excludes patients with co-morbid conditions, using multiple medications, pregnant women, elderly)
Questionnaire/case report form (CRF)/interview	Minimal, brief	Complex, lengthy
Endpoints	Hard endpoints (mortality, hospitalization or life-threatening events)	Virtually any
Required patient visits and procedures	Few, if any; follows normal practice schedule and assessments	Yes, frequent; visits and tests far greater than expected in clinical practice
Primary source of investigators or enrolling physicians	Primary care provider/ community based	Clinical research/academic centers
Site monitoring	Minimal	Frequent
Followed after randomized treatment discontinued	Yes	No, or for limited duration post discontinuation (e.g., 30 days)
Primary analytic method	Intention to treat (ITT)	ITT

methods for assessing the success of concealment and real-time central randomization to address the potential for selection bias.

The value of concealing medications to improve the validity of randomized study designs has been established in countless RCTs. Masking treatment allocation is possible and has been proven to be successful in LSTs (as described later). Therefore, pharmacoepidemiologists should start by evaluating whether concealment is feasible for their trial design. Given practical considerations, many LSTs will not be able to implement masking due to the costs and infrastructure complexity or other factors such as study duration. Regulators and policy makers may also find concealment undesirable, particularly when balancing the need for evidence that reflects real-world clinical practice. In fact, for some LSTs, the primary goal is to only compare treatment strategies in usual care. This requires minimal intervention so that physicians and patients behave as they normally would when taking a particular medicine. In these LSTs, investigators are less concerned with the causal effects of a medicine (as would be measured in a controlled clinical trial) and more concerned with the safety outcomes that occur due to the awareness of treatment allocation and the associated, and potentially differential, practices employed by physicians and patients as a result. LSTs that do not use concealment must address the potential

for bias and will be strengthened by comparing hard clinical outcomes or requiring similar medical work-up/testing across treatment arms for study outcomes.

Ultimately, whether to conceal medicine assignment is a critical design decision for the pharmacoepidemiologist that depends on numerous factors, including the research question, outcomes under study, patient population, preferences of patients, and the preferred balance between validity and reflecting real-world clinical practice.

Power/Sample Size

Study power is related to the number of events observed during the course of the study, which in turn is a function of the incidence rate for the event, sample size, persistence to the study treatment, and duration of observation (or follow-up). Power requirements can be satisfied by studying a population at high risk, enrolling a large sample size, and/or conducting follow-up for a prolonged period. The appropriate approach will be determined by considering the goal of the study and the hypothesis to be tested. Allergic or idiosyncratic events may require a very large study population, and events with latency periods must include duration of follow-up consistent with the hypothesized timing of symptom onset. The decision to study high-risk populations must be balanced with the need for generalizability. For example, while an elderly population may meet criteria for high risk of cardiovascular events, a study limited to this group would be inappropriate to assess the risk of these events in younger adults or children.

Data Elements

The data collection process can be kept simple by restricting the study to a few primary endpoints that satisfy the study hypothesis, are objective, are easily identified, and are verifiable. Some researchers may need to overcome their predisposition to comprehensive data collection when it comes to secondary outcomes (i.e., those that do not directly relate to the study hypothesis), as these must be ignored to eliminate unnecessary effort and complexity. Of critical importance, because confounding is controlled by randomization, data on all potential confounders need not be collected. Rather, a few basic demographic variables can be collected at enrollment in order to characterize the population studied and allow the investigators to confirm that effective randomization was achieved.

Data Collection

The data collection process itself can be streamlined. Follow-up data can be collected directly from participants via, for example, mailed questionnaires, telephone interviews, online using a secure website, or through mobile devices. Because the study will be limited to clear and objective outcomes which can be confirmed by medical record review or other means, reports from study participants, family care providers or, for some patient populations, healthcare providers can be an appropriate source of follow-up data. Other sources of follow-up data could include electronic medical records (e.g., for studies among subscribers of a large health care organization where it is likely that important outcomes will be recorded) or vital status records for fatal outcomes (e.g., the US National Death Index).

The primary advantage of this simplicity is that it allows very large groups of study participants to be followed at reasonable cost. The trade-off is that a simple trial cannot answer all possible questions about the safety of a drug but must be limited to testing, at most, a few related hypotheses.

When is a LST Appropriate?

Large simple trials are appropriate when all the conditions in Box 32.1 apply.

Box 32.1 Conditions appropriate for the conduct of a large simple trial

1) The research question is important
2) Genuine uncertainty exists about the likely results
3) Confounding by indication is likely
4a) The absolute risk is small
or
4b) The relative risk is small, regardless of the absolute risk

Important Research Question

Although a simple trial will likely cost considerably less per subject than a typical premarketing clinical trial, the total cost of a large study (in money and human resources) will still be substantial. The cost will usually be justified only when there is a clear need for a reliable answer to a question concerning the risk of a serious outcome.

Uncertainty Must Exist

An additional condition has been referred to as the "uncertainty principle." This was originally described by Gray *et al*. as a simple criterion to assess subject eligibility in LSTs [36]. It states that "… both patient and doctor should be *substantially uncertain* about the appropriateness, for this particular patient, of each of the trial treatments. If the patient and doctor are *reasonably certain* that one or other treatment is inappropriate then it would not be ethical for the patient's treatment to be chosen at random" (italic in the original). Very large randomized safety trials are justified only when there is true uncertainty about the risk of the treatment in the population. Apart from considerations of benefit, it would not be ethical to subject large numbers of patients to a treatment that was reasonably believed to place them at increased risk, however small, of a potentially serious or permanent adverse clinical event. The concept of uncertainty can thus be extended to include a global assessment of the combined risks and benefits of the treatments being compared. One treatment may be known to provide therapeutic benefits that are superior to an alternative, but it may be unknown whether the risks of important side effects outweigh the therapeutic advantage.

Power and Confounding

Large simple trials will only be needed if (a) the *absolute* risk of the study outcome is small and there are concerns about confounding by indication, or (b) the *relative* risk is small (in which case, there are inherent concerns about residual confounding) [37]. By contrast, LSTs would not be necessary if the *absolute* risk were large, because premarket or other conventional RCTs should be adequate, or where confounding by indication is not an issue, because observational studies would suffice. Also, if the *relative* risk were large (and confounding by indication is not a concern), observational study designs are likely appropriate.

When is an LST Feasible?

Large simple trials are feasible when all the conditions in Box 32.2 are met.

Box 32.2 Conditions which make a large simple trial most feasible

1) The study question can be expressed as a simple testable hypothesis
2) The treatment to be tested is simple (uncomplicated)
3) The outcome is objectively defined (e.g., hospitalization, death)
4) Epidemiologic follow-up methods are appropriate
5) A cooperative and motivated population is available for study

Simple Hypothesis

Large simple trials are best suited to answer focused and relatively uncomplicated questions. For example, an LST can be designed to test the hypothesis that the risk of hospitalization for any reason, or for acute gastrointestinal bleeding, is increased in children treated with ibuprofen. However, it may not be possible for a single LST to answer the much more general question, "Is ibuprofen safe with respect to all possible outcomes in children, whether or not they require medical attention?" Similarly, in a study of the clinical relevance of QTc prolongation, a LST can test the hypothesis that the risk of mortality is increased from this effect, but will not be able to evaluate the increased risk of ventricular arrhythmias or its specific forms, such as torsade de pointes.

Simple Treatments

Simple therapies (e.g., a single drug at a fixed dose for a short duration) are most amenable to study with LSTs. They are likely to be commonly used, so that it will be easy to enroll large numbers of patients, and the results will be applicable to a large segment of the population. Complex therapeutic protocols are difficult to manage, reduce patient adherence, and by their very nature may not be compatible with the simple trial design.

Objective and Easily Measured Outcomes

The outcomes to be studied should be objective, easy to define ("simple"), and easy to recall. An example might include hospitalization for acute gastrointestinal bleeding. Study participants may not recall the details of a hospital admission, but they likely will recall the fact that they were admitted, the name of the hospital, and at least the approximate date of admission. Medical records can be obtained to document the details of the clinical events that occurred. Events of this type can be reliably recorded using epidemiologic follow-up methods (e.g., questionnaires, telephone interviews, online surveys, mobile device applications, hospital discharge diagnosis codes, or linkage with public vital status records). On the other hand, clinical outcomes which can be reliably detected only by detailed in-person interviews, physical examinations, or extensive physiologic testing are not as amenable for study in simple trials. For example, an LST concerned about the QTc prolonging potential of a medicine will focus on the clinically relevant and measurable sequelae rather than on performing routine ECGs for study participants.

Cooperative Population

Particularly in LSTs, a cooperative and motivated study population greatly increases the probability of success. Striking examples are the large populations in the Physicians' and Women's Health Studies; the success of these studies is at least partly due to the willingness of large numbers of knowledgeable health professionals to participate [38,39]. Because of the participants' knowledge of medical conditions and symptoms and participation in the US healthcare system, relatively sophisticated information could be obtained using mailed questionnaires, and even biologic samples could be collected. In another example, success of the Boston University Fever Study (described later) was also largely due to parents whose motivation and cooperation were encouraged by their private physicians who had invited them to participate in the study [40]. Similarly, in the ZODIAC LST (also described later) among patients with schizophrenia, the motivation of psychiatrists and family caregivers around a clinically important question led to robust one-year follow-up despite a patient population difficult to follow, even short term (e.g., in 12–16-week RCTs) [41,42].

Logistics of Conducting a LST

An LST may be appropriate and feasible, but it will only succeed if all logistical aspects of the study are kept simple as well. In general, LSTs will involve an oversight body, sometimes organized as a scientific steering committee composed of epidemiologic, statistical, and clinical experts who are responsible for the scientific conduct of the study, as well as a central data coordinating facility, and a network of enrollment sites (e.g., offices of collaborating physicians or other healthcare providers). Healthcare professionals (e.g., physicians, nurse practitioners, and pharmacists in private practice or members of large healthcare organizations) can participate by recruiting eligible patients. Alternative methods to identify and enroll eligible subjects (e.g., direct mailings to professional groups, print or online ads, emails and mobile phone text messages) may be appropriate for some studies.

Because success depends on the cooperation of multiple healthcare providers and a large number of patients, it is best to limit the demands placed on each practitioner (or his/her clinical practice). One approach is to have the practitioner identify eligible subjects, obtain permission to pass their names to a central study staff, and leave to the study staff the task of explaining study details, enrollment, and obtaining informed consent. Another approach is to provide comprehensive training prior to site initiation followed by support to local administrative staff throughout the course of the study, particularly for research-naive and inexperienced sites. Obtaining informed consent, baseline data, and the medicine assignment is best handled during the course of a single visit.

To facilitate patient recruitment and to maximize generalizability of the results, minimal restrictions should be placed on patient eligibility. As Gray *et al*. have said, "Any obstacle to simplicity is an obstacle to large size, and the wider the range of the patients studied, the wider the generalizability of the results will be" [36]. Patients with a medical contraindication or known sensitivity to either the study or control drug should not, of course, be enrolled, but other restrictions should be kept to a minimum. Ideally, the restrictions are only those that apply in a usual care clinical setting, that is, those described in the approved medicine label.

Simple informed consent and registration documents should be completed. Registration of study subjects can also be accomplished online using a secure internet connection (or potentially through secure mobile phone applications) to the coordinating center, which allows for immediate confirmation of eligibility and randomization. Substantial bias can be introduced if either physician or patient can choose not to participate after learning (or guessing) which treatment the patient has been assigned.

Particularly in studies requiring a long duration of medication use, validity may be seriously compromised by poor adherence with the treatment regimen. A run-in period prior to randomization can be used to identify patients who are unable or unwilling to adhere to a chronic treatment regimen and are likely to drop out of the study. During the run-in period, eligible subjects are given a "test" medication and their compliance with the protocol is assessed. Patients who cannot comply with the protocol are withdrawn. Patients who remain in the study are likely to be highly adherent, so that relatively few will drop out after randomization. Depending on the characteristics of drugs under study, either the active drug or the control may be preferable for the run-in period. In the Physicians' Health Study, for example, the study drug aspirin was used for the run-in period to identify subjects who could not tolerate the gastrointestinal side effects of the drug [38]. A run-in period may lead to a study population that no longer reflects the real-world users of a medicine. This approach should therefore be used sparingly and only when the conditions justify it.

Importance of Complete Follow-Up

Because dropouts and losses to follow-up may not be random but rather may be related to adverse treatment effects, it is important to make every effort to obtain follow-up data on all enrolled subjects. For example, a study that has follow-up data on even tens of thousands of patients may not be able to provide a valid answer to the primary study question if this number represents only half of those randomized. The duration of the follow-up period can affect the completeness of follow-up data collection. If the duration of follow-up is too short, important outcomes may be missed (i.e., they may not be diagnosed until after the end of the follow-up period). On the other hand, as the length of the follow-up period increases, the number lost to follow-up or exposed to the alternate treatment (contaminated exposure) increases. In the extreme, a randomized trial becomes a cohort study because of selective dropouts in either or both of the treatment arms.

Beyond choosing a motivated and interested study population, investigators can minimize losses to follow-up by maintaining regular contact with study participants. Regular mailings of medication supplies or prescriptions filled at a local pharmacy that are reimbursed by the study, a study newsletter, or email and mobile phone text reminders can be helpful, and memory aids such as medication calendar packs or other devices may help maintain compliance with chronic treatment schedules. In addition, follow-up data collection itself can help maintain contact with study participants.

Follow-Up Data Collection

An important element of a successful LST is that the burden to healthcare providers for follow-up data collection is minimized. Healthcare providers cannot be expected to consistently obtain substantial amounts of follow-up data from large numbers of subjects. However, the subject's clinician may, with subject permission, provide limited follow-up data (e.g., vital status, occurrence of a primary outcome) or current contact information for the occasional patient who would otherwise be lost to follow-up. A mailed or electronically administered questionnaire, supplemented by telephone follow-up when needed, may work well, although the best means of communication will likely vary by physician specialty and practice size. The response rate will likely be greatest if the questions are simple and direct and the time required to complete the questionnaire is limited. With appropriate permissions, medical records can be reviewed to verify important outcomes, such as rare adverse events; the work needed to obtain and abstract the relevant records should be manageable. In addition, a search of public records (e.g., the National Death Index in the US) can identify study subjects who have died during follow-up.

Analysis

Primary Analysis

Analyses of the primary outcomes are usually straightforward and involve a comparison of incidence rates between the treatment and control groups. Under the assumption that confounding has been controlled by the randomization procedure, complex multivariate analyses are not necessary (and may not be possible because only limited data on potential confounders are available). Descriptive data collected at enrollment should be analyzed by treatment group to verify balance of potential confounders; any material differences between treatment groups suggest a failure of randomization.

Subgroup Analyses

It is important to remember that confounding factors will be distributed evenly only among groups that were randomized; subgroups which are not random samples of the original randomization groups may not have similar

distributions of confounding factors. For example, participants who have remained in the study (i.e., have not dropped out or been lost to follow-up) may not be fully representative of the original randomization groups and may not be comparable with respect to confounders. Despite all efforts, complete follow-up is rarely achieved, and because only the original randomization groups can be assumed to be free of confounding, at least one analysis involving all enrolled study subjects (i.e., an intention-to-treat analysis) should be performed. Also, unless a stratified randomization scheme was used, one cannot be certain that unmeasured confounding variables will be evenly distributed in subgroups of participants, and the smaller the subgroup, the greater the potential for imbalance. Therefore, subgroup analyses can be subject to the same limitations as observational studies (i.e., the potential for uncontrolled confounding).

Data Monitoring/Interim Analyses

Because of the substantial commitment of resources and large number of patients at risk for adverse outcomes, and the interventional nature of the study, it is appropriate for a data monitoring committee (DMC), independent of other scientific and operational study committees and infrastructure, to monitor the accumulating data over the course of the study. The study may be ended prematurely if participants experience unacceptable risks, if the hypothesis can be satisfactorily tested earlier than anticipated, or if it becomes clear that a statistically meaningful result cannot be achieved, even if the study were to be completed as planned.

LSTs in Practice: Two Case Studies

To illustrate these design principles, as well as how they are operationalized, the rationale, design, and results from two completed LSTs are described below.

Boston University Fever Study (BUFS)

Ibuprofen is a nonsteroidal antiinflammatory drug (NSAID) that is widely used among adults in the US, first by prescription and then as an over-the-counter (OTC) drug. In 1989, ibuprofen suspension was licensed as a prescription product for fever control in children, since premarketing studies in children established that it was appropriate for use under a physician's supervision. However, events known to occur in adults using ibuprofen, such as acute gastrointestinal bleeding, acute renal failure, and anaphylaxis, were either not observed at all during the relatively small premarketing trials in children or occurred so infrequently that it was not possible to obtain reliable estimates of the risk. Thus, whether these events, which affect adults, might rarely be caused by ibuprofen in children was unknown. In addition, it was at least theoretically possible that Reye syndrome (a toxic encephalopathy in children associated with another NSAID, aspirin) might be associated with ibuprofen use in children. Other events, possibly unique to children, might also be associated with this drug. Thus, premarketing studies were unable to exclude even a substantially increased risk of rare but important and serious adverse reactions.

Once available OTC, pediatric ibuprofen was likely to be widely used for the treatment of fever, which is typically a minor and self-limited condition. Given the generally benign nature of this indication, it was reasonable to require greater assurance of safety than might be expected for a drug used to treat a life-threatening illness. Further, an effective antipyretic with an excellent record of safety in children, acetaminophen, had been available OTC in the US for more than 20 years. For these reasons, the US FDA required additional data concerning the risk of rare but serious adverse events before it would approve pediatric ibuprofen for OTC sale.

The circumstances surrounding ibuprofen use in 1989–90 raised serious concern that

observational studies could not adequately control confounding. Specifically, prior to the availability of pediatric ibuprofen, febrile children in the US received no antipyretic or were given acetaminophen, which was generally considered safe by both physicians and parents. On the other hand, because ibuprofen was available only by prescription, treatment with this drug required contact with a physician. In addition, for fever less than 102.5 °F, the recommended dose of prescription ibuprofen was 5 mg/kg, whereas for fever of 102.5 °F or greater, the dose was 10 mg/kg.

Both its status as a prescription medication and the two-tier dosing schedule predicted that ibuprofen would be used for more severe illness than acetaminophen. This prediction was supported by a survey of 108 physicians (61 pediatricians, 47 family practitioners) conducted in 1992 [32]. More than half of the physicians in the study reported that they treated children with ibuprofen after acetaminophen failed, but none reported using acetaminophen only when ibuprofen was not effective. Further, both the minimum age and temperature at which the physicians recommended using these drugs were higher for ibuprofen than acetaminophen. It seemed clear that pediatric ibuprofen would be most commonly used among children whose illness was relatively severe or whose fever was particularly high or unresponsive to acetaminophen. Because of the greater severity of illness (and potential exposure to antibiotics or other medications), there was a reasonable basis to believe that ibuprofen users would experience relatively high rates of adverse clinical events, *unrelated to the ibuprofen itself*. Thus, to provide a valid assessment of the risks of pediatric ibuprofen, the study must be able to distinguish the risks of the drug from the risks associated with the illness for which ibuprofen was given.

To address this question, an LST design was used to conduct the Boston University Fever Study, an office-based study of the safety of ibuprofen use in children. The methods and results have been described in detail but are briefly summarized here [32,40]. The study was a practitioner-based trial designed to compare the risk of rare but serious adverse events among children treated for fever with ibuprofen or acetaminophen. Study participants were children between 6 months and 12 years of age with a febrile illness, which in the opinion of the managing physician warranted treatment with an antipyretic. Eligible children weighed at least 7 kg, had no contraindication to receiving either ibuprofen or acetaminophen suspension, and were in the care of a parent who could read and follow instructions written in English. Participants were identified by community-based pediatricians and family physicians and were randomized to one of three treatment groups: acetaminophen (12 mg/kg per dose), ibuprofen (5 mg/kg per dose) or ibuprofen (10 mg/kg per dose). Both the healthcare providers and parents were blind with respect to the drug/dose administered. The primary study endpoints were hospitalization for GI bleeding, acute renal failure, anaphylaxis, or Reye syndrome occurring within four weeks of enrollment. Follow-up data collection was conducted by mailed questionnaire, supplemented with telephone interviews and review of medical records for hospital admissions.

A total of 84 142 children were enrolled by 1735 practitioners. Approximately 28 000 children were randomized to each of the three treatment arms; demographic and clinical characteristics of the participants were balanced in the three groups. Overall, 795 children were hospitalized for any reason during follow-up; the risk of hospitalization did not vary significantly by treatment group (range 0.89–0.99%). Four children were hospitalized for GI bleeds, all of whom had been assigned to receive ibuprofen – two in each dose group. The risk of hospitalization for GI bleeding among all ibuprofen-treated children, 7.2 per 100 000 (95% confidence interval [CI] 2–18 per 100 000), was

not significantly greater than the risk among children randomized to acetaminophen, 0 per 100 000 (95% CI 0–11 per 100 000). No children were hospitalized for any of the other primary study endpoints, and the risk of each was no more than 5.4 per 100 000 (based on the upper bound of the 95% CI). The study provided substantial evidence of the safety of short-term use of ibuprofen in children and was used to support an application for OTC sales of pediatric ibuprofen suspension in the US.

Ziprasidone Observational Study of Cardiac Outcomes (ZODIAC) LST

Ziprasidone is an atypical antipsychotic for the treatment of patients with schizophrenia. Early evidence from premarketing clinical trials indicated that ziprasidone might be associated with improved lipids and lower incidence of weight gain. Despite the need for additional effective treatments for schizophrenia and these potential benefits, concerns about its safety, specifically whether the modest QTc prolongation associated with the drug would translate into increased mortality in patients using it in the real world, were voiced at the time of ziprasidone's review and approval by regulatory authorities in the US and Europe. QTc prolongation is of clinical concern because of its potential to induce torsade de pointes and other serious ventricular arrhythmias resulting in sudden death.

Prior to approval, the Sponsor (Pfizer, Inc.) completed a clinical study comparing six antipsychotics. The study found that the mean QTc prolongation was approximately 9–14 milliseconds greater for ziprasidone than for several others tested but approximately 14 milliseconds lower than thioridazine (a drug associated with reports of sudden death that resulted in a black box warning in the US). The study found similar results when the drugs were administered in the presence of a metabolic inhibitor. Although drugs associated with the risk of a greater degree of QTc prolongation than ziprasidone had been shown to increase the risk of sudden death, the precise relationship between QTc prolongation and the risk of serious adverse cardiac events was unknown at the time of ziprasidone's approval [41,42].

It is in this context that an LST was selected as the most appropriate study design for postmarketing safety evaluation. In typical psychiatric practice, patients treated with a new medication may be systematically different from those treated with other drugs, due to prescribers' channeling of the drug to patients with more severe schizophrenia and/or co-morbidities and risk factors. This possibility existed because ziprasidone was the newest antipsychotic at that time, and most likely to be used in patients who had failed prior therapies. In addition, despite the potential risk associated with QTc prolongation, it was possible that patients treated with ziprasidone might differ from those treated with other antipsychotic drugs, due to prescribers' channeling of the drug to patients with underlying cardiovascular disease or metabolic illnesses, especially given the low propensity for weight gain associated with ziprasidone. Given these likely selection phenomena, random allocation of patients was the only approach providing the certainty of an unbiased comparison between groups.

ZODIAC, a regulatory requirement for Pfizer from both the US FDA and the Swedish Medicinal Products Agency (MPA), compared the safety of ziprasidone and olanzapine. The methods and results have been described in detail but are briefly summarized here [41–44]. Olanzapine was chosen as the medication for the comparison group since it is also an atypical antipsychotic medication without the same effect as ziprasidone on the QTc prolongation. The study, which intended to randomize 18 000 patients, was unprecedented in psychiatric research, both in size and design. The primary objectives of the study were to estimate relative all-cause, nonsuicide, suicide, cardiovascular

and sudden death mortality among users of ziprasidone and olanzapine. The secondary objectives were to estimate the relative incidence of all-cause hospitalization and hospitalization for arrhythmia, myocardial infarction, or diabetic ketoacidosis, and to determine the rate of treatment discontinuation. The study design was not expected to permit a statistically powered evaluation of the differences in the incidence of uncommon but important adverse effects, such as torsade de pointes and sudden death. Instead, nonsuicide mortality was chosen as the primary endpoint for which the study was powered since even a larger increase in an uncommon cause of death like torsade de pointes or sudden death could be counterbalanced by a small decrease in a more common cause of death, like atherosclerotic events. In addition, torsade de points would not be reliably detected as part of normal medical or psychiatric care because of its rarity and the absence of frequent (or any) ECG testing in the routine clinical settings in which the study was carried out. The all-cause nonsuicide mortality aggregate measure was therefore deemed to be the most important and appropriate primary outcome measure.

After the enrolling physician determined a patient's eligibility and obtained informed consent, brief information, including demographics, disease severity, cardiac risk factors, and prior antipsychotic medication use, was collected on a baseline questionnaire. Social security numbers and information on up to two alternate contact/family caregivers were also collected. Following random assignment of medication, no further study-related interventions, tests, or visits were required. Physicians and patients were allowed to change regimens and dosing of the assigned study medication, and concomitant medications were permitted. In the US, patients were prescribed their assigned medicine and provided a pharmacy card to cover the costs of the medicine at a local pharmacy. Patients were followed as clinically appropriate and outcomes assessed for up to one year, regardless of how long they used the assigned medication. Information on the patients' vital status and whether or not they were hospitalized was obtained through follow-up with the treating physician or other designated member of the medical care team, family caregiver or through national death indices. A scientific steering committee was responsible for oversight of the study, a data safety monitoring board for safeguarding study participants, and an endpoint committee for assessing whether reported events met study endpoint criteria without knowledge of the assigned treatment.

ZODIAC enrolled 18 154 patients between February 2002 and February 2006 from 18 countries, including Argentina, Brazil, Chile, Hong Kong, Hungary, Korea, Malaysia, Mexico, Peru, Poland, Romania, Singapore, Slovakia, Sweden, Taiwan, Thailand, Uruguay, and the US. The primary analyses found no difference between the ziprasidone and olanzapine treatment arms with respect to nonsuicide mortality (relative risk (RR) 1.02, 95% CI 0.79–1.39). The incidence of nonsuicide mortality within one year of initiating medication was 0.91 for ziprasidone (n = 9077) and 0.90 for olanzapine (n = 9077). This finding was confirmed in numerous sensitivity analyses. The risk of all-cause hospitalization was 39% higher among persons randomized to ziprasidone versus olanzapine (RR 1.39, 95% CI 1.29–1.50). Analyses of the remaining secondary outcomes indicated no difference between the ziprasidone group and the olanzapine group. These findings were also supported in numerous *post hoc* analyses requested by the FDA [43].

In summary, despite the known risk of QTc prolongation with ziprasidone treatment, the findings of this study failed to show that ziprasidone is associated with an elevated risk of nonsuicidal mortality relative to olanzapine in real-world use and were incorporated into the approved medicine label in the United States and Europe.

Large Simple Trials Using Routine, Electronic Data Capture in Healthcare Systems

Data routinely collected within the healthcare system can sometimes be used to improve efficiency of LSTs. This can include data from electronic health records (EHRs) with information recorded by clinical staff at the point of care (e.g., in hospitals or outpatient clinics), administrative claims data (e.g., the Veterans Affairs database in the US), national/regional registries (e.g., population-wide databases in Sweden and Denmark), and patient disease/condition/drug registries (e.g., CORONNA rheumatoid arthritis registry).

Electronic health records and registries have been used in conventional RCTs to collect long-term follow-up data. An example is the West of Scotland Coronary Prevention Study which was a primary prevention trial in 45–64-year-old men with high low-density lipoprotein cholesterol. Over 6000 men were randomized to receive pravastatin once daily or placebo for an average of 4.9 years. Subsequent linkage to EHRs and registries allowed follow-up of major cardiovascular events for over 20 years [45]. Another example is the Scandinavian Simvastatin Survival Study that used national cancer registries to determine cancer endpoints five years after closure of the trial [46].

The use of EHRs and registries for the identification of potential trial participants has been increasing in recent years (see Chapter 13). As an example, the EHR4CR project has developed a platform that utilizes data from hospital EHR systems for clinical trials feasibility assessment and patient recruitment. The platform can connect securely to the data within multiple hospital EHR systems to assess the feasibility of a trial and locate the most relevant hospital sites [47].

The most recent development is the use of EHRs and registries for identification and recruitment as well as follow-up for trials, providing an efficient and reusable infrastructure for LSTs [48,49]. An example of this type of trial is the Retropro trial which recruited patients with high cardiovascular risk in routine clinical care and randomized them between two licensed medications (simvastatin and atorvastatin) [50]. The UK Clinical Practice Research Datalink® (CPRD®) EHR database was used to preselect potentially eligible patients (i.e., high cardiovascular risk estimated by a risk score). The CPRD includes anonymized EHRs for over 5 million patients currently registered at a participating general practice and can be linked to other datasets such as the national registry of hospital admissions, death certificates, and disease registries (see Chapter 13) [51]. As infrastructure for large simple trials, the CPRD can be used to identify eligible subjects who then can be consented and enrolled by their general practitioners. CPRD data are anonymized prior to being made available to the study research team (which uses coded patient IDs). In the Retropro trial, for example, clinicians were able to recruit preselected patients during consultation or during dedicated appointments. Software within the EHR system reminded clinicians through a system alert when a patient eligible for inclusion in the trial consulted the clinician. The flagging software also triggered a link to the study website, which randomized trial participants after guiding the clinician to confirm eligibility and obtain informed consent. The data from the EHRs and linked registries were used to collect follow-up outcomes (including persistence to treatment and major clinical outcomes). Suspected adverse drug reactions were also reviewed by searching the side effect fields or main clinical fields of the EHR. The quality of outcome assessment was strengthened by implementing the prospective randomized open blinded endpoint (PROBE) assessment with case adjudication by clinicians masked to treatment allocation [52].

Another example of an embedded LST is the insulin trial within the US Veteran Affairs

Healthcare System (VA). This trial compared two methods (a sliding scale versus a weight-based regimen) for determining the dose of subcutaneously administered insulin to be used in hospitalized patients, and was carried out to test the feasibility of conducting what the investigators refer to as a point-of-care clinical trial (POCCT). To accommodate this pilot trial, the VA data collection system was modified to support enrollment, randomization component, and better capture of study endpoints [53]. Order-entry screens at three VA hospitals were modified to include an option to enroll participants into the trial comparing these two regimens. Election of the menu choice "no preference for insulin regimen" triggered the EHR workflow to notify the research nurse to obtain informed consent, automatically place a note of participation in research in the medical record, and randomly assign treatment. The primary outcome of this ongoing trial was the length of hospital stay, and secondary outcomes included measures of glycemic control, all of which were ascertained from the EHR database.

The ADAPTABLE Aspirin Study is an ongoing three-year pragmatic trial comparing the effectiveness of low- and high-dose aspirin to prevent myocardial infarction and stroke in patients with cardiovascular disease. This study is embedded in PCORnet, the National Patient Centered Clinical Research Network, which is a distributed health data research network with EHRs and administrative data [54] (see Chapter 25).

Large simple trials embedded in health systems or registries may use cluster randomization, an alternative to trials that randomize individual patients. In cluster trials, entire areas or health service organizational units are randomly allocated to intervention or control groups with outcomes evaluated for individuals within each cluster. Cluster trials are increasingly used in public health and health services research and are especially important in the evaluation of health service and public health interventions [55]. An example is a cluster trial that evaluated whether antibiotic prescribing for respiratory tract infections can be reduced by reminding clinicians of the recommended clinical practice guidelines by providing an alert in the EHR during consultation [56].

Embedded LSTs with randomization to medicines are still relatively uncommon; however, healthcare systems and research groups are developing these capabilities, as noted above. The greatest opportunities are currently for research questions that help drive a learning healthcare system [57] such as the examples above in which the study results are directly relevant to patient care; the results help providers and payers identify regimens that maximize patient benefit and safety. As more of these studies reach the peer-reviewed literature, we suspect more healthcare systems will recognize the potential benefits and efficiencies, and will develop the capability to conduct embedded point-of-care LSTs.

The Future

With accelerated approval of new medications and rapid increases in their use, there may be a greater need for large postmarketing studies capable of randomizing exposures in order to assess small differences in risk. In the absence of techniques that reliably control for confounding by indication in observational studies, there may be a growing need for LSTs to evaluate larger relative risks. By virtue of minimal restrictions on participant eligibility, LSTs are more likely than classic randomized clinical trials to reflect the true benefits and safety of medications when used in actual clinical practice. The generalizability of the results of LSTs and other pragmatic clinical trials makes these studies particularly valuable to regulators and policy makers and may lead to increased use of these studies.

It is clear that safety LSTs can be conducted. It remains less clear, however, how frequently the factors that support the need for a very large trial (see Box 32.1) will converge with those that permit such a trial to be carried out (see Box 32.2). A review published in 2011 [58] discovered that only 13 LSTs evaluating safety outcomes as a primary endpoint had been completed or were ongoing prior to 2010. Among those identified, earlier studies tended to use more elements associated with a controlled clinical trial (e.g., double-blinds) whereas more recent studies had the most characteristics associated with observational epidemiology. Nonetheless, all the LSTs identified utilized observational methods of follow-up, but did so with varying degrees of intervention to meet the study objectives, primarily in the form of scheduled visits or required laboratory and diagnostic tests.

Although the LST design may be most appropriate when studying "hard" outcomes such as death or hospitalization, the same review found that researchers used the design to compare "soft" outcomes (e.g., incidence of physician-reported symptomatic hypotension and patient-reported complaints) or outcomes that require regular measurement (e.g., pulmonary function). This finding was unexpected since much of the literature on the use of LSTs for examining the therapeutic or preventive effects of an intervention suggest they are best suited to studying "hard" outcomes to avoid assessment and reporting bias. This may also be indicative of researchers' need to measure softer outcomes that are associated with and predictive of hard outcomes that occur later (e.g., death, cancer). Other unexpected differences noted were the use of person-time on treatment as a secondary analysis, which results in potentially biased comparisons between treatment groups (i.e., because participants discontinue their medications for reasons that may be related to potential outcomes), and sample sizes that were smaller than thousands of patients.

Large simple trials are likely rare as a result of the operational, financial, and scientific hurdles of implementing the design. Substantial resources are required to accrue large sample sizes; collect multiple forms of outcome data; manage hundreds of participating investigators and sites; and ensure appropriate scientific and ethical oversight. The lack of research infrastructure for conducting research at sites or with physicians inexperienced with randomized trials, including the complex regulations governing interventional study implementation and prohibitive financial costs, are barriers to conducting LSTs. This complexity illustrates that while the design is intended to be "simple" for participating healthcare providers and patients, it might be more accurately described as a "simplified" trial. Financial considerations are also important. Twelve of the 13 LSTs identified in the review described earlier were funded by the pharmaceutical or consumer products industry, six of which were postapproval commitments to the FDA or an EU regulatory agency [58].

A simple testable safety hypothesis, a motivated patient and physician population, and the ability to follow up patients to assess outcomes are important for the feasibility of a safety LST. Clearly, evaluating differences in very rare (e.g., Stevens–Johnson syndrome) or long-latency (e.g., cancer induction) outcomes is generally not practical with the LST design. Even hard outcomes such as death are difficult to study in a randomized study if the incidence of the outcome is low or the observed rate in the study is lower than expected when initial sample size calculations are performed. Because the design uses randomization, an appropriate comparator acceptable to physicians and patients is also a critical factor in the success of an LST. Equipoise must exist, and if a new medication or vaccine has a real or perceived benefit over available treatments, the LST design will not be feasible. The lack of equipoise may also become a challenge in situations where the study enrollment period is very lengthy. As knowledge of the

benefits and risks of treatments evolves, leading to less clinical uncertainty about the type of patients that might benefit from a particular study medication, investigators may find it increasingly difficult to enroll study participants.

Large simple trials should be considered as a potential design to understand the safety of any health intervention. However, the design's use with novel medicines, vaccines, diagnostics, and biologics is likely to be limited. The feature of randomization alone limits its application, since in some disease areas there may be no logical or ethical comparator (i.e., first-in-class medicine or vaccine, rare diseases, oncology). Biopharmaceutical development is increasingly focused on smaller indicated patient populations. This will result in insufficient exposure to reach the required event rate or, when feasible, it may take too long to accrue exposure to be acceptable to decision makers. Even in situations where the prevalence of a condition is much greater (e.g., schizophrenia or asthma), it may take many years to accrue the necessary patient population, which to some may be too long to address important safety questions. In settings where there is no appropriate control treatment and it is not ethical to randomize between active drug and placebo, an alternative to randomizing to comparator medicines may be to randomize to different doses, when possible, and search for a dose–response relationship. Another option may be usual care as a comparator or to randomize to treatment strategies rather than specific medications.

Despite these challenges to using the LST for comparative safety evaluation, the design is particularly suited to research questions in which confounding by indication or severity is likely to be pronounced and difficult to measure or control, but where assessment under routine care is important for decision making. LST designs are similar to observational studies in that they can, in principle, be effectively used to study the safety of health interventions in patient populations not typically exposed in clinical trials, such as the elderly, very young, or those with multiple comorbidities, and understand the safety of a health intervention as it is used with multiple concomitant prescriptions or OTC medications under routine medical care. With the increasing demand for real-world evidence to guide public health, regulatory, and clinical decisions, pharmacoepidemiologists are well suited to design and conduct LSTs and, most importantly, to develop more efficient methods of participant selection and follow-up data collection that can make these studies a more common option for the evaluation of small but important risks of medication use.

The Use of Pharmacoepidemiology to Study Beneficial Drug Effects

Brian L. Strom[1] and the late Kenneth L. Melmon[2]

[1] *Rutgers Biomedical and Health Sciences, Newark, NJ, USA*
[2] *Formerly Stanford University School of Medicine, Stanford, CA, USA*

In order to be approved for marketing in the United States, drugs must be proven to be safe and effective using "adequate and well-controlled investigations." Earlier chapters in this book have shown that this premarketing information often is insufficient to provide some of the information about drug toxicity which is clinically most important. The same applies to information about drug efficacy.

In this chapter we will begin by clarifying the different definitions of various types of beneficial drug effects. Then we will discuss the need for *postmarketing studies of drug effectiveness*. Next, we will present the unique methodologic problems raised by studies of beneficial drug effects, as well as potential solutions to these problems. Finally, we will evaluate the frequency with which these proposed solutions might be successful. Specific examples of approaches to the study of efficacy also will be presented.

Definitions

There are at least four different types of measurable drug effects of interest to a prescriber. *Unanticipated harmful effects* are the unwanted effects of drugs that could not have been predicted on the basis of their preclinical pharmacologic profile or the results of premarketing clinical studies. These effects are most often type B adverse reactions, as defined in Chapter 1. For example, chloramphenicol was not known to cause aplastic anemia at the time it was marketed [1], nor was the skeletal muscle pain associated with use of HMG-CoA reductase inhibitors. A major research challenge is to discover medically important unanticipated harmful effects as soon as possible after drug marketing. Quantitation of the incidence of these effects is medically useful as well.

Anticipated harmful effects are unwanted effects of drugs that could have been predicted on the basis of preclinical and premarketing studies. They can be either type A reactions or type B reactions (see Chapter 1). One example is the syncope that sometimes occurs after patients take their first dose of prazosin [2]. Although this effect was known to occur at the time of marketing, a major question remaining to be answered was how often the event occurred. The dominant research challenge that this type of drug effect presents is establishing its incidence.

Unanticipated beneficial effects are desirable effects of drugs that were not anticipated at the

Pharmacoepidemiology, Sixth Edition. Edited by Brian L. Strom, Stephen E. Kimmel and Sean Hennessy.

time of drug marketing. Although these effects may be medically useful, they are nevertheless side effects, if they are not the purpose for which the drug was given. An example of an unanticipated beneficial effect is aspirin's ability to decrease the probability of a subsequent myocardial infarction in patients who were given the drug for its analgesic or antiinflammatory action [3]. This effect was confirmed only after aspirin had been used as an analgesic for many years. A major research challenge is to discover this type of drug effect. For example, given the similar (although not exactly the same) mechanism of nonaspirin nonsteroidal antiinflammatory drugs, these drugs may have the same beneficial effects as aspirin [4]. However, recent data suggest that, in contrast, these medications might increase the risk of cardiovascular events.

Anticipated beneficial effects are the desirable effects that are known to be caused by the drug. They represent the reason for prescribing the drug. The study of anticipated beneficial effects has three aspects.

A study of drug *efficacy* investigates whether a drug *has the ability* to bring about the intended effect. In an ideal world, with perfect compliance, no interactions with other drugs or other diseases, etc., could the drug achieve its intended effects? Drug efficacy usually is studied using a randomized clinical trial.

In contrast, a study of drug *effectiveness* investigates whether, in the real world, a drug *in fact* achieves its desired effect. For example, a drug given in experimental conditions might be able to lower blood pressure but if it causes such severe sedation that patients refuse to take it, it will not be effective. Thus, an efficacious drug may lack effectiveness. Studies of drug effectiveness usually are performed after a drug's efficacy has been established. In contrast, if a drug is demonstrated to be effective, it also is obviously efficacious. Studies of drug effectiveness generally would best be conducted using nonexperimental study designs, although clinical trials using pragmatic designs may also be utilized (see Chapter 32). However, these raise special methodologic problems, which are discussed later.

Lastly, a study of *efficiency* investigates whether a drug can bring about a *desired effect at an acceptable cost*. This type of assessment falls in the province of health economics, which is discussed in Chapter 34.

Note that the outcome variable for any of these studies can be of multiple different types. They can be clinical outcomes (diseased/undiseased) (see Chapter 37 for a discussion of the validity issues involved in measuring such outcomes); measures of patient-reported outcomes (see Chapter 42), measures of utility, such as global measures of the desirability of certain clinical outcomes (see Chapters 37 and 42); economic outcomes (see Chapter 34); etc. Regardless, the same methodologic issues apply to each.

Clinical Problems to Be Addressed by Pharmacoepidemiologic Research

In order to make optimal clinical decisions about whether to use a drug, a prescriber needs to know whether, and to what degree, the drug actually is able to produce the intended effect (Box 33.1) [5]. Premarketing randomized clinical trials generally provide information on whether a drug can produce at least one beneficial effect. Specifically, premarketing studies generally investigate the efficacy of a drug relative to a placebo, where both are used to treat a particular illness. These premarketing studies of efficacy tend to be conducted in very atypical clinical settings, compared to those in which the drug ultimately will be used. Patient adherence (see Chapter 38) during these studies is typically higher than in actual practice, and the patients included are similar to each other in age and sex, do not have other diseases, and are not taking potentially interacting drugs (see Chapter 40). Such restrictions

Box 33.1 Clinically important information about intended beneficial effects of drugs

1) Can the drug have the desired effect?
2) Does the drug actually achieve the desired effects when used in practice?
3) Can and does the drug have other beneficial effects, including long-term effects for the same indication?
4) Can the drug achieve these desired effects better than other alternative drugs available for the same indication?
5) For each of the above, what is the magnitude of the effect in light of the many different factors in medical practice that might modify the effect, including:
   - variations in drug regimen: dose per unit time, distribution of dose over time, duration of regimen?
   - characteristics of the indication: severity, subcategories of the illness, changes over time?
   - characteristics of the patient: age, sex, race, genetics, geographic location, diet, nutritional status, adherence, other illnesses, drugs taken for this or other illness (including tobacco and alcohol), etc.?

Modified from Strom BL, Melmon KL, Miettinen OS. Postmarketing studies of drug efficacy: Why? *Am J Med* 1985; **78**: 475–80. Reproduced with permission of Elsevier.

maximize the ability of premarketing studies to demonstrate a drug's efficacy, if the drug actually is efficacious.

Additional information may then be needed on whether, in the world of daily medical practice, the drug actually achieves the same beneficial effects and whether it can and does have other beneficial effects. In addition, at the time of marketing there may be few data on a drug's efficacy relative to other medical or surgical alternatives available for the same indication.

Finally, a number of factors that are encountered in the practice of medicine can modify a drug's ability to achieve its beneficial effects. Included are variations in drug regimen, characteristics of the indication for the drug, and characteristics of the patient receiving the drug, including demographic factors, nutritional status, the presence of concomitant illnesses, the ingestion of drugs, and so on. Many, if not most, of these factors that can influence the effects of drugs are not fully explored prior to marketing.

In order to quantitate the need for postmarketing studies of the beneficial effects of drugs, a comparison was made of the 100 most common drug uses in 1978 (drug–indication pairs) to the information available to the FDA at the time of its regulatory decisions about the marketing and labeling of the drugs involved in these uses [5]. The comparison was restricted to drugs approved after 1962, when the Kefauver–Harris Amendments first introduced a requirement for the submission of data about drug efficacy prior to approval of a drug for marketing.

Of the 100 common drug uses, 31 had not been approved by the FDA at the time of initial marketing, and 18 still had not been approved at the time of the comparison. Eight of the 18 unapproved uses were probably medically and therapeutically inappropriate. For example, the use of antibiotics is not justified for the treatment of viral infections, but such use was common. Other unapproved drug–indication pairs could well have been quite appropriate, but the regulatory process does not need to and did not reflect the current medical practice.

Of the 100 common drug uses, eight were based on the assumption that a drug had a particular long-term effect, but only an intermediate effect had been studied prior to marketing. For example, antihypertensive drugs are used for their presumed ability to prevent long-term cardiovascular complications, but are approved for marketing on the basis of their ability to lower blood pressure. Five of the 100 common

drug uses may have been for either the intermediate effect or the long-term effect of the drugs, but only the intermediate effect was studied prior to marketing. For example, hypoglycemic agents may be used to control the symptoms of diabetes or to prevent the vascular complications of diabetes, but only the former were studied before drug marketing.

Drugs other than those in the list of 100 common uses were sometimes prescribed as treatment for each of the 52 indications included in those 100 uses. Yet, eight of the uses involved drugs whose effects relative to alternative drugs had not been studied prior to marketing.

The 100 common drug uses also included examples of clinical factors that are able to modify the effects of the drug, but these were not discovered until after drug marketing. Some are listed in Table 33.1 [6–19]. In addition, additional prescriptions accompanied 62% of the prescriptions studied, and 41% of the prescriptions were for patients who had illnesses other than just the one that the drug was being used to treat. Of the 100 common drug uses, the mean number of concomitantly administered drugs ranged from 0.04 to 2.1. The mean number of concomitant diagnoses ranged from 0.1 to 1.2. Yet, for none of the uses was the potential for modification of the drug effect by concomitant drugs or concomitant diagnoses fully explored before marketing.

The proportion of prescriptions which were for patients less than age 20 ranged from 0.0%, for 43 of the uses, to 97%. Yet many of these uses had not been tested in children prior to marketing. Analogously, only three of the drugs were approved for use in pregnant patients, yet we know that drug use in pregnancy was common, even then [20–22].

Thus, this study revealed considerable gaps in the information about beneficial drug effects at the time of drug marketing. These deficiencies in the available information should not be surprising, nor should they be considered inadequacies that ought to prevent the release of the drug to the marketplace. The data needed for clinical decisions are frequently and understandably different from those needed for regulatory decisions. Studies performed prior to marketing perforce are focused predominantly on meeting appropriate regulatory requirements, and only secondarily on providing a basis for optimal therapeutic decisions. This regulation is not aimed at telling a physician precisely how an agent should be used. The FDA is not allowed to regulate physicians but, rather, pharmaceutical manufacturers. In addition, the FDA does not initiate its own studies of drug effects, but generally evaluates those submitted to it by manufacturers.

Finally, there are reasonable logistical limitations on what can be expected prior to marketing, without undue cost in time and resources, as well as delaying the availability of a chemical entity with a proven potential for efficacy. Thus, it seems that more studies of beneficial drug effects are needed, perhaps as a routine part of postmarketing drug surveillance.

Methodologic Problems To Be Addressed by Pharmacoepidemiologic Research

Chapter 3 introduced the concept of a confounding variable, which is a variable other than the risk factor and outcome variable under study which is related independently to each of the other two and, thereby, can create an apparent association or mask a real one. This is discussed in more depth in Chapter 43. Studies of intended drug effects present a special methodologic problem of confounding by the indication for therapy [23,24]. In this case, the risk factor under study is the drug being evaluated and the outcome variable is the clinical condition that the drug is supposed to change (cure, ameliorate, or prevent). In clinical practice, one would expect

Table 33.1 Examples of factors determining drug efficacy that were demonstrated after marketing, selected from the 100 most common drug uses of 1978.

Factors	Drug	Indication	Comments	Reference
Regimen				
Dose per unit time	Ibuprofen	Rheumatoid arthritis, osteoarthritis	Daily dosage initially approved proved to be suboptimal	5
Distribution of dose over time	Furosemide	Congestive heart failure	Efficacy improved by more frequent, smaller doses	6
Duration	Clonidine	Hypertension	Tolerance develops in the absence of a diuretic	7
	Hypoglycemics (e.g., acetohexamide and tolazamide)	Diabetes mellitus	Tolerance develops in many patients	8
Indication				
Severity	Metaproterenol	Asthma	Patients with severe illness do not have a response without additional, supplementary therapy	9
Subcategories	Desipramine	Depression	May vary with endogenous versus exogenous depression	10
Changes over time	Ampicillin	Otitis media	No longer the drug of choice in some geographic areas due to bacterial resistance	11, 12
Patient				
Age	Diazepam	Anxiety	A given regimen is more effective in the aged than in the young	13
			Metabolism varies markedly from premature infants (half-life 54 hours), to full-term infants, to older children (half-life 18 hours); young children can have paradoxic reactions	14
Other illness	Gentamicin	Infection	Lower doses required in renal failure	15
Other				
Drugs	Lithium	Manic-depressive illness	Clearance impaired by diuretics, e.g., furosemide	16
	Acetohexamide	Diabetes mellitus	Many drugs interfere, by causing hyperglycemia (e.g., diuretics), displacing drug from binding sites (e.g., nonsteroidal anti inflammatory drugs), etc.	17
Diet	Diuretics (e.g., metolazone, furosemide)	Hypertension	A decrease in sodium intake can improve efficacy	18
	Lithium	Manic-depressive illness	Significant sodium depletion or excess can modify renal excretion	16

treated patients to differ from untreated patients, as the former have an indication for the treatment. To the extent that the indication is related to the outcome variable as well, the indication can function as a confounding variable.

For example, if one wanted to evaluate the effectiveness of a beta-blocker used after a myocardial infarction in preventing a recurrent myocardial infarction, one might conduct a cohort study comparing patients who were treated with the beta-blocker as part of their usual postmyocardial infarction medical care to patients who were not treated, measuring the incidence of subsequent myocardial infarction in both groups. However, patients with angina, arrhythmias, and hypertension, all indications for beta-blocker therapy, are at increased risk of subsequent myocardial infarction. As such, one might well observe an increase in the risk of myocardial infarction, rather than the expected decrease. Thus, even if use of the drug was beneficial, it might appear to be harmful!

Confounding by the indication for the treatment generally is not a problem if a study is focusing on unexpected drug effects, or side effects, unrelated to the indication for the drug, whether they are harmful or beneficial effects. In this situation, the indication for treatment is not usually related to the outcome variable under study. For example, in a study of gastrointestinal bleeding from nonsteroidal antiinflammatory drugs (NSAIDs), the possible indications for treatment, such as arthritis, dysmenorrhea, and acute pain, have little or no relationship in and of themselves to the risk of gastrointestinal bleeding [25]. Nevertheless, sometimes the problem of confounding by indication can emerge even in studies of unexpected drug effects (beneficial or harmful). For instance, in a study of hypersensitivity reactions associated with the use of NSAIDs, the increased risk of hypersensitivity reactions evident in patients taking NSAIDs was higher in those using the drugs for acute pain than in those using the drugs for osteoarthritis and other chronic conditions. This probably was because of the intermittent ingestion of the drug by those receiving it for acute pain [26].

Although confounding by the indication is a less common problem for studies of side effects, this is not the case for studies of anticipated beneficial effects. In these studies, one would expect the indication to be more closely related to the outcome variable. In fact, the problem presented by confounding by the indication has been thought by some to invalidate nonexperimental approaches to studies of the beneficial effects of drugs. Some have felt that questions of beneficial drug effects can be addressed only by using randomized clinical trials [27]. Yet, although postmarketing randomized clinical trials certainly can be very useful, they are vexed by many of the same logistical problems, ethical restrictions, and artificial medical settings found in premarketing clinical trials.

Currently Available Solutions

Not all studies of beneficial drug effects need be randomized clinical trials (Table 33.2) [23]. First, some questions do not require any comparative (analytic) research for their answer. For these, simple clinical observations, as reported in a case report or case series, can be sufficient. For example, the efficacy and effectiveness of naloxone, used as a narcotic antagonist, is demonstrable simply through the observation of a single patient. Consider a patient comatose from an overdose of methadone. An injection of naloxone results in his prompt awakening. However, 30 minutes later, as the effects of the narcotic antagonist wear off, the patient returns to coma. Another injection of the naloxone results in awakening once more, and then later the coma returns again. This sequence of events represents a convincing demonstration of the drug's ability to have its desired effect. No elaborate studies are needed to make this point. The same would be

Table 33.2 Classification of research questions according to their problems of confounding by the indication for therapy.

Situation	Example
1. Comparative studies unnecessary	
(a) Drug effect obvious in the individual patient, or	Naloxone used for methadone overdose
(b) Drug effect obvious in a series of patients	Penicillin used for pneumococcal pneumonia
2. Confounding by the indication nonexistent: there is no indication	Measles vaccine given routinely to healthy infants
3. Confounding by the indication exists but is controllable	
(a) The indication is dichotomous	
(i) Gradations in the indication do not exist, or	Anti-Rh (D) immune globulin given to Rh (D)-negative mothers who deliver Rh (D)-positive newborns to prevent future erythroblastosis fetalis
(ii) Gradations in the indication are unrelated to the choice of treatment, or	Penicillin used for endocarditis prophylaxis in patients with congenital aortic stenosis who are undergoing tooth extraction
(iii) Gradations in the indication are unrelated to expected outcome, or	Penicillin used to prevent tertiary syphilis, given to patients with an asymptomatic positive serologic test for syphilis
(iv) Special clinical settings	Anticoagulants used after myocardial infarctions to prevent death
(b) The indication is sufficiently characterizable	Isoniazid used for tuberculosis prophylaxis in a patient with an asymptomatic positive purified protein derivative
(i) Complete characterization of the indication as it relates to choice of therapy or as it relates to expected outcome, and	
(ii) Characterization must continue after initiation of therapy	
4. Confounding by the indication exists and is not controllable	Ampicillin used to treat urinary tract infection

Source: Strom BL, Miettinen OS, Melmon KL. Postmarketing studies of drug efficacy: when must they be randomized? *Clin Pharmacol Ther* 1983; **34**: 1–7. Reproduced with permission of John Wiley & Sons.

true for a case series of patients treated with penicillin to treat pneumococcal pneumonia.

However, in applying this simple approach of clinical observations based on a case report or case series, the course of a patient's disease must be sufficiently predictable that one can differentiate a true drug effect from spontaneous improvement. In particular, one must be able to exclude *regression to the mean* as the mechanism of the observed change: individuals selected to participate in a study based upon the severity of their disease spontaneously and usually will tend to improve. One example would be a patient with recurrent headaches. The patient would most likely seek medical attention when the headaches are most severe or most frequent.

A spontaneous return to the baseline pattern of headaches generally could be expected. However, if the patient were treated in the interim, then the treating physician likely would view the return to normality as evidence of successful therapy, no matter what treatment was used or whether it contributed anything to the recovery.

Second, some questions about beneficial drug effects can be answered using formal nonexperimental studies, because there is no confounding by the indication. If the decision about whether to treat is not based on a formal indication, but on some other factor that may not be related to the outcome variable under study, such as the limited availability of the drug in question, then there is no opportunity for confounding by the indication. This situation occurs most commonly in studies of primary prevention. The use of measles vaccine, routinely administered to healthy infants, is one example.

Third, there are several settings in which confounding by the indication may exist but theoretically can be controlled. When the indication can be measured sufficiently well, then traditional epidemiologic techniques of exclusion, matching, stratification, and mathematical modeling can be applied. The indication clearly can be sufficiently measured if it is dichotomous or binary. In this situation, the indication either is present or absent, but has no gradations in severity. The indication also can be sufficiently measured if any gradations in severity either are unrelated to the choice of whether or not to treat or are unrelated to the expected outcome. Alternatively, sometimes one can find special clinical settings in which the gradations are not related to the choice of therapy. For example, if the availability of drugs is limited or there are consistent philosophical differences among prescribers for using or not using the drug, then gradations in the indication will not be related to the choice of therapy (although, even then, confounding could occur due to, for example, differences in patients treated among prescribers).

Finally, if an indication is graded but can be sufficiently precisely measured, it can be controlled by mathematical modeling using, for example, multiple regression. Then confounding by the indication can be controlled and ruled out as the cause for an observed beneficial effect of the drug.

More recently, researchers have used *propensity scores* towards this end [28,29]. This approach uses mathematical modeling to predict *exposure*, rather than the traditional approach of predicting *outcome* [30]. This is, essentially, a direct measure of indication. One can then use the propensity score to create categories of probability of exposure, and control for those categories in the analysis. While this approach has many attractive features, especially as a direct way to control for confounding by indication, it is important to point out that it is still dependent on identifying and measuring those variables which are the true predictors of therapeutic choice. Further, propensity scores only have advantages when there are seven or fewer outcome events per confounder [31]. When there are at least eight outcome events per confounder, logistic regression represents a preferable approach [31]. (See Chapter 43 for a more detailed discussion.)

Another relatively new approach increasingly being applied is the use of *instrumental variables*. An instrument is a variable that is causally related to the exposure of interest, only weakly related to the uncontrolled risk factors of concern, and is not itself in the causal chain. Thus, an instrument is an external factor that influences an outcome only through its effect on treatment. By controlling for the instrument, it is thought that one can control for the indication for treatment. However, finding good instruments in pharmacoepidemiology is extremely difficult. This is discussed further in Chapter 43.

When questions of intended drug effects do not fall into any of the preceding categories, *confounding by the indication cannot be controlled*. Nonexperimental study designs cannot then be

used, or they can only be used to demonstrate qualitatively some degree of beneficial effect. Specifically, if confounding by the indication is such that treated patients would have a worse clinical outcome than untreated patients, yet the outcome observed in treated patients is better than that observed in untreated patients, some degree of confidence that the drug has a beneficial effect can be built. As an example, patients treated with corticosteroids for status asthmaticus would be expected to be sicker than those not so treated. If patients receiving corticosteroids stop wheezing sooner than those not receiving corticosteroids, corticosteroids would indeed seem to have a beneficial effect. However, if the patients receiving corticosteroids do not stop wheezing sooner than those not receiving corticosteroids, the results of the study are uninterpretable. It is possible that the corticosteroids in fact have no beneficial effect but it is also possible that a beneficial effect was present but was being masked by the difference in severity between the two treatment groups.

The qualitative approach illustrated above must be used with caution. First, the effect of the confounding by indication must be opposite in direction to the expected effect of the drug. Second, the effect of the confounding by indication must be absolutely predictable in its direction. Third, the effect of the confounding by indication must be sufficiently large so as to exclude regression to the mean as an explanation for the results. Even if all of these conditions are met, the results must be interpreted only qualitatively, not quantitatively.

Examples of each of these situations are presented in Table 33.2 and discussed further in Strom *et al.* [23].

Applicability of the Proposed Approaches

How commonly are the nonexperimental approaches we have described applicable for the study of beneficial drug effects? A list of the 100 most recently approved new molecular entities as of December 1978 was studied to determine what types of nonexperimental study designs, if any, could be used to evaluate drug effectiveness [32]. After excluding from this list seven entities that were used in contact lenses, the remaining 93 drugs were examined for all potential indications and clinical outcomes that could be used to evaluate intended drug effects. Ultimately, we assessed 131 drug uses, that is 131 drug–indication pairs. Each drug use was categorized as to whether a study evaluating the effectiveness of that drug for that indication would present the problem of confounding by the indication and, if so, whether one of the approaches described above would be adequate to address it. Eighty-nine (67.9%) of the drug uses could have been evaluated using simple clinical observations, without formal comparative research. A very few of these drugs were, in fact, approved by FDA on the basis of such studies, such as nitroprusside (approved for malignant hypertension) and bretylium (approved for life-threatening arrhythmias, in patients refractory to all other antiarrhythmics). The remaining 42 drug uses required comparative research for their evaluation, because they all presented the problem of confounding by the indication. In seven of the 42 (5.3% of the total), this confounding was not an obstacle to valid nonexperimental research. Most often, the validity of the approach rested on the observation that any given physician usually used the drug to treat either all or none of his/her patients with the indication.

In the remaining 35 of the 42 uses (26.7% of the total), confounding by the indication was judged to be uncontrollable using currently available nonexperimental techniques.

To place these findings in perspective, of the 42 drug uses that required comparative research to evaluate their effectiveness, 30 could not ethically be addressed using a randomized clinical trial and a placebo control. Most of these 30 involved the use of drugs to treat infections or malignancies. In these situations, patients could

not ethically be left "untreated," that is, assigned to the placebo group.

Studies of the effects of one drug relative to another active drug, of course, gave different results. Formal comparative research was necessary for all 131 drug uses. Nonexperimental studies theoretically could be conducted validly for 94 of the 131 drug uses (71.8%). Experimental studies would be ethical for all of them.

Of course, judging theoretically that a question of effectiveness is "studiable" by a given technique is not the same as proving that a valid outcome would emerge from such a study. There are many particular details in the actual conduct of such studies that must be addressed on a case-by-case basis. It is, therefore, instructive to examine some specific examples of nonexperimental research into beneficial drug effects.

Specific Examples

Estrogens for Prevention of Osteoporotic Fractures

One of the first series of studies of drug effectiveness using rigorous nonexperimental study designs examined whether exogenous estrogens could prevent fractures in postmenopausal women with osteoporosis [33]. Biochemical studies had documented that the menopause resulted in a negative calcium and phosphorus balance, and that the balance returned toward normal with the ingestion of exogenous estrogens [34]. Studies of bone density documented that exogenous estrogens prevented the loss of bone density that was associated with the menopause [35], for as long as the estrogens were continued [36]. It seemed plausible that the use of estrogens might prevent fractures from osteoporosis, but no data directly addressed that question. On the other hand, postmenopausal estrogens had been shown to cause endometrial cancer [37,38].

A randomized clinical trial would have been the ideal way to address the effect of estrogen on fractures. However, such a study, of this prophylactic therapy, was impractical for many reasons. Although postmenopausal fractures are common, they are experienced by a sufficiently small proportion of the population during any defined time period that an extremely large sample size would be needed. Also, the study would need to be carried on for many years before a beneficial effect could begin to be seen.

Instead of a randomized clinical trial, a series of nonexperimental studies were performed. Both case–control and cohort designs were used [39–56]. In general, these studies were rigorous and well done but the question of confounding by the indication was not addressed in most of the studies [33]. In particular, most of them failed to address why some of the women received the postmenopausal exogenous estrogens and others did not. Given the data already available on the effects of estrogens on bone density [57,58] and endometrial cancer [59–62], it is reasonable to assume that some physicians might preferentially and routinely use the drugs and others might routinely avoid them [63–65]. In such a setting, nonexperimental techniques could yield valid results, unaffected by confounding by the indication (category 3.a.iv in Table 33.2). However, many physicians might try to selectively prescribe the drugs for patients who have undergone hysterectomy, because these patients are at no risk of endometrial cancer. Alternatively, some physicians may try to use the drugs only on patients who they feel are at high risk of fractures or at high risk of complications from fractures. These situations would represent uncontrollable confounding by the indication – category 4 in Table 33.2.

Finally, one might expect that the direction of the confounding by indication might be opposite to that of the drug effect, allowing one to use these data to make at least qualitative conclusions. This assumes, however, that physicians can accurately predict who is at high risk of fracture. Such a presumption was not borne out by the available data [50].

In fact, the three studies that closely examined the comparability of the study groups were able

to document that they were not comparable [39,50,52]. Specifically, one study was a case–control study within an orthopedic service, and documented that cases with fractures of the hip or radius weighed less than controls matched for age and race, had a later menopause, and more frequently were alcoholics [39]. A second was a cohort study of patients with known estrogen deficiency. In this study, those who were treated with estrogens differed from those who were not in age, age of menopause, duration of follow-up, height, weight, blood pressure, marital status, race, economic status, and gravidity, as well as in the frequency of the following diagnoses: atrophic vaginitis, bilateral oophorectomy, premature ovarian failure, hypopituitarism, gonadal dysgenesis, endocrine disease, hypertension, and osteoporosis [50].

A third study used a case–control design to investigate patients admitted to surgical services [52]. It compared cases with hip fractures to a control group of surgical patients, divided into those with and those without trauma. Cases were noted to be older, taller, and to have a lower body weight than the controls. The cases more frequently had undergone ovariectomy, breastfed fewer times and for fewer months, and were hypothyroid less frequently than the controls. When these factors were controlled for as confounding variables, the effect of estrogens was still apparent. However, as in the other studies, there was no information on how or why the decision was made to treat with or withhold estrogens.

A number of other nonexperimental studies published since then showed similar results [59,61,62,66–71]. Since then, the finding that estrogens have a beneficial effect on hip fractures has been confirmed in a large clinical trial, the Women's Health Initiative [72].

Anticoagulants for Prevention of Recurrent Venous Thromboembolism

The use of intravenous anticoagulants reduces the risk of recurrent venous thromboembolism [73], and the addition of oral anticoagulants to intravenous anticoagulants probably reduces the risk even further [74]. However, how long oral anticoagulant treatment should be continued had not been well studied. Most explicit advice from experts on the optimal duration of anticoagulation therapy was based on anecdotal experience [75,76]. Most of the data that were used to suggest the appropriate duration of therapy are derived from clinical observations in a single medical center [77–80]. They represent an accumulating case series. Over time, gradually patients' treatment has been prolonged. Thus, changes in the duration of treatment are intermingled with other changes in medical care over decades. In addition, the studies do not compare patients receiving treatments of different lengths but simply observe when most recurrences tend to occur. The investigators have assumed that treatment should be prolonged sufficiently to include that time when recurrences can be expected. Problems with these studies have been detailed [75,76].

As with the question of the effect of estrogens on bone fractures from osteoporosis, a randomized clinical trial would be the ideal design to address the question of the optimal duration of anticoagulation after venous thromboembolism, but such a study is difficult. After patients have been anticoagulated in the hospital and followed for a short time as outpatients, the risk of recurrence is sufficiently small that an enormous population would be needed to detect a difference in outcome due to differences in therapy. For years, the only randomized clinical trial in the literature that addressed this question compared six weeks of outpatient treatment to six months of treatment. No difference in recurrence rate between these two groups of patients was observed [81]. However, only 186 subjects were included, yielding a total of only seven recurrences. In addition, over half the study subjects had some known short-term risk factors for venous thromboembolism. These included pregnancy, use of oral contraceptives,

and recent surgery. Patients with these transient underlying risk factors might be expected to be less likely to benefit from longer-term anticoagulant therapy than patients with idiopathic disease.

The question of the optimal duration of anticoagulation was addressed in a retrospective cohort study performed using medical records review in the Northern California Kaiser Permanente Medical Program [82]. The study required the use of 10 years of data from this population of 1.6 million, or a total of 16 million patient-years of experience. A total of 3384 individuals were identified as being hospitalized for venous thromboembolism. Of these, 2473 suffered from idiopathic venous thromboembolism. Their clinical outcomes were evaluated according to how long they had been treated with oral anticoagulants. Using those treated with six weeks of therapy or less as a control group, prolongation of therapy beyond that point was found to increase the risk of major bleeding dramatically but to have no effect on recurrence rates. Unfortunately, very few of these episodes of venous thromboembolism were objectively confirmed, that is, they were clinical diagnoses only, as that was not the practice at Kaiser.

The feature of this study that allowed the investigators to overcome the problem of confounding by indication was that physician behavior regarding how long therapy was continued was essentially random (category 3.a.ii in Table 33.2). The choice of how long to treat became random, because there was no prior information on how long one should treat. In fact, the duration of treatment was relatively uniformly distributed across the years of follow-up, and the results were no different when one restricted the analysis to those who had their anticoagulation stopped because of hemorrhage, rather than at the option of their physician.

However, these results were not necessarily confirmed in subsequent randomized trials. A decade later, a multicenter trial in Sweden, with 897 patients with first episode of venous thromboembolism treated with oral anticoagulants and followed up for two years, found a significant difference in the incidence of recurrent venous thromboembolism between the six-week and six-month groups (18.1% vs 9.5%, respectively), and no significant difference in mortality or the incidence of major hemorrhage between the two treatment groups [83].

Several other recent studies also showed the benefit of longer duration of warfarin anticoagulant therapy. One randomized trial also showed that long-term low-dose warfarin therapy was effective in decreasing the subsequent risk of recurrence of idiopathic venous thromboembolism, in patients who had already received full-dose warfarin for a median of 6.5 months [84].

Lidocaine for Prevention of Death from Myocardial Infarction

In another study, the efficacy of lidocaine in preventing death from myocardial infarction was studied using a case–control design [85]. Among patients admitted to a coronary or intensive care unit for acute myocardial infarction, those who died were compared to an equal number of patients who survived. The controls were matched to the cases for age, gender, race, and date of hospitalization. Overall, lidocaine did not protect against death. Lidocaine was effective only when deaths attributable to ventricular arrhythmia were analyzed separately.

In this careful study, the investigators obviously were well aware of the risk of confounding by indication. They attempted to control for this by using the epidemiologic technique of stratification, that is, classifying patients according to their risk of dying from myocardial infarction, in order to control for this inequality of risk as a confounding variable. Thus, they treated the study as a category 3.b question in Table 33.2. Unfortunately, however, it is doubtful whether one can accurately and fully measure the basis for physicians' judgments about who they think is at high risk of death from myocardial

infarction. Similarly, it is unlikely that each individual's risk of dying from a myocardial infarction can be predicted, especially death by ventricular arrhythmia. Certainly, a classification according to just the presence or absence of congestive heart failure, as was used, is overly simplistic. In fact, the rates of death attributed to ventricular arrhythmia were virtually identical in those patients with and without congestive heart failure. Nevertheless, the results do coincide with those of a randomized clinical trial evaluating the efficacy of lidocaine in preventing primary ventricular fibrillation [86]. However, while the drug prevented the arrhythmia in that randomized clinical trial, it did not alter mortality.

Since then, there have been more than 20 randomized trials and four metaanalyses, indicating that lidocaine reduces ventricular fibrillation but, contrary to the results of the nonrandomized trials, increases mortality in acute myocardial infarction [87]. This was not confirmed in a subsequent paper, which reanalyzed the data from the 43 704 patients enrolled in GUSTO-I or GUSTO-IIb [88].

Anticoagulants for Prevention of Death from Myocardial Infarction

Whether anticoagulants can prevent death from myocardial infarction was addressed using randomized clinical trials [89]. However, the results were inconsistent and inconclusive, possibly because of problems of sample size. Thus, this question would appear to be a good candidate for a case–control study. Such a study was done [90], with the investigators treating this research question as if it were a category 3.b question in Table 33.2. However, as with the study of the effects of lidocaine on myocardial infarction, it is doubtful whether one can measure and quantitate precisely the risk of dying from a myocardial infarction at the time of the acute episode.

This study might have been more convincing if the investigators had identified the patients of practitioners who always used anticoagulants for their patients with myocardial infarctions, and then compared them to a control group of patients of practitioners who never used anticoagulants for their patients with myocardial infarctions. Inasmuch as the choice of therapy in these patients would not have been made on the basis of any perceived difference among the patients in their risk of dying from myocardial infarction, confounding by the indication would not be a problem. Of course, if the investigators had designed the study as we suggest, they then would have had to consider whether the physicians themselves were somehow a predictor of outcome, and whether this was consistently related to their philosophy of using anticoagulants, across multiple physicians. Thus, randomized trials are really needed to provide the answer to this question, and of course in recent years, with the advent of low molecular weight heparin and thrombolytic therapy, many have been forthcoming [91–96].

Generic versus Brand Name Drugs

Another potential use of nonexperimental designs to study the beneficial effects of drugs arose with the passage of the 1984 Waxman–Hatch Act in the US. Generic drugs can now be marketed after simple demonstration of bioequivalence, that is, equivalent bioavailability, in 18–24 normal adults [97]. However, it is not clear whether bioequivalence assures clinical equivalence, that is, equivalent efficacy and toxicity [98]. *Clinical inequivalence is more likely to be evident as a difference in beneficial effects than as a difference in adverse effects*. In developing a drug, dosages are sought which optimize drug efficacy. Toxicity, other than idiosyncratic or allergic reactions, usually occurs at higher doses and concentrations than needed for efficacy. Modest variations in the plasma concentration of the active drug, created by receiving the same dose in different preparations, are most likely, therefore, to be a problem for drug efficacy than for drug toxicity. Variations in plasma concentration are even more likely to be a problem for drug effectiveness and

cost-effectiveness. Even a simple change in the physical appearance of the drug could conceivably lead to a decrease in adherence and, thereby, effectiveness.

Studies designed to evaluate differences in efficacy among different preparations of the same drug require enormous sample sizes, as one would be searching for relatively small differences. However, such sample sizes can be achieved relatively easily and efficiently as part of nonexperimental pharmacoepidemiologic studies. Thus, the suggestion has been made that studies of clinical equivalence could possibly be carried out as postmarketing surveillance studies [98]. Confounding by the indication might be unlikely to be a problem because, as far as the physician is concerned, he or she is dealing with different products of the same drug, products that are theoretically interchangeable. The choice among the alternative therapies might be expected to be made irrespective of patient characteristics, but rather by the pharmacist on the basis of product availability – category 3.a.ii in Table 33.2.

A few pharmacoepidemiologic studies (unpublished) on the relative effectiveness of different preparations used for the same purpose were performed by Strom, using the COMPASS[R] database. These studies compared patients who were started on a brand name product and were switched to a generic product when it became available with patients who remained on the brand name product. The drugs studied were thioridazine, chlorpropamide, and slow-absorption theophylline. These studies naturally raise concerns about the ability to identify the actual product dispensed. Very few of the pharmacoepidemiologic approaches described in Part III of the book are able to identify the specific product dispensed. Often the approach does not even distinguish whether it is a brand name product or a generic product that is being used. Even when the distinction is made (for example, most Medicaid datasets use the National Drug Code to identify specifically the drug, the manufacturer, the dosage form, and the dose), one is inevitably left with questions about whether a brand name is being billed for while a generic drug is dispensed. In addition, such studies raise concerns about how to define the clinical outcome variable. For example, how is drug efficacy reflected in a claims database? The studies described above used proxy outcomes such as number of physician visits, number of hospitalizations, and use of adjunctive therapy to obtain an estimate of drug efficacy.

Using these outcomes, the investigators first analyzed the baseline data, comparing the experience, prior to switching, of those who ultimately switched to generic products to the experience of those who did not switch. In each of the three studies, the future switchers were different from the future nonswitchers, prior to the switch. Thus, it appears that patients who were to be switched to generic products were different from patients who stayed on the brand name products: confounding by indication was indeed operating. Because of this, no analyses of efficacy after the switch were performed. Parenthetically, because of this, and questions about the uncertain interpretability of the clinical outcomes, it was elected not to publish the results of these papers.

Cost-effectiveness Studies

An important category of studies of beneficial drug effects includes studies of their cost-effectiveness. These measure the resources necessary to achieve a particular beneficial outcome, and thus have two main study variables – one that is clinical and one that is economic [99–102]. For example, one could perform a cohort study comparing treated patients to untreated patients, and determine whether the clinical outcomes they experience and the cost of the medical care they subsequently receive is different. In such a study, one would need to consider the possibility of confounding by the indication for both the clinical outcome and the cost

variables. It should be noted that the indication may have different effects on the clinical outcomes and the costs. Thus, while performing the clinical outcome assessment, one needs to consider and, potentially, quantify the implications of the indication for the treatment on the clinical outcome variable. In contrast, while performing the cost assessment, one needs to consider and, potentially, quantify the cost implications of the indication on both the clinical outcomes and the costs. The subject of health economics as applied to drug use is discussed in more detail in Chapter 34.

Vaccines

Nonexperimental study designs have been widely used to evaluate the efficacy of vaccines. Specifically, case–control studies have been used to explore the efficacy of pneumococcal vaccine [83,84,103–106], rubella vaccine [107,108], measles vaccine [109–113], *Haemophilus influenzae* type b polysaccharide vaccine [114–125], oral poliovirus vaccine [126,127], meningococcus vaccine [128–130], Japanese encephalitis vaccine [131,132], BCG vaccine in protecting against tuberculosis [133–140], diphtheria toxoid vaccine [141], mumps vaccine [142], and leprosy [143,144]. Cohort studies have been used to explore the efficacy of *Haemophilus influenzae* type b polysaccharide vaccine [116], measles vaccine [117,145], and pertussis vaccine [146,147].

Again, studies like these should ideally be conducted as randomized clinical trials. However, the relative infrequency of the diseases that the above vaccines are designed to prevent, particularly in populations which are partly vaccinated, make use of this design difficult, although not impossible. In fact, in one situation, a new Japanese encephalitis vaccine manufactured in China was studied for efficacy using a case–control design [131], while a study of its safety, conducted by the same authors, used a randomized clinical trial design [132]. In considering the applicability of nonexperimental study designs, the relatively indiscriminate use of such vaccines places the study in category 2 of Table 33.2. Patients who receive these vaccines differ from those who do not in their socioeconomic status, access to medical care, and physicians' attitudes towards vaccines. However, for most vaccines, an individual physician is not likely to give only some of his/her eligible patients the vaccine, withholding it from other eligible patients. Thus, patients receiving vaccines are not likely to differ from those who do not get the vaccine, at least in their physicians' perceptions about the patients' risk of contracting these diseases. Nonexperimental studies of such questions should produce valid results, therefore. Indeed, as is evident from the large number of examples, this is becoming a standard and accepted approach. We refer the interested reader to some methodologic papers on the subtleties of designing nonexperimental studies of vaccine efficacy [148–154].

Other Examples

Other analogous work using case–control study designs has explored the effectiveness of bicycle safety helmets in preventing face injuries [155,156], antibiotic prophylaxis in preventing postdental infective endocarditis [157,158], beta-blockers in preventing mortality in patients with acute myocardial infarction [159], beta-blockers and incident coronary artery events [160], etc.

The Future

Clinicians have long recognized the value of clinical observations and nonexperimental research. Much of our current knowledge about the usefulness of medical interventions is based on information that is nonexperimental. However, the information that observational techniques generate cannot be accepted uncritically. Perhaps in reaction to the limitations of nonexperimental studies, some scientists have insisted that "the

randomized clinical trial (RCT) is the only scientifically reliable method for assessment of the efficacy (and risks) of most clinical treatments" [27]. Sackett *et al*. argued "… to keep up with the clinical literature … discard at once all articles on therapy that are not randomized trials" [161]. In light of the analysis presented above, this position seems too simplistic and far reaching. If overbearing, it results in clinically necessary and potentially available information being uncollected and unused. The proper balance in attitude about the value of these approaches probably lies somewhere between the two extremes. To quote Sir Austin Bradford Hill, one of the developers of the randomized trial: "Any belief that the controlled trial is the only way (to study therapeutic efficacy) would mean not only that the pendulum had swung too far but that it had come right off its hook [162]."

Many investigators are now applying nonexperimental designs to studies of beneficial drug effects, including comparing active treatments with each other (see Chapter 26). With the passage of the 21st Century Cures Act, the US Congress embraced the use of "real-life evidence" and the fact that it might provide data on drug effects, including benefit. However, careful attention needs to be paid to the possibility of confounding by the indication. Some approaches to this problem are now available (see Chapter 43), and hopefully more will be available in the future. However, when confounding by indication can be addressed, clinical observations and nonexperimental research can be used. The results of nonexperimental research are unlikely to be as powerful or as convincing as those of experimental research. We are not suggesting that nonexperimental studies be used as replacements for experimental studies. However, when an experimental study is deemed to be unnecessary, unethical, infeasible, or too costly relative to the expected knowledge to be gained, there might be reasonable alternatives.

Pharmacoeconomics: The Economics of Pharmaceuticals

Kevin A. Schulman

Clinical Excellence Research Center, Department of Medicine, Stanford University, Stanford, CA, USA

Modern medicine is defined by the use of pharmaceutical products. The treatment of many conditions would be unthinkable without these essential products. Yet, the price of pharmaceutical products and their economic impact on the healthcare system remain controversial. In this chapter, we explore the economics of pharmaceutical products.

Clinical Problems to Be Solved by Pharmacoepidemiologic Research

A patient walks into a pharmacy with a prescription written by their physician for a new medication. The patient has health insurance from their employer that includes a specific prescription drug benefit. The pharmacist dispenses the medication and asks the patient to pay for their portion of the cost. The pharmacy then bills the insurer for the balance of the cost. These types of transactions are typical, and they occur daily at every pharmacy in the United States (and similar transactions occur in other countries). Yet behind this simple occurrence is the complex economics of healthcare and the pharmaceutical market. This chapter reviews the economics of the pharmaceutical market and provides some insights into potential ways in which this market may evolve in the future.

The Economics of Pharmaceutical Products

The science of drug development and assessment has been well described in the literature and throughout this book. Drug development proceeds through stages of discovery, optimization, clinical development, regulatory review, and launch with postmarket assessment. The economics of this process brings together concepts of finance, health economics, and behavioral economics in a manner that is truly unique.

Drug development starts with an investment in science. Historically, public grant funds through the National Institutes of Health or the National Science Foundation, or private funds through programs like the Howard Hughes Medical Institute, would support fundamental science that might be years or even generations away from translation into medical products. Academic researchers and the pharmaceutical industry would use the insights from this work to begin an effort at translation, moving from

Pharmacoepidemiology, Sixth Edition. Edited by Brian L. Strom, Stephen E. Kimmel and Sean Hennessy.

fundamental science to specific interventions for specific diseases. This work could still be publicly funded, but might be more likely to be funded through private resources such as pharmaceutical firms, or even applied science efforts such as the Bill and Melinda Gates Foundation. These efforts serve to translate biology into drug targets, identifying potential pathways to alter the target through the identification of small molecules or biologics that have (hopefully) unique effects on the target. The discovery of a candidate drug would lead to the filing of a patent, an opportunity for the inventor to own the rights to the discovery and to preclude others from practicing the invention (under a provision called the Bayh–Dole Act, universities own the patent rights to discoveries even if the work was funded using federal grants).

The patent rights are critical in the next stage of drug development. This is when the process moves from the laboratory to human testing. This is the most expensive step in drug development, and for the most part the work is privately funded. Investors justify their investment in a molecule with the opportunity for financial returns resulting from their ownership of the molecule through the patent. This transition from public to private support is challenging for many discoveries. The "Valley of Death" is deemed the gap between science that is funded by public grants and the ability to attract private investment to the development of a molecule.

Clinical testing of pharmaceuticals is carefully regulated by the Food and Drug Administration (FDA) and other global regulatory bodies. For most products, regulatory authorities require proof of safety and efficacy of products before they are approved for sale. Clinical testing can require up to a decade to complete and can require more than $1 billion in direct outlays [1].

At the end of drug development, with product approval by the FDA, the manufacturer can set a price and market the product. Prices set by manufacturers reflect their significant investment in clinical development, and the inherent risk they were required to assume, but also considerations of market access or barriers to full reimbursement for patients. The price can reflect the marginal cost of producing a product, but often this is a relatively minor consideration. The prices of specialty pharmaceutical products can be extraordinary, reaching $475 000 per patient for Novartis's CAR-T therapy [2]. Prices also vary across markets, with a 30-day supply of Janssen's Xarelto® priced at $48 in South Africa, $102 in Switzerland, and $292 in the United States, or 400 mg of Genentech's Avastin® priced at $956 in South Africa, $1752 in Switzerland, and $3930 in the United States [3]. Not only are drug prices high, but cancer therapies have experienced significant price growth. In one analysis, the monthly cost of oncology products has increased from approximately $100 as recently as 1980 to $10 000 by 2010 [4].

A lot of attention has been focused on the impact of health insurance on the prices of pharmaceutical products. Historically, prescription drugs were relatively affordable, and so were paid for by patients. As medications became more effective, the concept of prescription drug insurance began to develop. In 1960 in the United States, 96% of prescription drug spending was out of pocket by individuals. By 1980, out-of-pocket spending was still 71% of total spending. By 1990, it was down to 57%, 2000 to 28%, 2010 to 18%, and 2015 to 14% [5]. Prescription drug coverage has led to a transformation of the pharmaceutical market. Over this same period, the prescription drug market has grown from $2.7 billion in 1960 to $462 billion in gross sales in 2016 (resulting in net pharmaceutical sales to manufacturers of $318 billion) [6].

Insurance is a mechanism for sharing risk across individuals. Generally, insurance works best when the occurrence being insured is infrequent, can be catastrophic to the individual, and is not influenced by the individual or organization being insured. In insurance markets characterized by these conditions, insurance can be a

relatively inexpensive proposition. Health insurance has different characteristics. We use healthcare services frequently, and with medications even more frequently. While some healthcare costs can be catastrophic, not all are. While paying for a monthly medication is not enjoyable, for most people it is not financially catastrophic. Finally, consumption of healthcare services is inherently influenced not only by individuals (do you want to go to the clinician for that bad cold or sprained ankle?), but also by pharmaceutical manufacturers and healthcare systems commercializing medicinal drugs and services. Consequently, health insurance has become a very expensive insurance product. In truth, most health insurance combines the idea of prepayment for usual healthcare services with a catastrophic medical benefit (to some extent, high-deductible health plans try to separate out these two different elements of healthcare financing).

The idea of making a risky financial investment in order to garner a financial return is not unique to the pharmaceutical industry. The oil and gas industry faces a similar economic proposition in oil exploration, with risky new leases requiring years of development and the outlay of billions of dollars before realizing any return. One fundamental difference between pharmaceuticals and the petroleum industry is that the market sets the price for the products in the oil industry, not the oil producer. Also, consumers pay directly for the products in the oil industry while they often have insurance to help pay for pharmaceutical products. The final difference with the petroleum industry is that consumers may make very different purchase decisions in healthcare settings than they make in other aspects of their life.

In the next section, we explore the impact of health insurance on pricing decisions by manufacturers. We then explore an emerging area of economics, behavioral economics, and its ability to help us understand the unique price-inelastic behavior of segments of the healthcare market.

Health Economics

Moral Hazard

Health economists have long been worried about the economic impact of health insurance on the patterns of consumption of healthcare due to a concept called "moral hazard." Moral hazard describes the change in individual behavior between conditions of self-pay and conditions of third-party payment. Kenneth Arrow was awarded the Nobel Prize in economics for developing this framework [7], and Mark Pauly further developed the theory to focus on demand [8].

The basic framework is easy to understand. We all make purchases based on our concept of value. We generally make purchases of goods or products for $1.00 when we perceive that they offer $1.00 worth of value. This concept of value is an individual determination: we all have our own tastes, preferences, and needs which form our assessment of value.

Third-party payment alters this fundamental calculus. Consider going out to dinner with a group of friends. After the menu is passed around, you notice items of lower and higher price, say salad and steak. You can approach payment in one of two ways: individual checks or splitting the check. If you all decide on individual checks before you order, you may decide to purchase the lower-cost salad since you are on a budget. However, what happens if you decide to split the check before you order? You may be worried that everyone else at the table is likely to order the higher-priced steak, and you will have to pay your share of their higher-priced meals. Since you are paying for their steak, why not order your own steak so at least you get the benefit of the higher price you will pay for dinner? In this simple illustration, your behavior changes between self-payment and third-party payment models.

Health insurance is one form of third-party payment. Under health insurance, rather than

Table 34.1 Perception of value to the patient.

	Product 1	Product 2	Product 3	Product 4	Product 5	Product 6	Product 7
Value	1.50	1.25	1.0	.75	.50	.25	.10
Cost (No Insurance)	$1.00	$1.00	$1.00	$1.00	$1.00	$1.00	$1.00
Cost (Insurance)	$0.20	$0.20	$0.20	$0.20	$0.20	$0.20	$0.20

Note: Cost (no insurance) assumes only cash payments for the product. Cost (insurance) assumes the product is covered by an insurance policy with a 20% co-insurance requirement.

paying the full cost of medical products, you pay only a co-payment (fixed amount), or co-insurance (a percentage payment) for medical products. As illustrated in Table 34.1, products 1 through 3 offer at least $1.00 of value for $1.00 of cost. In a self-payment model, you would be expected to purchase only products 1 through 3 since only these products have a value of $1.00. In an insurance model, however, you only pay the co-payment of $0.20. Now, products 1 through 6 offer value equal to or greater than the $0.20 copayment, so using the same rule (only buying products that offer value greater than or equal to the price you pay), you would purchase products 1 through 6. Again, behavior changes under conditions of third-party payment. While many economists have argued that health insurance increases the overall cost of healthcare due to these changes in demand [9], there is also the concept of good moral hazard where people can purchase goods or products through insurance that would otherwise be unaffordable [10]. It is possible to develop a direct estimate of the increase in prescription drug costs between those with and without insurance [11].

To this point, the discussion has focused on the impact of moral hazard on the demand for healthcare products. However, the impact of moral hazard also extends to the supply side of healthcare [12–14]. While much of the literature examines the impact of moral hazard on the provision of services, there is also an impact on the price of products. Given insurance, the suppliers of high-value products can realize that products are perceived as significantly underpriced since insured patients only consider the out-of-pocket costs. Applying a value framework to pricing can lead manufacturers to raise their prices to meet the value threshold rather than simply developing a price to meet their internal financial expectations. This supply-side moral hazard effect on the price of pharmaceutical products has been much less discussed in the literature [15–17].

Again, going back to the basic example of product 1 in Table 34.1, this product provides great value to patients under conditions of self-payment and even more under conditions of third-party payment. Sophisticated suppliers will notice these conditions. In a competitive market, suppliers will have little ability to influence the welfare surplus enjoyed by patients in this example since the price is determined by the market and is driven by entry and exit of firms. However, there are circumstances when suppliers have power to influence prices, especially in healthcare. Suppliers can have market power when they have a barrier to market entry such as a patent awarded to a pharmaceutical manufacturer or a product developed for a niche category, such as an orphan drug, which is too small to attract competition. In these cases, suppliers can increase the price of product 1 based on value. If they decide to price at the total value of the product, they could raise

the price from $1.00 to $1.50 to capture the full value to patients. Under our conceptual model, this pricing strategy would be attractive to patients even in a cash pay market. However, under conditions of third-party payment, suppliers can consider an even more aggressive pricing strategy by considering that patients measure value against their co-insurance, not the full cost of the product. Under these conditions, suppliers can raise the price to $7.50 while consumers would have a cost-share of $1.50, or an amount equal to the value they expect to receive from the therapy. As a result of supply-side moral hazard, the cost increased from $1.00 to $7.50 in this simple example. Co-payment coupons or patient assistance programs can exacerbate this effect by artificially decreasing the amount individuals have to pay. This "discount" on out-of-pocket payments can allow suppliers even more latitude to raise prices under this framework.

The supply-side implications of moral hazard are potentially significant. Beyond the short-term impacts on patients, this effect can have longer-term effects by distorting the drug development portfolio. In Table 34.2, we imagine a manufacturer with a simple two-product portfolio, with each product having equal development costs and market price. In analyzing their options, the firm invests in the opportunity with the largest market size [18].

However, in Table 34.3, under conditions of market power, manufacturers can consider the question of value of the therapy to patients in setting a price. In this case, they chose to undertake development of product B despite its smaller market size.

Thus, the supply-side effects of moral hazard can be seen in both the prices of products in the marketplace and the portfolio of drug products available on the market.

Table 34.2 Pharmaceutical market under conditions of supply-side moral hazard.

Product	Cost of development	Size of target market	Price	Revenue
A	$50 000 000	20 000	$10 000	$200 M
B	$50 000 000	10 000	$10 000	$100 M

Note: Cost of development – out-of-pocket dollar costs of development (assumption). Size of target market – number of accessible candidates for therapy considering incidence and prevalence of underlying condition. Price – market price for the product (net price to manufacturer). Revenue – net revenue from the product (price times market size).

Behavioral Economics

This concept of patients being risk averse is consistent with the idea of buying health insurance in the first place. Buying health insurance is seen as a risk-averse financial decision. People pay some money annually for health insurance to avoid the potential financial consequences

Table 34.3 Pharmaceutical market under conditions of market power.

Product	Cost of development	Size of target market	Value of therapy	Price	Revenue
A	$50 000 000	20 000	1	$10 000	$200 M
B	$50 000 000	10 000	5	$50 000	$500 M

Note: Cost of development – out-of-pocket dollar costs of development (assumption). Size of target market – number of accessible candidates for therapy considering incidence and prevalence of underlying condition. Value of therapy – perception of value to the patient (in dollar equivalents). Price – value price for the product (net price to manufacturer). Revenue – net revenue from the product (price times market size).

associated with the rare risk of becoming severely ill. Consumers may even buy certain policies with limits on things that are not important to them when they are healthy – narrow networks of providers, for example, or limits on the drug formulary for specialty pharmaceutical products. However, buying health insurance is not the same as buying healthcare. Whether the risk-averse decision-making approach to buying insurance carries over to making treatment decisions for healthcare products or services is an open question.

Let's consider a clinical scenario. Assume an otherwise healthy patient comes into a physician's office. They feel great, have a full social and work life, exercise regularly, and have a lot to look forward to. Given a history of smoking in the past, the physician had ordered a chest X-ray. Unfortunately, the chest X-ray shows that the patient has a spot on their lung. After further work-up, it is found to be lung cancer that has spread. This otherwise healthy person now has a life-threatening condition. Obviously, this is a significant loss in life expectancy for the patient. How do they react to the shock of their diagnosis? They seek treatment for their condition. In this case, the patient will accept a treatment which has any chance of restoring their health, irrespective of the side effects of the therapy. They definitely don't ask about the cost of treatment. Under conditions of loss, the way that patients make decisions changes from how they felt about future potential treatment choices when they bought their health insurance policy [1].

This idea that people make different decisions under conditions of gains and losses earned Daniel Kahneman the Nobel Prize in Economics in 2002 "for having integrated insights from psychological research into economic science, especially concerning human judgment and decision-making under uncertainty" [19]. (He collaborated with Amos Tversky in developing prospect theory, but Amos passed away before the prize was awarded.) Under conditions of gains, we are risk averse, and under conditions of loss we are risk seeking. When a 70-year-old patient refuses a flu shot because of her concerns that she may get sick from the shot, she is under a condition of gain (full health) and is being risk averse. The unfortunate patient with lung cancer is an example of decision making under conditions of loss. The application of this framework to treatment choices by patients with life-threatening diseases helps to explain the apparently risk-seeking behavior of patients [20,21]. This study of the psychology of decision making in real-world settings has been called behavioral economics.

More recently, Kahneman and others have focused on the role of emotion in decision making [22]. They have developed a framework which considers two different ways of making decisions, System 1 and System 2. System 1 decision processes are autonomous decision-making efforts that represent our "gut" or emotional response to an uncertain situation. System 1 processes easily incorporate societal attitudes and are subject to many systematic flaws [23]. System 2 decision processes are more data driven and analytical, but have a high cognitive burden. In the normal course of events, we make most decisions using the System 1 framework, despite its limitations, so that we minimize our cognitive burden in making simple choices or completing simple job tasks. However, we have System 2 processes available for more complex decision making. Importantly, in a heightened emotional state, we generally rely on System 1 processes for decision making. This can be critically important in understanding medical decision making, where patients (or their loved ones) can experience significant anxiety arising from the care process or the diagnosis itself, or can be in a heightened emotional state from the experience of the symptoms of the illness,

especially when suffering from a disease with an acute presentation.

While the role of loss can make patients appear to be risk seeking in making treatment choices, we have suggested that the role of emotion can also lead to the same type of decision making by patients [24].

Public perceptions and communication around a diagnosis such as cancer can have significant emotional overtones. Patients "fight a cancer diagnosis" and society is in the midst of a "war" on cancer [25]. In light of this, heart disease was responsible for almost 300 000 deaths in women in 2013 [26] while only 40 000 women died of breast cancer that same year [27]. This is not to say that breast cancer is not a terrible disease, but why do we spend so much time talking about an illness that has one-tenth the mortality of another, more prevalent disease?

It is interesting to think that this was not always the case. In his fascinating book *The Emperor of All Maladies*, Siddhartha Mukkherjee profiles the career of Dr Sidney Farber [28]. Farber was very interested in trying to develop treatments for childhood leukemia which was almost uniformly fatal. However, there was little funding for cancer research at the time. He started the Jimmy Fund in 1948, highlighting the plight of his young patients to raise money for cancer research [29]. The success of this strategy of creating cancer as an emotional disease to attract research support continues to this day. Most recently, the Cancer Moonshot concept was used to develop support for the Precision Medicine Initiative at NIH [30].

While these efforts have been successful in raising support for cancer research (and genomic medicine), they shape the perceptions of patients with one of these diseases. Receiving a diagnosis of a disease with a higher emotional tone may lead to patients finding it difficult to engage in System 2 thinking when making treatment choices. Both emotion and loss can help explain treatment choices for patients with life-threatening conditions. The result is that there is demand for therapies where the risks can seemingly outweigh the benefits of therapy, or for therapies where the benefits seem especially modest given the high cost. These frameworks can help to explain the decision-making process used by those such as cancer patients who have significant demand for therapies despite the tremendous cost and limited benefit of many agents.

An important aspect of this discussion is that under either of these decision-making frameworks, loss or emotion, patients are not actively required to consider cost in their decision-making process, nor might the cost of therapies negatively affect the decision-making processes of patients with life-threatening conditions. This suggests that under these conditions, demand for products could appear to be price inelastic. This lack of an impact of cost on decision making contrasts this type of decision making with moral hazard. It also suggests that mechanisms to address moral hazard (cost sharing, for example) would not be expected to influence demand for therapies by patients experiencing emotion or loss. In fact, knowing this, excessive cost sharing for these patients might even be considered unethical. The price of products for these patients would still be affected by the impact of moral hazard on supplier pricing decisions (price-inelastic demand might even exacerbate this effect).

At this juncture, it is too soon to know if the Precision Medicine Initiative will extend our emotional characterization of disease to conditions which were not previously considered a separate disease or extend conditions experienced in emotional terms such as cancer. It is unclear if the efforts to establish genetic causes of common conditions or to develop new labels for subsets of common diseases will increase the emotional tone associated with these conditions in the mind of the public [31].

Clinical Example: Treatment of Hepatitis C

The development of a new generation of pharmaceutical therapies for the treatment of chronic infection with hepatitis C was greeted as a significant scientific advance [32,33]. However, the payer community was in shock over the original price of $84 000 per patient for a 12-week course of therapy (or double that amount for 24 weeks) [34]. This set off a debate around the price of the therapy and led to significant challenges for many public and private payers [35]. With the high prevalence of chronic hepatitis C infection in the population, providing therapy for the entire population could have doubled health insurance premiums in the United States for a year [23].

Quickly, the debate around sofosbuvir turned to pharmacoeconomics as an attempt to understand the price. The pharmaceutical manufacturer, Gilead, argued that the high price was justified by the significant clinical benefit experienced by patients (although this argument was absent in a Senate investigation of internal Gilead discussions in setting the price for sofosbuvir [36]). Progression of hepatitis C infection led to the development of cirrhosis, or liver failure, and hepatocellular carcinoma, a fatal form of liver cancer, leading to requirements for hospitalization, liver transplant if a donor organ was available, or to death. Yet, the clinical data were early. There were no long-term outcomes studies showing effectiveness of treatment on reducing these complications of hepatitis C infection, just on sustained virologic response in short-term clinical trials.

In the United Kingdom, there is a requirement for a formal economic evaluation of the impact of a new therapy on healthcare costs and outcomes to better understand the value of therapy as part of the consideration of whether it should be included in the national formulary. The determination of value is achieved by assessing the incremental cost of the new therapy in comparison with the incremental clinical benefit resulting from treatment, as discussed in detail in the section on Methodologic Issues in the Pharmacoeconomic Assessment of Therapies. The result of this analysis is a cost-effectiveness ratio, or an assessment of the additional cost of achieving an additional quality-adjusted life-year (QALY) for patients. In the UK, £20 000 per QALY is considered a benchmark of good value, but this means that spending will increase since the drug requires an additional expenditure to receive the additional benefit.

A detailed evaluation by the UK National Institute for Health and Care Excellence (NICE) [37], considering an independent technology review and a price of £34 504 per standard course of therapy [38], concluded that for some indications sofosbuvir had a high likelihood of meeting a cost-effectiveness ratio of £20 000 per QALY (and an even higher likelihood of meeting a ratio of £30 000 per QALY). They recommended that NHS England try to find the resources required to implement this therapy.

In the United States, Gilead's first-year revenue for sofosbuvir was $10 billion, making it one of the top-grossing pharmaceutical products in the world [39]. However, the entry of additional novel therapies for hepatitis C led to price competition in the marketplace, with prices ranging from $26 400 to $62 500 per treatment course by 2017 [40]. Still, Gilead reported sales of hepatitis C products of $19.1 billion in 2015 and $14.8 billion in 2016 [41].

The pricing of sofosbuvir represents an interesting dilemma in modern health economics. Clearly, the company could not have set such a high price for their product in the absence of health insurance coverage. In fact, the high price actually helped patients receive better coverage as a catastrophic medical expense than they would have received under standard insurance coverage. The company, and physicians, perceive hepatitis C as a potentially life-threatening condition, leading to demand for the treatment.

How should patients, physicians, and payers make a choice about the value of this therapy?

Currently Available Solutions

Pharmacoeconomics

Pharmacoeconomic studies have been designed to meet the different information needs of healthcare purchasers and regulatory authorities [42–55]. Economic data from Phase III studies are used to support initial pricing of new therapies and are used in professional educational activities by pharmaceutical firms. Postmarketing economic studies are used to compare new therapies with existing therapies and increasingly to confirm the initial Phase III economic assessments of the product [56].

No single study can possibly provide all interested audiences with complete economic information about a new therapy. Thus, specific studies are undertaken to address economic concerns from specific perspectives, such as a postmarketing study of a new therapy from the perspective of a health maintenance organization (HMO). They may also be undertaken to assess the effect of therapy on specific cost categories, such as an assessment of the productivity costs of treatment, to provide data to federal governments in Europe, since these governments fund both the health insurance system and the disability system.

Across the globe, technology assessment agencies have been established to help provide or evaluate economic data as part of the reimbursement process [57–60]. In the UK, NICE provides guidance to the National Health Service [61]. In Germany, the Institute for Quality and Efficiency in Health Care (IQWiG) evaluates the effectiveness of drugs [62]. In the US, the Institute for Clinical and Economic Review (ICER) is a private organization publishing independent economic analyses of new pharmaceutical products [63].

Economic Evaluation and the Drug Development Process

The drug development process allows for timely collection of data that can be used to evaluate the costs and effects of pharmaceuticals early in their product life, with an opportunity for further data collection and evaluation once the product has been approved and marketed.

Clinical economics has been integrated throughout the development process, with goals that parallel the clinical development stages. Phase I and II studies are used to develop pilot economic data, such as estimates of the mean and variance estimates for costs, quality of life, and utilities for patients with a specific clinical syndrome. These studies are also used to perform pilot tests of data collection tools, including items in case report forms to prospectively capture resources used by patients who will be entered into the Phase III and postmarketing clinical trials. From these data, issues such as sample size and power for pharmacoeconomic studies can be assessed.

Incorporation of economic analyses as part of Phase III clinical trials is well established [64]. Phase III studies can include economic assessments of new therapies as a primary or secondary endpoint (i.e., an assessment of changes in the use of specific resource categories resulting from treatment, such as changes in length of hospital stay or hospitalization rates) [65–71].

Lastly, a wide variety of postmarketing economic studies can be performed. These include comparative effectiveness/efficiency trials (also known as “pragmatic” or “practical” trials) in which comparisons between products are made in more realistic settings with less restrictive protocols than those designed for Phase III safety and efficacy trials (see Chapter 32) [72]. These postmarketing studies may include assessments of the new therapy compared with “usual care” or with specific therapeutic agents. Again, the economic analysis can serve as a primary or secondary endpoint of the study.

Developing economic data as an endpoint in a clinical trial requires integrating pharmacoeconomics into the clinical development process. While there has been an increase in the number of trials that collect economic data, the challenge remains to ensure that pharmacoeconomic endpoints are considered sufficiently early in the clinical development process so that designing the economic protocol does not impede the process of designing the clinical trial. Economic analysis requires the establishment of a set of economic endpoints for study (e.g., direct costs, productivity, intangible costs to patients and caregivers, quality-of-life or preference measures for patients and caregivers), review of the clinical protocol to ensure that there are no economic biases in the design of the clinical trial – such as requirements for differential resource use between the treatment arms of the study – and development of the economic protocol. Ideally, the economic study will be integrated into the clinical protocol, and the economic data will be collected as part of a unified case report form for both clinical and economic variables.

Economic analysis faces further challenges depending on the indication for the product and the size of the clinical trial. For primary care products, such as hypertension or diabetes, clinical trials are global undertakings, raising questions about the generalizability of the economic results for individual payers. For specialty pharmaceutical products, the issue is the potential small size of the clinical trials affecting the ability to make a reasonable assessment of the economic impact of a therapy. For example, a novel exon-skipping treatment for Duchenne muscular dystrophy, eteplirsen, was an orphan drug tested in a dozen patients in a clinical trial with an endpoint of dystrophin production and performance on a six-minute walk test. There were no long-term data for clinical outcomes available from the trial [73].

In the following sections, we briefly review the research methods of pharmacoeconomics, discuss some methodologic issues that have confronted researchers investigating the economics of pharmaceuticals, and illustrate the usefulness of pharmacoeconomic research.

Methodologic Issues in the Pharmacoeconomic Assessment of Therapies

Techniques of Clinical Economics

Economists emphasize that costs are more than just transactions of currency. Cost represents the consumption of a resource that could otherwise be used for another purpose. The value of the resource is that of its next best use, which no longer is possible once the resource has been used. This value is called the resource's "opportunity cost." For example, the time it takes to read this chapter is a cost for the reader, because it is time that cannot be used again; the opportunity to use it for another purpose has been foregone. Good investments are made when the benefits of the investment (e.g., what you learn) are greater than or equal to the value of the opportunities you have foregone (e.g., what you would be doing if you were not reading this chapter).

In addition to the fact that not all costs involve a transaction of money, it is important to remember that, at least from the perspective of society as a whole, not all transactions of money should be considered costs. For example, monetary transactions that do not represent the consumption of resources (e.g., social security payments, disability payments, or other retirement benefits) are not costs by this definition. They simply transfer the right to consume the resources represented by the money from one individual to another.

In considering economic analysis of medical care, there are three dimensions of analysis, represented by the three axes of the cube in Figure 34.1 with which readers should become familiar. Along the X-axis are three types of economic analysis—cost identification,

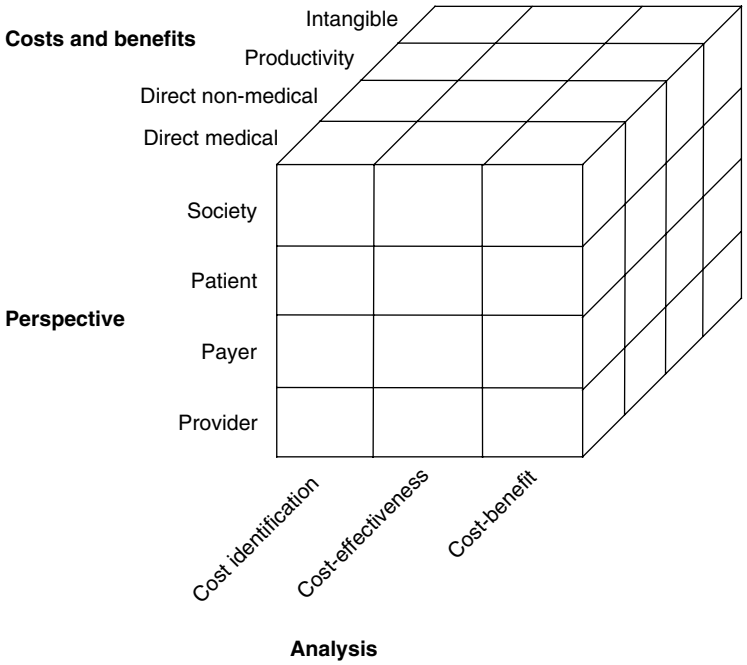

Figure 34.1 The three dimensions of economic evaluation of clinical care. *Source:* Bombardier C, Eisenberg J. Looking into the crystal ball: can we estimate the lifetime cost of rheumatoid arthritis? *J Rheumatol* 1985; **12**: 201–4. cost-effectiveness, and cost–benefit. Along the Y-axis are four points of view, or perspectives, that one may take in carrying out an analysis. One may take the point of view of society in assessing the costs and benefits of a new medical therapy. Alternatively, one may take the point of view of the patient, the payer, or the provider. Along the third axis, the Z-axis, are the types of costs and benefits that can be included in economic analysis of medical care. These costs and benefits, which will be defined below, include direct costs and benefits, productivity costs and benefits, and intangible costs and benefits.

Types of Analysis

Cost–Benefit Analysis

Cost–benefit analysis of medical care compares the cost of a medical intervention to its benefit. Both costs and benefits are measured in the same (usually monetary) units (e.g., dollars). These measurements are used to determine either the ratio of dollars spent to dollars saved or the net saving (if benefits are greater than costs) or net cost. All else being equal, an investment should be undertaken when its benefits exceed its costs.

The methods of cost–benefit analysis may be applied to evaluate the total costs and benefits of the interventions that are being compared by analyzing their cost–benefit ratios or their net benefits. Furthermore, the additional or "incremental" cost of an intervention (i.e., the difference in cost between a new therapy and conventional medical care) may be compared with its additional or "incremental" benefit. Incremental analysis is generally preferred to comparisons of totals because it allows the analyst to focus on the differences between any two treatment modalities. A zero-based budgeting approach would start from the base case. An

incremental analysis could overstate the value of a therapy if it compares a new therapy to an expensive but less effective therapy, while a zero-based budgeting approach would make the incremental costs and benefits of the new therapy more transparent.

One potential difficulty of cost–benefit analysis is that it requires researchers to express an intervention's costs and outcomes in the same units. Thus, monetary values must be associated with years of life lost and morbidity due to disease and with years of life gained and morbidity avoided due to intervention. Expressing costs in this way is difficult in healthcare analyses. Outcomes (treatment benefits) may be difficult to measure in units of currency. Such an exercise also raises methodologic and ethical questions of valuing human life differently across patients with different medical conditions, gender, occupations, or by age. Translating disease and treatment outcomes into monetary measures may be more difficult than translating them into clinical outcome measures, such as years of life saved or years of life saved adjusted for quality.

Cost-Effectiveness Analysis

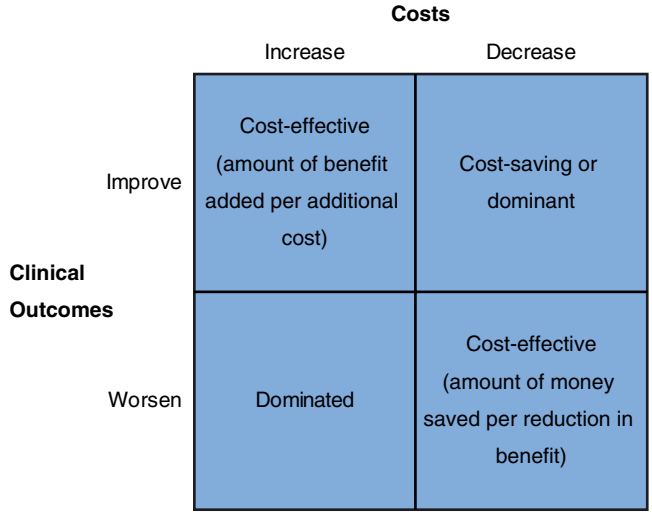
Cost-effectiveness analysis provides an alternative approach that avoids the dilemma of assessing the monetary value of health outcomes as part of the evaluation. While cost generally is still calculated only in monetary terms (e.g., dollars spent), effectiveness is determined independently and may be measured only in clinical terms, using any meaningful clinical unit. For example, one might measure clinical outcomes in terms of number of lives saved, complications prevented, or diseases cured. Alternatively, health outcomes can be reported in terms of a change in an intermediate clinical outcome, such as cost per percent change in blood cholesterol level. These results generally are reported as a ratio of costs to clinical benefits, with costs measured in monetary terms but with benefits measured in the units of the relevant outcome measure (for example, dollars per year of life saved).

When several outcomes result from a medical intervention (e.g., the prevention of both death and disability), cost-effectiveness analysis may consider these two outcomes together only if a common measure of outcome can be developed. Frequently, analysts combine different categories of clinical outcomes according to their desirability, assigning a weighted utility, or value, to the overall treatment outcome [3]. A utility weight is a measure of the patient's preferences for his/her health state or for the outcome of an intervention. The comparison of costs and utilities sometimes is referred to as cost–utility analysis, with the denominator expressed as QALYs.

In cost-effectiveness analysis, determination of value is based on the treatment's incremental costs and incremental effectiveness. In this approach, the analyst calculates the additional effect of one therapy compared with another (e.g., lives saved) per additional treatment dollar spent. Programs that cost less and demonstrate improved or equivalent treatment outcomes are said to be cost-saving or dominant and should always be adopted (Figure 34.2). Programs that cost more and are more effective are assessed by their cost-effectiveness ratio. Programs that cost more and have worse clinical outcomes are said to be dominated and should never be adopted. Programs that cost less and have reduced clinical outcomes may be adopted depending upon the magnitude of the changes in cost and outcome (the cost-effectiveness ratio assessing how much money would be saved in comparison with how little clinical outcomes were reduced).

As with the translation of clinical outcomes into monetary measures for cost–benefit analyses, there also are difficulties associated with combining different outcomes into a common measure in cost-effectiveness analysis. However, it is generally considered more difficult to translate all health benefits into monetary units for the purposes of cost–benefit analysis than to combine clinical outcomes measures. Thus,

Figure 34.2 Cost and clinical outcomes.



cost-effectiveness analysis is used more frequently than cost–benefit analysis in the medical care literature.

Net benefit, measured as a net monetary benefit or net health benefit, is a measure that combines estimates of incremental costs and incremental effectiveness (the components of an incremental cost-effectiveness ratio) with an estimate of the willingness-to-pay threshold. The willingness-to-pay threshold represents the maximum monetary outlay that would be acceptable for a one-unit gain in health benefit (e.g., $100 000 per QALY gained). Specifically, net monetary benefits are calculated by multiplying the willingness-to-pay threshold by the incremental effect (e.g., QALYs) and then subtracting the incremental cost. When net benefits are positive, the program should be adopted from a cost-effectiveness perspective. When net benefits are negative, the program is considered cost-inefficient and should not be adopted. An evaluation of net benefits differs from cost–benefit analysis because we do not directly assign monetary values to specific health outcomes, but instead use administratively determined valuations (e.g., $100 000 per QALY) [58,74,75]. Net benefit is particularly important for statistical evaluation of cost-effectiveness analysis (including sample size calculation and direct testing of economic value by use of patient-level data).

Cost Identification Analysis

An even less complex approach than cost–benefit or cost-effectiveness analysis would be simply to enumerate the costs involved in medical care and to ignore the outcomes that result from that care. This approach is known as cost identification analysis, by which the researcher can determine alternative ways of providing a service. The analysis might be expressed in terms of the cost per unit of service provided. For example, a cost identification study might measure the cost of a course of antibiotic treatment, but it would not calculate the clinical outcomes (cost-effectiveness analysis) or the value of the outcomes in units of currency (cost–benefit analysis). Cost identification studies, which include comparisons among different treatments based upon their costs alone, are appropriate only if treatment outcomes or benefits are equivalent among the therapies being evaluated.

Sensitivity Analysis

Most cost–benefit and cost-effectiveness studies require large amounts of data that may vary in reliability and validity, and could affect the overall results of the study. This is especially the case when models are developed for the economic analysis using secondary data sources, when data collection is performed retrospectively, or when critical data elements are unmeasured or unknown. Sensitivity analysis is a set of procedures in which the results of a study are recalculated using alternate values for some of the study's variables in order to test the sensitivity of the conclusions to these altered specifications. Such an analysis can yield several important results by demonstrating the independence or dependence of a result on particular assumptions, establishing the minimum or maximum values of a variable that would be required to affect a recommendation to adopt or reject a program, and identifying clinical or economic uncertainties that require additional research. In general, sensitivity analyses are performed on variables that have a significant effect on the study's conclusions but for which values are uncertain.

Types of Costs

Another dimension of economic analysis of clinical practice illustrated by Figure 34.1 is the evaluation of costs of a therapy. Economists consider three types of costs: direct, productivity, and intangible.

Direct Medical Costs

The direct medical costs of care usually are associated with monetary transactions and represent costs incurred during the provision of care. Examples of direct medical costs include payments for purchasing a pharmaceutical product, payments for physicians' fees, salaries of allied health professionals, or purchases of diagnostic tests. Because the charge for medical care may not accurately reflect the resources consumed, accounting or statistical techniques may be needed to determine direct costs [50,76–80].

Direct Nonmedical Costs

Monetary transactions undertaken as a result of illness or healthcare to detect, prevent, or treat disease are not limited to direct medical costs. There is another type of cost that is often overlooked: direct nonmedical costs. These costs are incurred because of illness or the need to seek medical care. They include the cost of transportation to the hospital or physician's office, the cost of special clothing needed because of the illness, the cost of hotel stays for receiving medical treatment at a distant medical facility, and the cost of special housing (e.g., modification of a home to accommodate an ill individual). Direct nonmedical costs, which are generally paid out of pocket by patients and their families, are just as much direct costs as are expenses that are more usually covered by third-party insurance plans.

Productivity Costs

In contrast to direct costs, productivity costs, sometimes referred to as indirect costs, do not stem from transactions for goods or services. Instead, they represent the cost of morbidity (e.g., time lost from work) or mortality (e.g., premature death leading to removal from the workforce). They are costs because they represent the loss of opportunities to use a valuable resource, a life, in alternative ways. A variety of techniques are used to estimate productivity costs of illness or healthcare [81–85]. Sometimes, as with varicella vaccination [86], the productivity costs of an illness are substantially greater than the direct costs of the illness [87,88].

Intangible Costs

Intangible costs are those of pain, suffering, and grief. These costs result from medical illness itself and from the services used to treat

the illness. They are difficult to measure as part of a pharmacoeconomic study, though they are clearly considered by clinicians and patients in considering potential alternative treatments. Although investigators are developing ways to measure intangible costs – such as willingness-to-pay analysis whereby patients are asked to place monetary values on intangible costs [46] – at present these costs are often omitted in clinical economics research.

Perspective of Analysis

The third axis in Figure 34.1 is the perspective of an economic analysis of medical care. Costs and benefits can be calculated with respect to society's, the patient's, the payer's, and the provider's points of view. A study's perspective determines how costs and benefits are measured, and the economist's strict definition of costs (the consumption of a resource that could otherwise be used for another purpose) no longer may be appropriate when perspectives different from that of society as a whole are used. For example, a hospital's cost of providing a service may be less than its charge. From the hospital's perspective, then, the charge could be an overstatement of the resources consumed for some services. However, if the patient has to pay the full charge, it is an accurate reflection of the cost of the service to the patient. Alternatively, if the hospital decreases its costs by discharging patients early, the hospital's costs may decrease but patients' costs may increase because of the need for increased outpatient expenses that are not covered by their health insurance plan.

Because costs will differ depending on the perspective, the economic impact of an intervention will be different from different perspectives. To make comparisons of the economic impact across different interventions, it is important for all economic analyses to adopt a similar perspective. It has been recommended that, as a base case, all analyses adopt a societal perspective [89]. The cost to society is the opportunity cost, the value of the opportunities foregone because the resource has consumed. Society's perspective usually is taken by measuring the consumption of real resources, including the loss of potentially productive human lives. As already noted, this cost does not count transfer payments, such as social security benefits. (From the point of view of the Social Security Administration, however, these payments would be a cost, because the perspective of the Social Security Administration is not the perspective of society.) If an intervention is not good value for money from the societal perspective, it would not be a worthwhile intervention for society, even if the intervention has economic advantages for other stakeholders.

Nevertheless, conducting the economic analysis from other perspectives, in addition to the societal perspective, is important. This is because the costs of medical care may not be borne solely by the same parties who stand to benefit from it. Economic analysis of medical care often raises vexing ethical problems related to equity, distribution of resources, and responsibility for the health of society's members [90,91]. Economic analyses from multiple perspectives shed light on the equity issues associated with new interventions.

In summary, economic analysis of medical technology or medical care evaluates a medical service by comparing its dollar cost with its dollar benefit (cost–benefit), by measuring its dollar cost in relation to its outcomes (cost-effectiveness), or simply by tabulating the costs involved (cost identification). Direct costs are generated as services are provided. In addition, productivity costs should be considered, especially in determining the benefit of a service that decreases morbidity or mortality. Finally, the perspective of the study determines the costs and benefits that will be quantified in the analysis, and sensitivity analyses test the effects of changes in variable specifications for estimated measures on the results of the study.

Currently Available Solutions: Imatinib Case Study

The previous sections of this chapter dealt with the principles of clinical economics and methodologic issues surrounding the economic analysis of pharmaceutical products. This section presents a case study that illustrates the practical application of these methods to the evaluation of pharmaceuticals. The following case demonstrates an approach to the economic evaluation of a new cancer therapy, imatinib (marketed as Gleevec® by Novartis).

Chronic myeloid leukemia (CML) is a malignant disorder of hematopoietic stem cells reported to account for 15–20% of adult leukemia cases. The disease presents with a relatively asymptomatic chronic phase but can be followed by accelerated and blast phases. While the disease has a median life expectancy of eight years, the life expectancy in advanced phases drops to months without treatment.

Chronic myeloid leukemia is an interesting disease. From a biological perspective, it results from a translocation between chromosomes 9 and 22, leading to the "Philadelphia chromosome" that is found in most of these patients. This translocation leads to the formation of a new gene, BCR-ABL, which produces a unique fusion protein, a tyrosine kinase. This protein includes effects such as activation of mitogenic signaling and inhibition of apoptosis leading to uncontrolled growth of white blood cells [92].

A unique collaboration between industry and academia searched for a kinase inhibitor that would be effective at targeting the BCR-ABL product. This eventually led to the discovery of the molecule that became imatinib [93].

Economic evaluation was an early consideration with this therapy. From the sponsor's perspective, CML was a limited market of approximately 5000 patients in the US [94]. However, if the drug was as effective as was hoped, the clinical benefit might help support internal expectations for a high target price for the therapy.

The International Randomized Interferon versus STI571 Study (IRIS) was an open-label trial that compared the efficacy of imatinib (the molecule was originally called signal transduction inhibitor [STI] 571) versus interferon (IFN-alpha) plus low-dose cytarabine (IFN+LDAC) in 1106 patients from 16 countries who were newly diagnosed with chronic-phase CML [95]. INF+LDAC had been the standard of care before imatinib was discovered but the regimen was not well tolerated and had limited clinical effectiveness. Thus, oncologists were excited about the potential for a novel therapy. However, given that the trial was open-label, the study suffered from significant patient cross-over. The study had a median follow-up of 19 months. While imatinib was generally well tolerated, 12.3% of patients in the imatinib group discontinued study medication while receiving first-line therapy (compared with 31.6% of patients in the IFN+LDAC group). However, the drug looked to perform as anticipated. At 18 months, the rate of complete cytogenetic response (CCyR) to first-line therapy was estimated at 76.2% for imatinib, compared with 14.5% for IFN+LDAC. Estimated rates of progression to accelerated phase or blast crisis were 3.3% in the imatinib group and 8.5% in the IFN+LDAC group. Overall, 2.0% of the patients randomized to receive imatinib and 57.5% randomized to receive IFN+LDAC crossed over to the alternate treatment after failing first-line therapy. This pattern of cross-over between study arms actually diminished the ability to detect an effect of imatinib in intention-to-treat analyses (see Chapter 32).

The economic investigators sought to estimate the incremental cost-effectiveness of imatinib compared with IFN+LDAC as the first-line treatment for patients with newly diagnosed chronic-phase CML [67].

Study Methods

The economic analysis of the IRIS study required construction of a model to assess the costs and benefits of therapies in both study arms. Data sources for this economic evaluation included data collected in IRIS and supplemental data from the literature. Given the significant cross-over in the clinical study, this usually challenging activity was even more complicated.

The economic analysis had to consider the use of imatinib as first-line therapy. The researchers therefore set up two treatment pathways. For patients on imatinib, they assumed that patients receiving imatinib as first-line therapy could switch to IFN+LDAC and then to hydroxyurea until disease progression. For the comparison group, patients receiving IFN+LDAC as first-line therapy, they assumed that the patients started therapy with INF+LDAC and then switched to hydroxyurea on discontinuation of IFN+LDAC until progression.

Since disease generally progressed from chronic phase to an advanced phase, the researchers developed separate estimates of resource use and quality of life for patients in each phase of their illness. For patients in the chronic phase, they developed different estimates of resource use and quality of life for each treatment arm, but assumed that both groups received the same therapies and had the same outcomes upon disease progression.

Since this was a model, best practice is to develop a framework for a broad sensitivity analysis to test critical assumptions in the model. In this case, the analysis explicitly incorporated the uncertainty associated with each parameter and provided the capability to test assumptions regarding efficacy, survival, duration of treatment, resource use, costs, quality-of-life weights, and discount rates. The analysis was conducted from the perspective of the healthcare system and considered only direct medical costs. In the base-case analysis, cost and survival estimates were discounted at 3% per year; discounting is an approach to understanding that we generally express more value for wealth or health today than at some point in the future. Thus, benefits today are perceived to be "worth more" than benefits in the future. To make current and future values equivalent, we can discount future values to show how nominal "future" values relate to "present" values today [2].

Survival Estimates

Given the high rates of treatment cross-over in the IRIS study, estimation of treatment benefit was a significant challenge. Survival for the two years after the initiation of treatment for chronic-phase CML was based on data from IRIS for patients receiving imatinib as first-line therapy. However, given the high rates of cross-over, the two-year survival rate for the IFN+LDAC arm could not be estimated from the IRIS trial. Instead, a historical control was used – a randomized trial conducted by the Italian Cooperative Study Group on CML for patients receiving IFN+LDAC [96].

While these analyses provided estimates of survival for the first two years of therapy, there was little observed progression during this time period since the chronic phase of CML can last up to eight years. However, there was an important biomarker of treatment effectiveness given the unique biology of CML. A complete cytogenetic response (CCyR) was reported to occur when there were no Philadelphia chromosomes found in white blood cells on a bone marrow biopsy. This was an important biomarker of treatment effect since the chromosome abnormality was felt to be the underlying cause of CML by producing the BCR-ABL protein.

Fortunately, there were survival data on a cohort of 322 patients who had achieved a CCyR by the European Study Group on Interferon in CML [97]. So, in the analysis of long-term survival, patients in either IRIS treatment arm could be considered as CCyR or nonresponders. For

responders, survival was modeled based on the survival distribution from the European Study Group. For nonresponders, survival data were available from the Italian Study Group trial.

Modeling survival over time usually requires some type of extrapolation method, such as a Markov chain model, where each year the surviving cohort is assumed to have an additional year of survival or to have expired during the year (death is an absorbing state in these models). This approach has some unusual characteristics, including generating a distributional tail of patients who survive out to very advanced age. Instead of using this approach, this study used a unique approach of modeling disease and treatment response as a function of increased risk of mortality on standard population survival models. Specifically, the researchers estimated log hazard ratios of the increased risk of death among patients with and without CCyRs compared with an age-matched and gender-matched cohort from the general population. They used the log hazard ratios and their standard errors to simulate survival curves for patients achieving and not achieving a CCyR at two years of follow-up, conditional on the patients being alive at two years. This approach was so unique that the survival estimation methods were published in a separate article concurrently with the economic analysis [98].

Advanced Phases of CML

During advanced phases of CML, the researchers assigned simulated patients in both treatment groups the same distributions for time in accelerated phase and blast crisis and the same distributions of utility weights and estimates of resource use using the published literature. Thus, there was assumed to be no additional benefit from the study therapy once disease had progressed.

Resource Use

Estimates of monthly counts of resource use, including medication use, physician visits, and hospital utilization, were based on data collected in the case report forms for patients in the IRIS study for patients receiving first-line therapy. The analysts assumed conservatively that patients receiving hydroxyurea experienced the same level of resource use as patients receiving imatinib. In the advanced phases of CML, estimates of resource use were based on pooled data from patients in both treatment groups in either the accelerated phase or blast crisis (again, all patients who progressed to this stage of disease were assumed to have the same costs). Resources were assigned the costs reported in Table 34.4 for the economic analysis.

Table 34.4 Resource costs for the economic analysis.

	Unit	Cost
Medication costs		
Imatinib	Cost per 100 mg	$19.68
Interferon-alpha	Cost per 1 MU	$12.24
Cytarabine	Cost per 100 mg	$ 5.74
Hydroxurea	Cost per 500 mg	$ 1.28
Chemotherapy		$6733
Outpatient visits		
Specialists		$78.93
Generalists		$78.93
Nurses		$34.73
Inpatient cost per day		
Chronic phase		$988.36
Accelerated phase		$1400.39
Blast phase		$1432.99

Utility Weights

As previously discussed, quality of life in an economic evaluation is based on an assessment of health utility. For the IRIS study, the EuroQol-5D (EQ-5D), a preference-based measure of health-related quality of life, was administered every three months to study patients. The EQ-5D has two components: a visual-analogue scale

(a health thermometer) and a set of five descriptive questions about health status that have categorical response scales. EQ-5D responses to the descriptive questions can be converted into standard community-weighted utility scores. In other words, patients on either treatment arm with the same response to the categorical questions would have the same utility weight assigned to their health status (there was no interaction of treatment arm and weighting).

Simulations

Once the model was developed, the analysts could calculate the costs and benefits of therapy for patients in either treatment group. Since all the inputs into the analysis had estimates of uncertainty, the modeling effect integrated this uncertainty into the analysis. For each population-level simulation run, the analysts simulated the outcomes for 1000 patients and computed mean estimates of costs, survival, and quality-adjusted survival for each treatment strategy. They varied the estimates for the parameters simultaneously according to their assigned distributions (each variable had a different distribution assigned to the data as appropriate), using means and standard errors. The results were reported as 95% confidence intervals (CIs) for the incremental cost-effectiveness ratios (ICERs), estimated using the percentile method, whereby the 26th and 975th rankings of the 1000 simulated ICERs were used as the 95% CI limits.

Sensitivity Analyses

While the analysts modeled uncertainty directly in the analysis, they had still made several critical assumptions that extended beyond the measurements of error in the model. Sensitivity analysis is an approach to addressing this issue, by questioning critical assumptions directly. The analysts conducted several sensitivity analyses to evaluate the impact of varying baseline estimates and assumptions. These included analyses which tested assumptions surrounding resource use, costs of medications, and outcomes.

Results

The model provided estimates of survival and costs for patients in each treatment arm. In the base-case analysis, patients receiving first-line therapy with imatinib were estimated to survive an average of 15.30 years compared to only 9.07 years for patients receiving first-line therapy with IFN+LDAC, an incremental gain of 6.23 years for imatinib. This is a very large treatment effect relative to other analyses of new pharmaceutical therapies. After adjusting for quality of life, the incremental gain was maintained at 5.85 QALYs (since having a disease like CML might impact your quality of life even if you are on effective therapy, the QALY estimates of benefits were less than the estimates of overall survival).

In terms of resource use, undiscounted lifetime costs were estimated to be $424 600 for patients receiving imatinib compared with $182 800 for patients receiving IFN+LDAC, a difference of $241 800. This cost difference included the difference in the cost of medications and the incremental additional years of treatment resulting from the additional survival of patients on imatinib.

After applying a 3% discount rate, the incremental gain in survival was 3.93 years and 3.89 QALYs. Discounted lifetime costs were $168 100 higher, on average, among patients receiving first-line therapy with imatinib. The net effect of discounting is to reduce the value of events occurring in the future, both on costs and survival.

Combining these estimates resulted in ICERs equal to $43 100 per life-year saved and $43 300 per QALY saved. Scatter plots of the ICERs from the 1000-patient analysis reveal a relatively low level of variability in the results and a high degree of correlation between incremental differences with regard to costs and survival. The results were remarkably consistent, with the upper limits of the 95% CIs for both cost-effectiveness

ratios (survival and QALY) less than $51 100 (Figure 34.3).

While the variability in individual parameters were considered in the scatter plot of Figure 34.3, there was still an analysis of variability of the different dimensions of the sensitivity analysis. Here, the results are presented as a tornado diagram, estimating the impact of each of the parameters of the sensitivity analysis on the overall study results (Figure 34.4).

This case study demonstrates an application of economic analysis to a new drug using data from the pivotal clinical trial to help justify the price for the therapy.

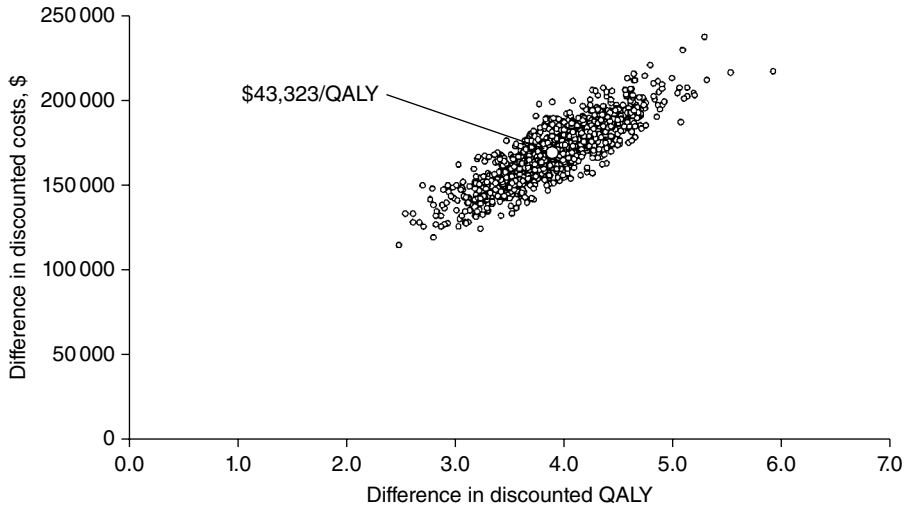


Figure 34.3 Bootstrap scatter plot of 1000 population-level simulations on an incremental cost-effectiveness plane [67].

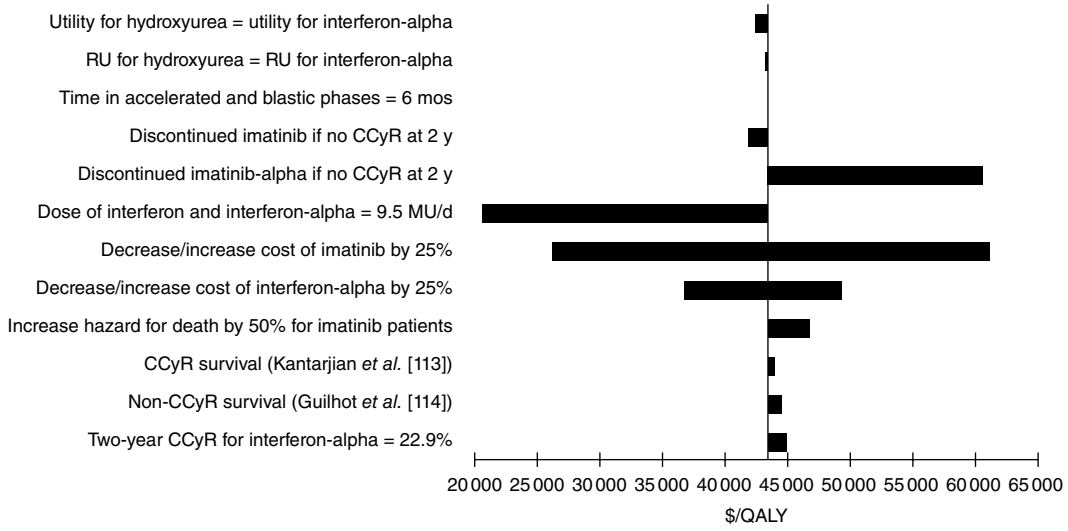

Figure 34.4 Tornado plot of the effects of multiple one-way sensitivity analyses [67].

This analysis was very controversial. First, the survival benefit in the analysis was entirely a modeling exercise, as a survival benefit had not been seen in the original IRIS study. Fortunately, this assumption of the relationship between CCyR and survival was later confirmed in a five-year follow-up of the original study [99]. Second, the economic analysis was based on the initial launch price of the therapy. However, the sponsor aggressively raised the price of therapy above the launch price over time, from $26 400 to over $120 000 [100]. Further, that price differs substantially by market, with costs in Canada less than 20% of the US costs in 2013 [101], down to a low of $2500 per year in India [102]. Patent expiry was expected to reduce the cost of imatinib significantly in the US [103], with a significant opportunity to reduce costs to a nominal level if the price comes down to the actual cost of active pharmaceutical ingredients [104].

The Future

Health economics helps to understand both the supply and demand for pharmaceutical products, while pharmacoeconomics provides insight into the value of products to patient, payers, and the marketplace. With all these elegant data, the next challenge for analysts and policy makers is to relate the results of the economic analysis to purchase decisions for pharmaceutical products. Should a patient, hospital, or payer (public or private) make a decision to approve payments for a therapy (for example, by adding the product to an approved drug list or formulary)?

Generally, if a product is thought to add clinical benefit and save money, it is an easy decision to add the therapy. These types of products are described as cost-saving or dominant (see Figure 34.2). For example, vaccines sometimes fall into this category, as do generic drugs (in comparison with brand-name products). If a product worsens clinical outcomes but raises cost, this is also usually an easy decision to not add the therapy. These types of products are described as dominated but are much less common. The major challenges in making formulary decisions generally relate to therapies that add clinical benefit at additional cost. This analysis requires further discussion on how this decision can be approached.

Outside healthcare environments, we make these types of decisions frequently. The new product on the shelf tastes better but costs more. Should we buy this product? The first question is a budget question – do we have the money to make this purchase? We have not said anything about prices but obviously, this is an important part of our consideration. If the new product is enormously more expensive (it is hand crafted in small batches and infused with gold and sold in a crystal decanter), we may not have the money to afford the new product and so the question becomes moot. This is a budget constraint. This constraint does not have to be so extreme; we can make a budget of $100 for a grocery list, and hold ourselves to meeting our budget in our shopping trip. With this budget, even a modestly priced new item may not meet our budget constraint.

Of course, we may decide we have some room in our budget to increase spending at the supermarket. For simplicity, let's assume we have two choices to consider for our increased spending: products A and B. Product A is the tastier version of one of our shopping staples, while product B is a new item that a friend recommended. Product A costs $5.00 more than our usual item, and product B costs $5.00, so our budget would now be $105 if either is added to the shopping list (a 5% increase in cost). How would you choose between these two? This is a cost-effectiveness question. Given the increase in cost, which product would provide more value to you as a consumer-enhanced flavor from A or the novelty of B? We make these types of decisions all the time, and the answer greatly depends

on individual taste preferences. So, in this simple case, cost is transparent and value is based on individual preferences.

Now, back to the pharmaceutical market. Budget constraints are built into healthcare spending. National health insurance programs often have a fixed allocation from government for annual spending. In private health insurance markets, health insurers estimate premiums for the coming year before selling policies during open-enrollment season, or as much as 18 months in advance of actual spending. So, the introduction of a new product that adds cost can face real budget constraints depending on the potential magnitude of the spending increase. Sofosbuvir had a list price of $84 000 in the US and a potential market size of 3.2 million people when it was first launched [105]. This would require a staggering budget of $269 billion to treat everyone with the infection. So, while the clinical potential of this therapy was tremendous, the budget constraint resulted in policies to limit its adoption.

As with the shopping example, budget constraints can be absolute. For example, the Medicaid program is jointly funded by federal and state governments, and states are not allowed to run budget deficits by law. Thus, if increased spending on a new therapy would require an increase in outlay by the Medicaid program, states may be forced to not offer the therapy, or to cut back in other areas of spending to stay within their budget. Going forward, if states wanted to add to their Medicaid spending, they would need to raise revenues (taxes) to support this increased spending, or find other parts of the budget to cut (education, for example).

Again, as with the shopping example, budget constraints may not be absolute. Imagine that a health insurance company calculated its premiums to incorporate new spending on drugs to be introduced in the coming year. Thinking about the budget from the perspective of premiums is interesting. We have called this approach the "benefit pool" perspective [106]. It suggests that we can calculate how much additional premium we would all have to contribute for us to have an increase in our pharmaceutical budget. The budget model looks at the issue from the insurer perspective, while the benefit pool perspective looks at the same issue from the perspective of everyone buying insurance (or paying taxes). With an increase in premium, we would still have a budget constraint, but one that allows for growth in pharmacy spending.

With the additional resources, we would need to develop a process for increasing our pharmacy spending. In our cash payment shopping model, the willingness to allocate additional resources to our budget was based on consumers' individual perceptions of value. In healthcare, we do not pay for our medicines directly, so the organization administering the benefit pool (which could be a public or private payer) needs to make this determination. Here, cost-effectiveness analysis can be used to assess the relative value of additional investments in different therapies. From here, one can consider the relative value across products and fund the product that is the most economically attractive (the lowest cost-effectiveness ratio) first. In this way, we will insure that incremental spending is for the product delivering the most value. You can continue adding therapies in this way until all of your resources are allocated [107].

Another way to use a cost-effectiveness ratio is to set a criterion of what represents good value for money, or what is "economically attractive." In the US, dialysis care has long been used to provide a benchmark of good value for money. Dialysis was added to the Medicare program in 1972, after consideration of the cost of care for patients with end-stage renal disease [108]. As a result, we have an example of a clinical program where Congress made an explicit decision to add a benefit to Medicare, one that added cost but that also extended life expectancy for beneficiaries who need the service. Since patients on dialysis can cost $50 000 per

annum, the benchmark for value as reflected in Congressional approval of this service was seen to be $50 000 per year of life gained. Since dialysis requires treatment three times a week for several hours at a time, the benchmark was thought to be even higher when considering quality-adjusted survival.

Does that mean that we can add therapies to the formulary that offer good value? The answer is, "it depends." Again, while cost-effectiveness analysis does a good job assessing the relative value of different therapies, the ratio itself is not tied to a budget impact or premium. In other words, a product that is not good value for money for a rare condition would have a relatively modest budget impact, while a drug that is good value for money for a common condition could have a significant impact on budgets. The value of a product can also change by indication. For example, since patients with known heart disease have higher risk for cardiovascular events than patients without heart disease, secondary prevention can provide more value for money than primary prevention [109]. To date, efforts such as pricing by indication have been challenging to implement.

Rather than providing an absolute recommendation, the UK has an implicit relative framework for value, with products that have a lower cost-effectiveness ratio more likely to be recommended by NICE [110].

Returning to the benefit pool perspective can be another way of looking at this question. This analysis looks at the impact on the health insurance premium resulting from the addition of a new product to the formulary. For example, the addition of PCSK-9 inhibitors (used to lower cholesterol) priced at more than $14 000 annually per patient was calculated to add $140 to the premium for everyone in the insurance pool under modest adoption assumptions [106]. This perspective can be generalized to the consideration of specialty pharmaceutical products more broadly (Figure 34.5). Here, we can see that health insurance premiums increase $250 for every 0.25% of the population that receives a $100 000 drug for any indication [23]. The relationship of access to innovation and affordability is an area of ongoing debate [111].

Finally, we have the quadrant where the products save money but at the expense of worse clinical outcomes. Actually, the use of therapies that meet this criterion is relatively common, as long as the amount of money saved is large relative to the loss of health benefits (a cost-effectiveness ratio of savings related to benefits lost where a higher number is the most economically attractive). For example, amoxicillin is recommended

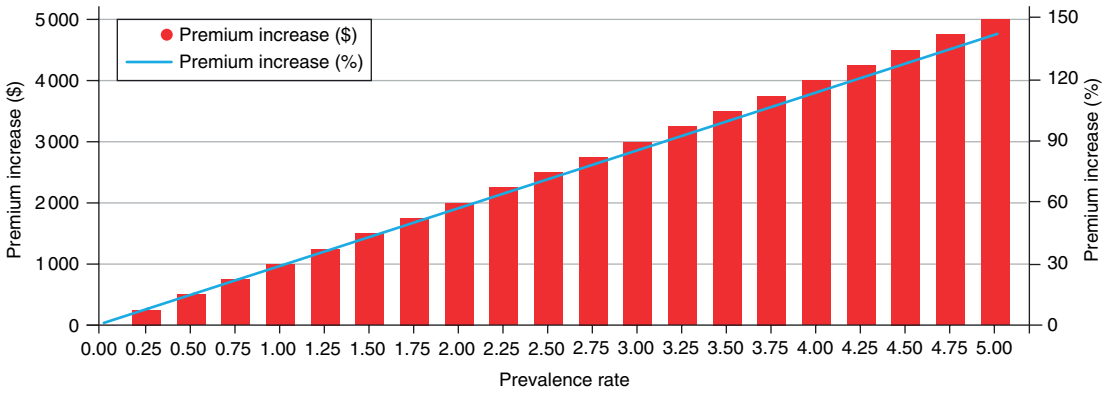

Figure 34.5 Specialty pharmaceuticals and premiums. *Source:* Hirsch *et al*. [24].

for first-line therapy for otitis media, despite the high level of resistance to this antibiotic [112]. This is because of the low cost of the therapy, and the low likelihood of significant complications of failure of this initial treatment.

Conclusion

The cost of pharmaceutical products is an important challenge for everyone involved in the healthcare value chain, including patients, physicians, payers, and government. While we all desire innovation in healthcare, it is not clear if it is possible to afford innovation at any price. We have outlined an expanded version of the study of the economics of pharmaceuticals to begin to flesh out a fuller discussion of this fascinating and complex subject.

As physicians are asked simultaneously to represent their patients' interests while delivering clinical services with parsimony, and as reimbursement for medical services becomes more centralized in the United States and other countries, decision makers must turn for assistance to collaborative efforts of epidemiologists and economists in the assessment of new therapeutic agents. Through a merger of epidemiology and economics, better information can be provided to the greatest number of decision makers, and limited resources can be used most effectively for the health of the public.

18 Private investors expect a risk-adjusted return from their investments. If we assumed that the entire cost of drug development occurred at the start of the project, that the research program took six years, and that investors demanded a 30% annual return on their investment to account for the high-risk of failure in drug development, and the time value of money is 6%, the capitalized cost of development would be $288 million at the start of year 7.

Benefit–Risk Assessments of Medical Treatments

Bennett Levitan[1], Rachael L. DiSantostefano[1], and Scott Evans[2]

Consider the challenges faced by a health authority reviewing a novel anticoagulant for people with atrial fibrillation. The drug reduces ischemic strokes and myocardial infarctions, but also causes intracranial hemorrhage, gastric bleeding, and increased propensity for hematomas. What chance of each type of bleed is too much for a given degree of ischemic benefit? Does this trade-off differ for different groups of patients? Does the nature of this trade-off differ between physicians and patients? How much uncertainty in the rates of these outcomes is acceptable? How can these trade-offs be assessed in observational databases where the outcome definitions vary and detailed information on transfusions and hemoglobin changes is not always available? Addressing these questions falls under the domain of benefit–risk (B–R) assessment.

Assessing the B–R balance of medical treatments has always been an integral part of drug development, regulatory, and public health decisions. However, methodology for B–R has advanced considerably in the last decade, and health authorities worldwide have seen growth and maturation of B–R policies relating to regulatory approval and postapproval decisions. Starting from a report on a 2006 Institute of Medicine public workshop which noted the need for improved consistency, methodology and communication of B–R assessment [1], the convergence of regulatory science and policy, patient engagement, decision analysis, and health economics has transformed the B–R field. For example, the Food and Drug Administration (FDA) has implemented a B–R framework to facilitate B–R assessment and communication in its reviews [2] and is developing means to include the patient perspective into B–R [3–7]. The European Medicines Agency revised its 80-day assessment reports to require rapporteurs to document the value judgments behind their B–R assessments and incorporate a detailed tabular summary of benefit and risk data [8,9]. The International Conference on Harmonization (ICH) revised guidance documents that now require pharmaceutical companies to use a structured approach to B–R in new drug applications/marketing authorization applications and in postapproval periodic benefit–risk evaluation reports (PBRERs) [10,11]. In parallel with these regulatory changes, numerous initiatives have been led by pharmaceutical and device trade organizations, patient advocacy groups,

Pharmacoepidemiology, Sixth Edition. Edited by Brian L. Strom, Stephen E. Kimmel and Sean Hennessy.

public–private partnerships, and academic groups. Their efforts have resulted in new qualitative and quantitative approaches to B–R, means to assess patient B–R preferences and incorporate them in B–R assessments, and compendia of approaches and recommendations [12–18,29]. These advances have driven the addition of this inaugural chapter in B–R assessment.

While definitions vary, benefit–risk is generally defined as weighing the key benefits of a treatment against its key harms. The term "risk" is ambiguous in the field of benefit–risk, and may refer to the general nature of the harmful effect, its frequency, its severity or a vague combination of these concepts [19,20]. To lessen this ambiguity, we will generally use the term "harm" or "unfavorable effect" as the analogs for "benefit" or "favorable effect," though we retain the phrase "benefit–risk" due to its ubiquity. The goals for B–R assessments vary – go/no-go decisions by a company, reviews by institutional review boards and data monitoring committees, patient group advocacy decisions, regulatory reviews by a health authority, and reconsideration of a treatment after gaining new information post approval. Benefit–risk is also a critical component of point-of-care decision making by a patient and physician.

The goals for this chapter are to introduce the key clinical and methodological challenges in B–R assessment, then summarize current and promising approaches to addressing these challenges. The focus of this book is pharmacoepidemiology, but because medical treatment B–R as a science has much of its origin and current applications in development and regulatory approval, this chapter touches on both regulatory development and postapproval settings. Our examples will primarily be in the cardiovascular domain – for the treatment of atrial fibrillation or acute coronary syndrome (i.e., myocardial infarction or unstable angina).

Clinical Problems to be Addressed by Pharmacoepidemiologic Research

Systematic Approach to B–R Assessment

While many B–R assessments are ultimately based on a qualitative interpretation of quantitative data [2,18], reaching the point where this qualitative interpretation is possible can be surprisingly challenging. Benefit–risk assessment can involve many outcomes, multiple conditions under which these outcomes are assessed, many data sources, multiple regimens, numerous comparators, different treatment paradigms, and numerous other considerations. There are also often several stakeholders whose perspectives on the importance of benefits and harms outcomes may need to be considered. All this information needs to be integrated into a transparent and defensible B–R assessment. There are also numerous quantitative models available for assessing B–R [16,21,22]. Because of all these complexities, different stakeholders use widely varying approaches to B–R assessment, with considerable differences in the depth, transparency, and clarity of the assessment. This has resulted in considerable inconsistency in how, for example, drug or device companies and regulators conduct and communicate a B–R assessment. What has emerged in recent years is the need for structured, framework approaches to rationally and defensibly frame, conduct, and communicate a B–R assessment [2,7,10,11,18,23]. We describe several of these frameworks and how they can be used.

Incorporating the Patient Perspective

Traditionally, the judgment calls required in design and conduct of clinical trials, registries, long-term extension studies, and the B–R assessments on their results have been the province of

physicians and regulators. Regulatory agencies, patient advocacy groups, and industry have increasingly been advocating for patient engagement: patients partnering with the drug/device development company, researchers, health authorities and payers in the development, review, reimbursement and public health (e.g., vaccines) decisions for their treatments [5,24–28]. Chapter 42 addresses the topic of patient engagement in detail. Here, we consider patient-focused benefit–risk, which can be regarded as the components of patient engagement involving the incorporation of the patient perspective on the nature of the illness, medical need, outcomes and trade-offs into a B–R assessment. While the idea of patient-focused B–R is well accepted, the challenge is to determine what information should be obtained from patients, how it should be obtained, and how it can be used.

There are numerous techniques for assessing the patient perspective, ranging from qualitative focus groups and structured interviews through rigorously quantitative conjoint analysis or discrete choice analysis preference surveys [16,19,29,30]. Patient preference studies and surveys have become particularly important [3,4,15,19,31–33]. Identifying the appropriate patient sample and methodology, establishing trust between the stakeholders involved in these surveys, and the application of the results to clinical trials or observational studies are part art and part science. We review key elements of patient preference studies and discuss several means by which the results can be incorporated into a B–R assessment.

Methodologic Problems to be Addressed by Pharmacoepidemiologic Research

Regulators, patients, and physicians need to understand the evidence regarding the benefits and harms of available therapies to make optimal therapeutic decisions. Methodologies for gathering, synthesizing, and communicating the B–R assessment based on available data are the key tools for optimal decision making, in both the regulatory and clinical realms.

Identifying Appropriate Data for Benefit–Risk Assessment

Data for B–R assessment come from a variety of sources including randomized controlled trials, spontaneous reports, and observational data sources (see Part III Sources of Data for Pharmacoepidemiologic Studies). These sources often define outcomes differently, measure effects over different time periods, have important differences between populations, and use different comparators. Even with similar data sources, studies can demonstrate dissimilar results. Some studies might find an association between a treatment and adverse event, while others may find a protective effect or no effect. There has been much discussion about discordant results between observational studies and randomized controlled trials and potential explanations [34–36]. A well-known discrepancy is the difference between the Nurses' Health Study, an observational cohort, and the Women's Health Initiative, a large randomized trial, on the relationship between hormone replacement therapy and cardiovascular and breast cancer outcomes. The populations studied differed on important confounders and effect modifiers [37–39].

The reliability in identifying and characterizing the important benefits and harms must be carefully evaluated through assessment of confounding, bias, study design, generalizability and ability to pool the data. The principles for choosing among the available data sources in pharmacoepidemiology are discussed in Chapter 17. The validity of exposure and diagnostic data is further discussed in Chapter 37. Design-based and analytic approaches to adjust for confounding and bias in observational studies are discussed in Chapter 43. The considerations in

these chapters for pharmacoepidemiology also apply to B–R assessment.

Integrating Benefits and Risks

Even with high-quality data, synthesizing the evidence in a structured manner can be challenging. For example, a typical psoriasis indication can easily have over 10 efficacy outcomes and 15 important safety outcomes. Some of these outcomes may favor one treatment, while others may favor the other. Even some "benefits" may favor the comparator, and some "harms" may favor the study treatment. Although comparisons may reach statistical significance, in benefit–risk, there are often several important outcomes for which formal statistical testing is not conducted, for the most part due to small numbers of events and insufficient power to detect differences. In cases like this, rendering a B–R assessment is not trivial. Approaches that integrate benefits and harms should be sufficiently comprehensive to account for the frequency, clinical impact, and uncertainty of potentially many benefits and harms considered under multiple conditions. Further, they should account for the context of the overall disease state, currently available treatments, and unmet needs of the population of interest. This challenge of integrating available evidence is complicated by the need to evaluate the effects upon important subgroups of patients, for example, children, the elderly or immune-compromised individuals, where the B–R may be more or less favorable. Different subgroups may also have differences in preferences and value judgments that impact the B–R balance.

Communicating B–R Assessment

Given the many outcomes, complex statistics or epidemiology, and clinical judgments or formal preference studies, communicating a B–R assessment in a clear and cogent manner can be a formidable challenge (see also Chapter 39 on risk communication). This challenge is compounded by the typically very heterogeneous background of the audience (regulatory reviewers, patient groups, clinicians) that might utilize this information in a B–R assessment.

Currently Available Solutions

Structured Approaches to B–R: B–R Frameworks

Perhaps the most significant advance in regulatory and industry approaches to B–R in the last decade has been the introduction of B–R frameworks, a set of principles, processes, and tools to guide decision makers in selecting, organizing, analyzing, and communicating evidence relevant to B–R decisions [18]. B–R frameworks lead to far greater transparency, consistency, and discipline in B–R decision making. They encourage discussions that force decision makers to be explicit about their assumptions and requirements and, as will be discussed later, they assist not only in the act of decision making, but in the act of communicating the decision.

There are several well-known B–R frameworks: the FDA B–R framework [2], the Pharmaceutical Research and Manufacturers of America Benefit-Risk Action Team (PhRMA BRAT) framework [13,14], the Multicriteria Decision Analysis (MCDA) framework suggested by the European Medicines Agency (EMA) for complex B–R decisions [40–42], and the framework embedded in the International Council for Harmonisation's (ICH) PBRER template and recent update to the ICH Clinical Overview template's B–R section [10,11]. There are also applications of the BRAT framework for nonprescription drugs [43] and a documentation system for regulatory agencies based on both BRAT and the ICH Clinical Overview update [17]. While the frameworks differ in focus and methodology, they share many steps

Table 35.1 Steps in the BRAT benefit–risk framework.

Step	Definition
Define decision context	Summarize the nature of disease, medical need for treatment, disease and treatment epidemiology, study treatment, dose/formulation, indication(s), patient population, critical subgroups, comparator(s), time horizon for outcomes, relevant decision-making bodies
Identify and define outcomes	Identify and define all important outcomes, define a preliminary set of measures for each outcome, document rationale for outcomes to be included and excluded
Identify and summarize source data	Determine and document all data sources, extract raw data, summarize over data sources, assemble effects table
Customize the framework	Modify the outcome list and their definitions based on review of the data and clinical expertise. May include tuning of outcomes not considered relevant to a particular B–R assessment or stakeholder group
Assess importance of outcomes – value judgments and patient preferences	If applicable, assess outcome clinical impact or weight from the perspective of patients, decision makers or other stakeholders
Integrated B–R assessment: analysis and visualization	Summarize data into tabular and graphical displays (e.g., effects table) to aid interpretation, identify and fill any information gaps, interpret summary information, potentially conduct quantitative B–R analyses and sensitivity analyses to assess the impact of uncertainty on clinical or preference data
Expert judgment and communication	Render and communicate a decision

similar to those in the BRAT framework presented in Table 35.1.

Given the ubiquity of B–R frameworks and their incorporation into the regulatory guidance for submissions and PBRERs, we structure this section based on these framework steps.

Define Decision Context

The main role of the decision context is to ensure all decision makers are aligned on key background elements of the assessment. Characterizing the severity of the disease and the medical need is particularly important, as the greater the severity or medical need, the more allowances regulators and other decision makers typically make for treatment-related harms [7]. The severity of the illness can reflect severity either untreated or with current standard of care therapy, whichever is most appropriate for the condition. Medical need typically reflects the B–R profiles or limitations of existing treatments. These background elements are also an important avenue for incorporating the patient perspective into B–R [6]. In observational B–R assessments, the context forces upfront agreement on an appropriate comparator, dose and population, the choice of which is often not straightforward in postapproval contexts. For example, for a recently approved drug, the most appropriate comparator may be the one used in recent clinical trials, the standard of care, or comparators available in the extant datasets.

Examples of decision contexts for numerous disease can be found in the FDA's "Voice of the Patient" reports [25] and in recent drug approvals, searchable at www.accessdata.fda.gov/scripts/cder/daf/.

Identify and Define Outcomes

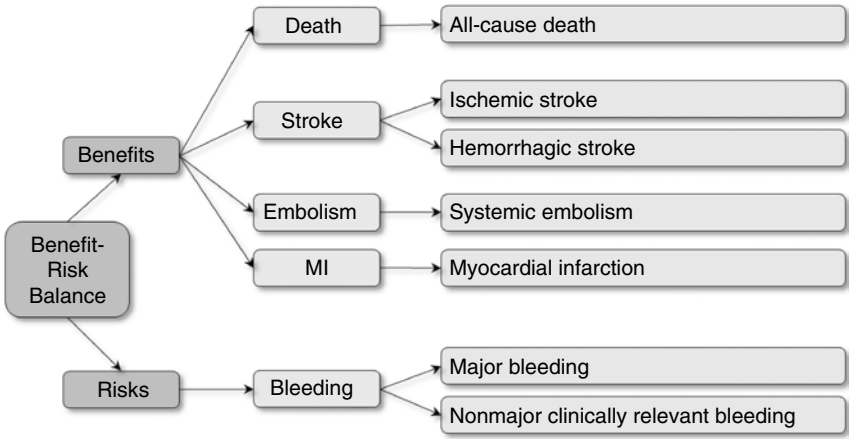
The second step of the BRAT B–R framework (see Table 35.1) is to identify and define the important outcomes: benefits, harms, and potentially other treatment properties of interest. While studies often measure many outcomes, many of these are highly correlated with each other or are causally dependent, some double-count events, and they may vary considerably in their clinical impact. Generally, B–R requires identifying a smaller set of key outcomes that drive the B–R assessment [11]. A tool often used to select and depict the outcomes used in B–R is a value tree, a hierarchic graph in which outcomes are grouped by anatomic, functional or clinical impact (Figure 35.1A). Identifying outcomes in the value tree also serves as a discussion tool in determining which outcomes are most important from patient and physician perspectives.

The value tree can also be utilized to understand problems caused by the interrelationships between outcomes. Outcomes that are easily interpreted individually can be problematic when considered collectively for B–R. For example, in the Randomized Evaluation of Long-Term Anticoagulation Therapy (RE-LY) study, the pivotal trial of dabigatran for atrial fibrillation, the primary efficacy outcome was stroke or systemic embolism, and the primary safety outcome was major bleeding [45]. Major bleeding is defined as the composite of fatal bleeding, critical organ bleeding (e.g., hemorrhagic stroke, intracerebral hemorrhage), transfusions ≥2 units packed red blood cells or whole blood, or hemoglobin drops ≥2 g/dL) [44]. Fatal and nonfatal hemorrhagic stroke events are included in both the primary efficacy and safety outcomes. This double-counting can lead to considerable confusion, as some events will count as both a benefit and a harm. Double-counting also occurs between all-cause death and other efficacy outcomes, as strokes, myocardial infarctions, and systemic emboli may be fatal. Counting these deaths twice can potentially distort the findings. Finally, major bleeding includes a mix of events that are fatal, cause irreversible harm or are transient without sequelae, yet each event is weighted equally in the composite outcome [44]. This large range of clinical impact under one outcome complicates the comparison between benefits and harms [46,47].

The value trees in Figure 35.1 show one way to resolve these issues [48,49,65]. Figure 35.1A shows a value tree using the key outcomes of a typical atrial fibrillation trial. Figure 35.1B's value tree includes the same events but with ischemic events classified only as benefits and hemorrhagic events classified only as risks. This provides a separation that mostly aligns with the treatment's mechanism of action and avoids any double-counting between benefits and harms (strokes with both ischemic and hemorrhagic components would need special consideration). Additionally, efficacy outcomes are defined to avoid double-counting. Finally, benefits and harms are classified by whether they are fatal or generally result in irreversible harm; fatal and critical organ bleeds are classified as fatal/irreversible, transfusions and hemoglobin drops are classified as reversible. This last classification is based on the FDA's approach to the approval of dabigatran and prasugrel, in which the FDA focused primarily on outcomes that were fatal or caused irreversible harm [50,51]. By separating the fatal and irreversible efficacy and safety events from less impactful ones, a first pass at the B–R assessment can be made with clinically comparable benefits and harms, then less impactful events can be included for additional detail in the assessment (see Figure 35.1B).

In some cases, having two or three value trees can be helpful. When there are different decision makers with different views on which events are most important, different value trees can be developed that reflect these different viewpoints, and the analyses conducted with each. For example, some decision makers may want to include

(A)



(B)

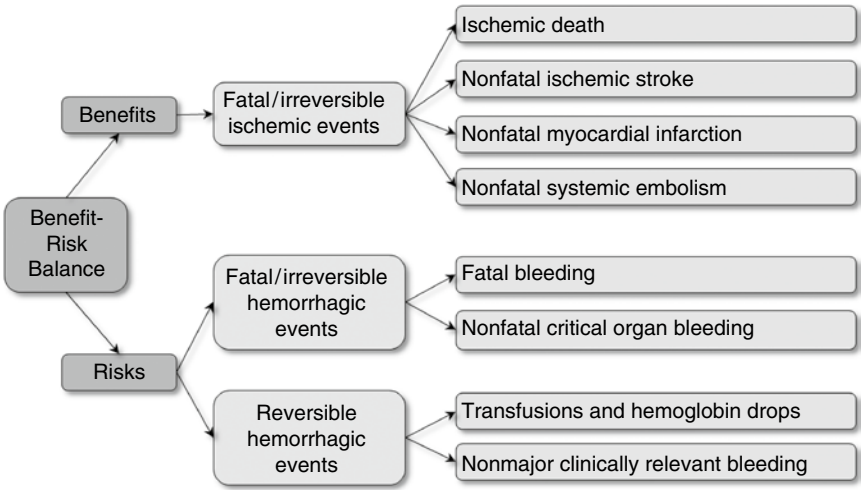


Figure 35.1 Example value trees for treatment of atrial fibrillation. (A) Endpoints from a typical atrial fibrillation statistical analysis plan. (B) Modified value tree with one approach for benefit–risk assessment. Major bleeding is defined as the composite of fatal bleeding, critical organ bleeding (e.g., hemorrhagic stroke, intracerebral hemorrhage), transfusions ≥2 units packed red blood cells or whole blood, or hemoglobin drops ≥2 g/dL) [44]. Nonmajor clinically relevant bleeding is defined as overt bleeding not meeting the definition of major bleeding but requiring medical intervention, contact with a health professional, a change in dosing of study drug/treatment or associated with discomfort or which impaired activities of daily living. MI, myocardial infarction.

some types of bleeding events besides critical organ bleeds under the irreversible harm category. In the Advanced Methods on the Horizon section, we outline a few approaches that sidestep some of these concerns of double-counting and multiple perspectives on which events are most important.

Identify and Summarize Source Data

The third step of the B–R framework differs considerably in preapproval (development) and postapproval contexts. In the preapproval phase, the choice of datasets for B–R is self-evident. The pivotal clinical trials must be used, and while the generally *post hoc* nature of B–R provides some flexibility, the protocol and statistical analysis plan prespecifies the populations and means for pooling data from multiple studies. Post approval, however, identifying and summarizing data for B–R has many more options and complexities.

Approaches for handling the choice of database, study design, and analysis approach that apply to pharmacoepidemiology in general also apply to B–R assessment. These topics are addressed in other chapters in this book, so we only briefly introduce important points regarding data sources more specific for B–R assessment, particularly as more data accumulate across the life cycle of a treatment.

The availability of electronic data sources, in particular claims data, registries, and electronic health records, has created new opportunities to conduct postapproval B–R assessments. This has also resulted in the increased discussion and utilization of pragmatic randomized trials and EHR-enabled prospective studies for the evaluation of effectiveness and safety, such as the Phase III pragmatic randomized Salford lung study in COPD [52,53]. With these electronic data sources, new challenges arise regarding evaluation of data quality and utility, and how to synthesize the data.

At the time of regulatory approval of a new medical treatment, B–R assessment is largely based on data from controlled clinical trials and preclinical studies. A necessary condition for the rigorous assessment of benefits and harms is the foresight to anticipate and accurately measure them. These studies often have a focus on well-characterized efficacy data. Specific safety outcomes may be collected based on anticipated harms due to the mechanism of action (for example, bleeding events in an anticoagulant trial). Otherwise, there is passive collection and reporting of adverse events by investigators if something appears to be abnormal.

With passive collection, it is therefore sometimes hard to distinguish between nonoccurrence of an event and underreporting of safety events due to informative censoring, early discontinuation, or inconsistent reporting. There are also harms that might not always be recorded in data sources, including "silent harms" that would be revealed with laboratory tests (for example, asymptomatic elevated liver enzymes that may be surrogates for future liver disease). Finally, analyses of serious, rare adverse events may not be adequately powered to detect differences between treatments. Thus, the absence of observed safety events or harms or their lack of statistical significance does not necessarily imply an absence of harm in a clinical trial or other setting.

There are analysis principles that can account for some of these limitations in the passive recording of safety events in clinical trials. For example, the intent-to-treat principle is used to capture important safety events resulting after early discontinuation or the end of the treatment period by following patients during these periods [54]. Sensitivity analyses of adverse event definitions may also be considered when it is suspected that a safety event may have been reported using different terminology. For example, community-acquired pneumonia in a trial in children might be recorded as community-acquired pneumonia, lower respiratory tract infection, and/or asthma exacerbation in the absence of a special adverse event collection

page, depending on the physician's judgment and accuracy of diagnosis. Further, the diagnosis of pneumonia might not be accurate, as there may be poor agreement on pneumonia diagnosis even when a chest X-ray is present [55–57]. In this example, the sensitivity and specificity of the pneumonia or lower respiratory infection event rates could be considered in the B–R assessment. However, additional studies may be required to investigate unexpected, rare but serious safety events noted in clinical trials to ensure adequate power and ascertainment, including subsequent trials or observational studies.

Following a medical treatment's approval, data informing B–R accumulate in a broader, larger sample of subjects in clinical practice and postapproval studies mainly through observational sources. B–R assessment is therefore often conducted by considering multiple studies conducted in a variety of settings, including randomized trials and observational studies. An understanding of strengths and weaknesses of study designs is important in weighing the B–R evidence across existing studies as well as in designing *de novo* observational or randomized studies.

We briefly describe important differences between randomized trials and observational studies that are important considerations for B–R assessment. Postapproval observational studies are more likely to compare two or more active treatments and observational studies generally do not contain a placebo arm, unlike many randomized controlled trials for registration. Some data limitations present in clinical trials also persist in the postapproval setting, including the passive reporting of safety data. Definitions of exposure and efficacy and safety outcomes in the observational settings are dependent upon the means of collection in the source data and generally vary from setting to setting. Medical diagnoses are typically recorded as a numeric medical code in the case of electronic sources as part of documenting healthcare encounters and/or processing medical insurance claims. Some diagnoses and symptoms might not be readily recorded in a claims or medical record, as they may not result in a healthcare visit (for example, stomach ache). Further, patient characteristics that may be important confounders or prognostic factors may not be available, particularly in healthcare claims data. For example, weight, smoking status, body mass index, and lung function tests may be available in an electronic medical record or patient registry but would not be reported in claims data as these data are not generally required to process healthcare claims. Efficacy or safety outcomes of interest may not be available or reported with the same granularity as required for a clinical trial. For example, specific types and severity levels of bleeding events that may be associated with an anticoagulant in observational sources are identified on the basis of medical codes [58] whereas more detail would typically be ascertained for bleeding events in randomized controlled trials [45]. More extensive discussion about validity of pharmacoepidemiologic data appears in Chapter 41.

The most robust data for B–R assessment are from randomized controlled trials and observational data sources where the important outcomes from the value tree have been rigorously captured and where confounding and selection bias have been rigorously accounted for (e.g., through randomization or statistical adjustment). A particularly important concern in observational data analysis is addressing confounding by indication or channeling bias, in which treatments are used differently depending on the degree of severity of the illness. For example, if a particular treatment is generally reserved for sicker patients, that treatment may appear to be associated with worse side effects than other treatments, simply because the sicker patients are more likely to have such side effects (see Chapter 43). Similarly, confounding by indication may mask the true benefit of a treatment

and even make the treatment look less efficacious than the comparator (see Chapter 33).

Merging the data quantitatively from many disparate sources and across different study designs is not always possible, desirable, or realistic. If comparisons are made between effect estimates across studies, the extent to which study populations, definitions, study designs, and analysis approaches are comparable should be described, including the potential for bias and confounding. Metaanalysis can be considered as a means to tabulate and combine effect estimates for benefits and harms when appropriate, using a transparent and systematic approach (see Chapter 36). Completed studies may sometimes be excluded from a metaanalysis on the basis of low methodological rigor. Metaanalyses can include direct or indirect comparisons between treatments depending on the availability of the data. A traditional metaanalysis approach would be applied when head-to-head studies have been conducted. For example, a metaanalysis of Phase III clinical trial data was conducted to compare oral anticoagulants to vitamin K antagonists in atrial fibrillation [59].

When head-to-head studies are not available, however, a network metaanalysis approach may be considered. For example, a network metaanalysis was conducted to compare oral anticoagulants relative to one another in atrial fibrillation [60]. The appropriateness of a metaanalytic summary might be questioned when results vary so much across studies that a single estimate loses interpretability. Methodological considerations for metaanalysis are further described in Chapter 36.

Customize the Framework

After identifying and summarizing source data, there may be a need to revisit the outcomes for B–R as described in Step 4 of the BRAT framework (see Table 35.1). Two common reasons for this revisiting are the emergence of new adverse events (AEs) not considered at the time the value tree was developed and differences between the B–R outcomes of interest and those available in the source data. New AEs may occur both during development and post approval, in which case additional harms can be added to the value tree. The available data do not always have the measurements desired or the granularity of outcomes to support the originally planned approach to B–R, particularly in claims and EHR data. In this case, the B–R assessment may require a revised set of outcomes. While constructing a formal value tree is simply a graphical exercise to facilitate selecting and communicating outcomes for B–R, customizing the outcomes to accommodate the limitations of the data sources may be necessary.

Consider the atrial fibrillation value tree in Figure 35.1B. The outcomes in this tree require distinctions such as fatal versus nonfatal myocardial infarctions and disabling versus transient major bleeds. If the available observational data sources cannot adequately measure these endpoints, the tree will need to be customized with proxy or less granular outcomes that are available. In some cases, an algorithm can be used to approximate a desired outcome. For example, primary hospital discharge diagnosis codes can be used to identify bleeding-related hospitalization and to differentiate upper and lower gastrointestinal bleeding [61]. The bleeding events in these algorithms may not fully align with the intended definition of major bleeding but may be sufficient, although different definitions make comparisons with RCT results potentially problematic.

Another approach used for atrial fibrillation is to simplify the value tree to two composite outcomes, potential thromboembolic events and intracranial hemorrhage, both defined by ICD-9-CM codes [62]. The risk differences for these outcomes can then be summed, potentially with a weight to reflect their relative importance, into what is typically called a "net clinical benefit" (NCB) outcome. There are

many variants of this approach, using different combinations of ischemic events and hemorrhagic events for the two composite outcomes, or some versions where both ischemic and hemorrhagic events are combined into a single composite endpoint [63–67]. An advantage of this approach is a more intuitive interpretation of the study outcomes compared to considering a large value tree. Using this approach, the weighting of two outcomes can be reduced to a single weight that is reflective of their relative clinical impact. This approach can also be implemented in nearly any clinical trial or observational dataset.

Disadvantages of using composite endpoints in this manner include that they are mixtures of disparate events that span the range of fatal or permanently disabling to transient with no sequelae. Comparing them without considering their components may fail to identify potentially important specific differences between treatments. Even with weights or patient preferences as described below, the comparison between outcomes with such a broad range of clinical impact can be difficult.

Assess Importance of Outcomes - Value Judgments and Patient Preferences

Step 5 of the BRAT framework (see Table 35.1) is to assess the relative importance of the outcomes. Consider an anticoagulant that reduces the chance of a cardiovascular death from 3% to 2% but increases the chance of a disabling hemorrhagic stroke from 1% to 5%. Is this B–R trade-off acceptable? The decision on whether the mortality benefit outweighs the hemorrhagic stroke depends not only on the changes in their chance of occurrence, but also on the importance one assigns to each event. These types of value judgments are a critical component of B–R.

Benefit–risk assessment is a combination of data-based probability assessment and value judgments [2–4,7,9,19,21,23]. Statistical analyses can provide the probability of different types of events prevented and caused, but they do not indicate how important those events are to decision makers [31]. In B–R, these value judgments are typically referred to as "weights" or "preferences." The preferences are most often for the different benefits and harms and other treatment characteristics, though they may also be assessed for treatments as a whole [68]. The measurement and application of preference is a growing field, with applications far beyond medical treatment B–R.

In many cases, these value judgments are based on clinical judgment. FDA and EMA B–R assessments reflect this approach [2,9]. For example, the FDA's anticoagulant B–R assessments described earlier use clinical judgment to partition events into two categories: events that are fatal or cause irreversible harm, and events that cause reversible harm [50,51]. This partitioning gives two effective "weights": clinically very impactful (very high weight) events and clinically much less impactful (much lower weight) events, and the B–R assessment is focused primarily on the very impactful events. Similarly, the EMA's guidance on review of drug applications (the rapporteur's day 80 critical assessment report) stresses the need to describe the value judgments used and notes that "a 'descriptive' approach with explicit considerations about the importance of the different effects and how trade-offs are weighed will generally be appropriate" [9].

Clinical judgment can be used to (i) rank endpoints in order of decreasing clinical impact, (ii) group them into categories such as the Common Terminology Criteria for Adverse Events (CTCAE) scale [69] or (iii) give rough decisions of what trade-offs are acceptable. These types of approaches are common not just in regulatory B–R, but in clinical practice. For example, physicians make similar judgment calls in determining which treatment might be best for an individual patient. Experts write treatment guidelines based on available scientific evidence,

clinical judgment, and, increasingly, patient preferences [70,71]. In a shared decision-making paradigm, physicians and patients discuss their B–R preferences for treatment, which may demonstrate that physicians and patients do not place the same weight on different outcomes [72,73].

While most B–R problems can be assessed with clinical judgment, there are many that are well served by formal, rigorous studies to assess how patients weigh benefits and harms [3,15,19,31,32,41]. Called "patient preference studies," these measure what attributes of a treatment are important to patients, the relative importance of these attributes, what trade-offs between them patients would accept, and the heterogeneity of these results among patients. Patient preference studies are taking on an increasing role in B–R and the literature in this discipline is growing [74–76]. Patient groups and pharmaceutical or medical device companies use them to incorporate the patient perspective into B–R. The FDA and the EMA are starting to consider preferences in decision making as complementary material along with efficacy and safety data. The Center for Devices and Radiological Health (CDRH) at the FDA has published a guidance document on the inclusion of patient preference information [4]. It has also conducted a patient preference study in surgical weight loss devices and approved a device in part based on results showing that a substantial proportion of the target population was willing to accept the risks associated with the device in exchange for the weight loss benefit [3]. In the FDA's recent approval of rituximab for the treatment of lymphoma and chronic leukemia, patient preference information assessed within the trial was included in a new Patient Experience section in the label [68]. The EMA has also piloted a preference study in patients with multiple myeloma [77], and both the FDA and EMA are conducting additional preference studies.

There are many different methodological approaches to elicit patient preferences, ranging from qualitative interviews through quantitative techniques, though in practice, a much smaller number is used in B–R assessment [16,19,29,30]. One of the most common quantitative methods is conjoint analysis, in which patients choose between sets of hypothetical treatments that have different combinations of benefit and harm attributes, and a regression analysis of the choices determines the relative importance of the attributes. Additional overviews of patient preference methods have been published [19,31,33,78].

There have been numerous preference studies for anticoagulants, in both patients and other stakeholders [75]. In general, atrial fibrillation patients are willing to accept certain bleeding risks for a decrease in the probability of experiencing a stroke. However, there is substantial variability in the threshold number of bleeds observed for the acceptance of an oral anticoagulant. Figure 35.2 shows the results of a preference survey for acute coronary syndrome [72]. The bars in the figure show the relative importance US patients place on death, different severities of stroke, myocardial infarction, different degrees of bleeding, and angina. US patients regarded nonfatal disabling stroke as equal in importance to death. The low height of the bars on the right indicates that patients are willing to accept considerable probability of bleeding, angina or even nonfatal heart attack in exchange for treatments that reduce the chance of death or disabling stroke. In a different preference study for atrial fibrillation, in exchange for reducing the chance of nonfatal disabling stroke by one percentage point, US patients would accept up to a 6.3% chance of nonmajor clinically relevant bleeding and up to a 2.0% chance of extracranial major bleeding [79].

In addition to population averages of preference as show in Figure 35.2, preference studies can measure heterogeneity in preferences. Some patients will be very tolerant of risks

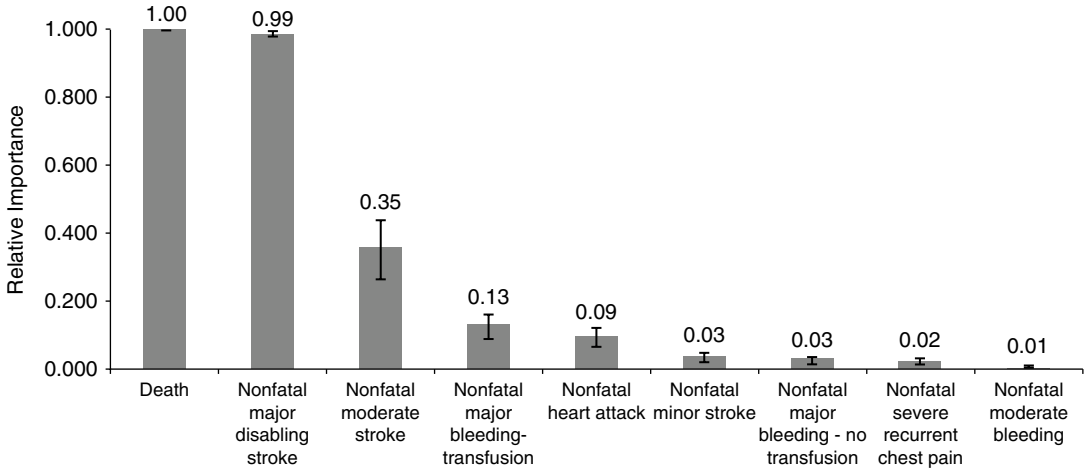

Figure 35.2 Relative importance to US patients of key treatment-related benefits and harms for acute coronary syndrome. The terminology for the benefit and harm attributes reflects the patient-friendly language used in the survey; for example, recurrent chest pain refers to angina. Bars show the relative importance of each attribute, with the most important attribute scaled to 1.0. *Source:* Yuan *et al*. [72]. Reproduced with permission of Taylor & Francis.

while others will be very risk averse. Preference studies can measure how widely patients' preferences vary and whether there are distinct subgroups of patients with important differences in preferences. While often referred to as patient preferences, the preferences of physicians, caregivers, and others can be ascertained and compared with these methods. For example, a preference study of patients and physicians was conducted in the US and Japan on the relative importance of benefits and harms of anticoagulant therapy using a conjoint analysis experiment. Japanese physicians and patients exhibited different preferences from each other, with physicians being less likely to tolerate the risk of bleeding in exchange for the reduction in the risk of stroke [79]. These results may in part explain lower prescribing rates of anticoagulants for atrial fibrillation patients in Japan compared with the US [80].

As popular as patient preference studies are becoming for B–R applications, there are many unanswered questions in terms of requirements in the design, conduct, and analysis of these studies for regulatory and health technology assessment purposes. We describe ongoing initiatives to address these questions at the end of the chapter.

Putting It All Together: Integrated B–R Assessment

Because synthesizing the evidence in a structured manner is often tightly linked with visualizing the data or analyses, we discuss integrated B–R assessment and communicating the assessment, Steps 6 and 7 of the BRAT B–R framework (see Table 35.1), together.

There are numerous approaches to combining data on medical need, outcome data, uncertainty, clinical judgment, preferences, heterogeneity, etc. into a B–R assessment [18,21,23,81–85]. Benefit–risk approaches are often categorized as qualitative, semiquantitative or quantitative. Qualitative approaches use textual descriptive summaries to make a B–R argument. They are most applicable when the assessment is self-evident from the data, such as statistically significant benefit and no appreciable AEs. Semiquantitative approaches use a combination of

tabular and graphical displays, potentially coupled with preference or weight information. Most B–R in regulatory and practical applications is descriptive or semiquantitative, and we focus on these approaches here [2,7,9]. Quantitative approaches compute summary metrics by combining the data and potentially preferences from multiple outcomes. We touch upon quantitative methods here but address them more fully in the Future section.

An increasingly common means to display B–R data is an effects table [9,81] which summarizes information on all key benefits and harms (Table 35.2). In most versions, there is one row for each benefit or harm. The columns vary but may include the outcome name, a brief outcome definition and units, the outcome value for each treatment, estimates of between treatment differences (e.g., risk difference) with associated uncertainty (e.g., 95% confidence intervals), brief notes on strength of evidence and a link to data sources. While relative measures such as relative risk, odds ratio or hazards ratio can also be included, these measures are generally less useful for B–R. Because the baseline rates for outcomes may be disparate, a large relative risk may correspond to a very small absolute difference in the number of events when the baseline rate is low, while small relative risks may correspond to large absolute differences when the baseline rate is high.

Table 35.2 shows an effects table for the atrial fibrillation value tree in Figure 35.1B. The data are simulated but realistic, and the term "study drug" is a proxy for any medical intervention. All outcomes in the example presented are in person-year rates, though effects tables in general can include any type of risk or rate calculation and can

Table 35.2 Effects table for atrial fibrillation (simulated data). All outcomes are measured per 10 000 person-years.

Outcome	Event rate (/10 000 person-years)		Rate difference /10 000 person-years (95% CI)	NNT or NNH
	Study drug	Comparator		
Efficacy				
Ischemic death, ischemic stroke, MI or systemic embolism	430	512	−87 (−143, −30)	−115
Ischemic death	189	221	−34 (−72, 3)	−294
Nonfatal ischemic stroke	154	172	−19 (−51, 13)	−526
Nonfatal myocardial infarction	83	100	−17 (−43,8)	−588
Nonfatal systemic embolism	4	20	−16 (−26, −7)	−625
Safety				
Major bleeding	398	345	49 (0, 99)	204
Fatal and critical organ bleeding	119	125	−6 (−33, 20)	−1667
Fatal bleeding	37	38	−1 (−15, 13)	−10000
Nonfatal critical site bleeding	82	87	−5 (−31, 21)	−2000
Transfusions > =2 units or Hbg drop > − 2 g/dL	308	245	60 (17,103)	167
Clinically relevant nonmajor bleeding	1192	1137	44 (−50. 138)	227

CI, confidence interval; MI, myocardial infarction; NNT, number needed to treat; NNH, number needed to harm. Positive NNTs or NNHs indicate more events on the study drug. Negative NNTs or NNHs indicate more events on the comparator.

show categorical or continuous outcomes. Because the incidence rate of most outcomes is low, the data are scaled to a hypothetical population (10 000 person-years) to simplify representation and comprehension of these data [86]. The rate differences represent the additional number of events caused or prevented by using one treatment compared to another treatment after 10 000 person-years exposure. With many outcomes considered in B–R, we generally show the 95% confidence interval (CI) as a measure of uncertainty but not for statistical hypothesis testing, with the exception of those endpoints for which a study was powered. Number need to treat (NNT) and number need to harm (NNH) are also included in the table. NNT is the number of person-years exposure with a treatment versus comparator to prevent one additional harmful event. NNH is the number of person-years exposure with a treatment versus comparator to cause one additional harmful event. NNT and NNH are calculated as the reciprocal of the corresponding rate differences [87,88].

Focusing first on events that are fatal or cause irreversible harm, per 10 000 person-years, there are 87 (95% CI 30, 143) fewer events per 10 000 person-years in the efficacy composite of ischemic death, ischemic stroke, MI or systemic embolism, and there are six (95% CI -20, 33) fewer fatal and critical organ bleeding events on the study drug. Note that the sign of the rate difference and confidence interval of the safety outcome is reversed when referring to fewer events on the study drug. The composite efficacy outcome is statistically significant favoring the study drug, while the fatal and critical organ bleeding shows no meaningful difference, suggesting benefits outweigh harms.

When considering the full set of outcomes, a forest plot of the rate differences in Table 35.2 is very helpful, particularly when communicating a B–R assessment (Figure 35.3). At a glance, the plot makes clear that death, ischemic stroke, myocardial infarction, and non-CNS systemic embolism each contribute meaningfully to efficacy. Major bleeding favors the comparator, but the forest plot makes it clear that this difference is driven primarily by less impactful bleeds. There is no difference in fatal and critical organ bleeding, while the comparator is superior in the less impactful transfusions, hemoglobin reductions as well as nonmajor clinically relevant bleeding (see Figure 35.3). The trade-off is preventing 87 (95% CI 30, 143) fatal/irreversible harm ischemic events versus causing 60 (95% CI 17, 108) reversible bleeding events, both per 10 000 person-years. Without taking patient preferences into account, in this simulated example, the benefits appear to outweigh the harms.

This B–R analysis can also be performed with NNT and NNH. Comparing the broadest efficacy and safety outcomes, one harmful ischemic event is prevented for every 115 person-years of exposure to the study drug versus comparator (NNT), while 204 person-years exposure is needed to see an excess major bleeding event (NNH) on study drug. That is, less study drug exposure is needed to achieve a beneficial effect than a harmful effect. Additionally, each beneficial event is far more clinically impactful than each harmful event, since there were few fatal bleeds or critical organ bleeds. Taken together, these points strongly suggest benefit exceeds harm. Additionally, the NNH for fatal and critical organ bleeding is -1667. The large absolute value indicates that the between-treatment difference is small. The negative value indicates that the difference favors the study drug despite the bleeding being classified as a harm. In this case, these three outcomes are sufficient to assess B–R. However, when considering many outcomes at once, NNT and NNH are less helpful. The techniques for comparing many NNTs and NNHs simultaneously are mathematically complex and require weights or preferences for each outcome [84,89]. Additionally, confidence intervals for NNT and NNH can be difficult to interpret when

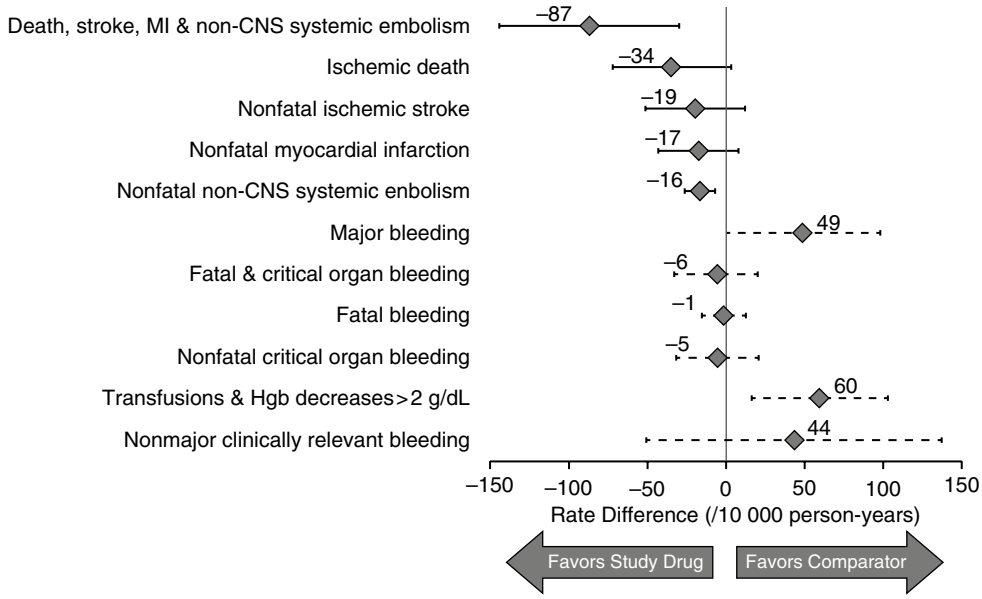

Figure 35.3 Forest plot showing rate differences per 10 000 person-years for key benefits and harms in atrial fibrillation treatment (simulated data). Diamonds are points estimates. Bars show 95% confidence intervals. Efficacy outcomes are shown as solid lines. Safety outcomes are shown as dashed lines. CNS, central nervous system; Hgb, hemoglobin; MI, myocardial infarction.

outcomes are not statistically significant [87,90,91]. For these reasons, NNT and NNH have limited application in B–R assessment.

Weighting and the Patient Perspective

The integrated B–R approaches reviewed above used clinical judgment to make a defensible B–R decision. The example in Table 35.2 and Figure 35.3 lends itself to such approaches. However, when the B–R trade-off is more complex, such as when some key outcomes favor the study drug and other key outcomes favor the comparator, weighting and preference assessments can be critical, both to incorporate the patient perspective and to make a B–R assessment.

There are numerous approaches by which the weighting or patient preferences can be incorporated into B–R. Figure 35.4 shows a forest plot with outcomes placed in order of decreasing clinical impact for patients, where clinical impact is based on standard gamble and time trade-off utilities (a type of weight) obtained from the Tufts Cost-Effectiveness Analysis Registry. In this approach, composite outcomes are not included when their components are displayed. The most severe outcomes all favor the study drug, while the least severe favor the comparator. Again, these data suggest that the benefits outweigh harms. An advantage of using the rank rather than actual weight or preference values for outcomes is that there is less opportunity for disagreement among decision makers about the values of the weights or their exact order. For example, in Figure 35.4, the five outcomes associated with the most severe clinical impact all favor the study drug. The B–R assessment is the same regardless of the ranking within the most severe outcomes.

Another class of approaches that incorporate weights or the patient perspective in B–R are

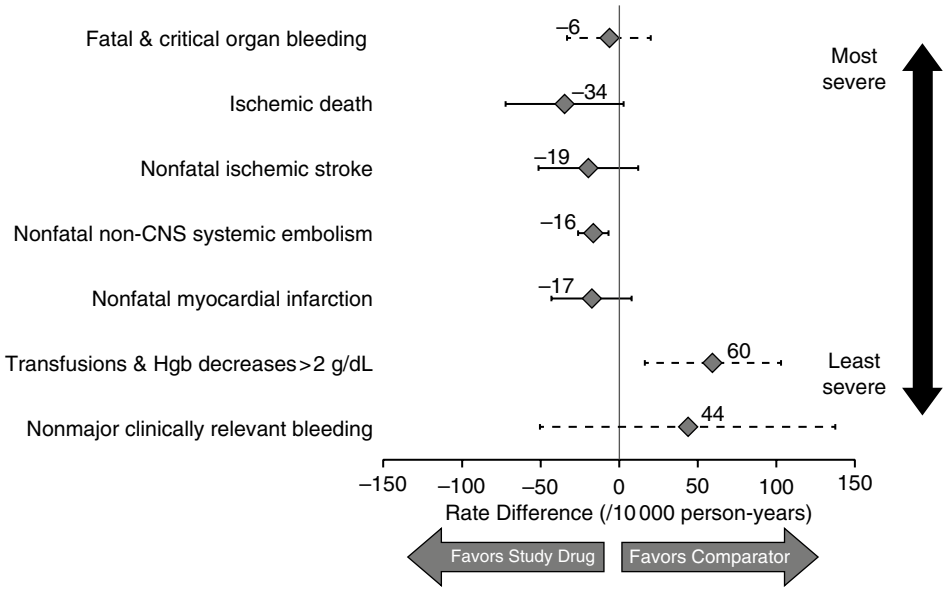

Figure 35.4 Forest plot for key benefits and harms in atrial fibrillation treatment ranked in order of decreasing clinical impact as measured by utility. Diamonds are points estimates. Bars show 95% confidence intervals. Efficacy outcomes are shown as solid lines. Safety outcomes are shown as dashed lines. CNS, central nervous system; Hbg, hemoglobin.

net clinical benefit (NCB) measures. While the terminology is not standard, we define NCB approaches as those that use a weighted sum of risk (or rate) differences between study drug and comparator to summarize the difference between treatments:

$$NCB = \sum_{i=1}^{N} w_i \times RD_i$$

where N is the number of outcomes, w_i is the weight associated with outcome *i*, and *RDi* is the between-treatment rate difference or risk difference for outcome *i*. Weights can be obtained from clinical judgment, clinical sequelae or any of the wide variety of patient or physician preference studies described above. Typically, beneficial events have positive weights and harmful events have negative weights. The larger the absolute value of the weight or the larger the risk difference for an outcome, the more that outcome contributes to NCB.

As a simple example, the NCB approach described above for atrial fibrillation uses two composite outcomes: potential thromboembolic events and intracranial hemorrhage [62]. In this case, net clinical benefit is defined as:

$$NCB = w_{TE} \times RD_{TE} + w_{ICH} \times RD_{ICH}$$

where RD_{TE} and w_{TE} are the risk difference and weights for thromboembolism, and RD_{ICH} and w_{ICH} are the risk difference and weight for intracranial hemorrhage. Risk difference here is defined as the probability of events on study drug minus that on comparator. Weights of 1.0 for potential thromboembolic events and 1.5 for intracranial hemorrhage were based on mortality and disability data from a large observational atrial fibrillation study [92], indicating that the clinical impact of a typical ICH is weighted 1.5 times that of a typical thromboembolic event. Since $w_{TE} = 1$, a unit change in NCB is equivalent to a unit change in the probability of thromboembolism. Hence,

this net clinical benefit is also in units of thromboembolic events. For example, if $RD_{TE} = -80$ (95% CI −85, −75) per 10000 patient-years and $RD_{ICH} = 30$ (95% CI 25, 35) per 10000 patient-years, the study drug is better than the comparator on thromboembolic events and worse on ICH events. Net clinical benefit is $-80 + 1.5 \times 30 = -35$ (95% CI −49, −21) thromboembolic event equivalents per 10000 patient-years. Thus, the difference between treatments is the equivalent of 35 fewer thromboembolic events per 10000 patient-years, favoring the study drug.

There are many other ways in which a net clinical benefit measure can be defined. For example, an NCB measure can be based on a weighted sum of the seven outcomes' rate differences from Figure 35.4, with weights obtained from the utility scores used to sort the outcomes in the figure or from a preference study such as in Figure 35.2. Sensitivity analyses can be conducted on NCB measures, where distributions for the weights are propagated into uncertainty in the NCB result. The distribution of NCB, whether the uncertainty is based on clinical data uncertainty, weight uncertainty or both, can give more complex metrics such as the probability that benefit exceeds risk (example in appendix 3 of [93]).

A more general approach to B–R assessment is multicriteria decision analysis (MCDA) [40–42,94]. MCDA is a general and flexible quantitative approach to decision making that can accommodate not just the dichotomous outcomes described earlier for NCB but any type of input, including continuous outcomes, categorical outcomes, and properties that may need specialized scales such as ease of use and drug–drug interactions. This flexibility comes at the cost of greater complexity, and MCDAs are generally reserved for more complex B–R problems.

Multicriteria decision analysis models have been applied to many B–R problems, including atrial fibrillation [95–98]. The EMA has started considering their use for complex B–R problems [41,77]. Figure 35.5 shows the results of an MCDA model for natalizumab, a treatment for multiple sclerosis [97]. Despite the very high weight (left column in Figure 35.5) given the treatment-related adverse event of progressive multifocal leukoencephalopathy (PML), the very small difference in between-treatment rates (middle column) causes PML to have negligible impact on the B–R analysis (right column). In contrast, despite its much smaller weight, relapse's large between-treatment difference causes it to be the main driver of the B–R balance. In this manner, MCDA models can help show the relative contributions of rates and weights for many outcomes. As for NCB approaches, MCDA models can also be extended with distributions for both weights on clinical inputs, often called stochastic multicriteria acceptability analysis, providing probabilistic assessments and sensitivity analyses for B–R results [99,100].

Preference studies can also be used to address the questions raised at the outset of this chapter – what probability of harm is acceptable in exchange for a given degree of benefit? A preference study can provide the maximum acceptable risk, that is, the maximum probability or level of severity of a harm that a patient will accept in exchange for a given benefit. Similarly, preference studies can provide the minimum acceptable benefit, that is, the minimum benefit that a patient will require in exchange for a given probability or severity of a harm. For example, on average, patients with mild cognitive impairment are willing to accept up to about a 5% chance of death or disabling stroke in exchange for reducing moderate dementia symptoms to mild symptoms for one year [101]. In atrial fibrillation, in exchange for reducing the chance of nonfatal disabling stroke by one percentage point, US patients on average would accept over a 6.0% chance of nonmajor clinically relevant bleeding and up to about a 2.0% chance of extracranial major bleeding [79].

Patient preferences are heterogeneous – different patients would accept different tradeoffs in exchange for the same benefit [4].

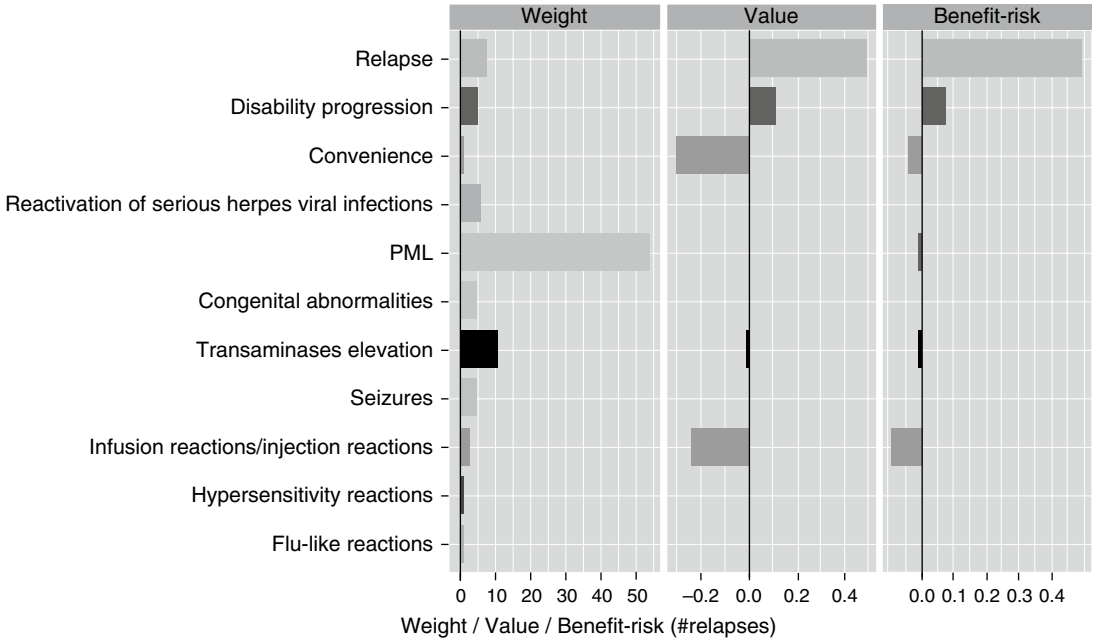

Figure 35.5 Output of multicriteria decision analysis (MCDA) model for natalizumab versus placebo. Weights (*left column*) reflect the relative importance of each outcome, value (*middle column*) reflects the risk difference between natalizumab and placebo on a normalized scale, and benefit–risk (*right column*) is the product of weight and value, reflecting the contribution of each outcome to the overall B–R assessment [97]. PML, progressive multifocal leukoencephalopathy.

Preference studies can measure this heterogeneity and identify subgroups of patients with different preferences. The balance of benefits and harms will differ in these subgroups, and preference studies can be used to assess the proportion of patients that would choose to use a given treatment – an assessment that was in part the basis for approval of a medical device to treat obesity [3]. Finally, preference studies can be used to understand the different perspective on acceptable B–R trade-offs in different stakeholder groups. For example, a preference study in patients with schizophrenia and psychiatrists who treat such patients showed that patients regarded improving the positive symptoms of schizophrenia as the most important benefit to a far greater degree than did their psychiatrists [102].

This section has covered the more common approaches to integrated B–R assessment. There are many ongoing initiatives advancing these methodologies and developing policy for their use in regulatory and other applications. An important role for these initiatives is addressing limitations in these methods. For example, there is a growing set of approaches for B–R that account for dependency between benefits and harms, consider competing risks, and combine patient-reported outcomes and patient preference studies. There are also numerous other approaches to communicating B–R [2,81,103,104]. In the final section, we address the ongoing initiatives to improve methodology and policy as well as some of the newer approaches for B–R.

The Future

Maturation of the Field: Initiatives, Guidances, and Partnerships

The many advances in structured approaches to B–R assessment and patient preference studies have also opened many lines of inquiry on methodology and policy. There are numerous ongoing research groups and public–private partnerships seeking to address these open questions.

As described at the start of the chapter, both the FDA and EMA have implemented a structured approach to communicating their B–R assessment. By 2020, the FDA is expected to publish guidance on B–R assessment for new drugs and biologics, focusing on its B–R framework [5,28]. Additional FDA guidance will focus on systematic approaches to collecting and utilizing patient and caregiver input for regulatory decision making, including patient preference studies [5,105,106]. Along with the updated approach to B–R in the ICH Clinical Overview template, this guidance will provide a foundation for FDA expectations in B–R assessment and reporting.

Public–private partnerships have an important role in aligning industry, regulatory agencies, patient groups, and academia on methodology and policy. The Innovative Medicines Initiative (IMI), Europe's largest public–private partnership, conducted IMI PROTECT, a large project that developed recommendations for B–R methodology and communication [16,81,97,103]. The Medical Device Innovation Consortium (MDIC) developed a framework on the assessment and use of patient preference studies in medical device development and regulatory review [19]. This framework is one of the key background documents supporting the FDA's guidance on patient preference studies [4]. The IMI is currently funding the IMI PREFER project that continues the MDIC work and will generate expert and evidence-based recommendations for industry, regulators, and health technology assessment groups on the assessment and use of patient preference studies for decisions in the medical treatment life cycle [15]. The Quantitative Sciences in the Pharmaceutical Industry (QSPI) Benefit–Risk Working Group has developed several novel statistical approaches to B–R [107]. These are just some of the key recent or ongoing initiatives.

Academic organizations such as the International Society for Pharmacoeconomics and Outcomes Research (ISPOR), the Society for Medical Decision Making (SMDM), and the International Academy of Health Preference Research (IAHPR) continue to develop standards for B–R decision making and the proper conduct and use of patient preference studies.

Finally, more and more patient advocacy groups are taking on a role in B–R. For example, Parent Project Muscular Dystrophy collaborated with a scientist from Johns Hopkins University to conduct preference studies in muscular dystrophy and developed a monograph on B–R in rare diseases [108]. Other patient groups in Parkinson disease, diabetes, lung cancer or other disease areas are doing similar work. These groups are potential collaborators for academic, industry or regulatory patient preference and B–R work.

Advanced Methods on the Horizon

Benefit–risk assessment is an evolving field that is critical to optimal medical and public health decision making. In the future, there will be increasing demand for and reporting of B–R assessment. Assessment will become increasingly more structured, systematic, and quantitative as methodologies improve and become widely accepted. Areas of emphasis will include (i) the refinement of B–R assessment tools and application techniques, (ii) development of methodologies with greater pragmatism and applicability to clinical practice, and (iii) transitioning B–R assessment from a *post hoc* exercise to one that has a prespecified methodology or, potentially, a testable hypothesis.

The evolution of improved means to communicate B–R must continue to progress. Greater emphasis will be placed on risk difference summaries rather than relative risks or hazard ratios for greater interpretability. For example, risk differences as measured by differences in Kaplan–Meier estimates are more appropriate B–R assessment summaries than hazard ratios obtained from proportional hazards regression [109,110]. Graphical summary displays will be used with greater frequency to more effectively communicate complex and multidimensional effects of treatments [103,104]. And B–R frameworks will provide the succinct textual summary that accompanies these displays.

Despite being the gold standard for evaluating the safety and effectiveness of treatments, clinical trials may have shortcomings in informing medical decision making [111]. A key goal of B–R assessment is to contrast the benefits and harms of therapeutic alternatives as they are experienced by patients to help inform medical decision making. However, typical summaries of the study data for B–R assessment treat benefits and harms independently, then compare outcomes using either clinical judgment or integrating them using NCB or MCDA types of approaches. B–R assessment based on combining the separate marginal effects of each outcome in this fashion has limitations, as it fails to (i) account for any associations between outcomes (e.g., patients who benefit from the treatment may not experience any treatment-related harms, while those who do not benefit may experience the harms), (ii) systematically incorporate the relative importance of combinations of outcomes (e.g., the weight associated with a rash and pain experienced simultaneously may not be the same as the sum of the weights for rash and pain independently), or (iii) effectively deal with competing risks (e.g., trials that censor patients once they experience certain adverse events may not track subsequent benefits or harms that patient may experience).

As an example, suppose 100 patients are treated with a new treatment versus placebo, and one efficacy outcome and one safety outcome are measured and considered of equal importance (weight). Further suppose the efficacy and adverse event rates for the new treatment are both 50%, while the rates for both are zero for placebo. If the 50 patients who experience a treatment benefit (i.e., the efficacy event) are the same patients who experienced harm (i.e., the safety event), then the net clinical benefit is zero for all patients and the drug is worthless (Figure 35.6A). However, if the 50 patients with benefit are different from the patients who experienced the harm, then the net clinical benefit is positive for half the patients and negative for half the patients; that is, it is a good drug for half of the patients and a bad drug for the other half (Figure 35.6B), with the accompanying challenge of being able to predict which individuals fall into each category. Marginal summaries on the benefit and harm separately cannot distinguish these two scenarios, emphasizing the information

(A)

	Benefit	No Benefit
Harm	50%	…
No Harm	…	50%

(B)

	Benefit	No Benefit
Harm	…	50%
No Harm	50%	…

Figure 35.6 Demonstration of the impact of dependencies between outcomes. Both tables show risk differences for one benefit and one risk. The benefit and harm are assumed to be equally weighted. Part A shows the case where the treatment benefits no one (NCB=0 for all patients); Part B shows the case where the treatment benefits half of patients (NCB >0 for 50 patients and NCB <0 for 50 patients). However, the marginal distributions of benefit and harm of the two tables are identical.

lost by considering the outcomes independently. Furthermore, in most clinical trials, efficacy and safety are typically evaluated in different analysis populations, challenging the ability to generalize results when aggregating them. New methodologies for B–R assessment that have greater practicality in translating to clinical practice are needed. There are several on the horizon.

Earlier approaches to account for benefits and harms within a patient included a graphical representation of B–R over time. The status of a patient at any time during the trial is depicted using one of five health states: benefit without AE, benefit with AE, neither benefit nor AE, AE with no benefit, and withdrawal [112]. Using a different color for each health state, each patient's B–R pattern is represented using colored bars. By stacking all patient B–R data over time, sorting by different health states and comparing the pattern for a treatment and comparator, the B–R for the sample overall could be ascertained by visual inspection. This approach allows for dependency between two outcomes – sufficient for the example in Figure 35.6 but not for much more complex problems. As acknowledged by the authors, this graphical representation of B–R over time offers a relatively limited view of the data but it can contribute to B–R assessment. A Bayesian approach to longitudinal B–R assessment based on this representation allows for several net clinical benefit types of B–R endpoints [113]. The primary advantage of the Bayesian approach for longitudinal data is its ability to borrow information from prior assessments and recursively update posterior estimates of B–R measures. This approach can also be extended to any number of endpoints. Other Bayesian approaches to B–R are reviewed in Costa *et al.* [114].

The Desirability of Outcome Ranking (DOOR) is an evolving novel approach to B–R assessment that also accounts for benefits and harms within an individual patient. It is pragmatic from the perspective of informing medical decision making [115] and addresses the limitations described above. Conceptually, DOOR uses outcomes to analyze the patients rather than the patients to analyze the outcomes. A key to utilizing DOOR is to determine how to analyze one patient before analyzing many. For example, consider the cardiovascular example discussed earlier where outcomes included mortality, stroke (disabling and nondisabling), MI, and bleeding events. Traditional B–R assessment in cardiovascular trials often use time-to-first-event analyses without incorporating the cumulative nature of multiple events, the association between events, the competing risk of death or the weight of multiple events in a patient. DOOR can address these issues. Consider the experience of each study participant in terms of the events that they may experience. Suppose that mortality is considered the worst outcome and disabling stroke is considered the next worst outcome. Nondisabling strokes, MIs, and bleeds are harmful events but are generally somewhat transient and thus may have similar importance to each other but less than that of a disabling stroke. More of any of these events is worse than fewer events. Zero events is the best-case scenario. Thus, DOOR for this setting may classify global patient outcomes into one of, for example. five mutually exclusive categories from most desirable to least (Table 35.3). The distribution of DOOR between competing treatment options can be compared.

Two distinct analyses of DOOR can be conducted. One approach consists of conducting all possible pairwise comparisons of patients between treatments. One can then estimate the DOOR probability, the probability that a randomly selected patient randomized to one treatment has a better DOOR than a randomly selected patient on the other treatment. This may have an intuitive appeal from a clinical perspective given the connection to a common and important question that arises during clinical practice decision making: what is the probability that a patient will have a better overall

Table 35.3 Example desirability of outcome rankings (DOORs) for an anticoagulant study.

Rank	Outcome
1	Survived with no events
2	Survived with one nondisabling stroke, myocardial infarction (MI) or bleed
3	Survived with more than one nondisabling stroke, MI or bleed
4	Survived with disabling stroke
5	Death

response on one treatment relative to another? The win ratio, the relative frequency with which a randomly selected patient randomized to one treatment has a more desirable versus less desirable DOOR compared to the other treatment, can also be estimated. In the second type of analysis, "partial credit" levels of the ordinal outcome are scored similar to an academic test [116]. The most desirable outcome (survived with no events) is scored as 100 and the least desirable (death) is scored as 0. Middle categories are given partial credit. The amount of partial credit may be obtained through patient preference studies or a survey of expert clinicians. Sensitivity analyses to varying partial credit scoring permits personalized analyses. These analyses were used to compare colistin with ceftazidime-avibactam in the treatment of infections due to carbapenem-resistant enterobacteriaceae [117].

The bond between B–R assessment and precision medicine will also continue to grow (see Chapter 30) and better connect with shared decision making. After all, the goal in practice is not to identify who will benefit or who will be harmed but who has a positive B–R profile. Benefit–risk assessment should include sensitivity analyses to investigate and illustrate how the B–R profile varies across patient subgroups defined by demographics, genetics or baseline disease status, and a variant of DOOR called DOOR subgroup treatment effect pattern plot (DOOR STEPP) displays the distribution of DOOR as a function of baseline patient characteristics [118].

Incorporation of patient preferences and values will be necessary for increasingly quantitative and systematic evaluation. Preference studies tied to specific trials and disease areas will become more prevalent. Sensitivity analyses to patient preferences should become far more common, assessing the robustness of the results for regulatory assessment and to allow for personalized assessment and decision making in practice.

As the science and practice improve, B–R assessment may begin transitioning from a *post hoc* exploratory nonsystematic evaluation to one that is prespecified, systematic, and a primary focus. For example, some studies have incorporated prespecified systematic formal B–R outcomes and analyses into clinical trial protocols. This can be challenging in trials developing novel treatments due to the potential emergence of previously unknown adverse events. However, this has been addressed in some instances by focusing on how patients feel, function, and survive in a general sense rather than a focused evaluation of specific adverse events. Patient preference substudies and the collection of quality-of-life information will be included more frequently in clinical trials rather than being separate and distinct evaluations. When formal B–R hypotheses cannot be prespecified, the planned methodology for assessing B–R can be prespecified, such as the use of risk differences rather than hazard ratios, the use of outcomes that avoid double-counting, and the use of an NCB or DOOR approach once the key benefits and harms are known after unblinding study results.

Benefit–risk assessment is also critical for the evaluation and comparison of diagnostic tests. Different diagnostic errors carry different

clinical consequences which should be carefully evaluated and incorporated into B–R evaluation of diagnostic application. To address this, Benefit-Risk Evaluation of Diagnostics: A Framework (BED-FRAME) was proposed as a strategy for pragmatic B–R evaluation of diagnostics using weighted accuracy and plots of diagnostic yield [82,119]. The average weighted accuracy (AWA), a composite B–R summary measure, is being used as the primary measure in a clinical performance study evaluating the utility of a host response-based diagnostic test categorizing acute respiratory tract illness into bacterial, viral, or neither etiology [120].

Conclusion

Assessing the B–R balance of medical treatments has always been an integral part of drug development, regulatory, and public health decisions. Methodology for B–R has advanced considerably, and health authorities worldwide have developed much more rigorous B–R regulatory policies relating to regulatory approval and post-approval decisions. These advances have led to transparent and rigorous systematic approaches to B–R which incorporate the patient perspective and can be communicated clearly and succinctly to clinical and patient audiences.

The Use of Metaanalysis in Pharmacoepidemiology

Jesse A. Berlin[1], Brenda J. Crowe[2], H. Amy Xia[3], and Stephen J.W. Evans[4]

Definitions and Rationale

Metaanalysis has been defined as "the statistical analysis of a collection of analytic results for the purpose of integrating the findings" [1]. Other definitions have included qualitative, as well as quantitative, analyses [2]. Metaanalysis is used to identify sources of variation among study findings and, when appropriate, to provide an overall measure of effect as a summary of those findings [3]. A systematic review has been defined by the Cochrane Group (https://consumers.cochrane.org/what-systematic-review) as a review that "summarizes the results of available carefully designed healthcare studies (controlled trials) and provides a high level of evidence on the effectiveness of healthcare interventions." This definition illustrates two features related to the Cochrane Collaboration; firstly, their emphasis on randomized trials and secondly, their emphasis on effectiveness. All good science seeks to take into account all the evidence related to a question of interest, and pharmacoepidemiology seeks to be a good science. There are two main processes involved in taking into account all evidence: identifying all the evidence, and providing a useful summary. This chapter concentrates on summarizing the evidence using statistical methods but the need to search the literature is usually also important. The term "metaanalysis" may be used synonymously with "systematic review" but here we employ the definition used in the report of the Council for International Organizations of Medical Sciences (CIOMS) Working Group X [4]:

> The statistical combination of quantitative evidence from two or more studies to address common research questions, where the analytical methods appropriately take into account that the data are derived from multiple individual studies.

Metaanalysis in medicine has been developed mainly for combination of data from randomized trials, but this chapter also includes evidence from observational studies. Metaanalyses themselves could be regarded as observational studies and should perhaps be simply seen as a technique for combining evidence rather than as possessing particular merit as studies in themselves. The *Journal of the American Medical Association*, in a statement by the Editors, goes

Pharmacoepidemiology, Sixth Edition. Edited by Brian L. Strom, Stephen E. Kimmel and Sean Hennessy.

even further: "JAMA considers meta-analysis to represent an observational design, such that outcomes, inferences, and interpretations should be described as associations rather than reported using causal terms such as 'size of effect' …" [5].

While epidemiologists have been cautious about adopting metaanalysis, because of the inherent biases in the component studies and the great diversity in study designs and populations [6–8], the need to make the most efficient and intelligent use of existing data prior to (or instead of) embarking on a large, primary data collection effort has dictated a progressively more accepting approach [8–13]. Metaanalysis of randomized clinical trials has found such wide acceptance that the Cochrane Collaboration has been built around the performance and updating of systematic reviews and metaanalyses of trials [14]. Cochrane reviews are maintained in a publicly available electronic library. More information is available on the Cochrane website (www.cochrane.org). A similar structure has developed in the social sciences, in the form of the Campbell Collaboration [15].

As the Cochrane Collaboration has increasingly looked at harms as well as benefits of health interventions, it has been realized that observational studies may make an important contribution, and that overall they are not as biased as some think [16]. The Cochrane Adverse Effects Method Group (AEMG) is focused on systematic reviews related to adverse effects (https://methods.cochrane.org/adverseeffects/about-caemg) [17] and this group notes that observational data are needed in some circumstances. The current version of the Cochrane Handbook [18] has chapters on "Including nonrandomized studies" and "Adverse effects." In the introduction on nonrandomized studies, they are now quite explicit:

> For some Cochrane reviews, the question of interest cannot be answered by randomized trials, and review authors may be justified in including non-randomized studies.

Several activities may be included under the above definition of metaanalysis. Perhaps the most popular conception of metaanalysis, for most clinically oriented researchers, is the summary of a group of randomized clinical trials dealing with a particular therapy for a particular disease. An example of this approach would be a metaanalysis that examined the effects of antiplatelet therapy in high-risk patients [19]. Typically, this type of metaanalysis would present an overall measure of the efficacy of treatment, such as a summary odds ratio. Summary measures may be presented for different subsets of trials involving specific types of patients, such as studies restricted to those with a previous myocardial infarction. More sophisticated metaanalyses also examine the variability of results among trials and, when results have been conflicting, attempt to uncover the sources of the disagreements [20].

In many instances, major collaborations have been set up to reanalyze the data at an individual level rather than just relying on published summary data. This "individual-patient-data" (IPD) approach is useful with both randomized and nonrandomized studies.

Metaanalyses of nonexperimental epidemiologic studies have also been performed [21–24], and articles have been written describing the methodologic considerations specific to those metaanalyses [25–31]. In general, both the metaanalyses of nonexperimental studies and the associated methodologic articles tend to focus more on the exploration of reasons for disagreement among the results of prior studies, including the possibility of bias. Given the greater diversity of designs and heterogeneity of patients included in nonexperimental studies, it is logical to find more disagreement among nonexperimental studies than among randomized trials.

Metaanalysis of randomized trials frequently has increased precision as the main motivation, especially in the context of safety of medicines where outcomes are rare. The sample sizes in

the original trials are often far too small to provide convincing evidence of the presence or absence of harms. This is not the same motivation in observational studies in general. They will have been undertaken with, usually, dramatically larger sample sizes so the issue of precision of estimation is often not at the forefront. The consequence is that the problems of uncontrolled bias can have a very much larger impact than the size of effect being studied. Sampling variation, in contrast to randomized trials, is not the main problem. Consequently, the danger is that such studies will have minimal sampling uncertainty but unknown bias.

This chapter summarizes many of the major conceptual and methodologic issues surrounding metaanalysis, especially for observational studies, and offers the views of the authors about possible avenues for future research in this field.

Clinical Problems to be Addressed by Pharmacoepidemiologic Research

There are a number of reasons why a pharmacoepidemiologist might be interested in conducting a metaanalysis. If randomized data are available, although each study allows for comparisons relatively free from the confounding and bias of nonexperimental studies, individual studies will often have insufficient power to detect as significant uncommon adverse outcomes of therapies that nevertheless can make a notable alteration in the risk/benefit balance. In addition, the exploration of reasons for inconsistencies of results across previous studies, the exploration of subgroups of patients in whom therapy may be more or less effective, and understanding whether risk factors affect the magnitude of treatment differences are all valid topics for study. The combination of studies involved in the approval process for new therapies or in the investigation of new indications for existing therapies, particularly when the outcomes being studied are uncommon, is another area where metaanalysis can be useful.

With the investigation of adverse events using nonexperimental studies, a major challenge involves obtaining information on these events that is unconfounded by indication (see Chapter 37). These adverse events often occur only rarely and will not have standardized assessment or validation, which makes their evaluation still more difficult. The results of nonexperimental studies of whether such events are associated with a particular drug may be conflicting, leaving a confusing picture for practicing clinicians and policy makers to interpret. Metaanalysis, by combining results from many *randomized* studies, may be better than relying on nonexperimental studies with their potential confounding and bias. When reports of several investigations of a specific suspected adverse drug reaction disagree, whether randomized or nonexperimental in design, metaanalysis can also be used to help explain these disagreements. These disagreements among studies may arise from differences in the choice of endpoints, the exact definition of exposure, the eligibility criteria for study subjects, the methods of obtaining information, differences in protocols, different methods to analyze the results or a host of other reasons possibly related to the susceptibility of the constituent studies to bias.

While it is not possible to produce a definitive answer to every research question, the exploration of the reasons for heterogeneity among study results may at least provide valuable guidance concerning the design of future studies. For example, separating those studies that had the possibility of recall bias in relation to drug exposure from those that did not, when examining associations of antihypertensive drugs used in mothers and congenital anomalies in their offspring [32], showed that cardiovascular anomalies were associated with drugs in studies

possibly subject to recall bias but not in those studies with ascertainment of exposure prior to birth.

Historically in drug development, it has been common practice to look at safety data from individual trials in isolation as they are completed. Subsequently, just prior to submission of a new product application, data from multiple studies are summarized in an "Integrated Summary of Safety" or "Summary of Clinical Safety" report. A possible consequence of these practices is that the opportunity to respond earlier to the evolving safety and tolerability profile (by collecting additional data or adjusting the sample size of pivotal studies, for example) may be missed. The result might be a gap (that might have been avoided) in the knowledge of the safety profile at the time of submission, and this may generate further questions by regulatory agencies or prompt the need for additional postmarketing commitments. In addition, the practice of simply using "crude pooling" can be misleading. This is the simple adding up across all studies of the numbers of patients with an event in the treatment group and the total number of patients receiving that treatment, and doing the same for the control group to produce a single 2 × 2 table which is then analyzed ignoring the fact that the data came from different trials (studies). This is often biased, unless the ratio of patients receiving the new drug to that receiving the comparator is approximately the same across all studies included in the integrated analysis, or the incidence of the event is nearly the same across all studies in the comparator group [33].

In cases where the individual studies require methods that take time into account (such as studies where the follow-up/exposure time among the treatment groups is substantially different), methods that take time into account are necessary. There may also be differences in length of follow-up across studies (independent of any differences in follow-up within studies). For a more in-depth discussion of issues related to follow-up time, we recommend Section 3.4 in the CIOMS X report [4].

Industry and regulatory agencies are placing increasing emphasis on identifying safety signals for new compounds early in the drug development process. As a response, the Safety Planning, Evaluation and Reporting Team (SPERT) was formed in 2006 by the Pharmaceutical Research and Manufacturers of America (PhRMA). The goal of SPERT was to propose a standard across the pharmaceutical industry for safety planning, data collection, evaluation, and reporting, beginning with planning first-in-human studies and continuing through the planning of postapproval activities [34].

Among the key recommendations from SPERT was that sponsors plan a series of repeated, cumulative metaanalyses of the safety data obtained from the studies conducted within the development program. Leading up to these metaanalyses, sponsors need to develop clear definitions of adverse events of special interest and standardize various aspects of data collection and study design, to facilitate combining studies and the interpretation of the combined analyses. These ideas were extended in the CIOMS X Working Group report. It is important to ensure that true adverse reactions to medicines and vaccines are known about so that clinicians and patients can be aware and take appropriate action, but it is equally important to show that the magnitude of any risks in absolute terms is such that the benefit/risk balance for a medicine in a particular situation remains positive. It is never possible to show with absolute certainty the absence of a possible harm since the confidence interval will always include such a possibility unless (assuming a well-designed study) the confidence interval excludes zero risk (in the direction of a benefit), in which case the adverse effect is prevented and is no longer a harm for that medicine.

By following a proactive approach during development, including periodic updating of cumulative metaanalyses, potential harms may

be identified earlier in the development process. This may increase the chances that the Phase III program will be able to provide a satisfactory understanding of the safety profile. Risk management plans will take into account the knowledge about the drug at the time of licensing (see Chapter 24) [35]. Furthermore, the needs for postmarketing commitments can be better defined.

The exploration of subgroups of patients in whom therapy may be more or less effective is a controversial question in individual randomized trials. Most trials are not designed with sample sizes adequate to address efficacy in subgroups. The finding of statistically significant differences between the effects of therapy in different subgroups, particularly when those groups were not defined *a priori*, raises the question of whether those are spurious findings. Conversely, the lack of statistical significance for clinically important differences between prospectively defined subgroups can often be attributed to a lack of statistical power. Such clinically meaningful but statistically nonsignificant findings are difficult to interpret. Metaanalysis can be used to explore these questions with improved statistical power. A prespecified protocol is important, especially in this context, since the potential for adjusting methods to find or not find effects can be dependent on the interests of those doing the metaanalysis.

The use of metaanalysis in the approval process for new drugs or devices represents another potential application, although experience in this area is as yet rather limited. However, many of the methodologic issues arising in the context of new drug approval also arise in the investigation of new indications for pharmaceutical products that have previously been approved for other purposes. For some therapies, such as streptokinase in the treatment of myocardial infarction, metaanalysis could have been used to summarize evidence prior to embarking on a very large-scale, multicenter, randomized trial [36].

Evidence-based medicine requires the use of the best evidence available in making decisions about the care of patients. Traditional metaanalyses, which have been one of the cornerstones of evidence-based medicine, often focus on placebo-controlled trials because head-to-head comparisons of medications are generally unavailable. But what healthcare providers, patients, and policy makers need to make better informed decisions is an analysis that provides comprehensive look at all available evidence – how a specific pharmacologic treatment compares with other available pharmacologic treatments in terms of safety and efficacy for the specific condition (see Chapter 32).

Extended metaanalytic techniques such as indirect comparisons [37] and multiple treatment metaanalyses can combine all available evidence in a single analysis [38]. These techniques provide estimates of the effect of each intervention relative to every other, whether or not they have been directly compared in trials, allowing ranking of treatments in terms of efficacy and safety, and can potentially strengthen the inference regarding a treatment because the results are based on more data. The main drawback of these analyses is that the validity of the findings depends on whether homogeneity and consistency assumptions, which we describe later, are met [39]. There has been a growth in "network metaanalysis" (NMA, also known as mixed treatment comparisons), which is another phrase to describe combining studies of multiple treatments allowing for direct and indirect comparisons and assessing their consistency. A helpful website is www.bristol.ac.uk/population-health-sciences/centres/cresyda/mpes/mtc/. There is more discussion of this in the section "Indirect comparison and simultaneous comparison of treatments" later. This technique can address the clinical problem when it is desired to make comparisons between active treatments but there are no or very few trials that make the direct comparisons.

Methodologic Problems to be Solved by Pharmacoepidemiologic Research

As the skeptical reader might imagine, many methodologic issues can arise in the context of performing a metaanalysis. Many, but not all, of these problems relate to the process of combining studies that are often diverse with respect to specific aspects of design or protocol, some of which may be of questionable quality.

Susceptibility of the Original Studies to Bias

Early work in metaanalysis used the term "study quality." More recent efforts (e.g., PRISMA [40]) have adopted language that refers to susceptibility to bias or likelihood of bias. We adopt that new terminology in the remainder of this chapter. The Cochrane Collaboration developed a "risk of bias tool" which is now used extensively (at least with many thousands of citations in the literature) in assessing the randomized trials to be included in a metaanalysis [41]. This paper describes some evaluation, and there is a chapter in the Cochrane Handbook that gives many more details [18].

The tool in use has been developed further and there are training materials available freely on the internet for their use (https://training.cochrane.org/resource/rob-20-webinar). A further development is the ROBIS tool which, rather than assessing the individual trials, assesses the risk of bias in a systematic review or metaanalysis itself [42]. The group that developed ROBIS has also developed a similar approach to risk of bias in observational studies, ROBINS-I (Risk Of Bias In Nonrandomized Studies – of Interventions) [43] but this has been less heavily cited and newer versions are under development.

As might be expected, the Cochrane groups are not the only ones which have developed such tools, but they have published a systematic review of such tools [44]. They conclude:

> There are several limitations of existing tools for assessing risk of reporting biases, in terms of their scope, guidance for reaching risk of bias judgments and measurement properties. Development and evaluation of a new, comprehensive tool could help overcome present limitations.

It is unrealistic to expect complete agreement on a single method of assessing bias but it is clearly an active area, and there is an obvious need for those doing metaanalysis in pharmacoepidemiology to be aware and to ensure that at least some attempts are made to assess bias in more than a trivial way.

Metaanalysis seems particularly prone to the "garbage in = garbage out" phenomenon. Combining a group of poorly done studies can produce a precise summary result built on a very weak foundation. This apparent precision may lend undue credibility to a result that truly should not be used as a basis for formulating clinical or policy strategies [7]. However, if the judgment about susceptibility to bias in an individual study is subtly influenced by the direction or magnitude of the findings of the study, excluding studies based on such a subjective judgment about their quality could open the metaanalytic process to a different, and potentially serious, form of bias.

Combinability of Studies

Different studies will look at different outcomes, with different treatments in different patients. Some studies will look at multiple outcomes, treatments or groups of patients. Clearly, no one would suggest combining studies that are so diverse in either outcomes or treatments that a summary would be nonsensical. For example,

one would not combine studies of hormone replacement therapy in relation to risk of breast cancer with studies of hormone replacement therapy in relation to risk of coronary heart disease. The outcomes are not expected to show the same effect. Beyond obvious examples like this, however, the choices may not be so clear. Should studies with different patient populations be combined? How different can those populations be before it becomes unacceptable to combine the studies? Should different hormone preparations be considered as being equivalent (those with estrogen only, those with estradiol, etc.)? It will require judgment; for some purposes it may be relevant to look at all hormone preparations as a single group, but for other purposes it will be important to distinguish products, or even different doses and durations of treatment for a single product. In pharmacoepidemiology, risks of adverse effects will vary notably with duration of treatment and length of follow-up. Careful consideration needs to be applied before combining studies with diverse outcome definitions and methodology. At the very least, some exploration of the sources of variation of effect should be done.

As an example where combining studies may be appropriate, a recent metaanalysis, Sabatine *et al*. [45], combines across all statins but looks at a very restricted population of patients with low LDL levels at baseline. In this context, it may be reasonable to combine different statins used under different conditions in order to see if effects are present in a group with already low LDL levels.

Should nonrandomized studies be combined with randomized studies? Should nonrandomized studies ever be used in a metaanalysis? Should studies with active drugs as comparators be combined with studies with placebos as comparators? These are questions that cannot be answered without generating some controversy. The CIOMS Working Group X concluded in regard to the first question: "A clear consequence of this is that the treatment of randomized and non-randomized evidence as equivalent (exchangeable) in a single analysis is a mistake; combination of data must distinguish between them" [4]. However, they go on to note: "Some efforts have been made, particularly in a Bayesian paradigm, to combine evidence from both sources in a single analysis, but the methods for doing this are not yet widely agreed." There would be little argument that they are not equivalent and reporting the results separately should be done, even if combined at some point.

Publication Bias

Unpublished material cannot be retrieved by literature searches and is likely to be difficult to find referenced in published articles. Publication bias occurs when study results are not published, or their publication is delayed, because of the results [46–56]. The usual pattern is that statistically significant results are more likely to be published than nonsignificant results, although this bias may not be as severe for randomized studies as it is for nonrandomized studies [48,57,58]. With the introduction of registration of randomized trials, publication bias in randomized studies should become less of a problem. As noted by the Office for Human Research Protections in the US Department of Health & Human Services, the International Committee of Medical Journal Editors announced a policy in 2004 that as a condition of publication, clinical trials would be required to be listed in a public registry [59]. Subsequently, regulatory authorities around the world began to require the posting of clinical trial information and, in some cases, the submission of summary results to a publicly accessible registry. Likewise, some research funding agencies are now encouraging or requiring the registration and results reporting of the clinical trials they fund. They go on to list three separate international registries as well as the best-known Clinicaltrials.gov from the US, a Canadian one,

five in Europe, and 16 from elsewhere in the world (www.hhs.gov/ohrp/international/clinical-trial-registries/index.html). Some of these registers also contain observational study protocols and results; notable is the register of Post-authorization Studies (PAS) maintained at the European Medicines Agency by the European Network of Centres for Pharmacoepidemiology and Pharmacovigilance (ENCePP®) (www.encepp.eu/encepp/studiesDatabase.jsp).

While one could simply decide not to include unpublished studies in a metaanalysis, since those data have often not been peer reviewed [60], unpublished data can represent a large proportion of all available data [61]. Published results are a biased sample – as noted in the Cochrane Handbook (Section 10.1 Introduction) [18]:

> Statistically significant, "positive" results that indicate that an intervention works are more likely to be published, more likely to be published rapidly, more likely to be published in English, more likely to be published more than once, more likely to be published in high impact journals and, related to the last point, more likely to be cited by others. The contribution made to the totality of the evidence in systematic reviews by studies with non-significant results is as important as that from studies with statistically significant results.

If the results of unpublished studies are systematically different from those of published studies, particularly with respect to the magnitude and/or direction of the findings, their omission from a metaanalysis would yield a biased summary estimate (assuming that the quality of the unpublished studies is at least equal to the quality of the published studies). For example, Decullier *et al.* have shown that in France, the filtration process from protocol to publication leads to more positive results appearing in the literature [62]. Hopewell *et al.* reviewed several publications and demonstrated that positive results were more likely to be published [63].

Publication bias is a potentially serious limitation to any metaanalysis. For example, Sutton and colleagues found that in four of 48 metaanalyses they examined, there was evidence that the statistical inferences would have changed after the overall effect estimate was adjusted for publication bias [64]. The retrospective identification of completed unpublished trials is clearly possible [61] in some instances, but generally is not practical. One study used a survey of investigators to attempt to identify unpublished studies [65]. The authors surveyed 42 000 obstetricians and pediatricians, asking whether they had participated in any unpublished trials completed more than two years previously, that is, during the period prior to the end of 1984. They identified only 18 such studies, despite an overall response rate of 94% to their survey.

Other forms of bias, related to publication bias, have also been identified [49]. These include reference bias, – preferential citation of significant findings [66]; language bias – exclusion of studies in languages other than English [67,68]; and bias related to source of funding [69–71]. These related biases have been termed "dissemination bias" by Sutton and colleagues, who found that the threat of such biases is more severe in nonrandomized studies of an intervention [64].

There is room to decrease publication bias even further: calls to simplify access to the US Food and Drug Administration (FDA) and other regulatory agency reviews, and to create links from such reviews to literature search engines such as MEDLINE, have been made [72]. Ladanie and colleagues have made practical suggestions regarding how to find FDA reviews [73].

Unfortunately, there is no guarantee that either the published trial or a published metaanalysis will follow the protocol. It seems that bias towards finding "interesting" results is pervasive. Hutton and Williamson showed that bias within a study in choosing outcomes to be

reported, when many have been studied, could affect the reported results and hence affect a metaanalysis [74]. Marzouki and colleagues, using the registered trial protocols at *The Lancet,* showed that in 11 out of 37 trials, there were major discrepancies in the primary outcome between those protocols and the subsequent publication [75]. Dwan *et al.* have reviewed the problem in a general way and find real causes for concern [76]. It is one thing to have the trial data biased, but then the systematic reviewers may add to the problem. Kirkham *et al.* studied protocols and subsequent publications from the Cochrane Library, which is thought by some to apply the highest standards of reviews, and reported "Over a fifth (64/288, 22%) of protocol/review pairings were found to contain a discrepancy in at least one outcome measure, of which 48 (75%) were attributable to changes in the primary outcome measure" [77]. Saini *et al.*, from the same group, using the same data source, also found that harms were particularly unreliably reported in Cochrane reviews [78].

Rising *et al.* [79] suggested that the published literature gave a more favorable impression than the FDA reviews had found, while in the narrower area of biologics, Amarilyo and Furst found discrepancies between FDA reviews and publications but there was no consistent difference in the direction [80]. It is clear that the published literature may not be as reliable as it should be and that regulatory review may be more reliable, and at the very least should also be searched for in any metaanalysis based on published data.

Bias in the Abstraction of Data

Metaanalysis, by virtue of being conducted after the data are available, is a form of retrospective research and is thus subject to the potential biases inherent in such research [81]. In a metaanalysis of gastrointestinal side effects of NSAIDs, Chalmers and colleagues examined over 500 randomized studies [82]. They measured the agreement of different reviewers when reading the "methods" sections of papers that had been masked as to their source and the results. There were disagreements on 10–20% of items, which had to be resolved in conference with a third person. These disagreements arose from errors on the part of the reader and from lack of clarity of the presentation of material in the original articles. Whatever its source, when such variability exists, the opportunity for observer bias may exist as well [81].

In a number of instances, more than one metaanalysis has been performed in the same general area of disease and treatment. A review of 20 of these instances showed that, for almost all disease/treatment areas, there were differences between two metaanalyses, of the same topic, in the acceptance and rejection of papers to be included [60]. While there was only one case (out of the 20) of extreme disagreement regarding efficacy, there were several cases in which one or more analyses showed a statistically significant result while the other(s) did not. These disagreements were not easily explainable. For example, differences between metaanalyses of the same topic in the acceptance and rejection of papers did not always lead to differences in conclusions.

More generally, the acceptance or rejection of different sets of studies can drastically change conclusions. Despite efforts to make metaanalysis an objective, reproducible activity, there is evidently some judgment involved.

In a separate commentary, DerSimonian reanalyzed data from one metaanalysis and one clinical review of parenteral nutrition with branched chain amino acids in hepatic encephalopathy [83]. She pointed to differences in the data extracted by the two sets of authors [84,85] for the same endpoints from the same original papers. When combined statistically, the data extracted by the two sets of authors led to substantively different conclusions about the efficacy of therapy.

In some instances, attempts are made to extract numerical data from figures and software exists to do this. There are suggestions that extracting data from figures with software was faster, with higher interrater reliability than manual extraction [86]. However, neither method will work for the type of large studies encountered in pharmacoepidemiology, and clearly it is better to obtain raw data from authors or repositories if possible.

There is the possibility of reducing reliance on abstraction of data by using the original data from trials or observational studies. As noted above, PRISMA has a guidance on utilizing IPD [87] and there have been a large number of metaanalyses both of randomized and nonrandomized IPD in the past. (e.g., on trials in breast cancer [88] and on hormonal factors in breast cancer [89]).

Metaanalyses based on IPD have several advantages (see, for example, Section 3.9 of the CIOMS report on metaanalysis [4] and Berlin *et al.* [90]). There are strong moves to make at least individual patient randomized trial data available, such as The Yale University Open Data Access (YODA) Project (http://yoda.yale.edu/welcome-yoda-project). "Alltrials" is an international initiative of multiple stakeholders including journals, academics, and foundations (www.alltrials.net/). European regulators have promised to make data more available (www.ema.europa.eu/docs/en_GB/document_library/Other/2013/06/WC500144730.pdf) but there are privacy barriers in some instances, and there is controversy over whether reanalysis of published data needs to have some constraints [91] or not [92].

Most of the interest in this area is around randomized trials, but there are also issues around the availability of observational data. Platt and Lieu have noted that there are challenges to overcome in spite of enthusiasm of the research community for wider availability of patient data [93]. They identify three reasons for the challenges: (1) confidentiality and proprietary concerns, (2) the cost and work required to make raw data usable for analyses, and (3) the need to create incentives for data holders that outweigh the disadvantages. Concerns over privacy led to the collapse of a major initiative in the UK to share patient data, known as "care.data" [94].

While these challenges relate to overall availability, there are similar problems in making individual records from observational studies available routinely. The major collaborations that have used individual data have had to ensure that the data are only available to named team members under strict control for confidentiality.

Currently Available Solutions

This section will first present the general principles of metaanalysis and a framework for the methods typically employed in a metaanalysis. Since much of the general framework for conducting systematic reviews and explanation of the methods typically employed in a metaanalysis have been presented in review articles in major clinical journals [10,11,95], freely accessible guidelines, and handbooks, only the most important points will be highlighted here. In this chapter, we will provide succinct descriptions of the most recent guidelines and references.

The PRISMA statement (Preferred Reporting Items for Systematic reviews and Meta-Analyses) was developed to increase the clarity and transparency of published systematic reviews and metaanalyses. It consists of a 27-item checklist and a flow diagram. It describes the rationale for including each of the items with supporting references and provides examples of good reporting, and there is a short paper published simultaneously in six journals, e.g., Moher *et al.* [96], as well as a fuller "Explanation and Elaboration" paper published in three journals [40]. The flow diagram describes the number of

studies at each phase of the metaanalysis, starting with the number of studies identified in database searching, moving to the number of studies screened, those determined to be potentially eligible, and finally the number of studies included. A similar guideline for reporting metaanalysis of observational studies is available as well [25].

A very large range of guidelines has been brought together under the "EQUATOR" (Enhancing the QUAlity and Transparency Of health Research) umbrella (www.equator-network.org/), including ones for trials (CONSORT) as well as systematic reviews (PRISMA), together with many extensions for specific topics such as harms. The PRISMA on harms is particularly relevant in pharmacoepidemiology and is, like most of the EQUATOR guidelines, continually under review [97]. There are two further guidelines of special interest to pharmacoepidemiology on network metaanalysis [98] and individual patient data [87]. An example evaluation of the use of the PRISMA guideline has been conducted in the field of gastroenterology and hepatology; Panic *et al.* claim that "The endorsement of PRISMA resulted in increase of both quality of reporting and methodological quality" [99]. However, Page and Moher, who examined all the published evaluations of the use of PRISMA in systematic reviews (SRs) they could find, concluded "Many studies have evaluated how well SRs adhere to the PRISMA Statement, and the pooled result of these suggest that reporting of many items is suboptimal. An update of the PRISMA Statement, along with a toolkit of strategies to help journals endorse and implement the updated guideline, may improve the transparency of SRs" [100].

We have cited another very useful source of information on how to conduct systematic reviews and metaanalysis, namely the Cochrane Handbook for Systematic Reviews [101]. The Handbook is a publicly available, comprehensive, and easy-to-read document that describes in detail the process of preparing a systematic review, combining data, and maintaining Cochrane systematic reviews.

In the second part of this section, specific solutions to the methodologic issues raised in the previous section are presented. Finally, case studies of applications that should be of interest to pharmacoepidemiologists will be presented, illustrating approaches to some of the clinical and methodologic problems raised earlier.

Steps Involved in Performing a Metaanalysis (Box 36.1)

The CIOMS X report suggests a metaanalysis protocol should include, but is not limited to, content implied by a series of topic headings [4]. That report elaborates on the content in the context of planning the metaanalysis. The reader is referred to the CIOMS publication for more detail. We focus here on a subset of that content.

Define the Purpose

While this is an obvious component of any research, it is particularly important to define precisely the primary and secondary objectives of a metaanalysis. A well-formulated question should have a clearly defined patient problem, intervention, comparator, and outcome of interest. This framework is called PICO which stands for patient, intervention, comparison, and outcome [102]. Some authors have expanded PICO to PICOS or PICOTS, with "T" standing for timing and "S" representing either "study design" or "setting".

Box 36.1 General steps involved in conducting a metaanalysis

1) Define purpose
2) Perform literature search
3) Establish inclusion/exclusion criteria
4) Collect the data
5) Perform statistical analysis
6) Formulate conclusions and recommendations

An example of an important primary question could be: "What is the magnitude of the increased risk of gastrointestinal side effects with NSAIDs used for the treatment of pain, compared with placebo?" Another might be: "Are corticosteroids effective in the treatment of alcoholic hepatitis, compared with placebo?" Secondary objectives might include the identification of subgroups in which a treatment appears to be uniquely more or less effective. For NSAIDs, estimating the absolute risk difference (and, thus, the public health implications) as well as the relative risk (and, thus, the etiologic implications) might be a secondary objective. We present more on the question of absolute risks, relative risks, and odds ratios later. It is important to consider that questions defined too broadly could lead to the criticism of "mixing apples and oranges" and that questions focused too narrowly could lead to finding no, or limited, data, or the inability to generalize the study results.

Perform the Literature Search (Included in "Sources of data" in CIOMS X)

While computerized searches of the literature can facilitate the retrieval of all relevant published studies, these searches are not always reliable. Several studies have examined problems with the use of electronic searches [103–105]. Use of search terms that are too nonspecific can result in large numbers of mostly irrelevant citations that need to be reviewed to determine relevance. Use of too many restrictions can result in missing a substantial number of relevant publications.

Search strategies to identify specifically reports of all definite or possible randomized or quasirandomized trials have been developed. One of these strategies is the Cochrane search strategy. Although this strategy is highly sensitive (it identifies 92% of trials), the specificity is very low (3.7%) (i.e., it identifies a lot of nonrelevant studies) [106]. Nonetheless, one term "random*[tw]" is able to retrieve all randomized controlled trials (RCTs) and improves the specificity of the search strategy to 29% [106]. This ability to fine tune searches is the result of the National Library of Medicine making improvements to MEDLINE indexing and of initiatives, such as the CONSORT statement, to improve reporting of RCTs.

Another way to decrease the number of nonrelevant citations is to modify the highly sensitive search strategy by excluding publication types that are almost certain not to provide primary data, such as commentaries, editorials, metaanalyses, reviews, or practice guidelines. It has been shown that this approach reduces by 20% the number of nonrelevant citations, without losing any of the relevant trials [107]. The Cochrane strategies have been evaluated carefully and should be consulted (a whole chapter of the Handbook is devoted to searching for randomized trials). There is also a section in the Handbook on searching for nonrandomized studies and in practice this is more difficult. It is also not clear that finding all published studies leads to an unbiased review, since observational studies are not necessarily registered, may not require ethical review, and hence may be completely untraceable. As stated in the Handbook, "Exhaustive searching, which is recommended for randomized trials, may not be justified when reviewing NRS (nonrandomized studies). However, there is no research at present to guide authors about this important issue." It seems likely that searching on methods will be much less fruitful than searching for particular adverse event terms, for example.

Other methods of searching, such as review of the reference sections of retrieved publications found to be relevant, and manual searches of relevant journals, are also recommended.

Establish Inclusion/Exclusion Criteria (Included in "Study selection" in CIOMS X)

A set of rules for including and excluding studies should be defined during the planning stage of the metaanalysis and should be based on the specific hypotheses being tested in the analysis.

One might, for example, wish to limit consideration to randomized studies with more than some minimum number of patients. In a metaanalysis of epidemiologic studies, one might wish to include studies of incident cases only, excluding studies of prevalent cases, assuming that the relationship between exposure and outcome could be different in the two types of study. Practical considerations may, of course, force changes in the inclusion criteria. For example, one might find no randomized studies of a particular new indication for an existing therapeutic agent, thus forcing consideration of nonrandomized studies.

In establishing inclusion/exclusion criteria, one is also necessarily defining the question being addressed by the metaanalysis. If broad inclusion criteria are established, then a broad, and perhaps more generalizable, hypothesis may be tested. The use of broad entry criteria also permits examination of the effects of research design on outcome (e.g., do randomized and nonrandomized studies tend to show different effects of therapy?) or the exploration of subgroup effects. As an example, in a metaanalysis of aspirin administered following myocardial infarction, restriction of the metaanalysis to studies using more than a certain dose of aspirin would not permit an exploratory, cross-study comparison of dose–response effects, which might prove illuminating.

A key point is that exclusion criteria should be based on *a priori* considerations of design of the original studies and completeness of the reports and, specifically, should *not* be based on the results of the studies. To exclude studies solely on the basis of results that contradict the majority of the other studies will clearly introduce bias into the process [12]. While that may seem obvious, the temptation to try to justify such exclusions on a *post hoc* basis may be strong, particularly when a clinically plausible basis for the exclusion can be found. Such exclusions made after having seen the data, and the effect of individual studies on the pooled result, may form the basis for legitimate sensitivity analyses (comparing pooled results with and without that particular study included), but should not be viewed as primary exclusion criteria.

The readers of systematic reviews and metaanalyses often cannot assess whether the exclusion criteria were defined after seeing study results; the registration of systematic reviews protocols will decrease this problem. For example, the Cochrane Collaboration publishes its approved protocols. Cochrane reviews must indicate reasons for deviations from the approved protocol. (Whether the initial question defined in a metaanalysis is motivated, in part, by knowledge of the results of the component studies is a more subtle, and perhaps more important, question.) The realization that reporting of both trials and systematic reviews is often altered by the authors even after a protocol has been recorded shows that the potential for bias is considerable.

Prespecification of the protocol and adherence to it (or at least a clear justification for departures) provides some limited protection against bias. There are registries of protocols for observational studies and one that is specifically for systematic reviews is "PROSPERO" (International **Prospe**ctive **Re**gister **O**f systematic reviews) (www.crd.york.ac.uk/prospero/). PROSPERO is an international database of prospectively registered systematic reviews in health and social care, welfare, public health, education, crime, justice, and international development, where there is a health-related outcome. Key features from the review protocol are recorded and maintained as a permanent record. By August 2018, PROSPERO contained close to 40 000 recorded review protocols. There also is a registry of studies maintained by the European Medicines Agency, under the auspices of the European Network of Centres for Pharmacoepidemiology and Pharmacovigilance (ENCePP). There is a code of conduct set out by ENCePP, and studies following that code must be registered, but other studies may also register there. It is not

particularly intended for metaanalyses though there are a few included in the register.

Another important note is that studies may often generate more than one published paper. For example, later reports might update analyses previously published, or might report on outcomes not addressed in earlier papers. It is essential, for two reasons, that only one report on the same patients be accepted into the metaanalysis. First, the validity of the statistical methods depends on the assumption that the different studies represent different groups of individuals. Second, the inclusion of a study more than once would assign undue weight to that study in the summary measure. A caution is that it is not always obvious that the same patients have been described in two different publications. Contacting the authors may be of some help in determining if there is duplication, although some authors may perceive the inquiry as questioning their academic integrity. It is also not always obvious what the right choice of report should be for a given study. Certain aspects of the methods may only be reported in earlier publications, which necessitates at least referring to those papers. Methods of analysis may change from paper to paper, or degree of control of confounding, or inclusion or exclusion of certain subpopulations. Thus, there is no general rule we can recommend in such situations, other than trying to exercise good judgment and reporting clearly the reasons for choosing one publication over others. The issue of multiple publications based on the same study has been addressed in more detail by Huston and Moher [108].

Collect the Data

When the relevant studies have been identified and retrieved, the important information regarding study design and outcome needs to be extracted. Typically, data abstraction forms are developed, pilot tested on a few articles, and revised as needed. As in any research, it is necessary to strike a balance between the completeness of the information abstracted and the amount of time needed to extract that information. Careful specification in the protocol for the metaanalysis of the design features and patient characteristics that will be of clinical or academic interest may help avoid over- or undercollecting information. For randomized trials, it is generally advisable, when possible, to collect raw data on outcome measures, such as numbers treated and number of events in each group, rather than derived measures such as odds ratios, which may not be the outcome measures of interest in the metaanalysis or may have been calculated incorrectly by the original authors. For observational studies, in contrast, it will most often be the estimates from each of the studies that are adjusted for confounding that will be of interest. For these studies, the derived measures will be more important to collect, along with information about what confounding factors were included in the adjustment.

Many articles on "how to do a metaanalysis" (e.g., Sacks *et al.* [10], L'Abbe *et al.* [11]), and the PRISMA guidelines) recommend that the metaanalyst assesses the quality of the studies being considered in a metaanalysis. Generally, "quality" is taken to mean freedom from bias, and that terminology has been adopted by PRISMA. Options that have been proposed for incorporating quality in metaanalyses include using a measure of study quality as part of the weight assigned to each study in the analysis, as an exclusion criterion (e.g., excluding studies with quality scores below some arbitrary threshold), or as a stratification factor allowing the separate estimation of effects for good-quality and poor-quality studies [109,110]. Several examples of quality evaluation systems that have been proposed may be of interest [111,112]. Issues related to quality scoring have been discussed more generally by Moher and colleagues [113], and an annotated checklist of quality scoring systems is available [114].

The argument has been made, however, that general scoring systems are arbitrary in their

assignment of weights to particular aspects of study design, and that such systems risk losing information, and can even be misleading [115,116]. Jüni and colleagues, for example, examined studies comparing low molecular weight heparin with standard heparin with respect to prevention of postoperative thrombosis [116]. They used 25 different quality assessment scales to identify high-quality trials. For six scales, the studies identified as being of high quality showed little to no benefit of low molecular weight heparin, while for seven scales, the "high-quality" studies showed a significant advantage of low molecular weight heparin. This apparent contradiction raised questions about the validity of such scales as methods for stratifying studies. One reason why the contradiction arose, the authors argue, is that the quality scores tend to measure a combination of completeness of reporting and factors that might relate to the potential for bias. They recommended, instead, a focus on particular aspects of study design as potential predictors of study outcome, such as whether or not the assessment of outcome is blinded to treatment status.

Thus, in a given metaanalysis, one might wish to examine *specific* aspects of study design that are unique to that clinical or statistical situation [115–118]. For example, Schulz and colleagues found that trials in which the concealment of randomized allocation was inadequate, on average, produced larger estimates of treatment effects compared with trials in which allocation was adequately concealed [119]. This specific finding was not detected when the same authors looked for an overall association between quality score and treatment effect. In the analysis of low molecular weight heparin, Jüni and colleagues found that studies with unmasked outcome assessment showed larger, and presumably biased, benefits of low molecular weight heparin than studies using masked assessment of outcome [116]. Such explorations clearly need to be guided by common sense. As these authors point out, for studies with total mortality as an outcome, masking of outcome assessment would not be expected to impact directly on study findings.

Other authors have suggested essentially similar approaches to that recommended by Jüni and colleagues. For example, Greenland and O'Rourke suggest the use of statistical models to investigate the association between specific design factors and study findings [120]. This approach, known as "response–surface estimation," can be used to derive the predicted outcome for a study with specified (and presumably desirable) characteristics, while at the same time borrowing strength from all the available studies. Once again, caution is needed in performing such analyses with respect to such issues as extrapolation beyond the range of the data. (What if there are *no* studies of sufficient quality on a given dimension included in the model? Is it valid to extrapolate to such studies based on trends observed for lower quality studies?)

The Cochrane Collaboration recommends, via use of the "risk of bias" tool cited above, that authors of systematic reviews assess six domains to determine whether bias in each of the studies included in the analysis is likely to affects their results and hence that of the metaanalysis [18]. These domains are: *selection*, *performance*, *detection*, *attrition*, *reporting*, and *other biases*. Aspects that affect the risk of bias then include the method used to generate the allocation sequence; whether allocation concealment was implemented; whether blinded assessment of outcomes was performed; the degree of completeness of outcome data; whether selective outcome reporting is likely; and "other" dimensions when researchers identify problems that could put the study at a high risk of bias and are not part of the above framework.

Two procedural recommendations have been made regarding the actual techniques for data extraction. One is that studies should be read independently by two readers. The justification

for this comes from metaanalyses in which modest but important interreader variability has been demonstrated [81,82]. A second recommendation is that readers be masked to certain information in studies, such as the identity of the authors and the institutions at which a study was conducted, and masked to the specific treatment assignments or results (when assessing the methods) [60].

While masking has a high degree of intuitive appeal, the effectiveness of masking in avoiding bias has not been demonstrated. Only one randomized trial examined the effect of masking on the results of metaanalyses [121]. This study compared the results of the same metaanalyses performed independently by separate teams of metaanalysts, with one team masked and the other unmasked. The masked and unmasked teams produced nearly identical results on a series of five metaanalyses, lending little support to the need for masking, though it is unclear whether this would be found in all circumstances. Given the propensity for selective analysis and reporting, it seems possible that such selection can take place but equally, it is not clear that masking will prevent this type of bias in practice.

Perform Statistical Analyses

OR, RR or RD – Does It Matter?

There are three summary measures of effect size that can be used in metaanalysis when the outcome of interest is binary (e.g., proportion of subjects with pain relief): relative risk (RR), odds ratio (OR), and risk difference (RD). Although the summary measure used does not affect the statistical significance of the results [122], the choice of effect measure could affect the transferability of results of the metaanalysis into clinical practice. Which summary measure to select depends on the ease of interpretation, the mathematical properties, and the consistency of the results when the particular effect measure is used [123].

Relative risk and RD are easier to interpret than OR. In general, probabilities are more intuitive than odds. When the baseline (untreated) risk is constant across studies, the RD also allows calculation of relevant public health measures (e.g., a number of events prevented or caused by a given treatment). A disadvantage of using RDs in metaanalysis is that, in an empirical study of a large number of metaanalyses, RDs displayed more heterogeneity than ORs, that is, the results from study to study appeared more inconsistent with RDs [124]. Because of this heterogeneity, the extrapolation to a broader population will only be correct at the average baseline risk and extrapolation to other baseline risks will be unreliable. RR and OR are more consistent than RD [122,124] and therefore are preferred from this perspective. There was no difference in heterogeneity in this same sample of metaanalyses, on average, between RR and OR [124].

Odds ratios have better mathematical properties than RRs. For example, switching the roles of the event and nonevent in the analysis is of no consequence for ORs; the new OR is the reciprocal of the original OR (i.e., OR for "benefit" is the reciprocal of the OR for "harm"). In contrast, switching the outcome can make a substantial difference for RR, affecting the treatment effect size and potentially introducing heterogeneity. In a metaanalysis the effect of this reversal cannot be predicted [124].

However, ORs are often incorrectly interpreted as RRs, and this can lead to apparent overestimation of the treatment effect when the outcome is common (when the interpretation is expressed in terms of probabilities, instead of odds). One solution is to discuss the results in terms of RR (or RD) by computing RR (or RD) and confidence intervals from ORs, using the methods described by Localio *et al.* [125].

Choice of Statistical Method

In most situations, the statistical methods for the actual combination of results across studies

are fairly straightforward, although a great deal of literature in recent years has focused on the use of increasingly sophisticated methods. If one is interested in combining odds ratios or other relative measures such as relative risks across studies, for example, some form of weighted average of within-study results is appropriate, and several of these exist [126]. A popular example of this is the Mantel–Haenszel procedure, in which odds ratios are combined across studies with weights proportional to the inverse of the variance of the within-study odds ratio [28,127]. Other approaches include inverse-variance weighted averages of study-specific estimates of covariate-adjusted relative risks and exact stratified odds ratios [126].

Bias in statistical methods is discussed by Tang, who shows that inverse-variance methods may introduce bias in metaanalyses of binary outcomes [128]. Essentially, the problem with those approaches is that the inverse-variance weights depend not only on study size but on the event rates themselves. For example, consider an analysis of 10 trials that all have sample sizes of 500 in both the treated and control groups. Suppose nine studies have event rates of 28% in the treated groups compared with 30% in the control groups. In this same analysis, a single study has event rates of 3% in the treated group versus 1% in controls. For an inverse-variance weighted analysis of risk differences, which are -2% in the nine studies and +2% in the single study, the single study with the low event rates would get 54% of the weight in the metaanalysis, compared with 5.1% of the weight for each of the other nine studies. For an analysis of (log) relative risks, the single study would get 0.4% of the weight, compared with 11.1% of the weight for each of the other nine studies. Appropriate use of weights is also addressed by Chang and colleagues [129].

One basic principle in many analytic approaches is that the comparisons between treated (exposed) and untreated (unexposed) patients are typically made within a study prior to combination across studies. In the combination of randomized trial results, this amounts to preserving the randomization within each study prior to combination. In all the procedures developed for stratified data, "study" plays the role of the stratifying variable. In general, more weight is assigned to large studies than to small studies because of the increased precision of larger studies.

A second basic principle to note is that some of these methods assume that the studies are all estimating a single, common effect, such as a common odds ratio. In other words, the underlying treatment effect (whether beneficial or harmful) that all studies are estimating is assumed to be the same for all studies. Any variability among study results is assumed to be random and is ignored in producing a summary estimate of the treatment effect [130,131]. One may wish to use methods for combining studies that do not make the assumption of a common treatment effect across all studies. These are the so-called "random-effects" models, which allow for the possibility that the underlying true treatment effect, which each study is estimating, may not be the same for all studies, even when examining studies with similar designs, protocols, and patient populations. Hidden or unmeasured sources of among-study variability of results are taken into account by these random-effects models through the incorporation of such variability into the weighting scheme when computing a weighted average summary estimate. Random effects models are described in much greater detail in several papers [132–135].

The practical consequence of the random-effects models is to produce wider confidence intervals than would otherwise be produced by the traditional methods [130,131].This approach is considered particularly useful when there is heterogeneity among study results, and exploratory analyses have failed to uncover any known sources of observed heterogeneity. However, random-effects models should not be viewed as

a panacea for unexplained heterogeneity. One danger is that a summary measure of heterogeneous studies may not really apply to any particular study population or study design; that is, they lose information by averaging over potentially important study and population characteristics [117].

A practical effect of random-effects models, which is only apparent from examining the mathematics involved, is that they tend to assign relatively higher weights to small studies than the traditional methods would assign [130]. This equalization of weights may have unwanted consequences in some circumstances, and can lead to counterintuitive results, with very small studies making contributions to the summary equal to those of very large studies. A thorough discussion of the interpretation and application of fixed-effect versus random-effects models is presented by Hedges and Vevea [136]. Villar and colleagues compared results of fixed-effect and random-effects models on an empirical basis [137]. As expected, in the presence of heterogeneity, they found that the random-effects models gave wider confidence intervals. Interestingly, these random-effects models also showed larger treatment effects than the corresponding fixed-effect models applied to the same data. Explanations for this phenomenon are considered in the section on publication bias.

In many metaanalysis packages (such as Review Manager (RevMan) [138] and comprehensive metaanalysis [139]), the random effects model is implemented with DerSimonian and Laird methodology [1]. However, this methodology is known to be suboptimal in several situations [132,140–145]. Another method that is worth considering is the Hartung–Knapp–Sidik–Jonkman (HKSJ) method for random effects metaanalysis [140–142,145–147]. IntHout *et al*. [147] suggested that the HKSJ method was straightforward and considerably outperforms the standard DerSimonian–Laird method, especially when the number of studies is small, though even with the HKSJ method, extra caution is needed when there are ≤5 studies of very unequal sizes [140–145]. Somewhat in contrast, Bender *et al*. point out that, because heterogeneity is difficult to estimate when there are only a few studies, the HKSJ method accounts appropriately for uncertainty but has very low power [148]. They note, for example, that it is possible for HKSJ to produce a statistically nonsignificant combined result when combining two statistically significant studies with effect estimates going in the same direction. Rover *et al*. proposed a modified Knapp–Hartung (mKH) method that performed well when only a few studies contribute to the metaanalysis and the involved studies' precisions (standard errors) vary [149].

Recently, Stanley and Doucouliagos challenged the two core conventional metaanalysis methods (fixed and random effects) and proposed a weighted least squares method that is neither fixed nor random [150]. They suggested that an unrestricted weighted least squares estimator is superior to conventional random-effects metaanalysis when there is publication (or small-sample) bias and better than a fixed-effect weighted average if there is heterogeneity. It should be noted that, unlike the Peto method, it is unable to deal with zero events in one of the comparison arms.

Another recent publication offers a variety of interpretations of fixed-effect models, going beyond the often-cited limitation that the methods assume a constant treatment effect across all studies [151]. The authors note that some statistical literature considers fixed-effect models appropriate when inferences are to be drawn about the "average" association. They note that Hedges and Vevea [136] offer a rationale for using fixed-effect models even in the presence of heterogeneity. Rice and colleagues go on to recommend exploration of potential sources of variability in treatment effects across studies, using methods described later in this chapter.

Bayesian statistical methods are also being proposed with increasing frequency in the

statistical literature [152–155].These methods can incorporate into the analysis the investigator's prior beliefs about the size of an effect or the factors biasing the observed effects. Bayesian methods are particularly appealing in the metaanalysis setting as they offer the ability to synthesize evidence from multiple sources under a unified framework, to make direct probability statements about any hypotheses, and to handle complex problems [4]. There are a few good practical examples of Bayesian metaanalysis. Askling *et al*. used the Bayesian hierarchical piecewise exponential survival model to investigate the cancer risk for the antitumor necrosis factor (TNF) drug class [156]. The Bayesian model was used to analyze the individual patient-level metadata, taking into account time-dependent covariates and model between study heterogeneity. Kaizar *et al*. used the Bayesian hierarchical model to quantify the risk of suicidality for children who use antidepressants [157]. Ibrahim *et al*. developed a Bayesian metaanalytical method to determine sample sizes for planning a Phase II/III antidiabetic drug development program [158].

Combinability of Results from Diverse Studies: Heterogeneity

The underlying question in any metaanalysis is whether it is clinically and statistically reasonable to estimate an average effect of therapy, either positive or negative. If one errs on the side of being too inclusive, and the studies differ too greatly, there is the possibility that the average effect may not apply to any particular subgroup of patients [159]. Conversely, diversity of designs and results may provide an opportunity to understand the factors that modify the effectiveness (or toxicity) of a drug. Glasziou and Sanders nicely summarize issues related to potential sources of heterogeneity [160]. They highlight an important distinction between artifacts that might be related to either the choice of summary measure or to study design features, and real biological or clinical variation in treatment effect. The former would include issues such as whether relative risk or risk difference is the more appropriate measure of treatment effect, and design issues mentioned above in the context of study quality, such as use of blinding in the evaluation of endpoints within a study. Such features are modifiable aspects of the conduct and analysis of studies. Variation due to clinical factors, in contrast, represents the potential to target therapy to the appropriate patient populations.

With respect to how one should approach the search for sources of heterogeneity, a number of options are available. One might stratify the studies according to patient characteristics or study design features and investigate heterogeneity within and across strata. To the extent that the stratification explains the heterogeneity, the combined results would differ between strata and the heterogeneity within the strata would be reduced compared to the overall result. In addition to stratification, regression methods such as weighted least squares linear regression could be used to explore sources of heterogeneity [3,161–163]. These might be important when various components of study design are correlated with each other, acting as potential confounders. Graphical methods for metaanalysis have also been proposed, that focus on issues related to heterogeneity [164,165].

The quantification of the among-study variability assessment of the degree of variation involves statistical tests. An important word of caution is that statistical tests of heterogeneity suffer from a notorious lack of statistical power [166,167]. Thus, a finding of significant heterogeneity may safely be interpreted as meaning the studies are not all estimating the same parameter. A lack of statistical significance, however, may not mean that heterogeneity is not important in a dataset or that sources of variability should not be explored.

The I^2 statistic seems to have been the most widely adopted approach to statistical

quantification of the among-study variability [168–170]. (Note: In many publications, this is called "between-study variability," based on the popular usage in the statistical literature.) It estimates the proportion of variability in point estimates due to heterogeneity rather than sampling error. The authors recommend I^2 because:

- it focuses attention on the effect of any heterogeneity on the metaanalytic result
- its interpretation is intuitive, that is, the percentage of total variation across studies due to heterogeneity
- it can be accompanied by an uncertainty interval
- it is simple to calculate and can usually be derived from published metaanalyses
- it does not inherently depend on the number of studies in the metaanalysis
- it may be interpreted similarly irrespective of the type of outcome data (e.g., time to event, quantitative, or dichotomous) and choice of effect measure (e.g., OR or hazard ratio).

Several approaches to the statistical modeling of heterogeneity have been proposed. Thompson and Sharp, for example, compared different forms of weighted normal errors regression and random effects logistic regression [171]. Hardy and Thompson reviewed regression methods to investigate heterogeneity [161].

It has been argued that because of the potential for bias in observational epidemiologic studies, exploring heterogeneity should be the main point of metaanalyses of such studies, rather than producing a single summary measure [8,117,172]. (For further information on the metaanalysis of observational studies we refer readers to Section 3.10 of the CIOMS report [4].)

As an example of the type of analysis that could be used to investigate study design issues, Hennessy and colleagues performed a metaanalysis of nonexperimental studies comparing third-generation oral contraceptives (those containing gestodene and desogestrel) to second-generation pills (those containing levonorgestrel) with respect to the risk of venous thromboembolic events [173]. A major issue in these studies has been the possibility of depletion of susceptibles. Specifically, the concern is that users of the newer drugs might tend to be new users of *any* oral contraceptives, whereas users of the older, second-generation drugs would tend to be established users. The risk of venous events tends to be highest for new users, who have events soon after beginning pill use. These susceptible individuals, the argument goes, would be depleted from the ranks of users of second-generation pills, but not from among the third-generation pill users, thereby leaving a more susceptible population of third-generation pill users. The authors found several studies that had performed subgroup analyses of new users in their first year of use. When combined, these subgroups still demonstrated an increased risk from third-generation pills. The power to look within subgroups was only available within the context of the metaanalysis, not within any of the individual studies.

The example just presented was motivated by a specific concern about a hypothesized source of bias in studies. It is sometimes instructive to perform more exploratory analyses of metaanalytic data as well. These may provide valuable insights into the biology of the problem and/or may generate hypotheses for future confirmation.

Analysis of Rare Events

We have mentioned that by combining results of many trials, metaanalysis can address the problems of rare events. However, the analysis of rare events in metaanalysis is still challenging. Many of the methods used to combine data in metaanalysis are based on large sample approximations and therefore may be unsuitable when events are uncommon. In addition, the results could vary substantially depending on the method used to combine the data. Recommendations as to what method to use under which circumstances are

based on studies that have used simulations in which the "truth" is generated by the investigators [174,175]. The results of these studies show that fixed-effect models should be used over random-effect methods [175] and that the inverse-variance-average should be avoided.

When dealing with rare events, many studies may have no events in any of the arms, and relative measures such as relative risk or odds ratios cannot be calculated. If relative measures are used, studies with no events in either treatment arm will be excluded by virtue of the mathematics, not because the metaanalyst chooses to exclude them. However, in these circumstances, risk differences can be estimated. The problem is that risk differences models in the presence of rare events produce biased results and have very limited power [174].

Relative measures in cases when there are no events in *one* arm can be calculated. Many of the methods require "continuity corrections," that is, adding a small value to all cells in a 2×2 table. The Mantel–Haenszel method often uses this approach. Traditionally, 0.5 is added to each of the cells and some statistical packages do this automatically. However, such continuity correction leads to bias in the presence of rare events, and is not necessary, even for the Mantel–Haenszel method [175,176]. Alternative continuity corrections such as the reciprocal of the sample size of the opposite treatment arm, in contrast with the traditional constant continuity correction, produce less biased results [175].

There are methods that do not require using any continuity correction, such as the Peto method and Bayesian methods. The Peto method, also known as the "one-step" model, is a fixed-effect model that focuses on the observed number of events in the experimental intervention and compares it with the expected number of events. Since it uses the expected number of events, it can deal with individual groups in individual trials with no observed events, as long as there is at least one event in at least one of the arms in the trial. The Peto method often produces less biased results provided there is no substantial imbalance between treatment and control group sizes within trials, and provided the treatment effects are not exceptionally large (less than an OR of 5) [175,176].

Bayesian methods can be appropriately applied to rare events metaanalysis. The use of Bayesian hierarchical models can modulate the extremes in the zero-event setting, borrowing information from studies with events to derive posterior inferences for the treatment effect estimates. A practical challenge of Bayesian metaanalysis for rare adverse event data is that noninformative priors may lead to convergence failure due to very sparse data. Weakly informative priors, which put weak restrictions on the size of the treatment effect, may be used to solve this issue [4].

Sensitivity analysis is especially important in the rare AE setting, because results may be sensitive to the choice of statistical methods, scale of measurement, specification of the prior distribution if the Bayesian approach is utilized, and continuity correction factors selected for analyzing zero-events studies, etc. Therefore, when a metaanalysis of rare events is contemplated, a thorough sensitivity analysis pertaining to the above considerations is recommended, and the results of such analyses should be reported so that the readers can assess the robustness of the results [177].

Other Considerations

A number of somewhat specialized statistical issues have been addressed in recent years. These include how to include both parallel and cross-over trials in a single metaanalysis [178–181], the inclusion of trials in which some form of group (e.g., medical practice or hospital) is the unit of randomization (so-called "cluster randomized" trials) in metaanalyses [182], converting odds ratios to effect sizes so that studies with dichotomous outcomes may be combined directly with studies having continuous outcome measures [183], and the analysis of single patient (N-of-1) trials to estimate population

treatment effects and to evaluate individual responses to treatment [184]. Nam and colleagues discuss the analysis of studies with multiple, correlated outcomes [185]. Recently published work of particular interest to epidemiologists includes the analysis of dose–response data from epidemiologic data [186,187], a method for combining disparate designs (case–control, comparative cohort, and uncontrolled cohort studies) [188], and exact methods for case–control and follow-up studies [189].

Formulate Conclusions and Recommendations

As with all research, the conclusions of a metaanalysis should be clearly summarized, with appropriate interpretation of the strengths and weaknesses of the metaanalysis. Authors should clearly state how generalizable the result is and how definitive it is and should outline the areas that need future research. Any hypotheses generated by the metaanalysis should be stated as such, and not as conclusions.

Publication Bias

As discussed earlier, when the primary source of data for a metaanalysis is published data, the possibility needs to be considered that the published studies represent a biased subset of all the studies that have been done. In general, empirical studies have found that it is more likely that studies with statistically significant findings will be published than studies with nonsignificant findings.

A practical technique for determining the potential for publication bias is the "funnel plot," first proposed by Light and Pillemer [190]. The method involves plotting the effect size (e.g., the risk difference) against a measure of study size, such as the sample size or the inverse of the variance of the individual effect sizes. If there is no publication bias, the points should produce a kind of funnel shape, with a scatter of points centered around the true value of the effect size, and with the degree of scatter narrowing as the variances decrease. If publication bias is a problem, the funnel would look as though a bite had been taken out, with very few (if any) points around the point indicating no effect (e.g., odds ratio of 1.0) for studies with large variances. This method requires a sufficient number of studies to permit the visualization of a funnel shape to the data. If the funnel plot does indicate the existence of publication bias, then one or more of the correction methods described below should be considered. In the presence of publication bias, the responsible metaanalyst should also evaluate the ethics of presenting a summary result that is likely to represent an overestimate of the effect in question.

Two examples of funnel plots are given in Figures 36.1 and 36.2. These plots represent studies of psychoeducational programs for surgical patients [190,191]. In the first plot, only the published studies are represented. The funnel appears to have a "bite" taken out of it where the small studies showing no effect of these programs should be. In the second plot, the unpublished studies, including doctoral dissertations, are included, and the former "bite" is now filled with these unpublished studies.

Sterne and Egger provide guidelines for the choice of axes in funnel plots of studies with dichotomous outcomes, recommending that the standard error of the treatment effect (e.g., the standard error of the log odds ratio) be used as the measure of study size and that relative measures (relative risk, as opposed to risk difference) be used as the treatment effect measures [192]. These same authors and a colleague point out that publication bias is only one possible explanation for funnel plot asymmetry, so that the funnel plot should be seen as estimating "small study effects" rather than necessarily publication bias [193]. A similar point is made by Terrin and colleagues [194].

Several mathematical approaches to the problem of publication bias have been proposed. An early method, first described by Rosenthal [195], is the calculation of a "fail-safe N" when the

Light and David B. Pillemer, Cambridge, MA: Harvard University Press. ©1984 by the President and Fellows of Harvard College.

result of the metaanalysis is a statistically significant rejection of the null hypothesis. This method, in a kind of sensitivity analysis, uses the Z-statistics from the individual studies included in a metaanalysis to calculate the number of *unpublished* studies with a Z-statistic of exactly 0 that would be required to exist, in order for the combined Z-score (published plus unpublished studies) to become nonsignificant. Because this method focuses only on Z-statistics, and ignores the estimation of effects (e.g., odds ratios), it is of limited utility. That is, the fail-safe N approach focuses only on the statistical significance of the combined result and does not help provide an overall estimate of the effect that is "adjusted" for publication bias.

A number of related methods to deal with potential unpublished studies have been developed in recent years. These include other methods for estimating the number of unpublished studies [196,197], formal methods to test for the presence of publication bias [198–200], and methods to adjust summary estimates to account for unpublished studies [136,196,201–203], but several of those methods make some fairly strong assumptions about the specific

mechanism producing the publication bias. A method called "trim-and-fill" has a fair amount of intuitive appeal [204], although it, too, relies on assumptions about the missing studies. It is based on the funnel plot, focusing on the studies that lead to the appearance of funnel plot asymmetry. Under this approach, a mirror image of the studies producing the asymmetry is imputed, using a carefully defined statistical algorithm to determine which studies to mirror, and the impact of adding those mirror image studies to the pooled analysis is assessed.

An additional methodologic caution generated by publication bias relates to the use of random-effects models for combining results. When the results of the studies being analyzed are heterogeneous and a random-effects model is being used to combine those results, one of the properties of the model, described earlier, is to assign relatively higher weights to small studies than would otherwise be assigned by more traditional methods of combining data. If publication bias is a problem in a particular dataset, one consequence implied by the funnel plot is that small studies would tend to show larger effects than large studies. Thus, if publication bias is present, one of the reasons for heterogeneity of study results is that the small studies show systematically larger effects than the large studies. The assignment of higher relative weights to the small studies could, when publication bias is present, lead to a biased summary result.

In fact, this appears to be exactly the situation presented by Poole and Greenland in an examination of studies of water chlorination and cancer [31]. Random-effects summary estimates of the relative risk for various cancers were larger than corresponding fixed-effect summaries. This was apparently due to the assignment of higher relative weights to small studies which, in this case, showed relatively larger effects, that may not be representative of the findings of all small studies. Data presented by Villar and colleagues found a similar phenomenon in studies in perinatal medicine [137].

As noted earlier, one solution to the problem of publication bias is the use of prospective registration of studies at their inception, prior to the availability of results [59]. Others have suggested obtaining unpublished data from the FDA, an approach used by Turner *et al*. [205]. These authors obtained reviews from the FDA for studies of 12 antidepressant agents, conducted a systematic literature search to identify matching publications, and compared the results based on published studies with the results based on the FDA data. They found that among the 74 FDA-registered studies, 31% were not published, and that there was an association between study results and whether or not the paper was published. Of the 38 studies viewed by the FDA as having positive results, 37 were published. Studies viewed by the FDA as having negative or questionable results were, with three exceptions, either not published (22 studies) or published in a way that, in the opinion of the authors of the review, conveyed a positive outcome (11 studies). The analysis restricted to published literature showed that 94% of the trials were positive. In contrast, the analysis of FDA data showed that only 51% were positive.

A further review in looking at other indications for antidepressants found a similar bias in the literature [206]. Although the estimate of effect size was only increased marginally, "Reporting biases led to significant increases in the number of positive findings in the literature." The Open Trials project and the Yale project (YODA) cited earlier are attempts to reduce the bias from using only published literature. There is a tool that allows FDA documents to be retrieved more easily [207].

Going one step further, prospective metaanalyses can be conducted [208–210]. These are metaanalyses that are planned, with complete protocols, including proposed tests of subgroup effects, prior to having knowledge of the results of any of the component studies. More on the topic of prospective metaanalysis is presented later.

Indirect Comparison and Simultaneous Comparison of Treatments Available for Specific Conditions

What healthcare providers, patients, policy makers, and payers often need in order to make informed decisions is to understand how pharmacologic treatments compare to other pharmacologic treatments, even in the absence of direct evidence (head-to-head comparisons). When the treatments of interest have been compared to a common comparator, for example placebo, it is possible to get comparative information via indirect evidence. (See references [211–217] for a series of seven tutorial papers on evidence synthesis for decision making, which includes manuscripts on indirect comparisons – also known as network metaanalysis.)

Indirect evidence involves using data from trials that have compared medication A with medication B, and from trials that have compared medication A with medication C, to draw conclusions about the effect of medication B relative to medication C (Figure 36.3). It is crucial that when an indirect comparison is estimated, the analysis respect the randomization. This means that the analysis must be based on treatment differences within each trial. Pooling the results from the various treatment arms of the clinical trials, by simply collapsing results for that treatment arm across studies, ignores the randomizations and produces biased and overly precise estimates [39]. To correctly assess how medication B compares with medication C, one needs to analyze all the trials that have compared medication A with medication B and calculate (in the case of dichotomous outcome) the appropriate metaanalytic OR and do the same for the trials that have compared medication A with medication C, and then divide these two ORs, that is, OR (B vs C) = OR (A vs B) / OR (A vs C). Section 3.11 of the CIOMS X report also has a high-level summary of the use of indirect evidence [4].

Other advantages of these multiple-treatment comparison techniques are that they can easily deal with trials that have multiple arms and account for the correlation due to multiple arms. In addition to being able to combine direct and indirect evidence, these techniques also permit the assessment of the inconsistency, that is, the disagreement between direct and indirect evidence [218]. These methods can also provide a probabilistic ranking of treatments.

Assumptions

The validity of the indirect comparisons and the extended methodologies we just described depend on meeting assumptions, which are similar to the assumptions of the traditional metaanalysis.

The first assumption is homogeneity. For example, if treatment A in our example is placebo, the results of the placebo-controlled trials that evaluated treatment B should be homogeneous enough to be combined, and the results of the placebo-controlled trials that evaluated

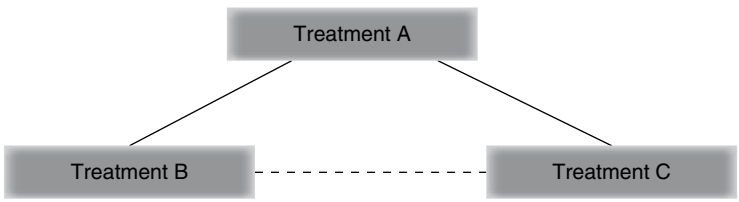

Figure 36.3 Indirect evidence involves using data from trials that have compared medication A with medication B, and from trials that have compared medication A with medication C, to draw conclusions about the effect of medication B relative to medication C (*dotted line*).

treatment C should be homogeneous enough to be combined as well.

The second assumption is similarity. All factors that affect the response to a treatment, effect modifiers, must be similarly distributed across the entire set of trials. This requires that the trials in the network are clinically similar with respect to patient characteristics, settings, follow-up, and outcomes evaluated, and that the trials are methodologically similar, as well. For example, suppose B and C have identical effects, but the size of the treatment effect for both B and C is different in patients with severe disease from that in patients with mild disease. In this situation, variability between studies of B and C with respect to the proportion of patients with severe disease will lead to spurious variability in results between studies of B and studies of C. Similarly, if some trials used enrichment and the others did not, the results are likely to vary across type of study, making questionable the advisability of combining results.

The last assumption to assure validity of the results is consistency (agreement between direct and indirect evidence). It requires that before combining direct and indirect estimates, the consistency of these estimates needs to be checked [39].

Adjusting for Covariates

As we just described, the validity of indirect estimates relies on the balance of factors that affect the response to a treatment in the various treatment arms. When such effect modifiers were measured and reported in the trials, the extended metaanalytic techniques can adjust for possible imbalances of such effect modifiers by incorporating these variables into the statistical mode [219,220]. This is a study-level adjustment for a study-level summary variable (e.g., the proportion of subjects with a particular effect-modifying characteristic), which does not substitute for having access to patient-level characteristics and performing appropriate subgroup analyses, as noted elsewhere in this chapter.

In addition to the study level adjustment for effect modifiers, a more recent approach by Signorovitch and colleagues has been proposed [221,222]. This method, "matching-adjusted indirect comparisons," uses IPD from trials of one treatment to match to baseline summary statistics reported from trials of another treatment; that is, the matching is most often at the level of ensuring the two groups have the same mean and standard deviation. After matching, outcomes can be compared across balanced trial populations by using an approach similar to propensity score weighting. These methods are more frequently being used in health technology assessment submissions. However, more work needs to be done to understand how this new methodology behaves under various scenarios. Philippo *et al*. [223] provided guidance on this methodology that is based on a Technical Support Document prepared for the UK National Institute for Health and Care Excellence Decision Support Unit, available from www.nicedsu.org.uk.

Case Studies of Applications of Metaanalysis

Investigation of Adverse Effects

As mentioned earlier, the investigation of adverse or unwanted effects of existing therapies is an important application of metaanalysis. As discussed in Chapters 1 and 4, adverse events associated with pharmaceutical products are often so uncommon as to be difficult to study. In particular, the usual premarketing randomized studies frequently have too few patients to provide any useful information on the incidence of uncommon adverse events. By the same token, individual studies may have low statistical power to address particular questions. Metaanalysis provides the benefit of increased statistical power to investigate adverse events. In fact, since 1982, the safety evaluation of drugs in the US has included pooled analyses from prospective metaanalysis [224].

The assessment of the cardiovascular safety of rosiglitazone, a medication used to lower blood glucose, provides an excellent example of a situation in which metaanalysis has been both helpful and challenging. The original approval of rosiglitazone was based on its ability to reduce blood glucose levels and glycated hemoglobin levels, and the studies were not powered to determine the effect of this medication on micro- or macrovascular complications of diabetes. To evaluate the effect of rosiglitazone on cardiovascular morbidity and mortality, a metaanalysis was conducted [225].

The authors of this metaanalysis searched published literature, the FDA website, and a clinical trials registry maintained by the drug manufacturer. The authors included RCTs with duration of more than 24 weeks. To combine the data, they used the Peto method. Forty-two trials met the inclusion criteria.

The authors concluded that rosiglitazone increased the risk of myocardial infarction and death from cardiovascular causes. The OR for myocardial infarction was 1.43 (95% CI 1.03–1.98), and the OR for death from cardiovascular causes was 1.64 (95% CI 0.98–2.74).

Not surprisingly, the results of this study generated a great deal of interest. To determine the next course of action, the FDA has reviewed data from observational studies, clinical trials, and the most recently conducted trial called RECORD (**R**osiglitazone **E**valuated for **C**ardiovascular **O**utcomes and **R**egulation of Glycemia in **D**iabetes). The RECORD study was designed to evaluate the cardiovascular safety of rosiglitazone. The FDA presented the results of this review at an Advisory Committee meeting in July 2010. Following this meeting, the FDA announced significant restrictions on the use of rosiglitazone, to patients who cannot control their diabetes on other medications. Under the restricted access program, doctors will have to document their patients' eligibility. Patients will have to review statements describing the cardiovascular safety concerns associated with this drug and acknowledge they understand the risks [226]. In 2013, most of the restrictions on rosiglitazone were removed by the FDA, saying it does "not show an increased risk of heart attack compared to the standard type 2 diabetes medicines metformin and sulfonylurea" based on additional review of the final results of the dedicated CV outcome trial (www.fda.gov/Drugs/DrugSafety/ucm376389.htm).

In 2015, the FDA went further and removed the need for the Risk Evaluation and Mitigation Strategy (REMS) for rosiglitazone-containing medicines. "The REMS is no longer necessary to ensure that the benefits of rosiglitazone medicines outweigh their risks" (www.fda.gov/Drugs/DrugSafety/ucm476466.htm). The license for rosiglitazone remains suspended in the EU in 2018.

This metaanalysis illustrates two of the challenges researchers face when performing metaanalysis: how to deal with rare outcomes and the impact of choosing a method to combine the data.

In this case, the incidence of myocardial infarction in the trials was low. Specifically, observed risks in the rosiglitazone arm ranged from 0 to 1.8% so the authors employed the Peto model to combine the data. As mentioned earlier, this method is recommended in the presence of rare events [174], but it is not recommended when there is substantial imbalance in the number of subjects in the trial arms (unequal treatment allocation), as was the case in this study; some of the studies have an allocation ratio of 4 to 1. When other methods to combine data are used, however, the estimates do not change substantially, but the statistical significance disappears [227]. As we describe in the section on rare events, it is important to assess routinely how robust the results are to the methods used to combine the data and report any discrepancies. We also note in that section (and reinforce here) that a prespecified protocol and careful sensitivity analysis can guard against overreliance on results that are strongly dependent on assumptions and the choice of method for analysis.

New Indications for Existing Therapies

Metaanalysis has also been used to assess the effectiveness of existing therapies for new indications. For example, antidepressants are medications used for the treatment of major depression and other depressive disorders, but they can also reduce pain even in the absence of depression. One of the painful conditions in which antidepressants can be used is fibromyalgia. This is a predominantly female chronic pain condition characterized by widespread pain and tenderness. It can affect up to 10% of women between 55 and 64 years of age [228].

To determine the efficacy of antidepressants in the treatment of fibromyalgia, a metaanalysis of randomized controlled clinical trials was conducted by Hauser and colleagues [229]. The authors searched MEDLINE, PsycINFO, Scopus, the Cochrane Library databases, and reference sections of original studies, metaanalyses, and reviews on antidepressants in fibromyalgia. They included randomized placebo-controlled trials with tricyclic and tetracyclic antidepressants, selective serotonin reuptake inhibitors, serotonin noradrenaline reuptake inhibitors, and monoamine oxidase inhibitors. Two authors independently extracted data. Effects were summarized using standardized mean differences (SMD), analyzed using a random-effects model. The SMD is used to summarize results from studies that used different measurement instruments to assess the same underlying psychiatric construct and are expressed in standard deviation units.

Eighteen randomized controlled trials, with a median duration of eight weeks, involving 1427 participants, were included. The authors found that antidepressants reduced pain intensity (SMD, –0.43; 95% CI –0.55 to –0.30), fatigue (SMD –0.13; 95% CI –0.26 to –0.01), depressed mood (SMD –0.26; 95% CI –0.39 to –0.12), and sleep disturbances (SMD –0.32; 95% CI –0.46 to –0.18). Antidepressants also improved health-related quality of life (SMD –0.31; 95% CI –0.42 to –0.20).

The effect sizes for pain reduction for older antidepressants appeared to be larger than those for the newer drugs. The SMD for tricyclic antidepressants was –1.64 (95% CI –2.57 to –0.71), while the SMD for the newer drugs, such as selective serotonin reuptake inhibitors, was –0.39 (95% CI –0.77 to –0.01) and –0.36 for serotonin and noradrenaline reuptake inhibitors (95% CI –0.46 to –0.25).

This metaanalysis illustrated the utility of metaanalysis for consolidating evidence for new indications for existing therapies. Antidepressants are efficacious for depression and provide short-term relief of fibromyalgia symptoms as well. Serotonin and norepinephrine reuptake inhibitors antidepressants are now approved for the treatment of fibromyalgia. The metaanalysis described here suggests that older antidepressants may be more effective than these drugs, although they also have a different tolerability and safety profile.

Differential Effects Among Subgroups of Patients

Antidepressants labels warn about an increased risk of suicidality in children and adolescents during treatment. To assess this risk in adults, the FDA performed an individual data metaanalysis [230]. Eight industry sponsors of 12 antidepressant products were asked to provide individual data from all completed double blind RCTs of their products, for any indication in adults, with at least 20 participants per arm. Trials limited to known drug responders, such as those using randomized withdrawal designs, were excluded.

Industry sponsors were asked to search their electronic databases for adverse events reported during the double blind phase of treatment, using text strings such as "accident-," "attempt," "burn," "cut," "drown," "gas," "gun," "hang," "hung," "immolat-," "injur-," "jump," "monoxide," "mutilat-," "overdos-," "self damag-," "self harm," "self inflict," "self injur-," shoot," "slash," "suic-," "poison," "asphyxiation," "suffocation," and "firearm." All events identified by this search were considered

possibly related to suicidality, unless they were identified as false positive, that is, events that included any of these text strings but were not related to suicidality, such as "epigastric pain" that would be identified in the search for the text string "gas". The sponsors adjudicated the events. Three individuals blinded to treatment assignment independently rated events. If the three raters were not unanimous in their ratings, a discussion among the raters, led by a fourth rater, was conducted to achieve consensus. In absence of consensus, the event was rated as indeterminate. The FDA staff reviewed the events the sponsors classified as false positives. Events were classified into seven mutually exclusive categories: 1. completed suicide, 2. suicide attempt, 3. preparatory acts towards imminent suicidal behavior, 4. suicidal ideation, 5. Self-injurious behavior, intent unknown, 6. not enough information (fatal), and 7. not enough information (nonfatal). The primary outcome was suicidal ideation or worse (categories 1, 2, 3, or 4). The secondary outcome was suicidal behavior (categories 1, 2, or 3).

Antidepressants were classified *a priori* into five classes: selective serotonin reuptake inhibitors, serotonin-norepinephrine reuptake inhibitors' other modern antidepressants, tricyclic antidepressants, and other antidepressants. Indication was classified into five groups: major depressive disorder, other depressive disorders, other psychiatric disorders, other behavioral disorders, and nonbehavioral disorders.

All the analyses were conditioned on (i.e., stratified by) study. The authors calculated ORs and RDs using conditional logistic regression and other methods, such as exact stratified methods, Mantel–Haenszel, Bayesian, and unconditional and random-effects logistic regression. These multiple methods were used to test the robustness of the findings to the choice of statistical approach. To assess the effect of age on the risk of suicidality, the investigators included age and the interaction of treatment with age as both categorical and continuous variables (in separate models). In addition, the authors performed subgroup analyses based on indication and drug class. To examine heterogeneity of treatment effects across studies, authors added treatment by trial interaction.

The analysis included a total of 99 231 participants in 372 trials, with about 75% of the patients from North America. It is worth noting that most of the studies included were unpublished and, for those that were published, the authors found that they seldom contained information concerning suicidality in the publication.

All the methods to combine the data provided similar results. For participants with nonpsychiatric indications, suicidal behavior and ideation were extremely rare. For those with psychiatric indications, the relative risk of suicidality, associated with treatment, was different for different age groups. The relative risk was higher in participants under 25, neither elevated nor reduced in those aged 25–64 and reduced in those aged 65 and older. For suicidal behavior or ideation, the ORs were 1.62 (95% CI 0.97 to 2.71) for participants aged <25, 0.79 (95% CI 0.64 to 0.98) for those aged 25–64, and 0.37 (95% CI 0.18 to 0.76) for those aged ≥65. For suicidal behavior only, for the same age groupings, the ORs were 2.30 (95% CI 1.04 to 5.09), 0.87 (95% CI 0.58 to 1.29), and 0.06 (95% CI 0.01 to 0.58), respectively. The OR for suicidal behavior or ideation declined 2.6% per year of age (–3.9% to –1.3%), and the OR for suicidal behavior declined 4.6% per year of age (–7.4% to –1.8%). Of note, the increased risk among those <25 years old was larger for suicidal behavior than when ideation was also included, suggesting a stronger association with the more specific definition of the endpoint.

No differences in effect among drugs and drug classes were noted, with the exception of a suggestion of some differences among selective serotonin reuptake inhibitors. Similarly, no difference between older and newer antidepressants was found [230].

This metaanalysis nicely illustrates the amount of effort and regulatory authority involvement necessary to coordinate and gather individual data from a great number of RCTs, involving many drugs and multiple industry sponsors, to assess whether or not a drug *class* increases the risk of a rare but serious outcome and whether or not the increase in risk varies with the characteristic of the subjects exposed. This metaanalysis shows the power of individual data metaanalysis to identify subgroups of patients at higher risk of developing adverse events, and the process of adjudicating adverse events that needs to be followed when the outcome of interest has not been prespecified in the trials or has not been reported in publications.

Saving Time and Resources If You Believe a Metaanalysis

One of the potential benefits of metaanalysis is the ability to shorten the time between a medical research finding and the implementation of regulatory or policy actions or change in clinical practice. This is a concern not only for the development of new drugs, but for the exploration of new indications for existing therapies. As a simple but elegant example of the use of metaanalysis in the approval context, Webber and colleagues reported the use of metaanalysis of ECG data from several clinical pharmacology studies for two drug application submissions [231]. They calculated a pooled estimate for the difference between active doses and placebo on a continuous measure of QT prolongation. This approach allowed the sponsor to avoid having to perform a new safety study to address the question of QT prolongation.

One prominent group has advocated the routine use of what they have termed "cumulative metaanalysis," which is performing a new metaanalysis each time the results of a new clinical trial are published [36,232]. Antman *et al.* applied this technique in combination with a classification scheme of the treatment recommendations for myocardial infarction found in review articles and textbook chapters [36]. They found many discrepancies between the evidence contained in the published randomized trials and the timeliness of the recommendations.

As an example, Antman and colleagues analyzed data from 17 trials of beta-blockers for the prevention of death in the years following a myocardial infarction [36]. In the left-hand side of Figure 36.4, reproduced from their paper, the data are presented as a traditional metaanalysis, with individual study results presented along with the summary odds ratio arbitrarily estimated after 17 trials had been completed. In the right-hand side of Figure 36.4, the same data are presented as a cumulative metaanalysis, with an updated summary estimate calculated after the completion of each new trial. The cumulative metaanalysis clearly shows that the updated pooled estimate became statistically significant in 1977 and has remained so ever since.

Some caution may be advised in interpreting cumulative metaanalyses. The issue of multiple statistical tests, for example, generates concerns about false-positive findings (type I error). In the early papers presenting cumulative metaanalysis, this problem of increased false-positive rates was largely ignored [232–234]. In an empirical study of published literature, Biester and Lange found that only 4% of the cumulative metaanalysis papers even mentioned multiplicity adjustment, and only 2% had made an adjustment [235].

There are several methods proposed to control the false-positive rate. These include sequential approaches [236–238], such as that proposed by Pogue and Yusuf [237], who considered application of conventional group sequential methods [239,240]. These approaches require knowing the number of trials or the sample sizes within the trials. Even when cumulative metaanalyses are planned, those plans can change. More recent discussions on sequential analysis have been published [241–247].

An alternative method was proposed by Lan *et al.*, based on the law of iterated logarithms

(LIL) [248]. That method penalizes the test statistic to account for multiple tests that accounts for estimation of heterogeneity in treatment effects across studies. The initial paper looked at continuous outcomes and was extended by Hu *et al*. for the analysis of relative risk, odds ratios, or risk differences [249]. A limitation of the approach is that there could be a loss of statistical power when the among-study heterogeneity is reasonably small [249] but the extent of the power loss is not always clear. Hu and colleagues recommend using simulation to determine the specific adjustment factor to control the type I error rate but also maintain statistical power.

Another view of cumulative metaanalysis, offered by Lau *et al*. [250], is that the most natural interpretation is a Bayesian framework, in which the existing data form the basis for the prior distribution. When new studies are added, the analysis is updated to generate a posterior distribution, which then becomes the new prior distribution when more data arrive. The concept of multiplicity is handled using prior probabilities for models or hypotheses. Conclusions (usually in the form of "credible intervals") are expressed as probabilistic statements about findings, not as statements about hypotheses.

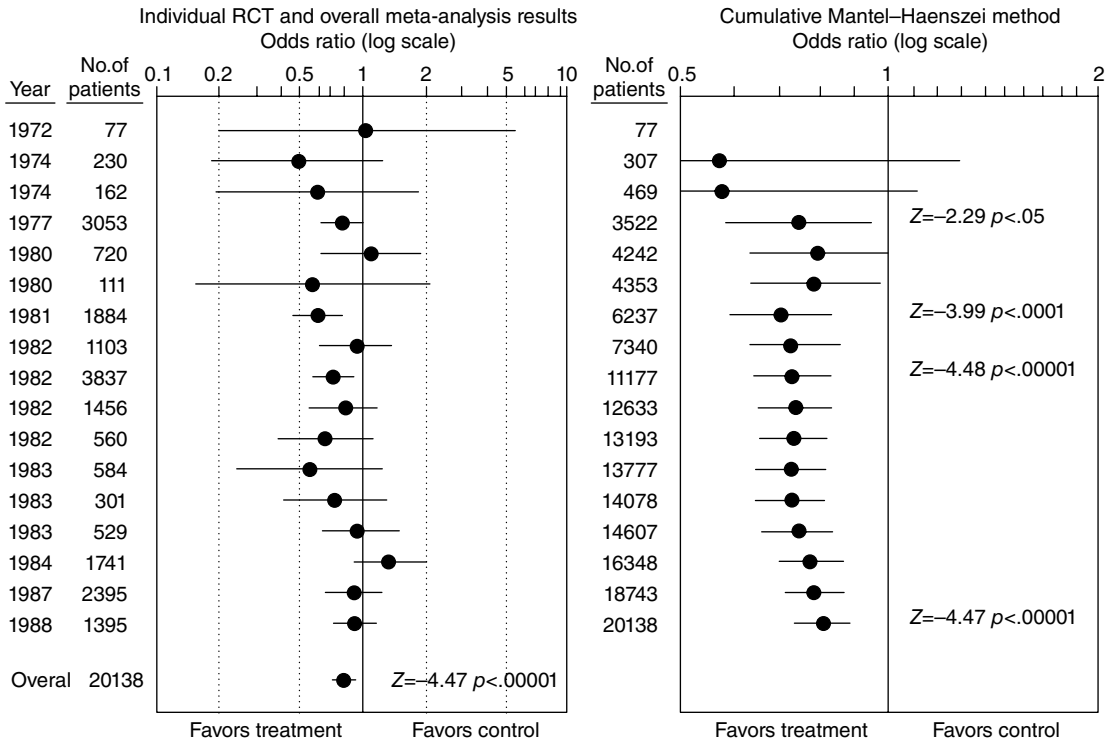

Figure 36.4 Results of 17 RCTs of the effect of oral beta-blockers for secondary prevention of mortality in patients surviving a myocardial infarction presented as two types of metaanalyses. On the left is the traditional one, revealing many trials with nonsignificant results but a highly significant estimate of the pooled results on the bottom of the panel. On the right, the same data are presented as cumulative metaanalyses, illustrating that the updated pooled estimate became statistically significant in 1977 and has remained so up to the present. Note that the scale is changed on the right graph to improve clarity of the confidence intervals. *Source:* Reproduced from Antman *et al*. [36] with permission from the American Medical Association.

There does not seem to be any consensus on a solution to the multiplicity problems generated by cumulative metaanalysis, so some use it mainly as an exploratory tool, providing caveats about the number of analyses performed without a formal correction for multiplicity. This approach is analogous to that for many conventional safety analyses, for which nominal *P* values from hypothesis tests are often provided without adjustment, when there are a limited number of prespecified outcomes.

Another consideration is that estimates of treatment effect may not be stable over time, perhaps due to changing clinical environments. In the beta-blocker example, there is an apparent "drift" of the effect estimate back toward the null in more recent years; that is, treatment appears to be less effective in the most recent studies. Thus, it may be important to reevaluate therapies as other treatment strategies evolve for the same conditions.

A final caution with regard to interpreting cumulative metaanalyses relates to the continuing need for well-designed randomized controlled trials. New indications for existing therapies, for example, are often suggested by nonexperimental studies, including cohort and case–control studies and nonrandomized Phase II clinical trials. The results of these studies are not always confirmed by subsequent, properly designed randomized trials. For example, consider the case of beta-carotene in the prevention of cancer. A series of observational studies (see Ziegler *et al*. [251] for a review) examined the relation between dietary intake of foods rich in beta-carotene and the risk of lung cancer. Overall, they showed a relatively consistent association between diets rich in beta-carotene and reduced risk of lung cancer. Subsequent randomized trials of this specific nutrient as a supplement have failed to confirm a protective effect against lung cancer [252].

For the reasons just outlined, the role of cumulative metaanalysis to demonstrate effectiveness of a therapy in a new indication has not been clarified in actual regulatory settings. Specifically, whether a metaanalysis could be used to support approval of a new indication has not been explicitly addressed. One concern relates to the possibility that the very choice of the question to be investigated may have been influenced by knowledge of the results of the individual studies. Thus, prospective planning of metaanalyses, prior to knowing the results of the component studies, may be useful.

Cumulative Metaanalysis as a Tool to Detect Harm Signals Earlier

Cumulative metaanalysis also could be used as a tool to detect safety signals earlier.

Rofecoxib, a cyclooxygenase-2 inhibitor, was withdrawn from the market in September 2004 because of cardiovascular adverse effects. A cumulative metaanalysis of RCTs was performed to establish whether robust evidence on the adverse effects of rofecoxib was available before its removal. The authors searched bibliographic databases and relevant files of the FDA and included all RCTs in patients with chronic musculoskeletal disorders that compared rofecoxib with other NSAIDs or placebo. Myocardial infarction was the primary outcome [253]. The authors identified 18 randomized controlled trials and found that by the end of 2000 (four years before the withdrawal), the relative risk was 2.30 (95% CI 1.22–4.33), and one year later it was 2.24 (1.24–4.02). The authors found no evidence that the relative risk differed depending on the type of control group (placebo, nonnaproxen NSAID, or naproxen) or trial duration. They concluded that the adverse cardiovascular effects of rofecoxib could have been identified several years earlier, and appropriate action taken.

Cumulative metaanalysis for the evaluation of safety signals brings to light potential methodologic problems that are shared by traditional metaanalysis. First, one might question the validity of pooling of trials that are not clinically homogeneous. For example, the authors

combined the results of trials with dissimilar control arms (placebo, naproxen and nonnaproxen NSAIDs).

Second, the validity of excluding trials that assessed the intervention of interest, but for other indications, can also be questioned. For example, the authors concentrated on trials that evaluated chronic musculoskeletal pain and excluded trials that evaluated Alzheimer's disease. In this case, the inclusion of such a trial would have made the early signal disappear [254]. Clearly, one would not combine trials for different indications to assess efficacy. Although the risks, or relative risks, of potential harms could also vary by indication (population), an approach often used in the regulatory setting is for studies from all indications to be included in at least some safety analyses (perhaps stratified by indication).

Third, one can ask whether efficacy and safety should be evaluated with the same methodologic standards. For efficacy, there are concerns that multiple looks at the data will lead to false-positive results and that *P* values should be adjusted accordingly. When evaluating safety, it could be argued that adjustments to *P* values should not be as large as they are for efficacy analyses (or should not be done at all). A more extensive discussion of the multiplicity issue in safety assessments is presented by Crowe and colleagues in the context of drug development [34]. Additional references can be found in that paper, as well as the discussion earlier on cumulative metaanalysis.

Fourth, it is uncertain whether cumulative metaanalysis (or any metaanalysis of RCTs) can systematically detect harm earlier. Rare adverse events, or the adverse events that occur late after exposure, will likely be absent in RCTs performed during drug development, and therefore cumulative metaanalysis would not always be expected to detect harms earlier.

Ryan and colleagues conducted a metaanalysis of 22 RCTs studying the effects of anti-IL-12/23 therapies [255]. These are antiinflammatory agents used to treat conditions such as psoriasis (the initial indication.) The studies included 10 183 patients. The primary outcome measure was major adverse cardiac events (MACEs). MACE definitions can vary; in this analysis it was defined as a composite of myocardial infarction, cerebrovascular accident, or cardiovascular death during the placebo-controlled portions of the included trials. The authors chose absolute risk differences as their effect measure, using the Mantel–Haenszel fixed-effects method. They found that 10 of 3179 patients receiving anti-IL-12/23 therapies experienced MACEs compared with no events in 1474 patients receiving placebo (Mantel–Haenszel risk difference, 0.012 events/person-year; 95% CI –0.001 to 0.026; $P = 0.12$). (NOTE: in the original paper, the authors use the term "risk difference" but report results in terms of person-time, which would usually require use of rate differences.) They concluded that there was no significant difference in the rate of MACEs associated with anti-IL-12/23 antibodies, but that even the metaanalysis may have been underpowered to identify a significant difference (because there were only 10 events).

In a second metaanalysis, Tzellos and colleagues also studied anti-IL-12/23 biologic agents (ustekinumab and briakinumab) with respect to risk of MACEs, specifically in the setting of treatment of chronic plaque psoriasis [256]. Studies of psoriatic arthritis were excluded, as in the Ryan metaanalysis. These authors used the Peto fixed-effect method to estimate odds ratios. They found a "possible higher risk of MACEs" in patients treated with anti-IL-12/23 antibodies compared with placebo-treated patients (OR 4.23, 95% CI 1.07–16.75, $P = 0.04$).

A lesson from these examples is that, particularly in the setting of rare events, conclusions of the metaanalysis can depend on the inclusion and exclusion criteria for studies and on the choice of statistical methods. Those points have been made throughout this chapter but this is a particularly telling example, because of the potential for impact on the product label.

Indirect Comparisons: Network Metaanalysis and Simultaneous Evaluation of Treatment Therapies for the Same Indication

The efficacy and acceptability of new-generation antidepressants for the treatment of major depression were assessed using multiple treatment metaanalyses. Authors of this metaanalysis included randomized controlled trials that compared 12 new antidepressants and excluded placebo groups where present. Trials were identified in the Cochrane Collaboration Depression, Anxiety, and Neurosis Review Group controlled trials registers, and the authors asked pharmaceutical companies, regulatory agencies, and study investigators to supply information.

Efficacy was evaluated as the proportion of patients who had a reduction of at least 50% from the baseline score on the Hamilton or Montgomery–Åsberg depression rating scales or the proportion of subjects who scored "much" or "very much" improvement on the clinical global impression at eight weeks, or between six and 12 weeks when data at eight weeks were not available. Acceptability of therapy was evaluated as the proportion of patients who terminated the study early for any reason during the first eight weeks of treatment.

The authors calculated the ORs for each of the drugs compared to fluoxetine, using a random-effects model within a Bayesian framework, using Markov chain Monte Carlo methods in WinBUGS [257] (a statistical program). In addition, they estimated the probability that each antidepressant was the most efficacious, or the most acceptable, the second best, the third best, and so on. The Bayesian analysis uses an iterative process to estimate treatment effects. For this analysis, the authors counted the proportion of iterations in which each antidepressant had the highest OR, the second highest, etc., in order to obtain the ranks of treatments in terms of efficacy and acceptability. To assess the consistency between direct and indirect evidence, the authors also calculated the ratio of odds ratios for indirect versus direct evidence.

Overall, 117 trials from 1991 to 2007 with 25 928 individuals assigned to one of the 12 antidepressants were included in the analyses. Overall, there was consistency between direct and indirect evidence. Only three out of 70 comparisons of direct with indirect evidence for efficacy and three out of 63 comparisons for acceptability were found to be inconsistent.

The authors concluded that not all the antidepressants were equally efficacious or equally well tolerated; they provided a matrix that simultaneously compared the 12 antidepressants for efficacy and acceptability and reported the ranking of antidepressants for efficacy or acceptability.

It is not surprising that studies of this nature generate a lot of attention. This study generated many "Letters to the Editor," whose content ranged from congratulations on how well the study helps healthcare providers identify the best treatments to severe criticism. One of the main criticisms was that excluding placebo-controlled data and including only one dose group when multiple doses were evaluated would lead to selection bias that could affect the rank-order of antidepressants. In fact, the ranks were different from those calculated in other studies [258]. Another shortcoming is that publication bias could invalidate the study findings.

Another study compared the results of FDA-registered antidepressant trials with the results from published trials, and found that 95% of the trials in the published literature were "positive" compared to only 51% of FDA-registered studies [205]. Therefore, a metaanalysis that relies primarily on published data, as this study did, will likely overestimate the effect size of treatments.

Food and Drug Administration's Regulatory Role

In recent years, the FDA has used metaanalysis to investigate adverse events associated with the use of certain drugs. The findings from those metaanalyses were used to support a regulatory decision to mandate a labeling change.

As an example, to review the possible association of suicidality events with antiepileptic drugs, the FDA contacted all sponsors of antiepileptic drugs and requested that they submit placebo-controlled trial data from all of their studies. The FDA statistical review of 199 placebo-controlled trials from 11 antiepileptic drugs found that there were 1.9 per 1000 (95% CI 0.6, 3.9) more antiepileptic drug patients than placebo patients who experienced suicidal behavior or ideation compared to the placebo patients (www.fda.gov/downloads/Drugs/DrugSafety/PostmarketDrugSafetyInformationforPatientsandProviders/UCM192556.pdf). Based on the findings, the FDA requested the sponsors of antiepileptic drugs, except for those indicated for short-term use, to include new information in the "Warnings and Precautions" section of the product labeling about an increased risk of suicidal thoughts or actions and to develop a Medication Guide to help patients understand this risk.

Not only does metaanalysis sometimes support the decision to change or update the current labeling of approved drugs, it can also provide evidence as to whether or not to keep a drug on the market. A decision may be made either to withdraw the drug completely or to withdraw its use for a particular indication. For example, metaanalysis was used to review the safety of cefepime, which is indicated for treatment of a variety of infections by susceptible strains of microorganisms. Cefepime was suggested to have potentially increased mortality in a study-level metaanalysis published by Yahav *et al*., based on 38 clinical trials [259]. The FDA performed its own metaanalysis on the study level, as well as the patient level, with data from 88 clinical trials. Based on the analysis results, the FDA concluded that cefepime remains an appropriate therapy *for its approved indications*, as neither metaanalysis showed a statistically significant difference in mortality with cefepime.

These examples highlight the point that, while publication bias is often a major concern in conducting a metaanalysis, the FDA has the unique authority to request the sponsors to submit data from all studies performed, regardless of the publication status. An added advantage for this purpose is the FDA's ability to work with patient-level data. As with the antiepileptic drug and the antidepressant cases, the FDA reanalyzed and presented the Nissen–Wolski study-level metaanalysis of rosiglitazone on patient-level data as well (Advisory Committee, July 30, 2007; https://wayback.archive-it.org/7993/20170405051827/www.fda.gov/ohrms/dockets/ac/07/briefing/2007-4308b1-02-fda-backgrounder.pdf). For this metaanalysis, the database for the FDA reanalysis differed on 14 studies compared to the database used in the Nissen–Wolski study; the FDA excluded four open-label trials, six trials that did not include myocardial infarctions or deaths in the analysis, and two long-term trials that were considered not to be suitable for combining with the rest of the short-term, small trials. By updating the database with additional available double-blind, randomized clinical trials, the FDA's reanalysis involved a total of 42 trials that used daily doses of 4 mg or 8 mg of rosiglitazone to treat patients with type 2 diabetes. The FDA's patient-level metaanalysis showed that the overall OR for total ischemic events was 1.4 (95% CI 1.1, 1,8; P = 0.02), and 1.4 for serious ischemic events (95% CI 1.0, 2.1; P = 0.06). These findings were consistent with those of Nissen and Wolski in that about a 40% increase in myocardial ischemia among diabetes patients taking insulin or those using nitrates is observed. However, the FDA reanalysis did not provide sufficient evidence to show an increased risk in the studies comparing rosiglitazone with metformin or a sulfonylurea.

The Future

The examples above have raised several important issues that will need to be addressed in the future. A set of issues not fully addressed above relates to the appropriate approach to evaluating safety during drug development. In particular,

how should the issue of multiplicity be addressed? The SPERT group outlined broad principles and pointed toward potential solutions, including the use of a tiered approach to defining adverse events [34]. During development, there is multiplicity with respect to the enormous number of adverse events that are routinely collected. Literally hundreds of categories are routinely tabulated. If cumulative metaanalyses are updated each time a trial completes during development, the repeated testing (even of events prespecified for formal testing) generates another level of multiplicity. In the safety setting, one would not necessarily want to be as strict in correcting for multiplicity as in the efficacy setting, but at an alpha level of 0.05, the possibility of generating an excessive number of false-positive signals is a real one. Although "compromise" corrections have been proposed, these tend to focus mostly on *P* values, ignoring direct consideration of the magnitude of effects and the clinical importance of the events in question.

We described earlier the current situation with respect to registration of clinical trial protocols and results. There is a wide array of mostly unconnected registries that make it impossible to find all the relevant studies in one place. What would be really useful is a dedicated search engine that, with low false-positive and false-negative rates, would be able to search all these registers to find all the trials with given characteristics, so that those doing a metaanalysis might be able to track unpublished as well as the published trials. It certainly seems there is potential for better ascertainment of *all* the relevant randomized evidence, but it is not clear whether this potential is being met.

When hundreds of categories of events are tabulated, it is likely that most specific events will have been experienced by a very small number of individuals. How broadly or narrowly to define *collections* of events (composite outcomes) becomes a key question in this context. One might wish to err on the side of being inclusive of all types of events that might be related to a drug. Doing so increases the actual counts of events, which can potentially increase statistical power. Conversely, choosing a narrower definition risks being too granular and losing statistical power by reducing the counts, but may also eliminate "noise" (events that are clinically less important or that may simply be associated with the underlying indication). Work to date suggests that more targeted definitions can sometimes lead to stronger signals (larger relative risks) and may actually make it more likely that signals will be detected [260,261].

The question of how to respond, from a sponsor or regulatory perspective, in the presence of heterogeneous results is also an open one. When there is little or no heterogeneity of results among trials, one might be willing to accept metaanalytic evidence as helping to establish effectiveness or harm. It is less obvious what to do with the results of a metaanalysis when there is substantial heterogeneity. If the heterogeneity is adequately explained in the analysis in terms of subgroup effects or trial quality, metaanalysis might still be an acceptable part of demonstrating effectiveness or harm, but such a conclusion might be conditional on the type of patient or other factors. How should results be interpreted when some trials show harm and others show no effect of a drug (relative risks or risk differences close to the null)? Is this an indication that treatment is harmful in some but not all situations? Does such a situation simply reflect random variability? The threshold for action in the face of heterogeneity of findings may well be different for safety endpoints than for efficacy endpoints, but work is needed to establish transparent criteria by which to evaluate such situations.

Earlier in this chapter we discussed the principles behind indirect comparisons. As the focus of policy and clinical decisions moves in the direction of comparative effectiveness (see Chapter 26), which also includes comparative safety, there are serious questions about how to define research agendas. In principle, one might

wish to make direct comparisons across all drugs (or therapies) for a given indication. Who will fund such studies, which will need to be large, is not at all clear. The principles defining validity of indirect comparisons have been described. Work is needed, however, to explore in practice the conditions under which indirect comparisons, or mixed treatment comparisons, may be both valid and useful. Are there particular types of questions that can be evaluated using these alternative approaches? One study showed that indirect comparisons often, but not always, agree with direct comparisons [262]. How and when to incorporate studies that are not head-to-head comparisons needs further empirical study.

The inclusion of nonexperimental observational studies in metaanalyses, particularly of serious but uncommon adverse events, will almost certainly be a necessity. To the extent that clinical trials performed in support of new drug approvals tend to include populations that are different from the population in which the drug will be used after approval, safety assessments done during development will need to be supplemented with studies done in actual clinical practice. Sample sizes during development also tend to be limited, making it necessary to study large populations to evaluate risks of uncommon but serious adverse events.

In the US, the FDA has established a network of observational databases, known as the Sentinel Network, aimed at exactly this type of assessment of drug safety in clinical practice (described in detail in Chapter 25). The legislative mandate was to provide access to claims or electronic medical records data from 100 million individuals by 2012 [263,264]. Current information regarding Sentinel can be accessed at the Sentinel website (www.fda.gov/Safety/FDAsSentinelInitiative/default.htm) [265]. Sentinel posts results of analyses conducted and provides open access to analytical tools used in those analyses.

Sentinel uses what is known as a distributed network (see Chapter 25). That is, providers of data house the data and provide analytical results, at the aggregate level only, to a central group that evaluates the appropriateness of combining results across data sources. A distributed network allows the data providers, who are most familiar with the idiosyncrasies of their respective databases, to be the ones manipulating the raw data. This approach also avoids issues related to privacy, as only the aggregate-level results are made public. Making such a distributed approach work efficiently and effectively requires the use of a common data model, that is, shared definitions of variables related to drug exposure and outcomes, across all data sources.

In a related effort, a public–private partnership, known as the Observational Medical Outcomes Partnership (OMOP), was funded by the pharmaceutical industry and included representatives from industry, the FDA, and academic institutions. OMOP investigators conducted methodologic research to determine which approaches to analysis of such observational data provide the "best" (least biased, most consistent, most precise) results (see Chapter 27). OMOP also adopted a common data model, which differs from the Sentinel common data model.

OMOP no longer exists but gave rise to two related efforts: Innovation in Medical Evidence Development and Surveillance (IMEDS: http://reaganudall.org/innovation-medical-evidence-development-and-surveillance) and the Observational Health Data Sciences and Informatics (OHDSI: www.ohdsi.org/) been established under the auspices of the Reagan–Udall Foundation. IMEDS is a public–private partnership that now provides access for private-sector organizations, such as the pharmaceutical industry, academic institutions, and nonprofit organizations to a system based on Sentinel. Selected Sentinel data partners and the Harvard Pilgrim Healthcare Institute, which functions as the analytic or coordinating

center, with governance by IMEDS, facilitate the analyses of medical product safety evaluations. The Reagan–Udall Foundation was established by the US Congress to advance regulatory science, for the purpose of helping the FDA advance its mission.

The OHDSI (pronounced Odyssey) program is a multi-stakeholder collaborative established to bring out the value of health data through large-scale analytics. All of its solutions are open-source. OHDSI has established a global network of researchers and observational health databases with a coordinating center housed at Columbia University. All the data sources available to OHDSI are part of a distributed data network and use the OMOP common data model.

Other distributed data networks have been established outside the US for similar purposes. For example, the Drug Safety and Effectiveness Network (DSEN) in Canada created a pan-Canadian collaboration of researchers, the Canadian Network for Observational Drug Effect Studies (CNODES: www.ices.on.ca/Research/Research-programs/Chronic-Disease-and-Pharmacotherapy/CNODES), to facilitate the study of specific drug safety and effectiveness questions using multiple (generally provincial) healthcare databases. The overarching aim of CNODES is to use collaborative approaches to provide rapid, population-based answers to questions about drug safety and effectiveness. The Asian Pharmacoepidemiology Network (ASPEN: http://aspennet.asia/) has also been created as a multinational research network. Similar to the other networks, it was formed to support the conduct of drug safety research and help identify emerging safety issues among the Asian countries. The European Network of Centres for Pharmacoepidemiology and Pharmacovigilance (ENCePP; www.ema.europa.eu/ema/index.jsp?curl=pages/partners_and_networks/general/general_content_000229.jsp&mid=WC0b01ac05801df747) was established in 2007 and also aims to strengthen the ongoing evaluation of benefits and risks of medicines, principally by facilitating the conduct of multicenter, independent (of the sponsors) post-authorization studies, almost all of which are observational research.

In conclusion, while there are no easy answers to many of the questions presented in this chapter, it is clear that metaanalysis will play an increasingly important role in the formulation of treatment and policy recommendations. Thus, the qualities of the metaanalyses performed, and of the included studies, are of the utmost importance and need to be reviewed by the scientific community in an open, published forum. If they are carefully interpreted in view of their strengths and weaknesses, metaanalyses should prove to be extremely helpful in pharmacoepidemiologic research.

To provide evidence-based care, clinicians need to know the benefits and risks of the medications they are prescribing (see Chapter 35), and this information needs to come from robust research. For example, evidence for medication efficacy typically comes from randomized controlled trials, whereas establishing the magnitude of a drug safety concern often comes from observational studies using self-reported data or from electronic data such as administrative claims data or electronic health records (EHRs). Previous editions of this chapter focused primarily on self-reported data or administrative claims, but with the growing availability of EHR data, pharmacoepidemiologists are increasingly using these data for research because they contain more granular information such as the reason for medication prescription, laboratory test results, and patient vitals (e.g., blood pressure and weight).

Clinical Problems to be Addressed by Pharmacoepidemiologic Research

Of particular concern to the subject of this book is the validity of data on drug exposure and disease occurrence because the typical focus of pharmacoepidemiologic research is often the association between a medication and an adverse drug event. Further, many potential confounders of importance in pharmacoepidemiologic research (although certainly not all) are either drugs or diseases. Clinicians recognize that patients very often do not know the names of the drugs they are taking currently. Thus, it is a given that patients have difficulty recalling past drug use accurately, at least in the absence of aids to enhance recall. Superficially at least, patients cannot be considered reliable sources of diagnosis information either; in some instances, they may not have even been told

Pharmacoepidemiology, Sixth Edition. Edited by Brian L. Strom, Stephen E. Kimmel and Sean Hennessy.

the correct diagnosis, let alone recall it. Yet, these data elements are crucial to pharmacoepidemiologic studies that ascertain data using questionnaires. Special approaches have been developed by pharmacoepidemiologists to obtain such data more accurately when using self-report for data collection, but the success of these approaches needs to be considered in detail.

Besides self-reported data, pharmacoepidemiologists have been using administrative claims data for more than 30 years to evaluate drug safety. We discuss validity issues with using these data for research. However, the changing landscape of healthcare requires reassessing the validity of the data pharmacoepidemiologists are now using for their research and how these data impact clinical practice.

More and more, pharmacoepidemiologists are turning to EHR data for their research.

Whereas the increased granularity of EHR data is a benefit for their use in pharmacoepidemiology, important limitations of these data include their potential incompleteness and lack of interoperability across health systems. Unless EHR data arise from "closed" healthcare systems where patients receive all their outpatient and inpatient care, then the EHR data may represent only a portion of the patients' health problems and care received. If EHR data from multiple health systems are used, even if the health systems use the same EHR vendor, the data may need to be restructured so that they are consistent across all data arising from all health systems. The clinician reviewing evidence for patient care that arises from studies using EHR data trusts that these data have been curated sufficiently to produce robust and valid study findings.

Methodologic Problems to be Solved by Pharmacoepidemiologic Research

There are five major methodologic problems associated with validity of data for pharmacoepidemiologic research: indices of measurement error, quantitative measurement of validity, quantitative measurement of reliability, measurement error in pharmacoepidemiologic research, and adjusting measures of association for measurement error.

Indices of Measurement Error

Two main comparisons may be drawn between two (or more) methods of data collection or sources of information on exposure or outcome: validity and reliability. Many different terms have been used to describe each, resulting in some confusion. Although the literature uses the term *validation study* or *verification* to describe the agreement between two sources of information, *concordance* or *agreement* might be a more appropriate term to describe the comparison between data sources because validation requires a "gold standard." In the following discussion, we define and differentiate between validity and reliability. Validity is assessed using sensitivity and specificity, while reliability is typically measured using percent agreement and kappa [1].

Quantitative Measurement of Validity

Only when one of the methods or sources is clearly superior to the other can the comparison be said to measure validity. The superior method or source is often called a "gold standard." In recognition that a method or source can be superior to another method or source without being perfect, the term *alloyed (or tarnished) gold standard* has been used [2].

For a binary exposure or outcome measure, such as "ever" versus "never" use of a particular drug, two measures are used to assess validity. Sensitivity measures the degree to which the potentially inferior source or method correctly identifies individuals who, according to the superior method or source, possess the characteristic of interest (i.e., ever used the drug). Specificity measures the degree to which the inferior source

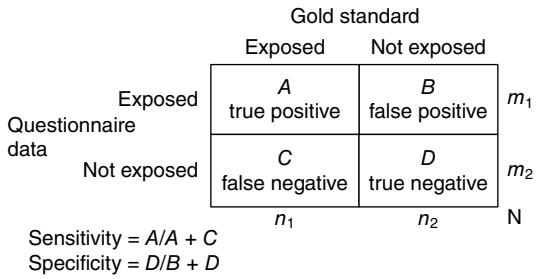

Figure 37.1 Formulas for calculating sensitivity and specificity.

or method correctly identifies individuals who, according to the superior method or source, lack the characteristic of interest (i.e., never used the drug). Figure 37.1 illustrates the calculation of sensitivity and specificity.

Sensitivity and specificity are the two sides of the validity coin for a dichotomous exposure or outcome variable. In general, sources or methods with higher sensitivity tend to have lower specificity, and methods with higher specificity tend to have lower sensitivity. In these very common situations, neither of the two sources or methods compared can be said to have superior overall validity. Depending on particulars of the study setting in which the research question is addressed, either sensitivity or specificity may be the more important validity measure. Moreover, absolute values of these measures can be deceiving. For instance, if the true prevalence of ever use of a drug is 5%, then an exposure classification method or information source with 95% specificity (and perfect sensitivity) will incorrectly double the measured prevalence to 10%. The ultimate criterion of importance of a given combination of sensitivity and specificity is the degree of bias exerted on a measure of effect such as an estimated relative risk due to measurement error.

As measures of validity, sensitivity and specificity have "truth" (i.e., the classification according to a gold standard or an alloyed gold standard) in their denominators. Investigators should take care not to confuse these measures with the predictive values of positive and negative classifications, which include the inferior measure in their denominators. We distinguish here between the persons who *actually* do or do not have an exposure or outcome with those who are *classified* as having it or not having it (using the potentially inferior or alternative data source). The proportion of persons classified as having the exposure or outcome who truly do have the exposure or outcome is the positive predictive value. The proportion of persons correctly classified as lacking the exposure or outcome is the negative predictive value.

Assessment of the positive predictive value (as is performed in many validation studies in administrative claims and EHR data) of an outcome does not directly measure the validity of the data source. Predictive values are measures of performance of a classification method or information source, not measures of validity. Predictive values depend not only on the sensitivity and specificity (i.e., on validity) but also on the prevalence of the exposure or outcome. Thus, if a method or information source for classifying persons with respect to outcome or exposure has the same sensitivity and specificity in two populations but those populations differ in their outcome or exposure prevalence, the source or method will have different predictive values in the two populations. Nonetheless, all measures are useful and the most important one will depend on the question being answered. Ideally, one would design a validation study to calculate sensitivity and specificity as well as positive and negative predictive values.

In some validation studies, one method or source may be used as a gold standard or as an alloyed gold standard to assess another method or source with respect to only one side of the validity coin. Studies that focus on the completeness of one source, such as studies in which interview responses are compared with prescription dispensing records to identify drug exposures that were forgotten or otherwise not reported by the respondents, may measure (more or less accurately) the sensitivity of the

interview data. However, such studies are silent on the specificity unless one acknowledges strong assumptions (e.g., that the respondent could not have obtained the drug in a way that would not be recorded in the prescription dispensing records). Similarly, in administrative claims data, prescriptions that are filled outside the insurance plan may not be captured in the database, especially for generic drugs that are less costly to purchase outright rather than using a co-pay.

For a drug exposure, a true gold standard would be a list of all drugs the study participant has taken (i.e., ingested), including dose, duration, and dates of exposure. This drug list might be a diary of prescriptions the study participants kept or, perhaps more readily available, a computerized database of filled prescriptions, although neither of these data sources is a genuine gold standard. Prescription diaries cannot be assumed to be kept in perfect accuracy. For instance, participants may tend to record that drug use was more regular and complete than it actually was or that use adhered to the prescribed regimen. Similarly, substantial gaps may exist between the point at which a prescription is filled and when it is ingested, if it is ingested at all. See Chapter 38 for further discussion of adherence.

Two methods are used to quantify the validity of continuously distributed variables, such as duration of drug usage. The mean and standard error of the differences between the data in question and the valid reference measurement are typically used when the measurement error is constant across the range of true values (i.e., when measurement error is independent of where an individual's true exposure falls on the exposure distribution in the study population) [3]. With the caveat that it is generalizable only to populations with similar exposure distributions, the product–moment correlation coefficient may also be used.

High correlation between two measures does not necessarily mean high agreement. For instance, the correlation coefficient could be very high (i.e., close to 1), even though one of the variables systematically overestimates or underestimates values of the other variable. The high correlation means that the over- or underestimation is systematic and very consistent. When the two measures being compared are plotted against each other and they have the same scale, full agreement occurs only when the points fall on the line of equality, which is 45° from either axis [4]. However, perfect correlation occurs when the points lie along any straight line parallel to the line of equality. It is difficult to tell from the value of a correlation coefficient how much bias will be produced by using an inaccurate measure of disease or exposure.

Quantitative Measurement of Reliability

When the same data collection method or source of information is used more than once for the same information on the same individual, comparisons of the results measure the reliability of the method or information source. An example of a reliability study is a comparison of responses in repeat interviews using the same interview instrument. Reliability is not validity, although the term is sometimes used, inaccurately, as such. In general, studies that measure mere agreement are all too commonly interpreted as though they measured validity or accuracy. The term *reliability* tends to be used far too broadly to refer variously not only to reliability itself, but to agreement or validity as well. Researchers and others should take greater care with the way they use such terms.

When different data collection methods or different sources of information are compared (e.g., comparison of prescription dispensing records with interview responses), and neither of them can be considered distinctly superior to the other, the comparisons measure mere agreement. Agreement between two sources or methods does not imply that either is valid.

To evaluate reliability or agreement for categorical variables, the percentage agreement between two or more sources and related (kappa) coefficient are used. They are used only when two imperfect classification schemes are being compared, not when one classification method may be considered *a priori* superior to the other [3,5]. The kappa statistic is the percentage agreement corrected for chance [3]. Agreement is conventionally considered poor for a kappa statistic less than zero, slight for a kappa between zero and 0.20, fair for a kappa of 0.21–0.40, moderate for a kappa of 0.41–0.60, substantial for a kappa of 0.61–0.80, and almost perfect for a kappa of 0.81–1.00 [1]. Figure 37.2 illustrates the percentage agreement and kappa calculations for a reliability assessment between questionnaire data and medical record information.

The intraclass correlation coefficient is used to evaluate the reliability of continuous variables [5]. It reflects both the average differences in mean values as well as the correlation between measurements. The intraclass correlation coefficient indicates the degree to which the total measurement variation is due to the differences between the subjects being evaluated and to differences in measurement for one individual. When the data from two sets of measurements are identical, the intraclass correlation coefficient equals 1.0. Under certain conditions, the intraclass correlation coefficient is exactly equivalent to Cohen's weighted kappa [3]. It is impossible to translate values of measures of agreement, such as kappa, into expected degrees of bias in exposure or disease associations.

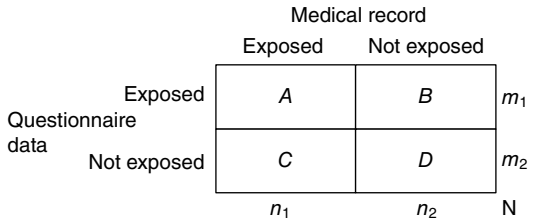

Figure 37.2 Formulas for calculating the percent agreement and K.

Measurement Error in Pharmacoepidemiologic Research

Epidemiologic assessments of the effects of a drug on disease incidence depend on an accurate assessment of the study exposure, disease occurrence, and variables to be adjusted in the statistical analysis. Measurement error for any of these factors may incorrectly identify a risk factor in the study that does not exist in the population or, conversely, may fail to detect a risk factor when one truly exists.

In an epidemiologic study, the measure of association is often based on the number of subjects categorized by the cross-classification of presence or absence of disease and exposure. For example, when questionnaire data are used to study the association between drug A and disease B, study participants who forget their past exposure to drug A would be incorrectly classified as nonexposed. Similarly, if a provider uses a diagnosis code to document the process of testing and ruling out a disease and then a researcher uses the diagnosis code as a study outcome, then the person would be incorrectly classified as having the outcome. This misclassification is a measurement error. Although the measurement process often involves some error, if this measurement error is of sufficient magnitude, the validity of the study's findings is diminished.

Surprisingly, measurement error is often ignored in epidemiologic studies. Jurek *et al.* [6] reported the results of a random survey of studies published in three major epidemiology journals; they concluded the following for exposure-measurement error (EME): "Overall, the potential impact of EME on error in epidemiologic study results appears to be ignored frequently in practice" (p. 871).

Measurement error is a potentially serious cause for concern in epidemiologic studies, and therefore, for several reasons, this should not be ignored when analyzing and interpreting pharmacoepidemiologic study results. First, small amounts of measurement error can cause large amounts of error in study results. For example, consider a pharmacoepidemiologic study of nonsteroidal antiinflammatory drug (NSAID) A versus NSAID B on gastrointestinal (GI) bleed (Figure 37.3). In a study with a total number of study subjects equal to more than 22 000, if only 10 subjects are misclassified with respect to their exposure or disease (five who actually took NSAID B are incorrectly classified as having taken NSAID A, and five users of NSAID A without GI bleed are incorrectly classified as having GI bleed), the observed odds ratio (OR) would be 2.1 when the correct OR is in fact 1.0.

Second, measurement error can cause study results to overestimate or underestimate true effect sizes, and there is no simple rule for predicting the direction of the error in real-life situations. We now understand that these old and often-cited heuristics are not necessarily true, except under special conditions that are not likely to occur in practice: (1) nondifferential misclassification always produces bias toward the null, and (2) bias toward the null always produces an observed relative risk that is an underestimate of

Case-Control Study of NSAIDs and Myocardial Infarction (MI)

No exposure misclassification

MI cases recall exposure just as well as those without MI

	NSAID use	No NSAIDs

No MI	396	444	

Figure 37.3 Example of differential misclassification of exposure.

the true relative risk. These heuristics are unlikely to be true in practice for the following reasons.

- Conditions beyond nondifferentiality are required to guarantee bias is toward the null [7–12] (e.g., when the degree of exposure measurement error systematically differs across levels of a polychotomous or continuous exposure variable, or when errors in measuring the exposure and outcome are not independent).
- Even when the above conditions beyond nondifferentiality are met, exact nondifferentiality is required to guarantee bias is toward the null [13,14].
- Also required to guarantee bias is toward the null is either (1) the absence of other study biases (e.g., absence of confounding, absence of bias due to nonrandom subject selection/participation) or (2) the combined effect of all other biases is also toward the null [13].
- Bias is a statistical term that is defined as the difference between the true value and the expected value of an estimator (i.e., the average of study results over hypothetical repetitions of the study). Bias is not the difference between the observed estimate for one repetition of the study and the true value. This important distinction was not appreciated in earlier writings on this topic, and even today we epidemiologists are not careful in our use of the term bias. Therefore, when bias is toward the null, the expected value of the estimator is shifted toward the null, but an observed estimate can be an overestimate of the true relative risk due to the influence of random error [13]. (Similarly, when there is no bias of any kind, one observed estimate can be an overestimate or an underestimate of the true relative risk simply due to random error.)

Third, error in measuring variables to be adjusted in the analysis can result in only partial adjustment for the mismeasured variables [15].

Adjusting Measures of Association for Measurement Error

One can use sensitivity analysis methods (also known as uncertainty analysis and bias analysis) [16–24] to adjust measures of association for measurement error as well as for other study biases. (As used in this context, the meaning of the term *sensitivity* differs from its other epidemiologic meaning as the counterpart to specificity as a measure of classification validity.) Sensitivity analysis is the last line of defense against biases after every effort has been made to eliminate, reduce, or control them in study design, data collection, and data analysis. In a sensitivity analysis, one alters key assumptions or methods reasonably to see how sensitive the results of a study are to those variations. (See Chapter 38 for discussion of sensitivity analyses in pharmacoeconomic studies.)

One key assumption, usually implicit, in any study that does not quantitatively account for the possibility of error in measuring the study exposure or study outcome is that the exposure and the outcome in a study have been measured accurately. With estimates of sensitivity and specificity from validation studies (from previous research or from a subsample within the study analyzed) or "guesstimates" from expert experience and judgment, one can modify this assumption and use sensitivity analysis methods to "back calculate" what the results might have looked like if more accurate methods had been used to classify participants with respect to outcome, exposure, or both [17,25].

For many years, a qualitative and informal version of this kind of assessment has been conducted. However, the net result is controversy, with investigators judging the bias small and critics judging it large. Further, in the absence of a formal bias analysis, intuitive judgments, even those of the most highly trained and widely experienced investigators, can be poorly calibrated in such matters. Formal sensitivity analysis makes the assessment of residual bias transparent and

quantitative and forces the investigator (and other critics) to defend criticisms that in earlier times would have remained qualitative and unsubstantiated. An important and well-known historical example is the bias from nondifferential misclassification of disease proposed by Horwitz and Feinstein [26] to explain associations between early exogenous estrogen preparations and endometrial cancer. When proper sensitivity analyses were conducted to assess this bias, only a negligible proportion of those associations were explained by bias [26–28].

Epidemiologic applications of quantitative methods with a long history in the decision sciences have become accessible for quantifying uncertainties about multiple sources of systematic error in a probabilistic manner [24,29–31]. These methods permit the incorporation of available validation data as well as expert judgment about measurement error, uncontrolled confounding, and selection bias along with conventional sampling error, and prior probability distributions for effect measures themselves, to form uncertainty distributions. These approaches have been used practically in pharmacoepidemiology studies such as in assessing selection bias in a study of topical coal tar therapy and skin cancer among severe psoriasis patients [30]; exposure misclassification and selection bias in a study of phenylpropanolamine use and stroke [24]; and selection bias, confounder misclassification, and unmeasured confounding in a study of less than standard therapy and breast cancer mortality [29], as well as in other clinical and nonclinical applications [18,31–39].

Sometimes biases can be shown to be of more concern and sometimes of less concern than intuition or simple sensitivity analysis might suggest. Almost always, the probabilistic uncertainty about these sources of systematic error dwarfs the uncertainty reflected by conventional confidence intervals (CIs). By the use of these methods, the assessment of systematic error can move from a qualitative discussion of "study limitations," beyond sensitivity analyses of one scenario at a time for one source of error at a time, to a comprehensive analysis of all sources of error simultaneously. The resulting uncertainty distributions can not only supplement but also supplant conventional likelihood and *P* value functions, which reflect only random sampling error. As a result, much more realistic, probabilistic assessments of total uncertainty attending to effect measure estimates are in the offing [19].

Currently Available Solutions

Conducting Validation Studies to Assess Self-Reported Data

In 1979, Leon Gordis commented that epidemiologists have become so enamored with analyzing their data that they have paid too little attention to the validity of the raw data being analyzed with these sophisticated techniques [40]. Gordis' comment reflects a time when pharmacoepidemiologic research was typically conducted by using questionnaires to gather data. The field was only just beginning to use data that arose from the provision of healthcare, including health insurer data such as Medicaid claims.

This section of the chapter focuses on the collection and validation of self-reported data for pharmacoepidemiologic research. We begin this section with a brief discussion of how individuals store and retrieve information from memory, tasks that are required when responding to a questionnaire. We use an example of how a person might recall a depression episode to illustrate retrieval of specific information from memory. Recognizing the challenges of information retrieval, we discuss best practices for designing questions to elicit specific drug and diagnosis information. Separately for drugs and diagnoses, we discuss the influence of comparator selection when validating self-reported data, the accuracy of recall, and the factors

influencing recall and provide examples for illustration.

Autobiographical Memory and the Response Process

Pharmacoepidemiologic research that relies on self-reported data requires asking study respondents to recall events or exposures that occurred at some time in the past, with recall intervals spanning from days to years. The types of temporal questions study respondents are often asked and that require the memory processes are as follows [41]:

- Time of occurrence, which requires respondents to provide a date when an event occurred, such as when they were diagnosed with a particular condition.
- Duration questions such as, "How long did you take drug A?"
- Elapsed time, which asks how long it has been since an event occurred, including questions such as, "How many months has it been since you last took drug A?"
- Temporal frequency questions that ask respondents to report the number of events that occurred over a specific time period, such as "How many visits did you make to your primary care practitioner in the past six months?"

To appreciate the accuracy of data derived by respondent recall for addressing these types of questions, it is important to understand how we process, organize, and recall autobiographical information, which is key to the response process. Creating and retrieving information from autobiographical memories is a three-step process. Information that comes in via sensory or emotional input (e.g., visual, hearing, semantic) is *encoded* into a construct that can be stored within the brain. The next step is *storage*, which refers to how the brain retains the information, typically in either short- or long-term memory. *Retrieval or recall* of memories requires reaccessing information that was previously encoded and stored. Recall effectively returns a memory from long-term storage to short-term memory, where it can be accessed for retrieval purposes [42,43]. Current thinking is that retrieval of information from autobiographical memory is goal oriented, where the retrieval process requires bringing together spatial, temporal, and social information with information derived from the emotions and senses [42].

The recall of encoded or catalogued information from memory is thought to be facilitated by using important personal milestones [41]. Thus, when respondents are asked to recall a visit to a doctor that may have occurred at a particular point in time, researchers believe that the respondents use scripts (a generic mental representation of the event) to help retrieval. For example, the respondent first contemplates a doctor visit in general and then supplements this script with details relevant to the particular visit that require contemplation for specific criteria (e.g., diagnosis) and timing (e.g., a particular year). In general, underreporting of medical conditions and health visits is more widespread as the interval since the event increases [44–46].

Recent evidence suggests that age affects memory details, with older individuals recalling slightly more details than younger individuals. Using an instrument focused on words used in everyday spoken and written language to measure autobiographical memory, Gardner and colleagues noted that recall of content and details for events and objects was slightly greater in adults 46–78 years old compared to those 26–45 years of age for both recent and remote memories [47]. There was little difference between the two age groups for recalling individuals and temporal details of events.

Applying what we know about how autobiographical memory is organized and the recall process in general helps us to understand survey response. A respondent undergoes four key tasks when asked to answer a questionnaire: (1) question comprehension and interpretation, (2)

search for and retrieval of information to construct an answer to the question depending on whether appropriate cues are given, (3) judgment to discern the completeness and relevance of memory for formulating a response, and (4) development of the response based on retrieved memories [41,48–50]. If survey instrument developers pay too little attention to the first two key tasks, their questions can be too vague or complex for respondents to marshal retrieval processes appropriately.

The following example best illustrates the response process [41] for recalling the date on which a respondent's depression was diagnosed (January 2015). The recall process begins with the respondent being uncertain whether the depression was diagnosed in 2014 or 2015. To work towards identifying the correct year, the respondent recalls that the depression occurred after he lost his job. The job loss was particularly traumatic because he and his wife just purchased their first home a few months previously, and now, with the loss of his income, they were at risk of losing the house. The home purchase was a landmark event for this respondent, and he remembers that it occurred in mid-2014, just as their children finished the school year. So, in 2014 he lost his job, near the end of the year because the holiday season was particularly grim. He remembers that his depression was diagnosed after the holidays, but was it January or February of 2015? It was January 2015 because he was already taking antidepressants by Valentine's Day, when he went out to dinner with his wife and he could not drink wine with his meal. This chronology is illustrated in Figure 37.4. We describe below how to use the response process to design questions to elicit the self-reported information requested.

As illustrated in Figure 37.4, landmark events probably serve as the primary organizational units of autobiographical memory and, as such, anchor information retrieval [51]. In particular, the example shows how the respondent used landmark and other notable events, relationships among datable events, and general knowledge (holiday period and children finishing the school year) to reconstruct when his major depression

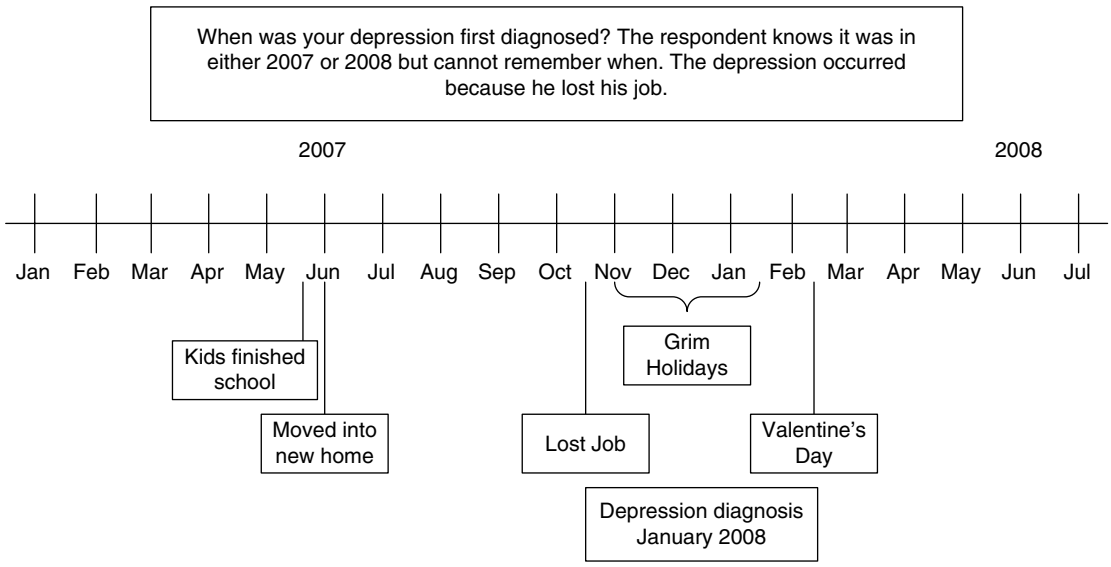

Figure 37.4 Recall schematic for showing how date of depression diagnosis was determined.

was first diagnosed. An important caveat is that this respondent was willing to expend considerable effort to search his memory to determine when his depression was diagnosed – this may not be the situation for all respondents.

The next section takes what we know about autobiographical memory and the response process to develop questionnaires for pharmacoepidemiologic research.

Best Practices for Questionnaire Design

Designing a questionnaire for collecting pharmacoepidemiologic data requires consideration of the challenges and limitations of autobiographical memory as described above and careful planning and pretesting [52] before fielding the study. Survey researchers encourage use of several general techniques to assist respondents in recalling information accurately, including use of reference periods (e.g., "in the past 12 months, that is, since December 1, 2017, how many times did you…"), event histories and calendars like the one in Figure 37.4, diaries, and photos of medications. We provide a more in-depth discussion of questionnaire design for collecting medication and diagnosis data later. We recommend that, after collecting the self-reported data using techniques to maximize their accuracy, and prior to the analysis, researchers assess their accuracy for addressing the study hypothesis by comparing the data to another data source such as health insurer claims or EHRs [53].

We suggest the following steps be considered during the design and initial analysis stages of a study requiring data collection via questionnaire.

- Use validated instruments or validated questions whenever possible.
- Consider question banks if new questions are required, such as World Bank's Living Standards Measurement Study [54] and Q-Bank [55,56].
- Use question assessment tools to determine the likelihood of response error. These tools include the Question Appraisal System [57], the Survey Quality Predictor (SQP) [58], and the Question Understanding Aid (QUAID) [59,60].
- Strive for a fifth-grade literacy level if you must develop new survey questions to be used for a general population [61].
- Pretest the questions using cognitive testing [62–64] to assess respondent comprehension of new questions.

The process of *satisficing* occurs when respondents expend the least psychological and emotional effort possible to provide an acceptable answer to a survey question rather than an optimal answer [65,66]. To minimize satisficing, questionnaire developers should consider the length of the instrument and the number of response categories. When faced with a long list of choices and depending on the mode of questionnaire administration (i.e., telephone versus self-administered), respondents may choose answers from either the top or the bottom of the list to minimize effort. For this reason, it is often recommended to randomize response options. Respondents with lower cognitive skills and less education, when challenged with discerning the best possible response, are more apt to settle for a satisfactory rather than an optimal response. Because accuracy of response is critical for pharmacoepidemiologic research, questionnaire developers must consider methods to minimize response burden leading to satisficing.

With the increasing availability of broadband and the population's access to the internet, more surveys are moving away from face-to-face and telephone interviewer administration to web-based surveys. This modality requires the same considerations for question design as described earlier, but because no interviewer is available, usability should be tested as well. Usability evaluates the survey–respondent interaction: essentially, how efficiently and effectively respondents can answer the web-based questions [67,68]. For example, usability evaluates screen size, button placement, and formatting issues specific to web

applications, especially for questionnaires using mobile technologies. Usability assessments can be combined with other pretesting modalities [52], including cognitive interviews, by embedding probes that allow respondents to explain why they provided their answers [69], a parallel to face-to-face cognitive testing without requiring an interviewer [52].

The earlier discussion focused on measurement error related to survey design and to respondent motivation. Measurement error can also be attributed to improper training of interviewers and poor data entry quality. The degree to which one understands the measurement error associated with key variables critical to the analysis can be assessed by using several different modelling approaches, which Biemer discusses in more detail [70].

Assessing the Accuracy of Self-Reported Data

Despite researchers using the best methods for designing questionnaires to elicit specific information on medications used previously and past diagnoses, self-reported data still require evaluation for accuracy to ensure valid findings. Ideally, researchers will have access to a truly accurate comparison source (i.e., gold standard) so that sensitivity and specificity can be calculated for use in bias analyses. For example, we can use pill counts, chemical markers inserted into the pills, electronic monitoring caps, or pharmacy dispensing databases to assess self-reported medication use. As discussed earlier, depending on the comparison data source, it may only be possible to calculate either sensitivity or specificity

Methodologic studies that use alternative data sources, such as prospectively collected drug data (e.g., from diaries), or databases of dispensed drugs can measure both sensitivity and specificity if one assumes that these databases are true gold standards. In pharmacoepidemiology, lower sensitivity is often more of a concern than lower specificity. Questionnaires that underreport diseases or miss drug exposures because the medication was filled without using the pharmacy plan (e.g., when the co-pay is higher than the cost of the medication) – that is, data sources with low sensitivity – cannot be used to rigorously evaluate drug–disease associations. Alternatively, low specificity is often less of a problem in pharmacoepidemiology unless the characteristic with low specificity also has very low prevalence in the population being studied. For example, because the incidence of Stevens–Johnson syndrome is low, a small degree of misclassification when using administrative claims data in which the case definition uses the *International Classification of Diseases, Ninth Edition, Clinical Modification* (ICD-9-CM) code 695.1 will include several skin problems other than Stevens–Johnson (i.e., the false-positive rate would be high) [71].

Besides the need for completeness on the individual level, the comparator database must have information for all persons whose information is to be assessed for accuracy. Systematic omissions of specific population groups, such as certain ethnic or racial groups, diminish the quality of the database.

In the next section of the chapter, we discuss issues in using the medical record as a comparator data source to evaluate the accuracy and completeness of survey data on medication and diagnoses ascertained via self-report. We discuss use of automated databases as a comparator data source for assessing validity and reliability of self-reported information in a later section.

Influence of Comparator Selection for Assessing Self-Report Accuracy

The early work on evaluating the completeness of self-reported diagnosis and medication data typically used paper medical records for comparison [72–74]. In summary, several studies from the late 1980s through 2000 indicated that inpatient medical records were often missing outpatient medications [75–77]. Similarly, outpatient

medical records were also often incomplete, and completeness varied by the number and type of medication the patients were taking [78–82]. Diagnoses or other relevant inpatient information were often omitted from patient records as well [83–86]. These studies indicate that the paper medical record may not be that useful for validation of diagnosis and medication data. With the greater availability of EHR software and policy levers incentivizing their use, providers and hospitals in the United States have been moving to EHRs, making paper medical records obsolete.

Nonetheless, regardless of whether the medical record is paper or electronic, one needs to understand its availability, completeness, and accuracy to determine whether it is adequate for evaluating the accuracy of self-reported information. Retrieval of medical records depends not only on a person's ability to remember and report who prescribed the drug or diagnosed the condition in question, but on whether the healthcare provider recorded the information (and recorded it accurately) and on the availability of the medical record for review. If the medical record cannot be retrieved because the healthcare provider could not be identified, the provider had retired, or the record was destroyed or lost, the events cannot be verified.

While paper medical records are often incomplete, how complete are EHR data for assessing the accuracy of self-reported diagnosis and medication data? This question requires reframing to consider EHR completeness at both the individual patient and the institution level. In the US, healthcare is fragmented. Patients see multiple providers, are treated in several different health settings (e.g., chiropractors, podiatrists), and may become inpatients at several different hospitals [87,88]. Thus, accessing patients' outpatient and inpatient medical records does not guarantee that a researcher will have all medical care provided and drugs prescribed to the patient. For example, if a researcher is able to access only the patient's primary care records, it is possible that the results of cardiology tests to confirm a diagnosis or medications for that diagnosis will not be available. However, when patients are seen by integrated delivery systems that include primary care, multiple specialties, and inpatient care, there is a greater likelihood that the EHR will contain most of the care provided and medications prescribed to the patient.

In addition, the EHR data themselves may be no more accurate than paper records if the EHR data simply substitute for paper records. For example, exposure information about medications or important confounders (e.g., smoking) may be incomplete if clinicians do not ascertain this information and correctly enter it into the EHR. Another problem introduced by EHRs is the potential for errors inherent to electronic data entry, such as copying and pasting of incorrect data from other parts of the record, of expired or irrelevant clinical information, or of incorrect and/or unverified medication lists [89].

Self-Reported Drug Data From** De Novo **Questionnaire Studies

This section summarizes what is known on how well respondents recall prescription and over-the-counter medication use, factors that influence recall, such as the type of medications being queried, as well as questionnaire design features suggested to improve recall accuracy.

Accuracy and Recall

Several studies have evaluated self-reported recall accuracy for current or past medication use compared with prospectively collected cohort data or pharmacy, hospital, and outpatient medical record documentation. Overall, published studies indicate that people accurately remember ever using a medication and when they first began using some medications, although they do not remember brand names and duration of use as well [90–98]. Current use of chronically used medications, such as statins, beta-blockers, and calcium channel blockers,

was recalled with ≥95% sensitivity and specificity when a mailed medication inventory was compared to pharmacy records [99]. In general, greater inaccuracies have been noted as more time elapsed between occurrence of exposure and its subsequent reporting [91,95,97]; this tendency was especially true for over-the-counter NSAID use in contrast with prescription NSAID use for recall over a two-month period [100].

Accuracy of self-reporting medication use varies by several factors. For example, chronically used medications (especially those with more refills) are recalled more often than acute exposures, as are the first and most recent brands in a class; a person recalls multiple medications in one class more frequently than single medication exposure; and salient exposures (those that prompted study initiation) are more accurately recalled than common and less disconcerting exposures [90,91,96,101–105]. For prescription drugs, recall between self-reported use and medical records was moderately accurate, but for over-the-counter medications and vitamin supplements, accurate recall was poor [106]. Discrepancies are due to both underreporting (e.g., respondent forgot medication was taken) and underdocumenting (e.g., physician was unaware of medication use or did not record patient's use in chart) [79–81 92,101,103,105–108] and differed by therapeutic class [106,107,109–116]. When self-reported data were compared to multiple sources (e.g., medical records and pharmacy dispensing), verification for self-reported use was higher than that for a single source [117].

Influences on Accuracy

Influence of Questionnaire Design

As reported in a systematic review, several factors affect the accuracy of medication exposure reported via questionnaire [118]. Researchers can facilitate recall and reporting of medication use by indication-specific questions, memory prompts (such as drug photo), a list of drug names, or a calendar to record life events [70–74,93,119]. Medication-specific or indication-specific questions can identify most medications respondents are currently using, rather than a general medication question such as, "Have you taken any other medications?" [105]. Similarly, open-ended questions such as, "Have you ever used any medications?" yielded less than half of the affirmative responses for use of three different medications [120]. Using the filter question "Did you use any medications in the three months before or during your pregnancy?", van Gelder and colleagues noted that many women failed to report medications that they had been dispensed for pain or infections. These findings could be attributed to poor recall, but they may also be due to women having chosen not to take the dispensed medications [121]. If researchers choose to use open-ended medication questions, adding indication-specific questions that facilitate recall of medication exposures may be useful. Finally, 20–35% of respondents reported drug exposure only when asked medication (name)-specific questions [120].

Response order may affect recall, as noted with malaria medications when respondents had more than one episode of malaria [122]. Regardless of how frequently the medication is used for treating malaria in general, medications listed earlier in the response set tended to be selected more frequently than those listed later – a finding that may be related to satisficing, as discussed earlier [65].

A comparison of self-report of current and recent medication use (within the past two years) to pharmacy records of dispensed prescriptions for multiple drug classes found that the number of drug dispensings recalled was highest for cardiovascular medications (66%) and poorest for alimentary tract medications (48%) [123]. Recall was influenced by the number of chronically used medications: 71% for one drug, 64% for two drugs, and 59% for three or more drugs, although duration of use was not related to recall. However, the questionnaire did not allow sufficient space to record all medications

used in the time period of this study. Thus, if respondents were unable to record all medications due to space limitations, a misleading validation might have occurred: it appeared that respondents were unable to recall all the medications dispensed according to the database.

Another methodologic study evaluated whether question structure influences the recall of currently used medications in 372 subjects with hypertension who had at least 90 days of dispensings in the PHARMO database [105]. The questionnaire had indication-specific questions first (e.g., medications used for hypertension, diabetes), followed by an open-ended question that asked if the subjects used any other medications not already mentioned. For hypertension, the sensitivity was 91% for indication-specific questions and 16.7% for open-ended questions. About 20% of subjects listed medications on the questionnaire that were not in the database, and a similar proportion failed to list medications on the questionnaire that were in use according to the pharmacy database. Based on these recall sensitivity results, indication-specific questions appear to invoke better recall accuracy. However, to adequately address the issue of question structure, a questionnaire could be designed to ask open-ended questions first, followed by indication-specific questions. This sequencing would allow a comparison of the number of medications recalled by each question structure.

Influence of Patient Population

Few studies have evaluated whether demographic and behavioral characteristics influence the recall of past medication use, but results to date suggest that recall does vary by these factors as well as by therapeutic class and study design. For example, research suggests that education attainment [104,108,124] and race/ethnicity [91,95] may affect recall accuracy. Studies are inconsistent for age [77,91,95–97,101,103,107,116], socioeconomic status [64,101,103,107,124], and smoking [95,97] as predictors of recall accuracy, and no study found that recall accuracy varies by gender [97,99,123]. The inconsistencies in the effect of age on recall accuracy might arise from differing study designs. The two studies that reported an age effect were methodologic studies evaluating recall accuracy [97,123], whereas the two that reported no age effects [91,95] were etiologic studies that reported verification of drug use as a measure of exposure misclassification for the association under study. Because of the paucity of information on predictors of recall, further research in this area is warranted.

Example

As indicated previously, accuracy of *de novo* questionnaire studies has been determined via comparison with pharmacy, general practitioner, and hospital records. To find an example of available study types, we conducted a literature scan of published studies, specifically searching for validation of NSAID use in questionnaire studies, and summarized our findings in Table 37.1.

Comparing use recalled during telephone interviews to a pharmacy database, West and colleagues found that 57% (95% CI 50–65%) of "any" NSAID use during the previous 12 years was accurately reported [97]. While a single dispensing was reported only 41% (95% CI 32–50%) of the time, repeated use was reported 85% (95% CI 76–94%) of the time, using the pharmacy records as the gold standard. Thirty percent of interviewees reported NSAID name and 15% reported both name and dose. Report was poorer with a shorter duration of use or over a longer recall period.

In summary, the methodologic literature on recall accuracy discussed above indicates that study participants have difficulty remembering drug use from the distant past, which contributes to misclassification of exposure in *de novo* studies. Researchers are using best practices in questionnaire design, including medication-specific and indication-specific questions, along with recall enhancements, which have been shown to produce better data. Calendars and photos of drugs augment recall to a greater degree than listing only the brand names of the

Table 37.1 Validation of NSAID exposure in studies using questionnaires.

Author	Recall period	Questionnaire and sample size	Study question	Memory aids	Comparison data source	Findings
West 1995 [97]	2–3 years 7–11 years	Telephone interviews n = 319	Nonsteroidal antiinflammatory drugs (NSAIDs)	Pictures of NSAIDs	Pharmacy database	Recall percentage for any NSAID use: 57 (95% CI 50–64) Single NSAID dispensed in 12 year period: 41 (95% CI 32–50) Repeated NSAID use: 85 (95% CI 76–94)
			For those with repeated NSAID use, a single NSAID was selected as the target drug for assessing name, dose, and dates of use			NSAID name: 30 (95% CI 24–36) NSAID name and dose: 15 (95% CI 10–20) Agreement: (a) ±6 months, (b) ±1 year, (c) ±2 years (a) (b) (c) First use 20 28 51 Last use 17 24 42 Duration 67 71 80

drugs in question. These techniques – namely, photos, calendars, and the two different types of drug questions – have become the state of the art for collecting self-reported drug data by personal or telephone interview.

The literature to date suggests that recall accuracy of self-reported medication exposures is sometimes, but not always, influenced by type of medication, drug use patterns, design of the data collection materials, and respondent characteristics. Given the current state of the literature, epidemiologists who plan to use questionnaire data to investigate drug–disease associations will need to consider which factors may influence recall accuracy in the design of their research protocols.

Self-Reported Diagnosis and Hospitalizations from De Novo Studies

Accuracy and Recall

Just as recall accuracy of past medication use varies by the type of drug, the ability of respondents to remember disease conditions varies by disease, particularly when it is chronic, like hypertension, or is viewed as threatening, such as sexually transmitted infections. The best reporting has been

noted with conditions that are specific and familiar, such as diabetes mellitus [113,125–131], hypertension [113,126,128,129,132], asthma [125,127,128], and cancers such as breast, lung, large bowel, and prostate [129,132–134]. However, assessing reporting accuracy is likely more difficult for common, recurring symptom-based conditions, such as sinusitis, arthritis, low back pain, and migraine headaches, which many people may have, or believe they have, without having been diagnosed by a clinician. For recall of acute conditions such as fractures, there is typically good agreement between self-report and the comparison data source, although the one methodologic study of fracture incidence indicated a slight tendency for overreporting of hand, finger, rib, or facial fractures [135], which might be attributed to confusing a fracture with other similar orthopedic problems like sprains and strains. Recall of acute conditions is likely to depend on the length of the recall period: mild traumatic brain injury that occurred prior to age 10 years was poorly recalled 15 years later [136].

Three studies assessed the recall accuracy for self-reported mental illnesses, comparing respondent information to clinical evaluation [127,128,137]. The results indicated poor agreement between the two data sources, with underreporting as the primary reason for poor agreement. It is unclear from these studies whether the reason for underreporting was the respondent's unwillingness to admit to mental illness or whether the conditions were actually underdiagnosed.

Both underreporting and overreporting of diagnoses have been noted in studies comparing self-reported diagnoses to clinical records [127,128], with overreporting occurring for conditions in which the diagnostic criteria are less explicit [138]. For common ailments, underreporting was often the major cause of disagreement [113,125,129,131]. Both overreporting and underreporting were noted for cardiovascular conditions, depending on the data source used for comparison [113,126,128,129,131,132,134,139–141]. In most instances of recall error, many respondents who had incorrectly reported myocardial infarctions (MIs) and stroke had other conditions that they may have mistakenly understood as coronary heart disease, MI, or stroke, based upon communication with their physician during their diagnostic visits [134,139–141].

Influences on Accuracy

Influence of Questionnaire Design

Questionnaire design also influences validity of disease and hospitalization data obtained by self-report. Simpler questions yield better responses than more complex questions, presumably because complex questions require the respondent to first comprehend what is being asked and then provide an answer. Inherent redundancy in longer questions and allowing more time to develop an answer to the question may increase recall [142]. However, longer questions could increase the cost of the research and could needlessly tire the respondents, leading to satisficing. Facilitating recall by providing respondents with a checklist of reasons for visiting the doctor improves recall of all medical visits [143].

Although specific guidance on best practices for improving the ascertainment of diagnoses and hospitalizations is lacking, there are several general approaches to questionnaire design that are useful (see, for example, Sudman and Bradburn [144] and McColl and colleagues [145] for further details). Briefly, researchers developing questionnaires should be mindful of question wording and sequencing and response formats. With regard to question wording, to increase response accuracy, questionnaire designers should attend to the cognitive processes involved in developing a response, especially those related to saliency for the respondent. Whether a respondent recalls having been diagnosed with a particular condition previously is likely to depend on the seriousness of the condition. Use of a filter question such as, "Have you had any side effects from use of drug X in the past year?" must be done with caution because respondents who

avoid the filter are not asked subsequent questions that may be important for the study. As noted for recall of medications, open-ended questions are not recommended, particularly if the questionnaire is self-administered. That said, all potential response categories must be listed when using closed-ended questions or when an "other" category is provided. Questionnaire design experts suggest that demographic questions be placed at the end because they may be regarded as threatening.

The typical rule of thumb for question sequencing is to ask general questions before delving into specific topics and to group questions according to topic. When laying out the questions in a questionnaire, researchers should consider whether ordering effects are possible: for example, ask about heart disease in general before asking about a heart attack. Ordering might influence response rates to particular questions and may vary with the topic and make-up of the respondent population. With regard to response formats, the response categories should be unambiguous, nonoverlapping, and exhaustive. When there is a possibility of biased response due to response ordering, it is best to randomize the response options to minimize the bias. Finally, satisficing is also possible when respondents are asked to identify the diagnoses they have been given previously.

Influence of Patient Population

Factors influencing accuracy of past diagnoses and hospitalizations include the number of physician services for that condition and the recency of services [44–46,146–148]. For reporting of diagnoses, the longer the interval between the date of the last medical visit for the condition and the date of interview, the poorer the recall was for that condition [44–46]. These differences in recall may be explained in part by recall interval, patient age, a cohort (generational) effect, or some intertwining of all three factors. Diagnoses considered sensitive by one generation may not be considered as such by subsequent generations. Further, terminology changes over time, with prior generations using different nomenclature compared with recent generations.

Conditions with substantial impact on a person's life are more accurately reported than those with little or no impact. More patients with current restrictions on food or beverages due to medical problems reported chronic conditions that were confirmed in medical records than did those without these restrictions [44]. Similarly, those who had restrictions on work or housework reported their chronic conditions more often than those who did not have these restrictions [44]. The major determinant of recall for spontaneous abortions was the length of the pregnancy at the time the event occurred: nearly all respondents who experienced spontaneous abortions occurring more than 13 weeks into the pregnancy remembered them compared with just over half of respondents who experience such abortions occurring in the first six weeks of pregnancy.

Perhaps as a result of the emotional stress, lifestyle changes, and potential financial strain, hospitalizations tend to be reported accurately [147]. Further, underreporting of hospitalizations occurred in only 9% of patients who received surgery compared to 16% of patients without a surgical procedure. Underreporting in those with only a one-day hospital stay was 28% compared with 11% for 2–4-day stays and approximately 6% for stays lasting five or more days.

Surgical procedures are also more likely to be accurately recalled. General practitioner records confirmed 90% of the surgeries reported during one study interview. For the remaining 10%, the medical record may have lacked the needed information [149]. Recall of surgery date (±1 year) was correct for 87.5% of patients interviewed. Researchers also agree that respondents remember the type of surgery accurately [116,148–150]. Recall accuracy was very good for hysterectomy and appendectomy [110,125,129], most likely because these surgeries are both salient and

familiar to respondents. Cholecystectomy [129] and oophorectomy [110] were not as well recalled and were subject to some overreporting. However, overreporting may have been due to the potential incompleteness of the medical records used for comparison [110]. For induced abortions, marginal agreement occurred, as noted by records from a managed care organization: 19% of women underreported their abortion history, 35% overreported abortions, and 46% reported accurately according to their medical record [151].

The influence of demographic characteristics on reporting of chronic illnesses has been evaluated in many studies, although the results are conflicting. The most consistent finding is that overall recall accuracy decreases with age [113,116,131,133,152], although this may be confounded by recall interval or cohort (generational) effects. Whether gender influences recall accuracy is uncertain. Men have been reported to recall more accurately than women, independent of age [125], whereas conflicting evidence found that women reported more accurately than men [127], especially in older age groups [44]. Further studies indicate that gender and age differences depended upon the disease under investigation [127], with women overreporting malignancies and men overreporting stroke [131]. No differences were found for reporting of hospitalizations by age or gender [147].

Reporting of illnesses, procedures, and hospitalizations tends to differ by race/ethnicity, but most studies had much larger proportions of whites than nonwhites [44,116,125,127,147,151]. Reporting by education level was equivocal; one study showed no difference [46] while another study indicated better recall for those with less education [44], and others suggested more accurate responses for those with a college education [131,133,135,151]. Those with a poor or fair current health status reported conditions more completely than those with good to excellent health status [44].

Although menarche and menopause are not medical conditions *per se*, the age at which they occur is often of interest in pharmacoepidemiologic studies. In the Menstrual and Reproductive Health Study, which had recall periods ranging from 17 to 53 years (mean 33.9 years), the exact age of menarche was recalled by 59%, and age within one year was recalled by 90% [153]. Similarly, for menopause, 45% of women were able to report their exact age at natural menopause and 75.5% reported age within one year. The percentage agreements for surgical menopause were 55.6% and 83.4%, respectively, for exact age and age within one year. The lower percentage agreement for age at which natural menopause occurred compared to that for surgical menopause may be attributed to the gradual occurrence of natural menopause compared to the definitive nature of hysterectomy [154].

Example

We conducted a literature scan of published studies searching for outcomes of MI and GI bleeding associated with use of NSAIDs to provide specific examples of validation and reliability studies for diagnoses (Table 37.2). Many of those identified were methodologic studies conducted specifically to determine the accuracy of the questionnaire; however, some of the accuracy assessments were embedded in empirical studies. Fourrier-Reglat and colleagues compared reported medical data from patient and prescriber self-administered questionnaires [155]. Myocardial infarction showed substantial agreement (kappa = 0.75; 95% CI 0.71–0.80), while upper GI bleeding had only slight agreement (kappa = 0.16; 95% CI 0.11–0.22) between the two reporting groups. When the prescriber data were used as the gold standard, patient reports of MI provided moderately complete data (sensitivity 77.7%; specificity 99.6%; positive predictive value [PPV] 77.1%; negative predictive value [NPV] 99.6%), and reports of upper GI bleeding by patients were not typically confirmed by the prescriber reports (sensitivity 44.6%; PPV 10.4%).

Jarernsiripornkul and colleagues also used a multistage process to develop a questionnaire to

Table 37.2 Validation of myocardial infarction (MI) or gastrointestinal (GI) outcomes in patients with nonsteroidal antiinflammatory drugs (NSAIDs) in questionnaire data.

Author	Questionnaire and sample size	Study question	Comparison data source	Conditions	Findings
Ambegaonkar 2004 [192]	Gastrointestinal Toxicity Survey (NSAID Induced) (GITS [NI]) – 11 questions, n = 400 patients	To test a new questionnaire designed to identify patients at high risk for NSAID-associated GI events	Stanford Calculator of Risk for Events (SCORE) – 6 questions	56.0% rheumatoid arthritis	The overall correlation between results for GITS (NI) responses and the total score for the SCORE questionnaire was 0.96 (P<0.001) Comparison: ordinary least square R^2 = 0.91 feasible generalized least squares (FGLS) R^2 = 0.93 Use of the FGLS regression analysis and comparison of the risk levels predicted by the SCORE questionnaire and the GITS (NI) questionnaire demonstrated a 79.8% agreement for all four risk categories and an 88.8% agreement when the two highest risk categories were collapsed into a single category The multinomial logistic regression (MNL) analysis showed agreement of 75.8% for four risk categories and an agreement of 86.8% for three risk categories For both methods, disagreement was equally distributed among overprediction and underprediction of risk levels by the GITS (NI) questionnaire relative to the SCORE questionnaire. In the case of four risk categories, disagreement by two risk levels was limited to 0.6% and 1.5% for the FGLS and MNL regression methods, respectively

(Continued)

Table 37.2 (Continued)

Author	Questionnaire and sample size	Study question	Comparison data source	Conditions	Findings
Fourrier-Reglat 2010 [155]	CADEUS cohort (French national cohort study of traditional NSAIDs and COX-2 users conducted between September 2003 and August 2004 that employed self-administered questionnaires to obtain medical data from patients and their prescribers) n = 18 530 pairs of patients and prescribers	To compare patients and prescribers reported medical data	Prescribers report as gold standard		Previous medical history: MI: kappa = 0.75 (95% CI 0.71–0.80) Sensitivity: 77.7% Specificity: 99.6% PPV: 74.1% NPV: 99.6% Upper digestive hemorrhage: kappa = 0.16 (95% CI 0.11–0.22) Sensitivity: 44.6% Specificity: 98.5% PPV: 10.4% NPV: 99.8% NSAID indication: For index NSAID indication, the proportion of agreement ranged from 84.3% to 99.4% and concordance was almost perfect (kappa = 0.81–1.00) for inflammatory rheumatism, flu-like symptoms, dysmenorrhea and dental pain; substantial for arthritis, back pain and headache; moderate for osteoarticular pain.
Singh 1996 [193]	Stanford Health Assessment Questionnaire (HAQ)	To evaluate the event rates for all NSAID-induced GI complications in patients with rheumatoid arthritis, describe the time course of these events, and evaluate the role of prophylactic therapy with antacids and H2 receptor antagonists	Face validity and hospital records (2.4% hospitalized)		Face validity has been studied by surveying patients to ensure their understanding of the symptoms that are listed in lay language on the questionnaire; appropriate modification of the confusing symptoms has been made. Patient recall and accuracy in reporting side effects have been evaluated by repeat questionnaire administration, interview, and review of physician records. To minimize underreporting by patients, those events that are severe enough to require hospitalization are also ascertained by record review of all hospitalizations.

CI, confidence interval; NPV, negative predictive value; PPV, positive predictive value.

have patients self-report potential adverse reactions to NSAIDs [156]. The questionnaire was designed to elicit adverse effects that would be reported to health professionals, to determine how well patient report compared with health professionals reporting to the Adverse Product Reaction Monitoring (APRM) Centre of the Thai FDA. The questionnaire was cognitively tested to finalize the version sent to the test sample along with pictures to facilitate recall. Of the 694 (42%) of questionnaires returned, 60% reported ≥1 symptom deemed as a possible or probably adverse drug reaction by a pharmacist. By comparison, only 5% of the self-reported symptoms indicative of adverse events from the questionnaires were recorded in the outpatient medical records.

These examples demonstrate the variation in methods used to collect and determine accuracy of questionnaire data. Although many methods are available for use, researchers should remember the principles discussed earlier in the chapter when they validate questionnaire data: not all validation is equivalent. Full disclosure of the process is important when reporting findings of any study.

In summary, the decision as to whether a person reports an illness during an interview appears to be related to age and type of illness, when it occurred, and its saliency, but is less likely to be mediated by demographic characteristics such as gender, race, and education. Illnesses that are considered embarrassing and that do not substantially alter the person's lifestyle are not reported completely, and these types of illnesses may change with each generation. Likewise, reporting accuracy depends on the consistency of documentation and the terminology utilized – from the questionnaire to the medical records – and finally, what has been communicated to the individual. Although difficult to measure, respondent motivation appears to influence the completeness of reporting as well [44,127,147].

Conducting Validation Studies to Assess Data Collected During Provision of Healthcare

In addition to conducting *de novo* studies to evaluate drug–disease associations, a variety of computerized, administrative claims, and EHR databases are available for pharmacoepidemiologic research, the structure, strengths, and limitations of which are reviewed in Chapters 14–14. One major advantage of using such databases for pharmacoepidemiologic research is the comparative validity of the drug data in lieu of questionnaire data, where recall bias is always a concern, as previously described.

In general, the administrative claims and EHR differ widely on many factors, such as size (e.g., from several hundred thousand to several million covered lives), number of health insurance plans and health systems included, the type of health services provided and therefore available for analysis (e.g., prescriptions, mental health benefits, general practice versus specialist visit data), inclusion of out-of-plan claims in the main database versus other databases, and the timeliness of the data (e.g., the lag for cleaning and obtaining data from a data vendor may be six or more months). The databases also differ on the number of available demographic variables: all have age (some may have date of birth) and sex, EHRs may have race (but administrative claims typically do not), or a measure of health status [157]. Because the administrative claims data were developed primarily for reimbursement, they all have relatively complete data on health service use and charges that are covered by the plan (and relatively incomplete data for services not covered by the plan). EHRs provide in-depth, granular data for a specific office or hospital visit but may not provide all health information for an individual in a longitudinal fashion, especially if the patient sees more than one healthcare provider. Linkage of EHRs and administrative claims can be resource intensive but may elucidate whether the data sufficiently capture the patient experience.

The drawbacks and limitations of these data systems are important to keep in mind. Their most critical limitation for pharmacoepidemiologic research is the manner in which health insurance is currently covered in the US, typically through the place of employment. If the employer changes plans, which may occur on an annual basis, or the employee changes among the plans offered by the employer, or the employee changes jobs, the plan no longer covers that employee or his or her family. In addition, the healthcare delivery system coverage for an employer may change over time. Thus, the continual enrolment and disenrolment of plan members hinder the opportunity for extended longitudinal analyses in both administrative claims and EHRs.

Best Practices for Validation Studies in Administrative Claims or EHR Databases

For the data in administrative claims or EHRs to be considered valid, people who appear in the computerized files as having a drug exposure or disease should truly have that attribute and those without the exposure or disease should truly not have the attribute. Validity and completeness are determined by comparing the database information with other data sources, such as comparison of paper medical records or EHRs, administrative claims, pharmacy dispensings, or procedure logs. Choice of an appropriate comparator varies by study question, variables used for the research study, the comparator, and availability of other data sources.

The study investigator must be aware of the limitations of both the administrative claims database and the chosen comparison dataset. The chosen comparator should provide sufficient data to validate both the exposure and outcome used for the study. A variable that provides linkage between the files in a data source, such as a medical record number, should be available so that accuracy can be evaluated within a subset of known study patients. For example, if a single claim contains six diagnosis codes and six months of claims were used to determine outcomes in patients, then all six diagnosis codes for all claims across the six-month study should be available in a comparison dataset to establish the validity of the outcome. As described earlier in the chapter, a validation assessment should include evaluation of patients with and without the exposure or outcome. Positive predictive value, negative predictive value, sensitivity, and specificity combined provide a complete picture of the agreement between the two data sources.

The following is a broad overview of how to conduct a validation study in administrative claims or EHR data. First, choose a meaningful number of patients for validation. This sample size should be statistically grounded; however, considerations of data availability, cost, and labor are understandable. Next, extract the variables needed to determine cohort selection, exposure, outcome, and other variables for validation. Calculate measures of agreement and error rates (e.g., standard deviations) between the two datasets. Finally, consider strengths and limitations of the two datasets to ascertain validity and completeness of the data source to answer the study question.

Influence of Data System

Completeness and validity of data are the most critical elements in the selection of a database for research. Completeness is defined as the proportion of all exposures, events of interest or both that occurred in the population covered by the database that appear in the computerized data. Missing subjects, exposures, or events could introduce bias in the study results [158]. For example, completeness of the drug data might vary by income level if persons with higher incomes and drug co-payments choose to obtain their medications at pharmacies not participating in a prescription plan, which is how pharmacy data are collected. Similarly, a bias may be introduced in the association

between a drug and a serious adverse drug reaction if hospitalizations for that adverse reaction are missing, for example if the researcher only has access to the outpatient clinic EHR database.

Influence of Clinical Coding Systems

Diagnoses, procedures, medications, and other therapeutics are included in administrative claims and EHR data through structured coding systems. Each coding system has its own ontology and is separated into specific codes, based on an established hierarchy. Further, the coding systems are updated periodically to reflect changes in the practice of healthcare as well as to incorporate new therapies and processes. Both codes and the general structure and hierarchy differ between coding systems. In many cases, a single code from a coding system is insufficient to define a variable and an *algorithm* needs to be developed. The algorithm may contain multiple codes, a required timing for codes, and/or a sequential process for determining the level(s) of the variable. It is likely that an algorithm developed in one coding system will require translation to be comparable to another coding system. Algorithms for each clinical concept should be developed and validated separately

The International Classification of Diseases (ICD) is the standard for classification of diseases for clinical and research purposes [159] and is used in many administrative claims systems, such as for billing purposes. The ICD is updated periodically, and adoption is asynchronous by country. For example, through the fall of 2015, most US administrative claims systems were using the clinical modification version of ICD-9, while many European administrative claims systems began using ICD-10 in the 1990s, and ICD-11 was released in 2018. As with the transition to ICD-10, we anticipate a staggered approach to implementation, with countries in Europe and Canada adopting the ICD-11 system (long) before the US. The ontology differs between the ICD systems, and codes have been mapped between ICD-9 and ICD-10 [160]. However, there is not a one-to-one correlation between codes; there are approximately 14 000 diagnosis codes in ICD-9 compared with approximately 70 000 in ICD-10 [161]. Mapping between codes can be used as a starting point to develop algorithms [162], but various techniques in mapping may yield different results [163]. As with other coding systems, any validation should be conducted separately between ICD systems.

Influence of Structured and Unstructured Healthcare Data in Computerized Databases Containing Administrative Claims or EHR data

In addition to the structured data in administrative claims and EHR, many components of healthcare are captured within clinician notes, images and descriptions of procedure results, and other unstructured data. The performance of an algorithm can be enhanced through use of this unstructured information in addition to the structured data from coding systems. Unstructured data can be converted into structured information (e.g., manually) for a specific project, or the algorithm can be modified to improve algorithm performance as cases are identified over time [164,165]. Liao and colleagues compared the performance of algorithms including unstructured data to detect coronary artery disease to algorithms using only structured elements in the same data source to assess validity in three chronic disease patient cohorts [166]. They found that inclusion of unstructured data increased sensitivity in all three cohorts, with the most improvement seen in the cohort where coronary artery disease prevalence was lowest. Note that while previous algorithms are sometimes used for comparison [165], patient charts (electronic or paper) are still often used as the reference standard for assessing validation [167].

Influence of Distributed Data Systems

Multiple health data sources may be included within a single study or for ongoing surveillance.

Simultaneous assessment of multiple data sources allows for better understanding of a larger population while also observing a diverse set of patients [168]. These multidatabase studies or distributed data systems may have differences in information collected, coding systems, language (e.g., across different countries), and even the underlying practice of medicine and overarching system of healthcare. Thus, even in the situation where distributed data systems use a common data model, careful consideration is warranted regarding how to assess validity of drugs, other therapeutics, diagnoses, procedures, and health-related events within each administrative claims data source contributing to the distributed data system. Whenever EHR data are utilized, differences across sites warrant assessment of validity within each health system to improve overall accuracy [167].

Validity of Drug and Other Medical Intervention Data in Administrative Claims or EHR Databases

Accuracy

Drug data in administrative claims databases are often not validated. Administrative claims data contain billing of a prescription that is dispensed (i.e., "filled") but do not contain information on the provider writing the prescription (or on the underlying condition the prescription is intended to treat). While prescriptions that are dispensed but unclaimed by patients should be removed from billing, they may remain within the administrative claims data. Furthermore, dispensing data cannot address drug ingestion or adherence, and over-the-counter medications are not typically included in the database at all. Thus, despite the widespread use of claims data to assess drug use, the data may not be accurate and validity should be tested, particularly when using a new drug exposure or database (e.g., some data sources may not contain a drug because it is not "on formulary" and thus is unavailable within the health system or allowed by the health insurer). Similarly, sensitivity analyses should be performed to determine the susceptibility of the results to possible misclassification, even within known data sources.

Unclaimed prescriptions, estimated to occur for approximately 2% of all prescriptions, present an adherence issue in administrative claims data [169]. For every 1000 new prescriptions, an average of 16.5 are unclaimed [170]. Antiinflammatory and antiinfective drugs tend to be the therapeutic class most often unclaimed [170–173]. Two-thirds of unclaimed prescriptions were for new prescriptions [171], and a similar proportion tended to be for nonessential medications [174]. Many unclaimed prescriptions were telephoned into the pharmacy [169,171], and the most frequent reason patients cited for not picking up a prescription was that they determined that they did not need the medication or they forgot to pick it up [169,172]. However, cost and having a similar medication at home were also often cited [169,172,174].

Drug data in EHRs represent the actual prescribing practice. EHR data account for the written prescription and may have sufficient detail to ascribe the prescription to the underlying condition it is intended to treat. Prescriptions or other documentation may also be available in the EHR for over-the-counter medications. However, they may not present a valid picture of the patient experience with the medication. The dispensing, ingestion, adherence, and pattern of use are typically not included as structured fields. Some of this information may be available in unstructured text such as the clinician visit notes.

Influences on Accuracy

Population and Representation in Data Source

One might ask how unclaimed prescriptions might affect the validity and completeness of pharmacy data. Many individuals have some type of pharmacy benefits plan in which reimbursement for medication costs is processed through a third-party payer. Entry into the reimbursement software is predicated on dispensing of the drug. However, a drug that is dispensed

but not claimed should be returned to stock and the appropriate adjustment be made to the patient's pharmacy benefits plan – failure to do this would be insurance fraud.

Unfortunately, when conducting research with pharmacy data, we do not know whether all such insurance adjustments have been made. So while we believe a substantial number of prescriptions were dispensed, they may not have been used at all. To the extent that dispensings in the database were not picked up, there is no chance that the individual had the drug exposure and our study would suffer from exposure misclassification. Exposure misclassification can occur even when dispensings were picked up but not actually used by patients. For these reasons, some researchers require a minimum of two dispensings for assessing patient exposure to chronic medications. This rule of thumb is thought to improve to the likelihood that the drug was taken by the patient.

Example

A handful of studies to date have assessed dispensing associated with prescriptions via linked administrative claims and EHR data. These studies indicated that 70–77% of initial prescriptions are dispensed [175,176]. Prescribed analgesics (i.e., pain medications, including NSAIDs) and lifestyle drugs (e.g., phosphodiesterase type 5 inhibitors) are least likely to be dispensed, while antimicrobials are most likely to be dispensed for an initial prescription. Substantial variation in dispensing was seen across medications within a class. In addition, results from Rowan suggest that <20% of patients taking analgesics and NSAIDs possessed adequate medication to be adherent throughout a 12-month period [176]; this finding may be consistent with intermittent or "as needed" utilization.

In summary, drug and medical intervention data are often considered to be correct when using administrative claims data and EHRs for research. Although this is generally the case, researchers should be aware of whether and how prescribing, dispensing, and administration of drugs are captured within each database they are contemplating using. We will likely see greater emphasis on data linkage and incorporation of more unstructured data from clinical notes into pharmacoepidemiologic research, which may lead to increased need for validation of drug and medical intervention exposures in the future.

Validity of Diagnosis, Procedure, and Hospitalizations in Administrative Claims and EHR Databases

Accuracy

Unlike the drug data, where many researchers are comfortable with data accuracy and completeness, inpatient and outpatient diagnoses in these databases raise considerable concern for investigators. The accuracy of outpatient diagnoses is more uncertain than inpatient diagnoses for several reasons. Hospitals employ experienced people to code diagnoses for reimbursement, which may not occur in individual physicians' offices where outpatient diagnoses are determined. Also, hospital personnel scrutinize inpatient diagnoses for errors [177], monitoring that does not typically occur in the outpatient setting.

Systematic errors as a result of diagnostic coding may influence the validity of both inpatient and outpatient diagnostic data. For example, diseases listed in administrative claims databases are often coded using the ICD coding system. Poorly defined diseases are difficult to code using the ICD system, and no way exists to indicate that an ICD code is coded for "rule-out" purposes. How healthcare plans deal with "rule-out" diagnoses is unclear; for example, should they be included or excluded from the diagnoses in the physician claims files? In a study of transdermal scopolamine and seizure occurrence, many patients with ICD codes indicating seizures had this diagnosis as a "rule-out" code when medical records were reviewed to confirm

the diagnosis, indicating that "rule-out" codes do become part of administrative claims data [178]. In addition, reimbursement standards and patient insurance coverage limitations may influence the selection of ICD codes for billing purposes [179]. The potential for abuse of diagnostic codes, especially outpatient codes, may occur when physicians apply to either an insurance carrier or the government for reimbursement and may be less likely in staff or group model health maintenance organizations (HMOs) such as Kaiser Permanente.

Influences on Accuracy

Validation Study Design

Abstraction of electronic data for validation studies is not subject to the issues of questionnaire design that are present with self-reported *de novo* studies; however, manual abstraction is subject to human error. Algorithms that are complex require substantial understanding of the healthcare environment in which the data were collected and necessitate review of lengthy portions of the patient chart, which may increase risk of error during record abstraction. Understanding of each specific healthcare system may be warranted to understand nuances of documentation practices. In one study, medical record documentation within a single multispecialty medical group showed that documentation varied across measures (e.g., medications documented 92% of the time, smoking history documented 38% of the time, and drug allergies documented in 62% of encounters) [180]. While no systematic patterns were noted across clinician and patient characteristics, differences in documentation were found between internists and pediatricians as well as between male and female providers.

Population and Representation in Data Source

At an institutional level, informaticists in the US have been concerned about the completeness of EHR data for research use [181,182]. Patient information in an EHR may be considered complete if it has sufficient detail regarding clinical encounters, if ongoing encounters are included over calendar time, if multiple types of data (e.g., labs, medications, and diagnoses) are available, and/or if sufficient information is available across a patient record to predict the condition of interest. In 2013, Weiskopf *et al.* reviewed all four of these definitions within a single healthcare system data warehouse in the United States and found that 26.9% of patients had complete records according to any one of the four definitions (8.4–18.5% of patient records were complete for each measure), and only 0.6% of patients had complete records according to all of these definitions of completeness [182].

Example

Continuing with the NSAID example, we conducted a literature scan of published studies validating MI or GI bleeding outcomes with use of NSAIDs in administrative claims databases; these studies are summarized in Table 37.3. Administrative claims data are often compared with medical records in a validation study. Most of these studies provide only a PPV that indicates whether the coding scheme is accurately classifying observed measures compared with another source. Validation measures such as sensitivity and specificity are not often calculated in these comparative studies.

In claims data, MI, denoted as ICD-9-CM code 410.xx, has been assessed in computerized health databases of Quebec [183], Saskatchewan Health [184], and the HealthCore® Integrated Research Database [185]. In all of these databases, this ICD-9-CM code had substantial or nearly perfect ability to validate the diagnosis of MI, with the PPV ranging from 88.4% to 96% across studies. Other ICD-9-CM codes used for possible detection of MI have shown poor ability to classify MI.

Both the overall PPV for ICD-9-CM 410.xx to measure MI and the PPV for MI among patients taking NSAIDs were evaluated in the HealthCore® Integrated Research Database. Among all the patients with a code for MI, the PPV was 88.4% (95% CI 83.2–92.5%). Among patients taking

Table 37.3 Validation of myocardial infarction (MI) and gastrointestinal (GI) bleeding events in studies using administrative claims data to evaluate harms of nonsteroidal antiinflammatory drug (NSAID) exposure.

Table 37.3 (Continued)

Author	Dataset	Study aim and sample size	Comparison data source	Conditions	Findings
Wahl 2010 [185]	HealthCore® Integrated Research Database	To validate administrative claims codes with medical chart review for MI, ischemic stroke, and severe upper gastrointestinal (UGI) bleed events in a large, commercially insured US population n = 200 charts per outcome	Medical charts	MI: ICD-9 code 410.xx excluding 410.x2 and a length of stay (LOS) between 3 and 180 days, or death if LOS is <3 days Severe UGI bleed events were defined as a hospitalization for either UGI hemorrhage or peptic ulcer disease, including perforation. In the claims data, this was defined as ICD-9 codes 531.x, 532.x, 533.x, 534.x, 578.0, 578.1, 578.9, or a physician service code for GI hemorrhage (CPT code 43255 or ICD-9 procedure code 44.4x)	Overall: PPV for MI = 88.4% (177/200; 95% CI 83.2–92.5%) PPV for ischemic stroke = 87.4% (175/200; 95% CI 82.0–91.7%) PPV for severe UGI bleed = 56.5% (109/193; 95% CI 49.2–63.6%) Among those taking NSAIDs: PPV for MI = 92.3% (97/105; 95% CI 85.4–96.6%) PPV for ischemic stroke = 78.9% (57/72; 95% CI 67.6–87.7%) PPV for severe UGI bleed = 57.9% (70/121; 95% CI 48.5–66.8%)

NSAIDs, the PPV for MI was 92.3% (95% CI 85.4–96.6%). The difference between the overall PPV and PPV among patients taking NSAIDs could highlight the potential for differential coding by patient status. Further study of differences in diagnosis coding by medication or disease status is needed to know whether validating the drug and disease pair is warranted or whether validation of the exposure and outcome separately is sufficient to imply veracity of the results.

A substantial proportion of cases identified by algorithms for probable or definite MI within all databases are confirmed as probable or definite MI in medical records, with PPV ranging from 55% to 97%. Validity for MI has been measured in the Group Health Cooperative (now Kaiser Permanente Washington) [186] (sensitivity 86.5%; specificity 85.4%) and in the General Practice Research Database [187] (sensitivity 89.3%), with substantial agreement between the administrative claims and medical records.

Measurement of GI bleeding is more varied across databases, and several algorithms using different combinations of ICD-9-CM and CPT (Current Procedural Terminology) codes have been used to determine event occurrence. The PPV for the studies range from 60% to 100%. In general, the PPV has been higher when both ICD-9-CM and CPT codes are used. However, in the US Department of Veterans Affairs (VA) administrative claims data, where sensitivity and specificity were also assessed, the higher PPVs with use of both coding systems resulted in a lower sensitivity and specificity [188]. Limiting further to only those patients using NSAIDs, the PPV increased to 80%. Both the overall PPV for severe GI bleeding and the PPV for GI bleeding among patients taking NSAIDs were determined in the HealthCore® Integrated Research Database [185]. Among all patients with an ICD-9-CM or CPT code indicative of GI bleeding, the PPV was 56.5% (95% CI 49.2–63.6%). Among patients taking NSAIDs, the PPV for GI bleeding was 57.9% (95% CI 67.6–87.7%).

The variation seen in comparisons of GI bleeding in administrative claims and EHR may be due to the differences in algorithms used to determine GI bleeding. The variation may be due also to differences in GI bleeding in the underlying populations captured in each database. Validation, including measures of sensitivity and specificity, of the same algorithm in multiple databases will aid in determining whether GI bleeding can be adequately assessed in administrative claims and/or EHRs.

In summary, validating the case definition developed for observational studies using administrative claims databases with original documents such as inpatient or outpatient medical records is an important step to enhance the quality and credibility of the research. Although many studies in the past few years have reviewed original documents to validate the diagnoses under study or have referenced those validation studies, a need still exists for validation of drug exposures and disease diagnoses in databases in which no previous validation has been performed. As medical practice changes over time, further validation of previously validated claims is also warranted. Evaluating the completeness of the databases is much more difficult, as it requires an external data source that is known to be complete [143,187,189,190]. Although administrative claims and EHR databases have greatly expanded our ability to undertake pharmacoepidemiologic research, we need to ensure that our tools, including the databases used for our analyses, are complete and of the highest quality.

The Future

Methods for conducting pharmacoepidemiologic studies have shifted over the past several decades from reliance on studies requiring *de novo* data collection from individuals, to extensive use of electronic data from either administrative claims or EHRs, to linked data sources

and distributed data networks. Yet *de novo* data collection will continue to be required to ascertain information on quality of life, patient-reported outcomes (see Chapter 42), and medications either not included in pharmacy dispensing files or not reliably entered into EHRs, such as herbal and over-the-counter medications. In fact, with the advent of wearables and the Internet of Things, we anticipate that *de novo* collection of health data may increase in the coming years.

The improved computer technology that resulted in faster processor speeds and increased storage capacity facilitated storage of healthcare data in an electronic format, such as EHRs, and allowed development of distributed data networks using data from multiple health plans. The availability of these data for research has improved our ability to conduct studies [168] and the increasing uptake of EHRs is leading to increased availability of more granular clinical data for pharmacoepidemiologic research (e.g., lab results, clinical notes). Initial evaluation of EHR data suggests great promise, but increased data quality and standardization of terminology and codes will be required to make these data, collected for clinical care, useful for research purposes [191]. Similar processes will be warranted for use of data from wearables and prior to integration of new data from biobanks, mobile apps, social media, or other sources into a rigorous research framework.

As part of the standardization process, data holders will have to document that their data are valid for conducting research and surveillance activities. This will require investigators to apply their knowledge and practices from use of administrative claims and EHR data to linked data and to these novel data sources. Both medication exposure and outcome diagnosis data from these novel data sources do not carry the same level of comfort regarding validity as claims data and EHR data. As these data are considered for research, we hope and expect to see studies validating their use.

In this chapter, we will describe the importance of adherence in pharmacoepidemiologic research, the methods for measuring adherence, methodologic issues that arise once adherence has been measured, and future directions. While we use many different drug–disease examples, we focus on examples from HIV and cardiovascular diseases because these areas have been major focuses of adherence research.

The underuse of essential medications imposes significant clinical and financial burdens on healthcare systems. Data show that as many as half of patients do not take their medications as prescribed, resulting in more than $100 billion in excess annual spending in the US [1]. Nonadherence is also thought to contribute to 11% of US hospitalizations each year [1]. Without accurate measurements of adherence incorporated into research and practice, the problem will remain underappreciated and poorly addressed.

Despite its importance, medication adherence is difficult to define. Earlier research has used the term *compliance*, or "the extent to which the patient's dosing history conforms to the prescribed regimen," to describe this behavior [2]. However, this term implies that patients passively "conform" to the prescriber's directions; therefore, the term *adherence* is now strongly preferred [3]. *Adherence* better conveys the idea of a patient–provider relationship where the patient implements the provider's recommendations.

Another reason why adherence has been difficult to define is that it is not a single static behavior but instead encompasses a set of behaviors over time. One common taxonomy developed by a scientific consensus group classifies adherence along three phases: (1) initiation, (2) implementation, and (3) persistence (Figure 38.1) [4]. *Initiation* describes initial engagement with the prescribed medication. Research suggests that as many as 30% of newly prescribed therapies are never actually filled by patients [5], which is often referred to as primary nonadherence. *Implementation* represents how well the patient follows the prescribed regimen while s/he is engaged with treatment. While varying greatly across diseases, approximately 50% of patients are thought to not correctly follow prescribed regimens. *Persistence* refers to how long the patient continues to follow the regimen [6].

Pharmacoepidemiology, Sixth Edition. Edited by Brian L. Strom, Stephen E. Kimmel and Sean Hennessy.

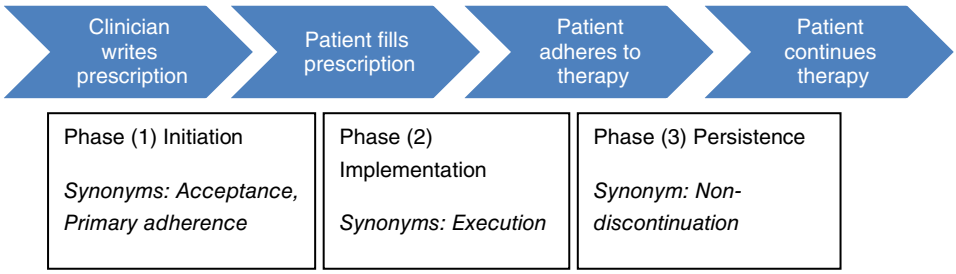

Figure 38.1 Phases and taxonomy of adherence.

Poor treatment adherence can occur along any of these phases.

The actual behaviors involved in taking a prescribed medication as directed become more complicated when considering each adherence phase. This taxonomy helps distinguish patients who never initially fill a prescription from patients who occasionally forget to take doses as well as patients who take a medication regularly at first but then later discontinue. Classifying all three types of patients simply as "nonadherent" ignores the fact that each of these patients may differ with respect to treatment outcomes and likely have different adherence barriers requiring different interventions [3]. This taxonomy also highlights the multifactorial behaviors required for sustained medication adherence and why measuring it, identifying the barriers, and then improving adherence has been difficult. Regardless, practical approaches to measuring and analyzing adherence have been successfully developed, and we will discuss the challenges and utility of various approaches to measuring adherence throughout the chapter.

Clinical Problems Addressed by Pharmacoepidemiologic Research

Adherence research confronts the truism attributed to former US Surgeon General C. Everett Coop, MD that "drugs don't work in patients who don't take them" [7]. Measuring adherence is essential in order to address several issues in the interpretation of studies of beneficial and adverse effects of medications. In randomized trials, treatment adherence can be an important factor that affects the estimates of efficacy and safety of the tested medications (see Chapter 32). Poor adherence to the drug being tested can lead to underestimates of drug efficacy [8]. Further, information about adherence allows for a more accurate assessment of drug safety because those who do not take the drug cannot experience its toxicity. Because perfect adherence is not attainable, even in clinical trials, measurements of adherence can elucidate whether a drug fails to exert an effect because it did not work or because it was not taken properly. Poor adherence may itself also be a marker of toxicity or adverse events.

Once a medication is marketed, information from clinical trials gives only a limited view of how drugs are used by patients. Patients who volunteer for clinical trials are thought to be more motivated than those in usual care [8,9]. Therefore, measuring adherence in observational studies of drug effectiveness and safety may be even more important than in clinical trials. Furthermore, assessing adherence in observational studies provides a more "real-world" estimate of adherence in clinical populations. Finally, because adherence itself is a major determinant of treatment outcomes, it can also be the specific focus of pharmacoepidemiologic research.

Nonadherence can be intentional or unintentional. Studies have identified many potential barriers to adherence, broadly categorized as patient-, system-, and medication-specific factors. Common patient barriers consist of forgetting to take the medication, lack of knowledge or health literacy, and psychosocial factors such as depression and lack of social support [10–12]. System barriers include logistical difficulty in obtaining the medication and, in some settings, sporadic drug unavailability ("stock outs") [13,14]. Key medication-specific factors include regimen complexity and adverse effects [15,16]. Further, patients may decide on a dose-by-dose basis whether to take medicine as prescribed, perhaps to avoid side effects at inconvenient times (like avoiding increased urination at night). Finally, postmarketing studies have observed "pill fatigue" (in that adherence can decrease over time from being emotionally overwhelmed by taking medication), particularly when patients are followed for longer than typically done in trials [17,18]. It is a well-known phenomenon that the optimal adherence seen early in therapy often decreases over time [19]. Thus, observational adherence studies provide unique data not available from trials.

While missed doses are a more common adherence problem, taking extra doses can also be a problem. For example, extra doses of drugs with a narrow therapeutic window, such as warfarin for anticoagulation, may result in toxicity [20]. Patients may also take extra doses of narcotics prescribed for the treatment of pain because of inadequate pain relief or for potential abuse (see Chapter 28).

Measuring adherence can also be useful for determining the threshold of how much medication must be taken to obtain desired clinical outcomes; these dosing thresholds likely differ by drug and disease. In hypertension, taking at least 80% of prescribed medication has been an acceptable standard for blood pressure control [21]. However, in HIV, 80% adherence is often insufficient. For example, in a study of patients starting protease inhibitors for HIV, those who took 80–95% of doses were more likely than those with lower adherence to achieve complete suppression of viral replication [22]. Unfortunately, such detailed information is not available for most drugs and diseases. Despite the likelihood that 80% of doses taken is not the optimal universal cut-point for acceptable adherence, this threshold persists across research and quality measures [23]. Therefore, the default adherence goal should be to encourage the patient to take as many prescribed doses as possible, and future research is focusing on identifying more empiric and robust dose–response thresholds for various diseases.

Finally, adherence can also impact public health, especially in infectious diseases. For example, in tuberculosis and HIV, nonadherence can actually lead to resistance to medications. Because these resistant diseases are transmissible [24], the measurement of nonadherence and adherence interventions takes on greater public health importance.

Methodologic Problems to be Solved by Pharmacoepidemiologic Research

Challenges in the Measurement of Adherence

The gold standard for measuring adherence to treatments is directly observed therapy [14]. However, this approach is only practical in limited settings, such as the administration of a novel agent in a controlled environment. While many approaches exist, as will be discussed later, whatever the approach, the discovery of nonadherence in clinical settings can be embarrassing for patients, because it can imply lack of respect for the provider's advice or for one's welfare. Thus, knowledge that one's adherence is being monitored risks influencing the behavior it is

measuring (i.e., a Hawthorne effect). Moreover, tracking a daily activity can be burdensome regardless of whether individuals are aware of their own nonadherence. Therefore, measuring adherence requires creative approaches to accurately capture a daily activity performed at different times per day for different individuals.

Challenges in the Analysis of Adherence Data

Once adherence is measured, there are various approaches to analyzing the data depending on the data sources used. In clinical trials, adjusting results for adherence is complicated by the fact that being adherent itself is associated with better outcomes (i.e., placebo effect). For example, in a randomized double-blind placebo-controlled trial of propranolol after myocardial infarction, poor adherers had a 2.8 higher odds of mortality compared with good adherers in the same active arm, after adjustment. However, the adjusted odds ratio of mortality in those with poor adherence to placebo was, similarly, 2.7 [25]. Presumably, adherence to either agent, whether propranolol or placebo, was strongly associated with other unmeasurable lifestyle factors associated with mortality. How to control for this healthy adherer effect is an important analytic consideration.

Other analytic challenges include the duration and timing of adherence measurements. Because adherence behaviors vary over time, individuals may have substantial changes across the observational period. For example, individuals are prescribed lifelong regimens for many chronic diseases. When initiating treatment, adherence over the first 12 weeks may not be the same as adherence over the final 12 weeks. Simply summing adherence over an entire 52-week interval will provide an average of adherence, but short periods of nonadherence can substantially impact clinical outcomes [26]. Therefore, when conducting adherence analyses, researchers need to carefully consider the appropriateness of the adherence "interval(s)". Many adherence studies of chronic medications choose intervals that are at least 180 or 365 days long to capture enough variation in use; however, this choice must be balanced with the length of follow-up available on patients to ensure external generalizability [27].

Whatever the interval, the summation of adherence data can also be accomplished in different ways. The simplest is the percent of doses taken, but this may not be the most clinically relevant metric. Depending on drug pharmacokinetics and pharmacodynamics, gaps and variability in adherence may be more important than the proportion of prescribed doses taken. However, a composite measure of percentage of doses taken over an entire time period is often still used as the sole adherence measurement in research publications and measures of healthcare quality. There have been recent advancements in measuring adherence, which are discussed later in this chapter.

Additionally, many diseases are treated with combination therapy (either multiple medications in the same formulation or multiple separate formulations). When drugs are studied in combination to determine their effect (e.g., antihypertensive or antituberculous therapies), it is challenging to determine how to weight differential adherence or switching among the drugs [27]. Many of these issues can be addressed with currently available solutions, although methodologic challenges remain to be solved.

Currently Available Solutions

There are many different methods for measuring medication adherence, and each method has strengths and weaknesses. Which method is most appropriate depends upon the situation in which it will be used and how precise the measurement needs to be. Some measurements require more intensive patient-level contact than others, and some provide more granular

data with respect to timing of dose taking. For example, in prospective clinical trials, because of the direct patient contact, many of these techniques can be used. In other settings like retrospective studies using databases, options are more limited. Therefore, the use of multiple measures or sources of data may be helpful to confirm findings. For all approaches, the interpretation of adherence findings may also change depending on whether incident users or prevalent users of medication are examined, as adherence tends to be higher among prevalent users, in part because discontinuation is highest in the first few months after initiation. Therefore, many studies focus on incident users, but there are situations in which studying prevalent users may be more relevant, especially because new initiators are only a small proportion of all patients using a therapy at a given time [28–30].

We will describe each of the strategies, their strengths and weaknesses, and discuss considerations for the timing of assessing adherence.

Specific Techniques for Measuring Adherence

Self-reports

Among many approaches to assessing adherence, patient self-reported measures asking respondents about their adherence behaviors have been the most common method. They are simple, relatively inexpensive, quick and feasible, and can be obtained over the telephone, in person, or with paper or electronic surveys. Self-reported measures vary greatly in the phrasing of their questions, recall periods, and response items. Several different validated methods for assessing self-reported adherence are described here.

Self-reported adherence measures range from one-item questions inquiring about the frequency of missed doses to longer multi-item assessments evaluating beliefs associated with adherence and identifying barriers to adherence [31]. Most self-reported measures involve count or estimation-based recall focused on the implementation phase, in which respondents report the number of doses missed or taken within an interval or to estimate their overall execution of adherence. Some scales use a recommended adherence cutpoint while other scales identify a continuous measure of the degree of adherence.

In a systematic review, Nguyen *et al*. identified 43 validated self-reported adherence scales in the English language [32]. Perhaps the most common self-reported adherence tool historically used is the eight-item Morisky Medication Adherence Questionnaire (MMAS-8) [33,34]. However, the use of this scale requires licensing fees. The adult AIDS Clinical Trials Group (ACTG) adherence questionnaire [12] and Brief Medication Questionnaire [35] are other examples of common, publicly available tools that explore both behaviors and barriers to adherence. A recent three-item tool by Wilson *et al*. queries patients about how many days they missed medications over the last 30 days [36]. Other studies have used a single measure such as a visual analog scale, which asks participants to mark a point on a line from 0% to 100% to indicate the amount of medication taken over a specified recent time period [37]. Overall, the choice of measure may depend on the context of its use (e.g., clinical use or research), the burden to patients, and the disease states in which it has been validated. In addition, self-report may be the easiest method for clinicians to administer and more easily used to isolate the reasons for poor adherence for targeting interventions.

Self-reported adherence measures are moderately correlated with methods using electronic drug monitoring (EDM) or pharmacy dispensing data (described later in the chapter), though concordance can vary depending on the patient's level of adherence or the measurement window [31,38–40]. For example, in a study comparing three-day, seven-day, and one-month self-reports, the one-month window best approximated adherence obtained using EDM [41,42]. On the other hand, because of potential

overreporting, self-reported measures are thought to have high specificity and low sensitivity (i.e., self-reported nonadherence is generally accurate, while high self-reported adherence may not be accurate) [31]. Either way, self-reported measures have shown weaker associations with clinical outcomes than EDM or dispensing data [31,42].

There are some additional limitations to self-reported adherence measurements. Though they can be self-administered in high-literate patients or conducted by an interviewer, they are all limited by a patient's ability to recall missed doses and may be subject to social desirability bias (i.e., overreporting adherence to please providers or researchers). Social desirability can be mitigated by acknowledging the difficulty of always taking all medications. Interviews are also potentially limited by language barriers, poor literacy, time burden, and difficulty with medication names. Using computer-assisted self-administered interview can reduce these barriers by reading instructions and questions aloud and including high-resolution photographs of the medicines. These questions can be administered at a kiosk or computer in a waiting room. Empirical data suggest that computer-aided self-reports are less likely to overestimate adherence [43]. However, poor patient recall is still a problem, and self-reported measures are also limited by their ability to precisely describe the timing or patterns of dose taking.

Pharmacy Dispensing Data

Pharmacy dispening measurement was pioneered in the late 1980s and has been widely used in various chronic diseases [44]. These measures typically derive from secondary data from health insurers and are some of the most common ways of measuring adherence in pharmacoepidemiology.

Pharmacy dispensing data are generally considered to be accurate because the dispenser (e.g., a pharmacy) would not get reimbursed by insurance if the medication fills are not recorded. Compared with self-reported data, pharmacy dispensing data are not biased by poor recall, can be obtained from computerized records, and can be assessed retrospectively [38]. Another advantage is that the data can be easily processed by software and are available on large numbers of patients (often millions in the same database). However, the data quality may be less assured in settings where such tracking is less crucial for reimbursement or if prescriptions are obtained outside insurance plans [45]. Some approaches use data from pharmacies directly to capture all medications dispensed to patients and not just those paid by insurers. Also, in the US, these pharmacy dispensing data are generally only accurate for medications dispensed in the outpatient setting, because medications are not specifically paid for separately during hospitalization [46]. For questions related to adherence to one-time prescriptions (e.g., short courses of antibiotics), these data may not be useful beyond studying primary nonadherence because repeat dispensings are required to calculate an amount of medication consumed.

There are several different methods for measuring adherence using pharmacy dispensing data. In all approaches, adherence is measured indirectly based on patterns of medication dispensings (using the dispensing date and days supplied) by generating a "drug supply diary" that strings together consecutive medication dispensings based on the dates on which medications are dispensed to the patient at the pharmacy and the duration of the supply dispensed [19,47]. This supply diary can adjust for overlapping fills (e.g., truncating the days supplied for medications which are refilled before the medication supply from the prior dispensing would have been exhausted) and any known interruptions that may have occurred (e.g., by hospitalization). When generating the supply diary, researchers generally consider medications that are chemically related and not intended for use in combination to be interchangeable (e.g., two beta-blockers). For example, patients may

initiate one beta-blocker and later switch to a different beta-blocker. In this case, beta-blocker adherence is often measured continuously, rather than separately measuring adherence to each medication, to generate one continuous exposure episode. Sometimes, medications within the same disease state but chemically different (e.g., beta-blockers and calcium channel blockers) could be considered interchangeable.

Several types of adherence metrics can be calculated using these data, such as a continuous variable for adherence assessed from the first to last prescription record, a dichotomous variable in which patients are classified as adherent or nonadherent based on a threshold, or examining the time between dispensings. In the most common approach, the proportion of days that patients had an available supply of medication, or the proportion of days covered (PDC), is calculated. The PDC is calculated by dividing the number of days with an available supply of medication by the number of days in the interval being evaluated (an interval-based measure) [48]. Other approaches include calculating the medication possession ratio (MPR). MPR is calculated as the quotient of (1) the total number of days supplied of all dispensings in a given analysis interval for the medication under investigation, and (2) the total number of days in the analysis interval. The primary difference between the PDC and MPR adherence metrics is how overlapping days supplied of the same medication are handled. MPR assesses the total daily medication supply from all dispensings in a given analysis interval whereas PDC assesses the total days where a medication supply "covered" each day in a given analysis interval. The specific approach is typically determined by researcher preference, although may depend to some degree on the structure of the database or the pharmacodynamics of the drug/disease in question. Regardless, the results of the different approaches are typically very similar [23].

In addition, these data can be used to measure persistence (e.g., the time until medication discontinuation) by evaluating whether clinically meaningful treatment gaps or discontinuations are observed in the dispensing data [49]. Potential approaches include evaluating whether a dispensation overlaps with the end of a follow-up period (i.e., 365 days after initiation) or measuring the availability of drug supply at a fixed time after the last medication dispensing (e.g., whether patients have a gap of at least 30, 45, or 60 days with no medication after the supply is presumed to be exhausted). Whichever method is chosen, investigators should conduct sensitivity analyses of the "gap rule" to determine the robustness of the findings.

These adherence measures are limited in additional ways. The vast majority of dispensings for chronic medications in the US are for supplies of 30 days, and increasingly 90 days [47,50]. Measuring adherence in intervals shorter than 180 days can then make it difficult to observe variation in adherence since by definition, the first 30 or 90 days are always considered as full adherence (100%), regardless of actual patient behavior [51]. This problem becomes less pronounced with longer measurement intervals. However, shorter intervals may be more clinically desirable since they might allow nonadherence to be detected and acted upon sooner [52].

Although adherence metrics, using pharmacy dispensing data, often estimate the supply of medication during a given time period, they do not measure or monitor actual pill-taking behavior, either on average or day to day. Consequently, they cannot be used when the timing of missed doses is pivotal. However, the estimation of adherence with pharmacy dispensing data has been shown to be valid for chronic medications where measuring overall exposure between refills is clinically relevant [38]. Pharmacy dispensing measures of adherence have also been shown to be strongly associated with clinical outcomes [53,54]. For example, a time-to-dispensing measure of adherence has been associated with changes in HIV viral load [55]

and changes in blood pressure [44]. Furthermore, the measure has been shown to provide additional information beyond self-reports. In a study of antiretroviral therapy, individuals who self-reported 100% adherence actually varied in their treatment response based on adherence metrics from pharmacy dispensing data. As expected, those with higher adherence, as defined using pharmacy dispensing data, had higher rates of treatment response, despite claims of perfect self-reported adherence in both groups [56].

A limitation of adherence measures derived from pharmacy dispensing data is the estimate of the maximum potential adherence, since these metrics assume all medication supplied has been consumed between dispensations. It is also difficult to disentangle clinically directed medication discontinuation wherein persistence is no longer the behavior being studied, from patient-directed discontinuation against provider recommendation, which is defined as nonpersistence. Furthermore, pharmacy dispensing data may also overestimate adherence measures when dispensing programs automatically dispense a new supply on a prespecified schedule, irrespective of patient request for resupply [57].

A final consideration is how to accurately measure adherence to multiple medications for the same condition (e.g., antihypertensives). One common approach is to measure adherence at the therapeutic class level and "average" adherence across the entire chronic condition for patients exposed to any medication for that condition [27].

Pill Counts

While less commonly used, adherence can also be measured indirectly by pill counts. Pill counts are similar to pharmacy dispensing data in that percent adherence is calculated by dividing the days supply consumed by the number of days observed. Data collected include the dispensing date, quantity dispensed, number of pills per dose, and number of pills left in the bottle, adjusted for doses taken that day and any additional pills left over from the last count.

Like adherence measures estimated using the medication dispensing date and days supplied (e.g., MPR and PDC), adherence measures using pill count data also cannot determine if the medication was actually consumed or the patterns of consumption. However, they do provide direct evidence that the medication was not taken when pills are left over. Pill counts are susceptible to deception since "dumping" pills on the way to the pill count visit is simple and can be done impulsively before a visit. Unannounced pill counts, in person or by telephone, are valid alternatives to mitigate this type of misclassification [55]. During calls, subjects review the contents of each of their pill bottles. Of course, this approach is also susceptible to intentional deception; however, the estimated adherence from pill bottle review was shown to be associated with treatment response [58]. The time for both staff and participants is a potential disadvantage of pill counting and an additional source of error. In addition, missing data can result when patients do not bring in their pill bottles or have them available during telephone calls. Reinforcing the importance of accuracy with staff is vital to ensure validity of this measure.

Medication Diaries

Although the adherence measures described above summarize how much medication was taken over a specified time period, they provide no detail on the timing of missed doses. Depending on drug pharmacokinetics and pharmacodynamics, missing doses may have different consequences depending on whether the doses were missed consecutively or at separate times that are evenly spaced. These data may in fact be vital to classifying adherence, and medication diaries can provide a solution. In this method, participants keep a record of the date and time of each dose of medication and often whether or not it was taken with or without food. These data can be collected either

electronically or handwritten; with newer technologies like smartphones, data collection could be even easier [59]. Diaries may be particularly useful for medications like insulin or inhalers that are difficult to track using other methods [60]. For example, medication diaries are regularly used in pediatric patients [61].

However, medication diaries are susceptible to both overreporting and underreporting of adherence. Social desirability results in patients listing doses even though they were not taken, but the potential is lessened somewhat by the burden of creating a detailed falsified record. In fact, the risk of underreporting may be greater because of the burden of tracking each dose. It is also not easy to employ this method at scale for larger studies. Newer approaches are exploring the use of apps on enabled smartphones to track these more nuanced medication-taking patterns.

Electronic Drug Monitoring Technology

Electronic drug monitors (EDMs) feature the same advantages as medication diaries, but are less susceptible to deception, forgetting, or ignoring the need to write down the dose data. In contrast to the prior approaches, EDMs provide time-stamped data for adherence behaviors to enhance precision of adherence measures. While there are several different hardware options, electronic drug monitors employ electronic date/time stamp technology that is triggered by opening a container (i.e., pill bottle), puncturing a blister pack to obtain a dose, or ingesting a dose. The data are downloaded to a computer or smartphone via hardwired or wireless linkage.

Electronic drug monitor data have been shown to have some correlation with other measures, including pharmacy dispensing and self-report, though EDM measures are more sensitive (i.e., they are more likely to identify poor adherence) than self-reported measures [31,62]. While EDMs are less susceptible to deception than self-report, they could theoretically could be more susceptible than pharmacy dispensing data [63]. However, it is highly unlikely that subjects will open and close the monitor to record doses over long periods of time without actually taking the medication, though this does occasionally happen accidentally [63,64]. EDMs are also less susceptible to underreporting than diaries because they often do not require the subject to do anything other than take the prescribed medication.

Though EDM technology is advancing rapidly, the packaging and cost of EDMs can still be burdensome and difficult to scale [64]. For example, EDMs have been found to be particularly hard for patients with psychiatric conditions to use [64–66]. In addition, they often preclude the use of pillboxes by generally requiring that the medication remain in the package until taken. Consequently, they are susceptible to underestimating adherence (e.g., a one-week supply taken from the container at one time will appear as one dose taken). However, EDMs could be used even when the medication is not kept in the container. In a warfarin study, individuals using pillboxes were given an EDM in an empty pill container and asked to open the empty bottle whenever they took warfarin from the pillbox. The association between adherence and outcome was nearly as strong as those who kept the warfarin in the monitored bottle [20].

Newer approaches are being developed, such as integrating EDM technology with text messaging that reminds patients when they miss doses. In 2015, the US Food and Drug Administration approved the first ingestible sensor technology that measures actual intake time through ingestion of a medication that communicates with an adhesive patch. The device sends a signal to the doctor or research team monitoring adherence [67]. Other research is exploring the utility and accuracy of adherence measures in which patients take date- and time-stamped photographs of themselves or their pills each time they take a dose.

Drug Concentrations

Identification of the presence of a drug in plasma or other tissues provides direct evidence of drug ingestion. However, the use of drug concentrations to measure adherence is limited by variability across patients (i.e., absorption, distribution, metabolism, and clearance – see Chapter 2). The more frequently concentrations are measured, the fuller the picture of adherence behavior that can be obtained but the cost and patient inconvenience may be a limitation. Measurement of drug concentrations in hair using liquid chromatography and confirmed by mass spectrometry can be a useful indicator of long-term medication exposure. For example, antiretroviral drug levels in hair give an average of the exposure to drug over the past weeks to months and predict HIV viral response better than serum drug levels [68].

Unfortunately, many assays are unavailable commercially. Furthermore, the serum drug level is not the relevant measure for many drugs when the site of action is elsewhere (e.g., intracellularly rather than in serum or in hair) [69]. Finally, unless these assays are done quickly, they are not useful clinically.

Another approach to assessing drug concentrations is to use a marker drug that is easily added to a formulation and can be measured more easily than the actual drug of interest. The primary example here is the incorporation of riboflavin into active drugs as a urine metabolite drug marker to assess adherence to medication in clinical trials [70]. Of course, this strategy is only relevant in settings where researchers have control over the formulation and direct access to the patient (e.g., clinical trials).

Measuring Primary Adherence

Each of the approaches described above has focused on later adherence phases (e.g., implementation and persistence). Measuring medication initiation (i.e., primary adherence) has been difficult using some of these methods, particularly because secondary data require a medication to be dispensed for adherence behaviors to be monitored. Some techniques, for example self-report, may allow for easier study of primary adherence. Without linkage to other types of data (e.g., electronic health records that include provider medication orders), it can be difficult to evaluate initiation without knowledge of what was prescribed [5]. Newer approaches are beginning to link these data sources to allow better assessment of the full cascade. On their own, electronic health record data limited to physician orders are not useful at evaluating patient adherence because they do not provide information about medication consumption.

Measuring Adherence to Nonpill Formulations

Measuring adherence to nonpill formulations can be difficult for several reasons, largely because these medications are generally administered with a variable dosing schedule. Injectable medications like insulin may be administered based on a sliding scale, with doses adjusted as needed, so measuring adherence using indirect dispensing data may be imprecise. Recently, other insulin persistence-based measures have been developed to overcome some of these limitations [60,71]. Inhaled medications are also difficult to measure; for those with specific schedules (e.g., tiotropium), dispensing data could be used [72]. Medication diaries and self-report could also theoretically be used but are subject to the same biases as pill formulations. EDMs have been used for metered dose inhalers [73] and ophthalmologic solutions [74]. The monitors increase the size of packaging, but the inhalers and solutions cannot be taken out of the package, unlike pill formulations. Measuring adherence will continue to be a challenge for newer nonpill formulations, including biologics, and in disease states in which both oral and injectable formulations are used interchangeably (e.g., osteoporosis or venous thromboembolism).

Topical treatments pose a particular challenge. For transdermal formulations in patches

(e.g., nicotine, testosterone), adherence based on dispensation data is a viable option because the supply is typically fixed. However, for creams and ointments, because the amount used at each application varies by the size of the lesion being treated or the size of the individual, self-reports and medication diaries may be the only currently viable options [75]. Adherence to intravaginal gels could be monitored by counting the number of empty tubes and used applicators returned at each visit, but this measure is subject to self-report errors due to intentional falsification or mixture of used and unused applicators in the same bag.

Analysis Issues in Adherence

Using Adherence Data in Clinical Trials and Comparative Effectiveness Studies

While clinical trial participants may be more motivated to adhere to treatments than those in clinical practice, nonadherence occurs for all types of self-administered therapies. Missed doses will typically make the active drug less effective and diminish observed differences compared to placebo in intention-to-treat analyses. In order to compensate for this effect, Phase III trials may inflate sample sizes to account for this variability in drug exposure [8]. Clinical trials may also incorporate run-in periods to try to minimize poor adherence (see Chapter 32).

In analyzing trials, the standard approach remains intention to treat. This approach limits the introduction of bias and makes the results more generalizable [76]. However, secondary analyses can be performed on subgroups of adherent patients, but these patients may differ for reasons that may not be easily measurable (i.e., more willing to take therapy, a type of healthy adherer bias) [77,78]. The benefits of randomization would therefore be negated. Moreover, when lifestyle changes are co-interventions along with medication in a trial, the results of secondary analyses will not be true measures of drug efficacy. Of course, medication adherence itself can also be a primary or secondary outcome in randomized trials, particularly for studies of interventions [79–83].

The inclusion of adherence data in analyses of trials is particularly important when a treatment fails. Reasons for failure might include lack of biological effect or lack of adherence. Unless adherence is measured and identified as the cause of failure, the results of the trial will be only partly useful. While regulators will only approve a drug for the studied indication if it is shown to result in improved outcomes, it is important for the drug developer to know if the efficacy of the drug was potentially limited by poor adherence. For example, in one trial, rates of coronary heart disease events were compared in patients randomized to receive either cholestyramine or a placebo [84]. Adherence in the cholestyramine group (defined as taking at least five out of six prescribed packets of cholestyramine per day) was only 50.8% compared to 67.3% adherence in the placebo group due to side effects. Because of the poor adherence, treatment response in the cholestyramine group was attenuated. Thus, because adherence was measured, it was possible to determine that the high rate of intolerable side effects resulted in lower adherence and thus, perhaps, lower treatment effectiveness.

Similarly, observational cohort studies of comparative effectiveness and safety of medications often benefit from measuring and evaluating the relationship between medication adherence and treatment response. First, "as-treated" analyses of safety evaluations often censor follow-up in patients who discontinue therapies for reasons other than toxicity to decrease bias toward the null. Second, marginal structural modeling approaches often include medication adherence as a time-varying exposure. Exploring the relationship between adherence observed between comparators may enrich the conclusions derived from these studies.

Selecting Adherence Intervals

For all adherence measures, a prespecified window for assessing and evaluating adherence must be chosen. The selection of the duration of an adherence interval depends on two important factors: the pharmacokinetics/pharmacodynamics and the granularity of the adherence measurement. For drugs with short half-lives and short onset of action, short intervals are likely to be more clinically relevant than when the drugs have long half-lives and longer onsets of action. For adherence measures that can accurately assess adherence over short periods of time, such as electronic data monitors, shorter intervals can be calculated. By contrast, when measures derived from pharmacy dispensing data are used, adherence analysis intervals must be longer because adherence is based on evaluating patterns between medication dispensing dates in conjunction with the days supplied per dispensing (e.g., 30 days).

The relationship between adherence and outcomes has been well described in antiretroviral therapy and oral contraceptives. Using pharmacy dispensing data, intervals of adherence as long as one year [56] and as short as 30 days [85] have been associated with viral load outcomes with antiretroviral therapy; however, a 90-day measure was found to be more strongly associated with viral load than a 30-day measure. For oral contraceptives, two consecutive days of nonadherence resulted in an unacceptably high rate of treatment failure (i.e., pregnancy) [86].

Unfortunately, for many medications, the most clinically relevant adherence interval may be unknown, and more research is needed to optimize the assessment of adherence. While the choice of interval length depends on the research goals, in general, monitoring adherence over shorter intervals would be desirable, because interventions can be more rapidly implemented. However, shorter intervals are subject to decreased accuracy regarding true adherence behavior. In general, without direct guidance, choices for an adherence interval should be made based on pharmacokinetic and pharmacodynamic data (see Chapter 2).

Statistical Analysis

The simplest approach to summarizing adherence across different methods is the percentage of doses taken (or missed). For electronic monitors, because the timing of each dose is available, percentage of doses taken "on time," standard deviation of time between doses, duration of maximum time gap between doses, and many others can be calculated [4]. For adherence metrics derived from pharmacy dispensing data, the analysis focuses on either the percentage of available medication or the duration of gaps between dispensings [44]. Self-reports focus on the proportion of doses the patients have taken or the time since the last dose was missed [31].

Whichever metric is used, one must choose whether to include adherence as a continuous or dichotomous variable. As previously described, dichotomous thresholds must consider both the likelihood of failure and clinical consequences of treatment failure. Few thresholds have been established based on evidence, yet in research and quality improvement efforts, to dichotomize these adherence variables, patients are often defined as fully adherent if they take at least 80% of prescribed doses. Certainly, many studies in cardiovascular diseases have demonstrated this association; however, there is recognition that different levels of adherence may be required for viral suppression in HIV. In treatment settings with a linear relation between amount of drug taken and therapeutic response, evaluating differences in adherence on a continuous scale would be clinically more meaningful than binary measures. Alternatively, when neither dichotomous nor continuous measures capture the clinically relevant dose–response relationship, assigning ordinal adherence categories (e.g., <70%, 70– < 80%, 80– < 90%, etc.) may be preferable [87].

In addition, evaluating regimens with multiple medications poses analysis challenges [88]. Many classify adherence based on optimal adherence to at least one medication for that disease state (e.g., hypertension) to be fully adherent, although this misclassifies individuals who are nonadherent to some but not all components of the regimen. Fortunately, there is some evidence to suggest that for medications taken simultaneously, adherence to one is highly collinear with adherence to the other [89]. However, differential nonadherence has been documented [90].

Finally, it is difficult to determine whether an individual is poorly adherent or whether the medication is no longer being prescribed when access to medical records is unavailable. This phenomenon poses the greatest challenge for adherence measures derived from pharmacy dispensing data. Further, even when medical records are available and the provider documents the recommendation to discontinue, the exact date of patient medication discontinuation can be difficult to determine.

Time-Varying Nature of Adherence and Trajectory Modeling

Adherence is a nonstatic behavior, and methods are needed to capture changes in adherence over time. This phenomenon has historically been ignored in studies that measure adherence only once or over short intervals. Even when measured longitudinally, adherence data are often averaged. For example, quality measures in the US are based on the proportion of patients with ≥80% adherence (e.g., MPR or PDC) of their prescribed medications over the prior year. However, patients may experience substantial increases and decreases in adherence that are not fully captured by these composite measures.

Consider, for example, one patient who takes a medication perfectly for the first six months but then discontinues for a six-month gap compared with another patient who alternates taking medications perfectly every other week interspersed with week-long gaps over a year. Both patients would have the same calculated adherence (50%) but very different medication use patterns. Composite, cross-sectional measures obfuscate the potential for each patient to experience different health outcomes and require different adherence interventions.

Advanced statistical methods are beginning to take advantage of repeated measurements in adherence data, particularly in dispensing data, to enhance analysis beyond composite measures. One such method applied is group-based trajectory modeling which estimates changes in an outcome that is measured repeatedly over time and identifies individuals with similar longitudinal patterns [91]. In brief, this approach fits a semiparametric (discrete) mixture model and assigns groupings in longitudinal data (e.g., monthly PDC) based on probability distributions for a prespecified number of groups [92]. The probability of belonging to each potential group is modeled as a multinomial logistic regression, and within each group, adherence is modeled as a smooth function of time using up to a fourth order polynomial. The statistical output includes each individual's estimated probabilities of group membership and estimated trajectory curve of adherence over time for each group. For example, a study by Franklin *et al.* of statin initiators identified six distinct patterns of adherence over 15 months, including patients who had (1) near-perfect adherence, (2) poor adherence initially and then improvement, (3) slowly declining adherence, (4) rapid declines in adherence, (5) occasional use, and (6) immediate discontinuation [92].

Researchers ultimately select the best trajectory models based on fit criteria, having sufficient members in each trajectory group (i.e., at least 5% of the overall cohort in each group), narrow confidence intervals and posterior probabilities of membership ≥0.7 (in which each member assigned to that group has at least a 0.7 probability of being in that group) [91].

Trajectory modeling can be accomplished using statistical software with continuous, binary, and count data.

Overall, group-based trajectory models have been shown to summarize adherence patterns better than composite approaches and are strongly associated with clinical outcomes [93]. However, trajectories provide general patterns for adherence behaviors; that is, no one individual follows the exact pattern described by the trajectory of the group to which they are assigned. For example, although a rapid declining trajectory group might be depicted as having adherence decrease starting at month 4, any one individual assigned to that group might begin to be nonadherent at month 3 or month 5. Also, the number of distinct adherence trajectory groups, while guided by the fit criteria above, can also be subjectively based on researchers' interpretations and differ by disease state. Additionally, describing the individual patterns in words can be challenging; labels such as "mid-year discontinuation" and "early nonadherence followed by later return to partial adherence" can be cumbersome. More research is needed to optimize the approach, explore applicability in other adherence data sources, and facilitate communication of findings.

Prediction of Adherence for Interventions

Unfortunately, low rates of adherence have persisted despite extensive efforts to identify and predict patients at risk of poor adherence with the goal of developing interventions to improve adherence. Despite the expansion of databases with rich patient data, prediction of future adherence remains poor. Traditional approaches have focused on clinical and demographic factors at the time of medication initiation, with discriminative ability that is modest at best even with dozens of predictor variables (e.g., c-statistics ranging between 0.6 and 0.7) [52]. Even machine learning, with the capability of measuring complex interactions among predictor variables, has not led to drastically improved prediction, likely because the true factors associated with poor adherence are usually not observable in databases.

One of the more successful approaches has been evaluating patterns of medication filling shortly after initiation. For example, in pharmacy dispensing data, researchers have found that failing to refill in the second and third months after initiation is highly predictive of poor adherence over the following year (i.e., past adherence predicts future adherence) [51]. Predictions of adherence by providers have also been shown to be no better than chance [94], so they should not be used routinely in adherence studies or in practice.

Future Directions

As outlined throughout this chapter, though many methods have been developed to evaluate adherence, many challenges remain. Better methods for detecting and addressing poor adherence as well as the reasons for poor adherence will be welcome developments. Objective measurement of adherence to nonpill formulations in particular is difficult, especially for injectable, liquid, and topical treatments. The optimal adherence metric for most drug–disease dyads remains unknown. This is further complicated by the enormous number of possible combinations of regimens.

Adherence studies are likely to advance in several ways. First, because optimal adherence thresholds may differ across individuals and diseases, researchers are beginning to explore personalized adherence targets. For example, in a machine-learning analysis among patients with diabetes, Lo-Ciganic *et al*. observed that optimal adherence thresholds for an individual's hospitalization risk varied greatly based on their underlying health status [95,96]. Novel approaches using other types of data are likely to emerge as well, including the use of more advanced microelectronic technology, often

linked with communication systems that both identify and report nonadherence, or the enhancement of mobile and smartphone technology for tracking and intervening on adherence. Refinements to currently available electronic monitors will also likely include more convenient packaging that can both help with adherence (e.g., a reminder or organizer system) and provide two-way personalized communication with patients.

Hopefully, with greater recognition of the importance of nonadherence, more research will be conducted over the next several decades to solve some of these problems as well as develop better approaches to improving adherence so that evidence-based medications can be optimally used.

All medications have risks. Although many different definitions exist, risk is usually defined as a potential harmful outcome that can occur with a known or unknown probability [1]. Some medication-related risks are more serious than others and some are well understood whereas others are clouded by uncertainty. The responsibility of ensuring that medications are used as safely as possible is shared by the pharmaceutical companies that develop, investigate, manufacture, and market medications; the governmental agencies charged with regulating these processes; the healthcare providers who prescribe or dispense prescription medications and make recommendations concerning the use of over-the-counter products; the governmental agencies that license and regulate healthcare providers and healthcare facilities; and the patients who ultimately must decide whether or not to use a medication and, in most cases, have control over how they use the medication.

Since passage of the Kefauver–Harris Amendments to the Food, Drug, and Cosmetic Act in 1962, market approval of a new drug in the United States has required that the Food and Drug Administration (FDA) determine that the medication is safe and effective (see Chapter 1) [2]. Similar criteria are used by regulatory agencies in other countries as well [3]. For example, in Europe, the European Medicines Agency (EMA) is responsible for the scientific evaluation of medicines for the 28 member states of the European Union. Similar to the FDA, the EMA is required to evaluate whether medications are acceptably safe and effective prior to drugs being permitted a marketing authorization or product license [4]. Other chapters in this book provide information concerning how these determinations are made (see Chapters 1 and 8). Here, we simply reiterate that even medications that are judged as meeting safety standards have risks.

A drug is considered "safe" if the risks associated with it are deemed to be acceptable [5]. In some cases, medications with substantial and serious risks are judged as meeting safety standards because the benefits of the medication outweigh the risks. This is most often the case for medications used to treat debilitating or life-threatening illnesses where few other effective treatment options are available. It is also important to recognize that the safety of a medication is not solely an inherent property of the medicine, but also the circumstances in which the medication is used (e.g., expertise of

Pharmacoepidemiology, Sixth Edition. Edited by Brian L. Strom, Stephen E. Kimmel and Sean Hennessy.

prescribers, procedures used to monitor potential adverse effects, presence of interacting medications). Thus, many medication risks may be minimized through the implementation of appropriate risk management strategies.

To minimize medication risks following market approval, all parties involved in the medication use process must have access to up-to-date information concerning potential risks, including measures that can be used to prevent or control these risks. Moreover, this information must be provided in a timely manner and in a way that is understood by the target audience and that facilitates informed decision making. In this chapter, we discuss some of the clinical and methodologic challenges that must be addressed to meet these goals. We also discuss approaches that are currently used to enhance the dissemination and usability of information concerning medication risks. We conclude by suggesting directions for future research in this area.

Clinical Problems to Be Addressed by Pharmacoepidemiologic Research

Five major clinical issues involving medication risk communication need to be addressed by pharmacoepidemiologic research.

First, one must determine the information that patients need about medication risks to be able to participate in shared decision making and use medications safely. Most medications have many risks (e.g., stomach upset, liver toxicity, cancer, potential for allergic reactions) and each risk has many dimensions that can affect judgments of acceptability. These dimensions include probability, severity, controllability, reversibility, and time of onset (e.g., whether potential harm usually occurs soon after initiation of therapy or may not arise for many years) [6,7]. In addition, although uncertainty is an inherent characteristic of any risk, the risks associated with some medications are more uncertain than others. For example, the risks associated with medications that have been used for many years in a large number of patients may be fairly well understood [8]. Conversely, we often have limited understanding of the risks associated with recently marketed medications, particularly those that are first-in-class, and previously unrecognized risks may continue to emerge for several years after a medication is first marketed. Given that it is probably neither feasible nor desirable to provide comprehensive patient education concerning all medication risks, there is a need to determine how different types of information should be prioritized.

Second, one must determine what information patients need about potential medication *benefits* to be able to make informed decisions regarding the need for therapy and the selection of a specific treatment when therapeutic alternatives are available. Serious risks associated with a particular medication may be acceptable if the medication offers substantial benefits, especially if no acceptable therapeutic alternatives are available [7]. However, the same risk may be unacceptable for a less effective medication that does not provide unique advantages over other treatment options (see Chapter 35).

Third, there is a need to identify the most appropriate targets (e.g., healthcare providers, patients with a specific health problem or taking specific medications, consumers in general) for different types of communications and the most feasible and cost-effective way to communicate the information needed by different target audiences. Although patients can obtain information about medication risks and benefits from a wide variety of sources, most express a preference for obtaining this type of information from their healthcare provider [9,10]. Yet healthcare providers often struggle to remain abreast of recent research findings given the sheer volume

of emerging information as well as conflicting findings from different studies [11]. In addition, physicians may lack the skills in evidence-based medicine needed to critically evaluate the literature [12,13].

Fourth, one must determine how information should be tailored to individuals' needs, preferences, abilities (e.g., health literacy and numeracy), risk status (i.e., presence of factors that affect the probability/severity of medication side effects; presence of factors that affect benefits that might be gained by using the medication and risks associated with deciding to forego therapy), and current status in the medication use process (e.g., deciding whether to initiate therapy with a new medication; self-managing a stable, chronic medication regimen). Tailoring is also needed when working with special populations (e.g., children, individuals with cognitive impairments).

Finally, there is a need to address ethical issues that arise when communicating information about medication risks and benefits. Potentially, educating patients about medication risks and the uncertainty associated with experiencing medication benefits may increase patient reluctance to use an effective prescribed medication [14].

Methodologic Problems to Be Addressed by Pharmacoepidemiologic Research

In addition to the clinical issues described above, five major methodologic issues need to be addressed by pharmacoepidemiologic research. First, effective risk communication requires the availability of high-quality information concerning the risks and benefits of different therapeutic options, including the option of foregoing treatment. This need goes beyond simply knowing that a certain risk/benefit is possible. Information is needed concerning all the risk dimensions discussed in the previous section (e.g., probability, severity, controllability, reversibility, time of onset). Moreover, the information included in risk communications must be relevant to the target audience. Thus, the generalizability (and limits to generalizability) of pharmacoepidemiologic studies must be well understood.

Second, there is a need to determine the best format for providing risk/benefit information. Most risk communications include probabilistic information, which even healthcare providers can find difficult to interpret [15–17]. A wide variety of formats can be used to convey probabilistic information: qualitative descriptors (e.g., common, rare), numbers (e.g., absolute risk, relative risk, odds ratios), and graphics (e.g., bar charts, pictographs). Many studies have demonstrated that the format used to express probabilistic information can have a substantial impact on judgment and decision making [18,19]. Experts recommend against providing risk information only in relative terms, isolated from baseline rates and other information that would contextualize the risk [20,21]. Experts also recommend that verbal descriptors should either be avoided or defined explicitly in numerical terms as part of the risk communication [22,23]. However, many questions remain concerning the optimal way to convey this type of information.

Third, there is a need to better understand the factors that influence individual differences in how people perceive and respond to risk. Risk evaluation is not simply a cognitive exercise where estimates of probability and severity are entered into a mathematical formula to derive an estimate of acceptability that is invariant across individuals. People respond affectively to risk information [24–27] and different people may respond differently to the same information based on their past experiences and tolerance of uncertainty.

Fourth, there is a need to develop communication strategies that address the tendency for

patients and providers to overestimate the probability and magnitude of medication benefits. Hoffman and Del Mar identified a "medical optimism" among patients who express overly optimistic expectations about interventions, while simultaneously underestimating the chance of harm associated with treatments [28]. In comparison, it might be expected that clinicians have more accurate expectations of the benefits and risks associated with treatments. However, it has been demonstrated that, similarly to patients, clinicians rarely hold accurate expectations of treatment benefits and harms and also tend to overestimate benefit and underestimate risk [29]. Potential reasons for this may include a tendency to make decisions based on an understanding of how a treatment works as opposed to how effective it is [30] or may result from deficits in training. Hoffman and Del Mar also propose the existence of therapeutic illusion, "an unjustified enthusiasm for treatment on the part of both doctors and patients," as a factor that may influence perceptions [29]. Clinicians' understanding of risk and benefits is essential to ensure that patients receive accurate information to make unbiased and informed decisions about their treatments, so this is clearly an issue that requires resolution.

Fifth, there is a need to determine the most appropriate methods to use when evaluating communication effectiveness. In most cases, the ultimate objective of risk communications is to improve health outcomes by reducing the incidence of adverse events. However, it is helpful to consider the causal mechanisms through which desired effects on health outcomes might be achieved. As shown in Figure 39.1, the most proximal effects of risk communications are likely to be increased knowledge and, in many cases, emotional arousal. Next, the information communicated may be incorporated into decision-making processes. At this point, it is important to consider whether the purpose of the risk communication is to inform or persuade. If the purpose of the communication is purely informational, it would not be appropriate to evaluate message effectiveness in terms of the specific decision made. However, many risk communications include components that advocate specific actions (e.g., initiating precautionary behaviors to reduce a specific risk) and, therefore, have a persuasive intent. In these cases, the message would probably not be considered effective unless the desired behavior changes were realized. Evaluators must also give careful consideration to the time required for different types of effects to become evident [31]. For example, one would expect knowledge change to be evident immediately following message exposure. However, effects on health outcomes may require substantial time to become evident.

Two additional issues related to the evaluation of communication effectiveness deserve special attention. First, when evaluating the effect of risk communications on knowledge, investigators must determine what knowledge is needed for patients to make informed decisions and use medications safely. For example, is it important for patients to know that the probability of experiencing a particular medication side effect is 1%? Or is it sufficient to know that the side effect is possible, but unlikely? Reyna has argued that informed decision making does not require recall of precise verbatim information (e.g., exact probabilities), but does require understanding and recall of the essence of the information communicated [32,33]. Second, when evaluating communication effectiveness, it is important to consider unintended as well as intended effects. Risk communications concerning one medication have the potential to raise concern about unrelated medications and result in patients discontinuing efficacious medications that pose minimal risks. Unintended consequences might best be evaluated by assessing changes in health-related quality of life and changes in the use of medications other than those that are targeted by the risk communication.

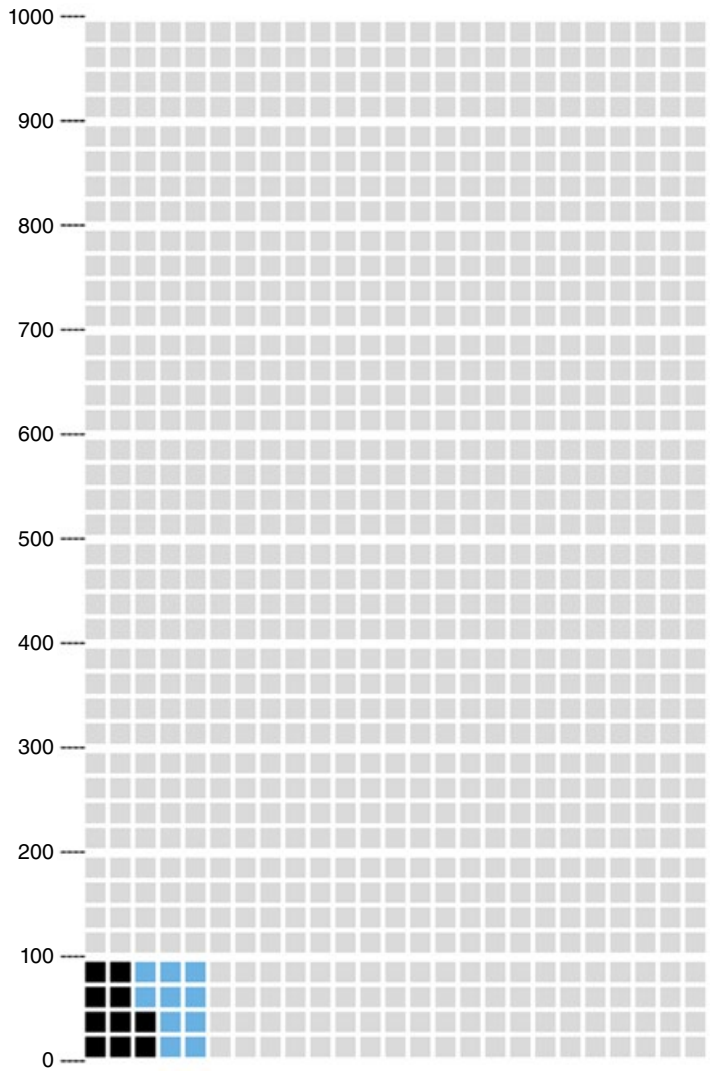

Figure 39.1 Sample pictograph.

Currently Available Solutions

Health Professional and Consumer Medication Information

Many countries have implemented regulatory measures in response to the challenges of communication about medication risks and benefits. For example, in order to promote the principles of transparency and develop methods of improving risk communication, the EMA requires the production of several documents which all play a role in risk/benefit communication. These include the European Public Assessment Report (EPAR), the Risk Management Plan (RMP), and the Patient Information Leaflet (PIL).

The EPAR is a lengthy public document which details the scientific assessment of a pharmaceutical product. These regulatory documents

are written for professionals, but pharmaceutical companies must also provide a user-friendly lay summary. The aim of the lay summary is to communicate how the decision to license the medicine was made. It is essential to ensure that such documents can be understood by potential users, and user testing is one potential method for ensuring that readability is optimized [34].

To adhere to good pharmacovigilance guidelines set out by the EMA, medicinal products are authorized "on the basis that in the specified indication(s), at the time of authorisation, the risk-benefit balance is judged to be positive for the target population" [35]. The EMA requires that pharmaceutical companies publish RMPs which must include information on the medicine's safety profile, how any risks will be prevented or minimized in patients, any plans for studies or other activities to gain more knowledge about the safety and efficacy of the medicine, and to assess the effectiveness of risk minimization measures. There is a requirement that RMPs are updated and modified as needed throughout the lifetime of the medicine, as additional information becomes available.

Patients in the UK and throughout the countries of the European Union must, by law, receive written information with their medicine which includes some communication on the risks and benefits associated with taking it. In 1992, a Directive from the European Commission on the labeling of medicinal products for human use mandated that all medicines are accompanied by a regulated patient information leaflet (package insert) inside the medicine box [36]. The Directive aimed to provide a standardized format for patients in order to provide consumer protection and ensure access to full and comprehensible information about medicines. For some patients, this might be the only written information they receive about their medicines.

European PILs follow a standardized format and include information about the following: potential side effects and their estimated frequency; what the medicine does and what it is for; dos and don'ts; and how to take the medicine [37]. Effective and balanced risk communication occurs when there is presentation of information about both the risk of harm and likelihood of benefit associated with taking a treatment. European PILs currently contain both textual and numerical descriptions of the estimated frequency of harms associated with taking the drug, as well as an indication of severity, aiming to inform patients about potential adverse effects in order to encourage help seeking, but also to support patients in making informed decisions about treatments.

Initially, guidance required European pharmaceutical license holders to present the risk of harm using a combination of qualitative and quantitative descriptions for five bands of risk frequency, ranging from "very common" (>10% frequency) to "very rare" (<0.01%). While the inclusion of the risk frequencies meets patients' identified need for information about the side effects of their treatments [38], the use of percentages to communicate numerical information about risk of harm can lead to overestimations of risk [39], which have been noted both in patients and in doctors [40]. Consequently, updated guidance recommends the use of frequency bands using a natural frequency numerical format (e.g., "less than 1 in 100"). UK PILs now communicate risk using the following regulatory standard [41].

- Very common – occurs more frequently than 1 in 10 administrations of a drug.
- Common – occurs in between 1 in 10 and 1 in 100 administrations of a drug.
- Uncommon – occurs in between 1 in 100 and 1 in 1000 administrations of a drug.
- Rare – occurs in between 1 in 1000 and 1 in 10 000 administrations of a drug.
- Very rare – occurs in less than 1 in 10 000 administrations of a drug.
- Frequency not known.

Use of the five verbal terms (very rare; rare; uncommon; common; very common) alone has

been shown in a number of studies to produce risk estimates that are inconsistent with the assigned frequencies of incidence. For example, "common" was assigned to incident rates between 1% and 10% but was found to result in mean risk estimates of 45.3% by members of the public asked about a hypothetical antibiotic [40]. Furthermore, the term "rare," which had been assigned to rates of 0.01% to 0.1%, produced average risk estimates of 8%. These findings were replicated in a study with a similar study design but which asked people using statin (cholesterol-lowering) medicines to respond to information about real side effects (and their incidences). The "common" side effect of constipation was estimated to occur in 34.2% statin users, while the "rare" side effect of pancreatitis was estimated to occur in 18% users [42]. If these significant overestimates of risk frequency were translated into behaviors (such as deciding not to take the medicine), then their use would be problematic.

One notable point from these and other studies of risk estimation is the high levels of variation in estimates found in study samples. In the study by Berry *et al.*, the standard deviations around the estimates of "common" and "rare" were 22.5% and 7.5%, respectively, a pattern replicated elsewhere [42]. Risk estimates among people are highly variable, which may in part result from relatively stable differences between them in their perceptions of risk susceptibility or their numeracy skills [43]. However, verbal terms appear to add another layer of variation and it seems to be much more difficult to achieve consensus in their meaning than it is for numerical risks descriptors.

Verbal terms do have some strengths, as they may be seen as less intimidating by some patients and as closer to the everyday language of risk; in conversation, people will tend to use words to give a gist or estimate of the degree of risk associated with an uncertain event. However, when used in the context of medicine side effects, words seem to have framing effects, tending to produce inflated estimates of risk that might lead patients to make inaccurate judgments [44]. PILs, as produced currently according to European law, are perceived as containing information about medicines as risky, side effect-inducing products [45]. Therefore, it is important that the terms used, both in writing and in conversation with patients, are proportionate and not prone to misinterpretation.

When space allows, using graphical representations of risk (e.g., bar charts, pictographs) can be helpful, although they are not a panacea and evaluation is essential. However they do seem to have positive effects on accuracy of risk estimates, as well as other benefits, and appear particularly useful for information users who are less skilled or adept at risk interpretation [46]. A sample pictograph is shown in Figure 39.1. In this graph, each square corresponds to one person in the at-risk population. The black squares depict the risk of experiencing liver toxicity within five years of initiation of therapy with Medication B. Thus, this figure suggests that 10 out of every 1000 patients taking Medication B will experience liver toxicity within five years of therapy initiation. The dark gray squares depict the increase in risk associated with Medication A. That is, out of every 1000 patients treated with Medication A, 10 extra cases of liver toxicity would be expected to develop among individuals taking Medication A as opposed to Medication B. Pictographs provide a relatively simple way to convey information concerning both relative and absolute risk. However, they may not be useful when the risk(s) of interest occur very infrequently (e.g., 1 case/10 000 patients treated).

One criticism that patients express about European regulated PILs is that, while information about side effects is valued, when included in written information it can provide an overly negative impression of the medicine. Consequently, in order to support patients to make balanced and informed decisions about treatments, there is a need to also provide information about the

likelihood of benefit from the treatment alongside the likelihood of harm. Currently, there is no consensus on the best format for the presentation of this type of positive information although the EMA notes that benefit information should be compatible with the Summary of Product Characteristics, a document required for the licensing of a drug, and should not be promotional.

The inclusion of information about the potential benefits of medicines in written medicines information is not without its challenges. As noted previously, there is a tendency for patients to overestimate the benefits of their treatments [28] and this can translate to "concern and upset" for patients when they are provided with numerical information that contextualizes the likelihood of benefit they receive from their treatments. A series of qualitative studies exploring patient perceptions and opinions on the provision of textual and numerical benefit information in patient information leaflets have all presented similar findings.

Hamrosi and colleagues recruited focus groups of medicine users in the UK and Australia and provided information about the medicine clopidogrel in two different formats, which had been revised specifically for the study [47]. The revised leaflets contained additional benefit information about clopidogrel in either a text-only format or a numerical format based on the number needed to treat (NNT) to prevent a heart attack or stroke. The NNT statement was written as follows, based on the best available clinical trial data:

> "If 100 people took this medicine for 2 years:
> - 3 of them would be saved from having a heart attack
> - 1 of them would be saved from having a stroke"

A key finding from this study was that while the inclusion of benefit information was valued and seen as a positive addition to the leaflet, the numerical benefit information provoked strong feelings of shock and surprise at the perceived low chance of benefiting from treatment. Some participants did not understand the numerical information, while others struggled to comprehend the magnitude and made an assessment of potential benefit based on a crude interpretation of the data.

Similar research has been undertaken exploring patient opinion and perception of different presentations of benefit information for medicines with different magnitudes of risk. In a focus group, study participants were presented with benefit statements for two different drugs (i.e., sumatriptan and simvastatin) using one of three different numerical formats (percentages, natural frequencies, and NNT) [48]. An example of the different magnitude of benefit seen in the two drugs is presented as follows using the NNT format.

- If 4 people like you take sumatriptan, 1 of them will have a less severe migraine headache after 2 hours.
- If 20 people like you take simvastatin over the next 5 years, 1 of them will be stopped from having a heart attack or stroke.

Participants reported similar levels of shock and surprise at the perceived poor benefits from the two medicines. Other key findings included the following:

- Textual format information was preferred, but did not provide enough information to help contextualize the magnitude of benefit.
- The NNT format was frequently misunderstood.
- The natural frequency format was challenging to understand but when participants invested time to understand, they reported that it helped understanding.
- Numerical information was perceived as worrying, but it was valued.
- Some participants thought that if information on the chance of benefit is available, it should

not be withheld from patients, who may want it to help with their decisionmaking.

One concern noted was that numerical benefit information has the potential to influence patient behavior and could lead to the rejection of a beneficial treatment, perhaps based upon the affect heuristic, a mental shortcut that results in decisions being made based on an emotional response to information rather than reason [49].

There is evidence that "patients" shown numerical benefit information are more likely to choose not to take a treatment, rather than when they are shown nonnumerical information [50]. The inclusion of numerical information on the chance of benefit can influence decision making resulting in a tendency to reject a treatment. This study also explored the impact of the provision of numerical information about side effects and found the opposite – when individuals are provided with nonnumerical side effect information, they are less likely to take a medication than those provided with numerical information about the likelihood of harm. A key finding from this study is that presenting side effect and benefit information in nonnumeric format appears to influence decision making in opposite directions. Although numeric information for both benefits and side effects may enhance decision making, providing numeric benefit information may decrease individuals' willingness to take the medicine, creating both an ethical dilemma for prescribers and providers and a public health concern for policy makers when the chance of benefit from a medicine makes its use attractive at a population level, but which may not be persuasive for individual patients.

In the United States, all prescription medications are required to have an FDA-approved package insert, targeted primarily for prescribers, that comprises the official product label. However, with a limited number of exceptions, there are no regulations that require patients to receive written information about medication risks/benefits when they obtain prescription medications. This is despite FDA recognition that:

> … people are able to make better decisions about their healthcare and better use of the prescription medications available to them when they are well informed about the medications they take. Access to useful written information about prescription medications is important to ensuring appropriate use of these products [51].

Since the late 1960s, the FDA has required that patients receive a patient package insert when they obtain prescriptions for oral contraceptives and estrogens [51]. In 1979, the FDA proposed regulations requiring that manufacturers develop and distribute written patient information, to be approved by the FDA, for all prescription medications. However, the regulations were revoked prior to implementation, based in part on assertions made by pharmaceutical manufacturers and other private sector stakeholders that the goals of the regulations could be accomplished without governmental regulation. Unfortunately, although the availability of consumer medication information has increased over the past 40 years, the quality of the materials distributed is variable and often poor [52]. For example, a study reported in 2007 found that although most pharmacies in the US distribute written materials with prescription medications, many of the materials failed to include information such as contraindications and precautions needed for safe medication use [53]. Notably, there was considerable variability in the consumer medication information distributed by pharmacies in the three countries examined: the US, Australia, and the UK. The materials distributed in the US were evaluated the least favorably.

In an attempt to assist private sector developers, the FDA issued a Guidance document in 2006 entitled "Guidance on Useful Written Consumer Medication Information (CMI)" [51].

Table 39.1 FDA Action Plan criteria for defining useful consumer medication information.

Criterion
Drug names, indications for use, and how to monitor for improvement
Contraindications and what to do if they apply
Specific directions about how to use and store the medicine, and overdose information
Specific precautions and warnings about the medicine
Symptoms of serious or frequent possible adverse reactions and what to do
Certain general information, including encouraging patients to communicate with healthcare professionals, and disclaimer statements
Information that is scientifically accurate, unbiased in tone and content, and up to date
Information in an understandable and legible format that is readily comprehensible to consumers

Source: FDA [55].

Although this document does not establish regulations or legal requirements, it does provide recommendations for the content and format of CMI. As shown in Table 39.1, the Guidance document identifies eight criteria that can be used to assess the usefulness of CMI. It recommends that CMI not include all possible side effects but rather focus on those that are the most serious and most common. The Guidance document does not include any recommendations concerning how to communicate information concerning the likelihood of experiencing the side effects included. However, the examples provided in the Guidance suggest that no numerical information is needed. For example, in a section labeled "Possible side effects," the sample CMIs included in the Guidance state: "The most common side effects are mild upset stomach, diarrhea, and rash. Call your health care provider if these side effects bother you or do not go away" [51]. Finally, although the Guidance document highlights the need to write CMI using plain language principles, it does not recommend user testing to assess consumer comprehension.

A study conducted in 2008 assessed the extent to which CMI distributed by retail pharmacies in the United States met these criteria [54]. This study found that although 94% of the pharmacies visited by secret shoppers provided CMI with prescriptions for lisinopril and metformin, the materials met only about 60% of the eight criteria specified in the FDA Guidance document. Moreover, less than 50% of the materials were judged as meeting the criteria for comprehensibility/legibility, leading the investigators to conclude that "Private sector initiatives to provide useful CMI have failed."

The FDA Amendments Act (FDAAA-PL 110-85) of 2007 gave the FDA authority to require that pharmaceutical manufacturers submit a Risk Evaluation and Mitigation Strategy (REMS) to the FDA when deemed necessary to ensure that the benefits of a drug or biologic product outweigh its risks [55]. The FDA may require a manufacturer to submit a REMS as part of the initial drug approval process or in response to a new safety concern identified via sources such as adverse event monitoring systems, peer-reviewed biomedical literature, clinical trials, and the FDA's Sentinel Initiative [56]. As of February 2018, 73 products have an approved REMS.

All REMS must include at least one safety-related goal that identifies the specific health outcome that the REMS is designed to accomplish [55]. For example, the goal of the Prolia® (denosumab) REMS is to:

> … mitigate the risks of hypocalcemia, osteonecrosis of the jaw, atypical femoral frac-

tures, serious infections, and dermatologic reactions by:

1) informing healthcare providers and patients about the risks of (1) hypocalcemia, (2) osteonecrosis of the jaw, (3) atypical femoral fractures, (4) serious infections, and (5) dermatologic reactions associated with PROLIA®.
2) informing healthcare providers they should counsel patients about the risks associated with PROLIA® [57,58].

Risk Evaluation and Mitigation Strategies may include three major components [55]. First, the manufacturer may be required to develop a Medication Guide or a patient package insert which must be given to patients when a prescription is filled. Medication Guides must be approved by the FDA and become part of the official drug label. Approximately half of the currently approved REMS include a Medication Guide. However, the FDA can require a Medication Guide for drugs and biologic products that do not have a REMS if they determine that "certain information is necessary to prevent serious adverse effects, patient decision making should be informed by information about a known serious side effect with a product, or patient adherence to directions for the use of a product are essential to its effectiveness" [59]

Currently, approximately 600 products have Medication Guides. A 2012 study [60] examined all the Medication Guides that were available in April 2010 to determine the extent to which they met criteria of suitability for use among individuals with limited literacy skills [61]. Of the 185 Medication Guides assessed, only one was deemed suitable for individuals with low literacy skills. In a separate substudy, the investigators asked study participants to review three Medication Guides (taken one at a time) and their comprehension of the information contained in the Guides was assessed using "open book" methods. Participants answered an average of only 52.7% (SD 22.6) of the comprehension questions correctly, with lower scores observed among those with low and marginal literacy. Another study analyzed the results of 66 unique Medication Guide assessments submitted to the FDA between September 2008 and June 2012 [62]. On average, participants correctly answered 63.5% of questions concerning the primary drug risk(s). Only 20 Medication Guide assessments (30.3%) reported knowledge scores of 80% or higher. In general, higher knowledge scores were reported for Medication Guides that were part of a REMS that also included either a Communication Plan or Elements to Assure Safe Use, as described below. Other studies have also demonstrated that many patients have difficulty understanding the information contained in Medication Guides, including the critical safety information included in these documents [63,64]. Thus, although the number of Medication Guides available has expanded dramatically over the past decade, work to improve the usability of these Guides is urgently needed.

Second, a REMS may be required to include a Communication Plan targeted at healthcare providers [66]. For example, the Communication Plan for Prolia targets healthcare providers likely to prescribe this medication [67] and includes: (1) a letter to healthcare providers; (2) a letter to professional societies; (3) a patient counseling toolkit that includes a patient counseling chart for healthcare providers, a patient brochure, and a Medication Guide; (4) a journal information piece that was published quarterly for 12 months in three targeted journals; (5) a plan for the dissemination of REMS information at scientific meetings; and (6) a REMS Website that provides access to all the materials included in the REMS [68]. In line with FDA requirements, the landing page of the REMS website includes a statement encouraging patients and healthcare providers to report suspected adverse reactions and provides a link to the MedWatch reporting system (see Chapter 10), as well as toll-free telephone numbers to both the FDA and the manufacturer.

The final REMS component involves elements to assure safe use (ETASU). These elements

may include specific training, experience, or certifications for healthcare providers who prescribe or dispense the drug; restricting the types of healthcare settings in which the drug can be dispensed; special requirements for patient monitoring; documentation of required safety measures (e.g., laboratory testing); and patient enrollment in a drug registry.

Manufacturers are required to evaluate the effectiveness of their REMS 18 months, three years, and seven years after the REMS is approved. The results of these evaluations must be reported to the FDA so that it can determine whether modifications to the REMS are needed. Morris has provided guidelines for the assessment of REMS programs [69]. In 2011, the FDA created a REMS Integration Initiative to better understand the overall effectiveness of the REMS requirements and identify ways in which current regulations might be improved, particularly in ways that would reduce burdens associated with the regulations while not compromising the effectiveness of the program [70].

Patient–Provider Communication

Although healthcare providers have a professional obligation to counsel patients about medication risks, they may be reluctant to discuss potential risks with patients due to concern that it may decrease patient adherence to the prescribed medication regimen [71]. However, research suggests that the opposite is true. Patient–provider communication concerning potential medication risks and incorporation of patient preferences into the decision-making process may increase adherence and decrease the likelihood of premature discontinuation of therapy [72–74]. Unfortunately, research suggests that this type of communication during patient office visits is not the norm. For example, Sibley and colleagues found that medication concerns (e.g., expected side effects) were discussed in only 2.7% of visits involving diabetes patients and a nurse prescriber [75]. In another study, Richard and Lussier found that potential adverse reactions were discussed in fewer than 17% of physician office visits in which a new medication was prescribed [76].

In a study that analyzed audiotaped visits of patients with rheumatoid arthritis and their rheumatologist, Blalock and colleagues found that, when medication risks were discussed in relation to a medication that was being proposed for addition to the patients' regimen, the types of information most frequently provided were the importance of monitoring to detect potential problems early (30%), probability of side effect occurrence (29.8%), steps to take to minimize risk (25.5%), and severity (21.8%) [77]. When discussing risks associated with medications the patient was currently taking, only the importance of monitoring and steps to take to minimize risk were discussed in over 20% of the conversations. These findings highlight that patient information needs vary depending on their stage in the medication use process (e.g., deciding whether to initiate a new medication, managing a current medication regimen). This study also found that patients often were not able to extract meaningful gist from the information communicated by the rheumatologists [78]. For example, in 14% of the visits, patient coders indicated that it was not clear if the rheumatologist thought the medication was needed and, in 29% of the visits, the coders indicated that it was not clear if the rheumatologist was concerned about the safety of the medication. These findings highlight the need to focus not only on the types of risk/benefit information communicated, but also on the clarity of the communication.

Pharmacists also have a professional obligation to counsel patients about medication risks. Internationally, the rates of verbal counseling provided by pharmacists in community pharmacy settings tend to be low, but vary widely depending upon the research methods used. Observational studies using simulated

patients (i.e., actors trained to portray patients with a specific condition) tend to yield lower estimates of the rate of counseling [79]. Few states in the US require pharmacists to provide verbal counseling to patients when prescriptions are filled, with most states requiring only that pharmacists offer to counsel patients [80]. In a study using simulated patients, Svarstad and colleagues examined the rates of verbal counseling provided in 306 community pharmacies distributed across eight states in the US [81]. Risk communication, defined as providing information about at least one side effect or precaution, occurred in 17% of visits in which a prescription for amoxicillin was presented and 31% and 37% of visits in which a prescription for ibuprofen or paroxetine, respectively, was presented. Patients who filled a prescription in states with more strict regulations concerning pharmacist counseling (e.g., pharmacists required to provide face-to-face counseling) were more likely to receive risk information than patients in states with less strict regulations.

The Internet, Direct-to-Consumer Advertising, and Social Media

The availability of medication-related information via the internet, direct-to-consumer advertising, and social media has expanded dramatically since the turn of the century [82–86]. Unfortunately, the quality and accuracy of available information vary widely from source to source, and few safeguards are in place to allow consumers to evaluate the quality of information available from different sources [86,87]. Direct-to-consumer advertising (DTCA) and social media sites managed by pharmaceutical companies present special challenges. In a recent study that examined notices of violation and warning letters issued to companies by the FDA, 95% involved a branded drug website, online paid advertisement, or an online video [88]. Of the 179 violations examined, most involved the lack of risk information or the misrepresentation of benefit information. Although few countries allow DTCA, online materials travel across borders, presenting a global challenge [89].

Finally, some websites enable consumers to provide reviews of their medications, potentially opening up a Pandora's box for the spread of anecdotal information. A recent study examined over 100 000 reviews provided on the website WebMD [90]. The investigators found that in about two-thirds of the cases where differences in patient satisfaction ratings were observed for two drugs used to treat the same condition, the differences were consistent with findings reported in the published literature. However, where differences were observed, drugs with an FDA black box warning were reviewed less favorably by patients than would be expected based on the results of published studies, suggesting that these types of warnings may bias patient judgment and decision making. Clearly, more research is needed to better understand the effects of this type of internet-facilitated patient-to-patient communication.

The Future

Much of the literature on risk communication focuses on environmental risks and the risk of disease. The field of medication risk communication is still relatively young. The extent to which findings from other areas generalize to communication concerning medication risks remains unknown. Over the next few years, much will be learned as companies evaluate their REMS. For knowledge gain to be optimized, it will be important that REMS evaluation plans include a comprehensive assessment of both proximal and distal outcomes. The conceptual model depicted in Figure 39.2 may help to structure future evaluation efforts.

More basic research is also needed to assess how people process and use information about

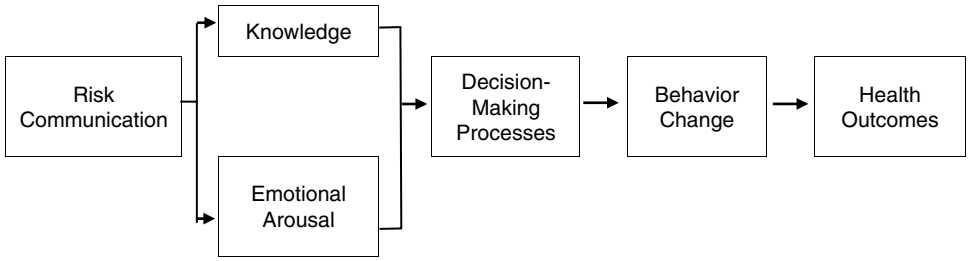

Figure 39.2 Conceptual model for evaluating the effectiveness of risk communication efforts.

medication risks. One promising approach involves the use of *fuzzy-trace theory* [91–94]. Briefly, fuzzy-trace theory posits that when an individual is exposed to risk information, two representations of the information are encoded in memory: a verbatim representation and a gist representation. The verbatim representation reflects the precise information received (e.g., 10% of patients who take Medication X experience Side Effect Y), whereas the gist representation captures the essential meaning of the information as understood by the receiver, in qualitative terms (e.g., Medication X can cause Side Effect Y). Different people exposed to the same information may form different gist representations, depending on their preexisting knowledge, previous experiences, emotional state, developmental stage, and worldview. A central tenet of fuzzy-trace theory is that when making judgments and decisions, people tend to rely on gist representations that are stored in memory and only retrieve verbatim representations when it is required by the task at hand. Further, this preference for gist processing of information increases with age and the acquisition of specialized expertise [94].

Currently, much of the risk communication literature focuses on how probabilistic information is best conveyed. From this perspective, the difficulty patients have in accurately recalling probabilistic information is viewed as problematic. However, from the perspective of fuzzy-trace theory, that conclusion might not be warranted. From a fuzzy-trace perspective, misunderstandings are most problematic when individuals interpret the gist of the information incorrectly. Numerical differences may have little effect on subsequent decisions. This possibility is supported by findings from an experimental study by Brewer *et al*. [95]. After reading a clinical vignette that portrayed a hypothetical patient, physicians in one group were asked whether the chance that the patient had a pulmonary embolism was greater or less than 1% and physicians in the other group were asked whether the chance that the patient had a pulmonary embolism was greater or less than 90%. Physicians in both groups were then asked to provide a point estimate of the chance of embolism and select from among a choice of treatment options. The irrelevant anchor (i.e., 1% versus 90%) used in the initial risk estimate had a large effect on physicians' subsequent point estimates of the probability of embolism, 23% versus 53% for physicians exposed to the low or high anchor, respectively. However, the treatment decisions made by the physicians were unaffected by the anchors. Thus, as suggested by fuzzy-trace theory, physicians appear to have based their treatment decisions on their gist representation of the information presented and were able to make rational decisions even in the presence of irrelevant information.

The findings described above illustrate the complexity of the risk communication process. Research using fuzzy-trace theory attempts to better understand the psychological processes

that underlie risk communication by systematically examining three central issues. Within the context of medication risk communication, these central issues are: (1) how do patients or clinicians extract gist from medication-related information obtained from a variety of sources (e.g., written information distributed by pharmacies when prescription medications are dispensed, direct-to-consumer advertising, healthcare providers, family/friends)? (2) what reasoning principles are invoked by contextual cues (e.g., format of the communication, images included in the communication) that affect patients' or clinicians' judgments and decisions concerning medication use? and (3) what factors (e.g., limited health literacy skills, emotional state) interfere with information processing and lead to errors in reasoning [92]? We believe that systematic research examining these types of issues has the potential to greatly expand current knowledge concerning communication of information regarding medication risks and benefits.

In conclusion, we began this chapter with the assertion that all medications have risks. The responsibility for communicating information about medication risks is shared by many entities within the healthcare system. In addition, we must recognize that we live in the Information Age. Information about medications and medication risks is disseminated by many outside the healthcare system, in some cases by individuals and groups without appropriate expertise and whose primary motive may not be the improvement of patient health outcomes. The challenge to investigators working in the field of pharmacoepidemiology is to develop communication strategies that reflect an understanding of both psychological and social issues that affect how message recipients interpret and use the information communicated.

Methods for Studying the Health Effects of Drug–Drug Interactions

Sean Hennessy[1], Charles E. Leonard[1], Joshua J. Gagne[2], James H. Flory[1,3], Colleen M. Brensinger[1], and Warren B. Bilker[1]

[3] *Memorial Sloan Kettering Cancer Center, New York, NY, USA*

A drug–drug interaction (DDI) occurs when one or more drugs affect the pharmacokinetics (the body's effect on the drug) and/or pharmacodynamics (the drug's effect on the body) of one or more other drugs. In two-drug DDIs, the affected drug is called the **object** (or *victim*) and the affecting drug is called the **precipitant** (or *perpetrator*). The expected outcome of most hypothesized DDIs is an exaggeration of the major pharmacologic effect of the object, such as serious hypoglycemia from sulfonylurea antidiabetic agents or bleeding from anticoagulants. Other DDIs may result in reduced effectiveness of the object, such as the hypothesized reduced effectiveness of clopidogrel in lowering the risk of stroke resulting from the inhibition by proton pump inhibitors of the enzyme that converts clopidogrel to its active moiety. The precipitant of a DDI may or may not have an inherent effect on the health outcome in the absence of the object. For example, in a study of potential DDIs that involves warfarin as the object, nonsteroidal antiinflammatory drugs but not antibiotics as precipitants would be expected to increase the risk of bleeding in persons not taking warfarin.

Numerous pharmacokinetic and pharmacodynamic mechanisms are responsible for DDIs [1,2]. Because the pharmacokinetic pathways and pharmacodynamic effects of most drugs are not completely understood, it can take many years to identify, confirm, and fully understand a DDI. For example, tamoxifen and paroxetine were approved in 1977 and 1992 respectively, although it was not until 2003 that scientists identified a potential DDI between them that was hypothesized to reduce tamoxifen's effectiveness in lowering the frequency of breast cancer recurrence [3]. Although *in vitro* experiments, animal studies, and clinical trials are used to examine the effects of one drug on the pharmacokinetics of another drug, pharmacoepidemiologic studies are the principal way of studying the health effects of potential DDIs. This chapter focuses on methods for studying the health effects of potential DDIs.

Pharmacoepidemiology, Sixth Edition. Edited by Brian L. Strom, Stephen E. Kimmel and Sean Hennessy.

Clinical Problems to Be Addressed by Pharmacoepidemiologic Research

Drug–drug interactions are a large and growing clinical and public health problem, especially in older adults, 40% of whom take five or more prescription drugs in a given month [4]. Although the frequency with which DDIs cause adverse health outcomes is not well studied, in older adults known DDIs are estimated to cause 13% of adverse drug events (ADEs) [5] and 5% of hospital admissions [6]. As new drugs are developed, old drugs are repurposed, and per capita drug consumption continues to rise, the clinical and public health consequences of DDIs are likely to rise correspondingly.

There are many approaches to identifying novel potential DDIs, including physiologically based pharmacokinetic models (see Chapter 2) and data mining of spontaneous reporting databases, social media posts, and healthcare data (see Chapter 27). Potential DDIs, however, may not have observable effects on health outcomes, and relatively few studies have examined the health effects of specific potential DDIs in populations. This leaves critical knowledge gaps for clinicians, patients, caregivers, editors of DDI compendia, and those who manage clinical decision support systems. Recognizing these knowledge gaps, stakeholders attending a 2009 meeting on DDIs made the conduct of additional research on the health effects of DDIs their principal recommendation [7].

False warnings about DDIs that are sent to clinicians in the context of automated messaging in the healthcare setting, such as during prescribing or dispensing, can reduce the use of valuable combinations of medications because of unsubstantiated fears that they may interact detrimentally. Further, physicians and pharmacists who are subjected to frequent alerts about apparently inconsequential potential DDIs often become desensitized to them in a phenomenon known as "alert fatigue" [8]. This provides additional importance to conducting studies of the health effects of potential DDIs, as well as studies of better ways in which the healthcare system can avoid harmful DDIs.

It seems likely that some subgroups of people are more or less susceptible to the effects of a given DDI than other subgroups (see Chapter 30). Therefore, providing information about the health effects of potential DDIs that is relevant to identifiable subgroups is an important goal of DDI research.

Methodologic Problems to Be Addressed by Pharmacoepidemiologic Research

A number of methodologic problems are more prominent in pharmacoepidemiologic studies of DDIs than in those examining the effects of individual drugs. For example, pharmacoepidemiologic studies of DDIs usually require data from larger populations than those needed to study the effects of individual drugs. This is because, in any population, a small proportion of people will take any given drug, and a small proportion of those will concomitantly take the second drug of a drug–drug pair of interest. An additional problem is confounding by indication (see Chapters 3 and 43), which is regarded by many as the single biggest challenge in using the results from nonrandomized pharmacoepidemiologic studies to infer causation.

The problem of confounding by indication is more pronounced in DDI studies, which need to address confounding by the indications of two or more drugs. An additional problem is the inability of available healthcare data to validly identify all study outcomes of potential interest. In particular, while nonpharmacoepidemiologic studies of DDIs often examine serum drug

concentrations or other biomarkers such as the electrocardiographic QT interval or the international normalized ratio as outcome measures, pharmacoepidemiologic studies typically examine health outcomes such as clinically evident cardiac arrhythmias or serious bleeding. Further, some important outcomes of DDIs (e.g., serotonin syndrome) may not be validly identifiable using claims data. Thus, as in studies of the effects of individual drugs, investigators' ability to validly (and hopefully completely, or at least in a way that does not lead to biased results) ascertain outcomes that represent toxicity or lack of effectiveness using available healthcare data is essential. A further methodologic problem is that little attention has been given to optimizing pharmacoepidemiologic methods to perform well in screening for previously unanticipated associations (see Chapter 27), as may be desired when the goal is to identify hypotheses of novel potential DDIs. In addition to the need to increase the efficiency of such screening studies with regard to tasks performed by humans and by computers, screening large numbers of drug–drug pairs raises concerns that the conventionally accepted type I error rate of 5% may not be appropriate in such settings.

Currently Available Solutions

Available Research Designs for Studying the Health Effects of DDIs

Table 40.1 lists available pharmacoepidemiologic designs to study the health effects of DDIs using data derived from the provision of healthcare. The most basic and intuitive epidemiologic design is the cohort study, which compares the frequency of an outcome in different groups (i.e., cohorts) that are defined based on exposure. One possible but, as we shall see, generally unhelpful approach to assessing whether a health-affecting DDI exists is to measure the incidence rate (IR) of the adverse health outcome in four cohorts: (1) those taking the object with the precipitant (IR_{11}), (2) those taking the object without the precipitant (IR_{10}), (3) those taking the precipitant without the object (IR_{01}), and (4) those taking neither the object nor the precipitant (IR_{00}) (Table 40.1, Design 1). For DDI effects defined as a departure from multiplicity, an effect would be inferred if the following null hypothesis (H_0) were rejected:

$$H_0 : \left(IR_{11} / IR_{00}\right) = \left[\left(IR_{10} / IR_{00}\right) \times \left(IR_{01} / IR_{00}\right)\right]$$

This is to say that an effect of a DDI defined as departure from multiplicity would be inferred if the rate ratio for both-exposed vs neither-exposed were statistically different (i.e., either higher or lower) than the object-exposed vs neither-exposed rate ratio multiplied by the precipitant-exposed vs neither-exposed rate ratio. For DDI effects defined as a departure from additivity, an effect would be inferred if the following null hypothesis were rejected:

$$H_0 : \left(IR_{11} - IR_{00}\right) = \left[\left(IR_{10} - IR_{00}\right) + \left(IR_{01} - IR_{00}\right)\right]$$

This is to say that an effect of a DDI defined as a departure from additivity would be inferred if the rate difference between the both-exposed vs the neither-exposed were statistically different than the object-exposed vs neither-exposed rate difference plus the precipitant-exposed vs neither-exposed rate difference.

In practice, Design 1 is rarely if ever used to identify either multiplicative or additive effects of potential DDIs. This is because it implausibly assumes that neither the object nor the precipitant have clinical indications (i.e., reasons for taking the drug) that affect the outcome rate, or that these indications can be fully measured and controlled for. However, persons taking a given drug (whether object or precipitant) generally

Table 40.1 Pharmacoepidemiologic designs used to study health effects of potential drug–drug interactions.

Design	Relative measure of association	Key assumptions	Comments	Example
1. Cohort study examining incidence rate (IR) of the outcome in: (1) those taking the object with the precipitant (IR_{11}); (2) those taking the object without the precipitant (IR_{10}); (3) those taking the precipitant without the object (IR_{01}); and (4) those taking neither the object nor the precipitant (IR_{00})	Incidence rate ratio due to interaction (IRR_I), defined as $IRR_I = (IR_{11}/IR_{00})/[(IR_{10}/IR_{00}) \times (IR_{01}/IR_{00})]$*	No among-person unmeasured confounding by use of either object or precipitant	While this design yields the theoretically correct overall relative measure of association, the key assumption is implausible for most drug pairs	We are unaware of any published examples
2. Cohort (or case–control) study nested within person-time exposed to the object, comparing persons exposed vs unexposed to the precipitant	Incidence rate ratio (or odds ratio) associated with use of the precipitant among persons receiving the object	No among-person unmeasured confounding by use of precipitant No effect of precipitant in absence of object	Will show association if precipitant has inherent effect on outcome apart from interaction mechanism May be useful for precipitants with a chronic indication that is unlikely to be associated with outcome Use of a negative control object and/or negative control precipitant can help to assess validity of the key assumptions	Case–control study nested in person-time exposed to glyburide, examining the association between cotrimoxazole and serious hypoglycemia [9]
3. Cohort (or case–control) study nested within person-time exposed to the object, comparing person-time exposed to the precipitant vs the negative control precipitant	Incidence rate ratio (or odds ratio) associated with use of the precipitant vs control precipitant among persons receiving the object	No among-person unmeasured confounding by use of precipitant vs negative control precipitant No effect of precipitant in absence of object that is not shared by negative control precipitant No interaction between negative control precipitant and object	Preferable to Design 2 because use of a valid control precipitant reduces susceptibility to confounding by indication for the precipitant It can be difficult to know for certain that the control precipitant does not interact with the object or otherwise affect the rate of the outcome	Cohort study within person-time exposed to clopidogrel, examining the rate of ischemic stroke associated with individual proton pump inhibitors, each vs pantoprazole [13]

(*Continued*)

Table 40.1 (Continued)

Design	Relative measure of association	Key assumptions	Comments	Example
4. Cohort (or case–control) study nested within person-time exposed to either the object or the control object, comparing person-time exposed to the precipitant plus the object vs the precipitant plus the negative control object	Incidence rate ratio (or odds ratio) associated with use of the precipitant among users of the object vs use of the precipitant among users of the negative control object	No difference in direct effect of the object vs negative control object on the outcome No among-person unmeasured confounding by use of object vs negative control object No interaction between the precipitant and negative control object	Can help identify an inherent effect of the precipitant in the absence of the object	We are unaware of any published examples
5. Self-controlled case series (or case–crossover study) nested within person-time exposed to the object, comparing person-time exposed vs unexposed to the precipitant	Incidence rate ratio (or odds ratio) associated with use of the precipitant vs no exposure among persons receiving the object	No within-person unmeasured confounding by precipitant vs non-use of precipitant No effect of precipitant in absence of object	Self-controlled design inherently eliminates confounding by factors that remain constant within the individual over the study period Necessitates within-person variability in exposure to precipitant and accurate knowledge of onset and offset of exposure to precipitant For precipitants with an acute indication (e.g., antibiotics), Design 3 may be preferred if a valid control precipitant Results can be affected by secular or within-person trends in exposure to the precipitant	Case–crossover study nested within person-time exposed to warfarin examining within-person odds ratio for exposure to antimicrobial agents [16]

*IR_{11} is the incidence rate in person-time exposed to both the object and the precipitant; IR_{00} is the incidence rate in person-time exposed to neither the object nor the precipitant; IR_{10} is the incidence rate in person-time exposed to the object but not the precipitant; IR_{01} is the incidence rate in person-time exposed to the precipitant but not the object.

have an indication for that drug, while persons not taking the drug generally do not. Pharmacoepidemiologists often use the term "indication" as shorthand for denoting all the observed and unobserved factors that lead to a given patient receiving a particular medication rather than a comparator medication, or no treatment. If any aspect of this indication

(or contraindication, i.e., reason to avoid a given drug) directly affects the risk of the outcome or is otherwise associated with the outcome, then *confounding by indication* exists. Such confounding can cause the observed association to differ from the true causal effect. Confounding by indication is among the most important challenges facing pharmacoepidemiologists. Given the widespread potential for confounding by indication, it is often unrealistic to assume that the baseline rate of those taking a drug is the same as that in those not taking the drug.

If use of the precipitant in the absence of the object has no effect on the outcome, and if the precipitant is not used for an acute indication that affects or is otherwise associated with the outcome, then one can use Design 2. Design 2 is a cohort or nested case–control design that measures, within person-time exposed to the object, the incidence rate ratio of the outcome in those taking the precipitant versus in those not taking the precipitant. For example, Juurlink *et al*. used a healthcare database from older adults in Ontario to conduct a case-control study, nested within person-time exposed to glyburide [9]. Their aim was to examine the association between use vs nonuse of cotrimoxazole and serious hypoglycemia. They found that the adjusted odds ratio (OR) for the association between cotrimoxazole use and serious hypoglycemia was 6.6 (95% confidence interval [CI] 4.5–9.7). The exposure OR is the measure of association produced in case–control studies. If a case–control study uses a sampling frame known as *risk set sampling* for selection of controls, then the resulting OR is an unbiased estimator of the incidence rate ratio (IRR) that would have been produced by an analogous cohort study [10]. Risk set sampling randomly selects controls from the underlying cohort of those who were still at risk of the outcome when the corresponding case experienced the outcome.

The advantage of the nested case–control design for studies that use existing data is that it is less computationally intensive than the corresponding cohort study. Given the high computational intensity of cohort studies that account for time-varying exposures and potential confounders such as concomitant medications, this computational efficiency can be more important in studies of DDIs than in studies of individual drugs that do not account for time-varying exposures and confounders. However, when conducting nested case–control studies, care is needed in defining the time at which potential confounding variables are assessed. In a cohort study, it is intuitive and correct to assess confounding variables at baseline, before exposure has begun. In the case of studies of DDIs, exposure may be said to begin with the onset of concomitant intake of the object and precipitant. However, many nested case–control studies assess potential confounders as of the index date, often defined as the date of the outcome in cases and some corresponding date in controls. Potential confounders that are assessed after exposure can be affected by exposure. Adjusting for factors that are affected by exposure can introduce bias unless the analysis uses appropriate methods for handling time-varying confounding (see Chapter 43) [11]. Therefore, ascertaining covariates at the index date can introduce bias into nested case–control studies.

The IRR for presence vs absence of the precipitant among persons taking the object can be interpreted as the effect of a DDI (as in Table 40.1, Design 2) if there is no effect of the precipitant in persons not taking the object, and if there is no unmeasured confounding by the indication for the precipitant. Unfortunately, the assumption of no unmeasured confounding by the precipitant is often implausible. To assess its validity, investigators sometimes measure the corresponding association with a **negative control precipitant**. A negative control precipitant is a drug that is used in similar clinical circumstances as the potential precipitant under study, yet by virtue of the control precipitant's pharmacology is not believed to interact with

the object or to have an inherent effect on the outcome in the absence of the object that is not shared by the precipitant. In the setting of Design 2, the association with the negative control precipitant is used qualitatively to place into context and aid in the interpretation of the association measure for the precipitant of interest. For example, in the previously described study that measured the OR for the association between cotrimoxazole as the precipitant and serious hypoglycemia among persons receiving glyburide (the object), the investigators also examined the association with amoxicillin as a negative control precipitant. In that study, the association between amoxicillin and serious hypoglycemia (adjusted OR 1.5; 95% CI 0.8–2.9) helped provide reassurance that the association with cotrimoxazole (adjusted OR 6.6) was unlikely to be due primarily to confounding by the need for an antibiotic or a shared effect of all antibiotics [9].

To help distinguish a DDI from an inherent effect of the precipitant, one can measure the association between the precipitant and the outcome within the person-time exposed to a **negative control object**. A negative control object is a drug that is used for similar indications as the object under study, but is not believed to interact pharmacologically with the precipitant. For example, in a study of DDIs between sulfonylureas as objects and antihyperlipidemics as precipitants, Leonard *et al*. used metformin as a negative control object, which is not believed to interact with the precipitants [12]. In the setting of Design 2, the association with presence vs absence of the precipitant in users of the negative control object is used qualitatively to place into context and aid in the interpretation of the association measure of primary interest. For example, in the previously described study by Leonard *et al*. of sulfonylureas and antihyperlipidemics, the possibility of an association (although not quite statistically significant) between fenofibrate (a precipitant) and serious hypoglycemia among users of metformin (as a negative control object) suggested the possibility of an inherent hypoglycemic effect of fenofibrate in the absence of sulfonylureas [12].

Design 3 is just like Design 2 except that the association measure is the IRR (or OR) of the precipitant of interest explicitly versus the control precipitant, among persons taking the object. For example, Leonard *et al*. conducted a cohort study of persons taking clopidogrel, examining the rate of ischemic stroke among persons taking individual proton pump inhibitors, each versus pantoprazole as the negative control precipitant [13]. Pantoprazole was selected as the negative control precipitant because it is not a potent inhibitor of the enzyme responsible for activating clopidogrel (cytochrome P450 2C19) and therefore is believed to have a low potential for interacting with clopidogrel. The multiplicative interaction parameter can be produced either through performing a single regression that estimates, among those exposed to the object drug, the association between the precipitant vs the negative control precipitant; or performing one regression that estimates the association between the presence vs absence of the precipitant in those receiving the object and one that estimates the association between the presence vs absence of the negative control precipitant in those receiving the object, and then calculating the ratio of ratios and the corresponding confidence limit from these two regressions using the delta method [14]. The advantage of Design 3 over Design 2 is that it uses the association between the outcome and the control precipitant quantitatively rather than qualitatively.

Similarly, Design 4 is just like Design 2 except that the association measure is the IRR (or OR) for the precipitant of interest in those receiving the object drug of interest vs the precipitant of interest in those receiving a negative control object drug. As with Design 3, this parameter can be calculated either through a single regression or by combining the results of two

regressions using the delta method [14]. We are unaware of any published examples that have used this design.

Although use of a negative control precipitant can be a valuable strategy, there are at least three reasons why it is not a panacea for the problem of confounding by the indication for the precipitant. First, there are potential DDIs for which there is not a plausible negative control precipitant. For example, if one wanted to examine whether aspirin as the precipitant increased the risk of serious bleeding in patients receiving warfarin as the object, it would be difficult to identify a negative control precipitant that had the same set of indications as aspirin and was not believed to increase the risk of bleeding in patients taking warfarin. Second, even if there is a plausible negative control precipitant, there may still be residual unmeasured confounding between the precipitant and the negative control precipitant. For example, when amoxicillin is used as a negative control precipitant in studies examining cotrimoxazole as a potential precipitant, there may be residual confounding because amoxicillin and cotrimoxazole are not used in identical groups of patients. Third, there can be no guarantee that the negative control precipitant does not have an unknown interaction with the object or an unknown inherent effect on the outcome. This may be particularly true for older drugs, for which pharmacokinetic pathways and pharmacodynamic effects may be less well studied than for newer drugs.

Self-controlled designs include only persons who experienced the outcome, using each person as her/his own control. Such designs therefore inherently control for both measured and unmeasured potential confounding factors to the extent that such factors do not change within individual over the study period. Self-controlled designs are useful for identifying short-term effects of acute or intermittent exposures, which are often of interest in studies of DDIs. The self-controlled case series (SCCS) design is a self-controlled design that is analogous to the cohort design [15]. The case–crossover design is a self-controlled design that is analogous to the nested case–control study design [15].

Design 5 is a SCCS or case–crossover study nested within person-time exposed to the object, examining the IRR (for the SCCS design) or OR (for case–crossover design) associated with use versus nonuse of the precipitant. For a SCCS or case–crossover study to be feasible, there must be within-person variability in exposure to the precipitant while the person is taking the object. That is, a person whose entire time taking the object is either always co-exposed or never co-exposed to the precipitant will not contribute to the estimation of the drug interaction parameter, although they can contribute to the estimation of other model parameters such as time-varying confounders (if any) in analysis of a self-controlled study of the DDI. Thus, on one hand, self-controlled designs are better suited to examine DDIs involving precipitants that are taken acutely or episodically rather than chronically. On the other hand, acutely taken drugs often have acute indications that may affect the rate of the outcome, rendering the design susceptible to within-person confounding by indication.

For example, Schelleman *et al*. used the case–crossover design to examine the within-person association between use of antibiotics as precipitants and hospitalization for gastrointestinal bleeding among persons taking warfarin as the object [16]. They found that all antibiotics examined were associated with an elevated rate of bleeding, including those not believed to interact pharmacokinetically with warfarin. However, there were large differences among antibiotics. The observation that all antibiotics were associated with an increased rate of bleeding suggests either that all antibiotics share a mechanism for causing bleeding in persons taking warfarin (and possibly even in those not taking warfarin), or that the indication for antibiotics (acute infection) itself is associated

with bleeding in those taking warfarin (and possibly even in those not taking warfarin). Clinically, whether the increased bleeding risk observed during antibiotic use is due to a DDI, is a shared effect of all antibiotics, or is an inherent effect of infection may not matter as long as clinicians monitor anticoagulated patients carefully during episodes of acute infection. Thus, from a methodologic perspective, even though self-controlled designs are generally useful to study acute exposures, within-person confounding by the indication for drugs with acute indications may complicate their use for DDIs when the precipitants have acute indications.

Therefore, in the setting of acutely administered precipitants, a cohort study that quantitatively employs a negative control precipitant (Design 3) may be useful in addition to or perhaps instead of a self-controlled study (Design 5), provided that a good negative control precipitant is available. In addition, one could use a negative control precipitant in a case-case-time-control study [17] (see Chapter 43), although we are unaware of any studies that have used this design to study DDIs. Further, although self-controlled studies are generally thought of as a poor choice for studying chronically administered drugs, exposure to medications that are intended to be chronically administered is often actually intermittent because of poor persistence, incomplete adherence, or other reasons. Therefore, self-controlled designs can sometimes be useful for studying precipitants that are intended to be used chronically, although they may be vulnerable to persistent user bias [18].

One could consider performing a SCCS (or case–crossover) study nested within person-time exposed to the object, explicitly comparing person-time exposed to precipitant vs a control precipitant. This design would include only persons who took both the precipitant and the negative control precipitant while taking the object, and who experienced the outcome while taking the object plus either the precipitant or the control precipitant.

Suppose, for example, that an investigator wished to perform a self-controlled study to compare bleeding risk in warfarin users associated with concomitant use of cotrimoxazole, with amoxicillin as a negative control precipitant. A self-controlled study of this question would include only persons who experienced bleeding while treated with warfarin plus either cotrimoxazole or amoxicillin as a precipitant, and who also took the alternative precipitant at some point during warfarin therapy. Because few such persons are likely to exist even in a large population database, this design seems unlikely to be of practical use. However, one could quantitatively incorporate a negative control precipitant in a self-controlled study by fitting one regression that estimates the association with the precipitant in users of the object, fitting a second regression that estimates the association with the negative control precipitant in users of the object, and calculating the ratio of these ratios (with the corresponding confidence limits) using the delta method [14]. Similarly, one could quantitatively incorporate a negative control object using a self-controlled design by fitting one regression that estimates the association with the precipitant in users of the object, fitting a second regression that estimates the association with the precipitant in users of the negative control object, and calculating the ratio of these ratios (with the corresponding confidence limits) using the delta method [14]. For example, Han *et al*. used this approach to examine the association between numerous potential precipitants and serious hypoglycemia in users of sulfonylureas as objects, using metformin quantitatively as a negative control object [19].

As is evident from the discussion above, selection of a pharmacoepidemiologic design to study a specific potential DDI includes consideration of numerous factors including the existence of a plausible negative control precipitant and control object, the relative importance of among-person confounding versus within-person confounding, and whether the precipitant

is in real life taken acutely or intermittently versus chronically. Investigators studying a given potential DDI should consider using multiple, complementary research designs.

Outcome Assessment Methods

Many studies have used review of medical records to examine the validity and performance characteristics of algorithms to identify outcomes using administrative healthcare data [20]. Such studies usually examine outcomes that reliably result in treatment in the emergency department (ED) and/or hospital admission rather than office-based treatment. Thus, investigators studying the effects of potential DDIs on acute health outcomes usually study events that lead to ED treatment or hospitalization. Given the transition in the US from the *International Classification of Diseases*, 9th revision, clinical modification (ICD-9-CM) to ICD-10-CM that occurred on October 1, 2015, researchers using administrative data from this date or later in the US will need to examine the validity of algorithms that use ICD-10-CM codes for identifying outcomes.

As healthcare databases increasingly include laboratory values and vital signs, such measures can also be used as outcomes in DDI studies. A typical study design using such outcomes would examine change in a laboratory value from baseline when a precipitant is initiated in a person receiving an object. For example, changes in serum glucose were used to identify a possible DDI between the antidepressant paroxetine and the antihyperlipidemic pravastatin [21] and between proton pump inhibitors and metformin [22]. Compared to studies that rely on binary outcomes such as the occurrence of serious hypoglycemia, studies examining a continuous measure such as serum glucose require much smaller sample sizes and may raise fewer concerns about outcome validity, assuming that the laboratory value is accurately measured and recorded. A related limitation is that such measures are generally intermediate endpoints or biomarkers, rather than the actual clinical events that matter most to patients. In addition, handling of missing data deserves careful consideration, particularly if drug exposure affects the likelihood that providers measure or record the study endpoint.

Using a Positive Control Pair to Assess Assay Sensitivity

The use of a negative control precipitant and negative control object is discussed above, either as an explicit control group or implicitly to help assess the potential for confounding by the indication for the precipitant, or to help assess an inherent effect of the precipitant in the absence of the object. To assess the sensitivity of the pharmacoepidemiologic study to capture a known DDI similar to the one being studied (i.e., demonstrate the sensitivity of the pharmacoepidemiologic assay), investigators should consider studying a **positive control precipitant**, which is a precipitant known to produce an association with an outcome in patients receiving the object of interest. For example, if one were to study a DDI between warfarin as the object and an antibiotic as the precipitant with bleeding as the outcome, it may be useful to reproduce the well-established DDI between warfarin and cotrimoxazole as a positive control to demonstrate the ability of the study procedures and database to reproduce this known positive association. While this can be helpful, the investigator should consider the possibility that confounding might be different for the precipitant and positive control such that replicating the known association for the positive control is no guarantee that the study will yield the truth for the precipitant. In addition, other considerations such as sample size may negate the ability of a precipitant to serve as a reliable positive control.

Considering Initiation Order of Object and Precipitant

Concomitant administration of an object and a precipitant can be divided into three categories based on order of initiation of the two drugs. When both drugs are initiated simultaneously, the concomitancy is **combination triggered**. When the object is started in a person already taking the precipitant, concomitancy is **object triggered**. When the precipitant is started in a person already taking the object, concomitancy is **precipitant triggered**.

An adverse event due to a DDI involving a dose-titrated object may be more likely if concomitancy is precipitant triggered rather than either object triggered or combination triggered. This is because in precipitant-triggered concomitancy, the dose of the object may be titrated to produce its desired effect in a patient who is not receiving the precipitant, and this titration is later followed by initiation of the precipitant. For example, if warfarin is started and cotrimoxazole is later added, the prescriber may be unaware of the need to retitrate the dose of warfarin, and overanticoagulation and bleeding may result. In contrast, if warfarin and cotrimoxazole are started simultaneously or if warfarin is started in a patient already receiving cotrimoxazole, the warfarin dose will be titrated to the desired level of laboratory-measured anticoagulation in the presence of cotrimoxazole, avoiding clinical consequences of the DDI in that patient, provided that the patient continues to take cotrimoxazole. Naturally, if the cotrimoxazole is later discontinued, the patient may be at risk of the effects of underanticoagulation, that is, thromboembolic events.

If an investigator wished to include only instances of precipitant-triggered concomitancy to increase the likelihood of identifying a clinically important DDI, a larger study population would naturally be needed to detect the same level of increased risk, since only a subset of all instances of concomitancy are precipitant triggered. If sufficient sample size is available, it may be desirable to calculate separate measures of association for precipitant-triggered, object-triggered, and combination-triggered concomitancy when studying dose-titrated objects.

When studying precipitant-triggered and object-triggered concomitancy, it is critical to avoid including immortal person-time (see Chapter 43). Immortal person-time is a period of observation that is guaranteed to be event free through design of the study [23]. In an analysis of a putative DDI between clopidogrel (object) and proton pump inhibitors (precipitants), Stockl *et al.* compared clopidogrel initiators to clopidogrel initiators who also filled a prescription for a proton pump inhibitor [24]. Follow-up began at clopidogrel initiation, and patients were classified into clopidogrel-only or clopidogrel-plus-proton pump inhibitor groups based on whether they had at least one prescription for a proton pump inhibitor in the 90 days before or 90 days after the clopidogrel initiation date. Thus, patients who qualified for inclusion by receiving a proton pump inhibitor in the 90 days following the clopidogrel initiation contributed immortal person-time to the analysis – the time from clopidogrel initiation to the proton pump inhibitor prescription – since patients that entered the analysis in this way, by definition, could not have had a fatal outcome in this period. Beginning follow-up after or at the time of (but not before) concomitancy can help to avoid immortal person-time bias.

Studying the Time Course of the DDI

Even in the absence of a potentially interacting drug, the rate of an ADE often varies with amount of time since initiating the drug. This is part of the rationale for the increasingly standard practice in pharmacoepidemiology to restrict studies to new users of the drugs being examined, an approach known as the **inception cohort design** [25]. For many drug–outcome pairs, the incidence rate would

be expected to peak shortly after starting the drug and decline thereafter.

Such a declining pattern may be attributed to at least three different mechanisms. The first mechanism is depletion of susceptible patients, in which patients with an inherent susceptibility to the drug's adverse effect experience the adverse effect soon after initiation, and subsequently discontinue the drug because of the adverse event or a prodrome thereof [26,27]. Under this mechanism, the patients who remain on the drug for the long term are more robust to the drug's adverse effects, since the susceptible patients have been depleted from the cohort. The second mechanism leading to a declining event rate over time is biological adaptation to the drug's pharmacologic effects. The third mechanism is dose reduction prompted either by early signs of toxicity (e.g., a reduction in the dose of a statin due to mild myopathy that reduces the risk of rhabdomyolysis) or in response to measurement of the serum drug concentration or other biomarker used in clinical practice to adjust doses (e.g., a reduction in warfarin dose due to supratherapeutic values of the international normalized ratio, a laboratory marker of warfarin's pharmacologic effect). While each of these mechanisms would be expected to produce a declining rate, an increasing rate can be observed for drug–outcome pairs that are characterized by cumulative toxicity, such as corticosteroid-induced avascular necrosis and anthracycline-induced cardiomyopathy.

Given that the rate of an ADE often varies with the amount of time since initiating the drug, it is predictable that the rate of an outcome caused by a DDI may vary as a function of the amount of time since initiation of concomitancy, particularly for DDIs acting through metabolic inhibition [28]. The initial increase in plasma concentration of the object may cause a rise in the rate of the ADE initially, followed by a reduction in the rate as the metabolism of the object returns to baseline.

Figure 40.1A illustrates a scenario in which initiation of a precipitant to a person already receiving an object (i.e., precipitant-triggered concomitancy) leads to an event rate that is transiently increased but then declines to baseline. The rate might actually decline to below the baseline rate because the persons susceptible to the adverse effect become depleted from the cohort or because the body compensates to increase pharmacologic clearance of the object. If the scenario illustrated in Figure 40.1A is operating, and one evaluates a potential DDI by calculating the average rate during all time treated with the object–precipitant combination and dividing this rate by the rate observed during the time treated with the object alone, then one could falsely conclude that the potential DDI had no effect on the rate of the adverse event, even if the precipitant has a large but transient effect. This is because, as illustrated in Figure 40.1A, the transiently increased rate seen shortly after the initiation of the precipitant in patients is outweighed by the prolonged time during which the rate of the adverse event has reverted back to (or even below) the baseline rate associated with use of the object alone. In other scenarios, the increased risk associated with a precipitant-triggered DDI may remain elevated throughout the course of concomitancy, as illustrated in Figure 40.1B.

Careful consideration must also be given to the timing of concomitancy when the rate of the ADE varies with the amount of time since initiating the object. For example, a study of a DDI between corticosteroids and some precipitant on avascular necrosis should account for time on corticosteroids since the rate of avascular necrosis increases with time on corticosteroids. If, for example, an investigator conducted an analysis in which a large portion of the time unexposed to the precipitant was shortly after corticosteroid initiation, and the majority of time concomitantly exposed to the precipitant was longer after corticosteroid initiation, then there would be a lower baseline risk of avascular necrosis during unexposed time than in exposed time, even if there were no effect of the precipitant.

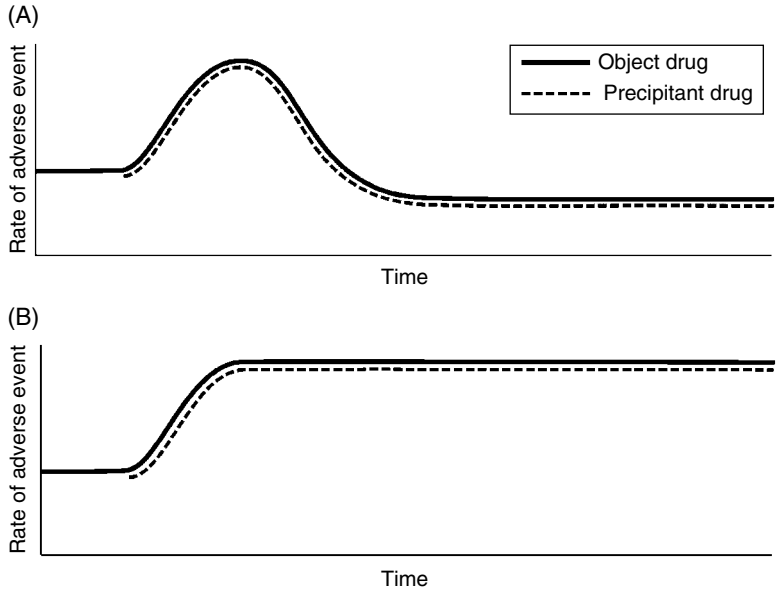

Figure 40.1 Schematic depiction of the two different potential time-courses of a precipitant-triggered drug–drug interaction. In (A), the rate of the adverse event rises transiently, while in (B), the rate of the adverse event rises and remains persistently elevated.

Given that, as illustrated in Figure 40.1A, the *overall* rate ratio may not be observably elevated for a DDI with a substantial but transient effect, it can be important to look for an association within time-specific strata (i.e., examine the duration–response relationship of the DDI) regardless of whether or not an overall association is observed over the entire period of concomitancy. However, looking for associations both overall and within strata defined by time since initiation of concomitancy can raise potential concerns about multiple testing. Given that DDI studies using even very large population databases can have low statistical power, adjusting for multiple comparisons across time strata may have a crippling effect on investigators' ability to identify important risks associated with DDIs. For example, Schelleman *et al.* used a population database of approximately 108 million person-years of follow-up to evaluate potential DDIs involving sulfonylureas as objects and lipid-lowering drugs as precipitants [29]. They studied only precipitant-triggered instances of concomitancy. For each object–precipitant pair, they examined the overall association as well as associations for 0–29 days, 30–59 days, 60–119 days, and ≥120 days. They found statistically elevated association measures for several time-specific strata, but would not have done so had they accounted for multiple testing due to the 56 possible duration-specific association measures, many of which had insufficient data even to estimate a multiplicity-unadjusted measure of association.

We believe that for exploratory analyses of time-specific measures of association, refraining from accounting for multiplicity is justified because of the manifestly low statistical power associated with multiplicity-adjusted estimates, provided that such association measures are interpreted as exploratory in light of their corresponding higher-than-nominal type I error rate. The issue of multiple testing can be mitigated in settings where the pharmacologic mechanism of

the potential DDI is sufficiently well characterized so that the time course of the interaction can confidently be predicted *a priori*, and analyses within specific time windows considered primary, with other time windows considered secondary.

Pharmacoepidemiologic Screening to Identify Potential DDIs

In addition to performing hypothesis-driven DDI studies, pharmacoepidemiologic methods can be used to perform hypothesis-free screening of healthcare data to identify potential DDIs. For example, Han *et al*. used the SCCS design to screen healthcare data for precipitants that are associated with serious hypoglycemia in persons taking insulin secretagogues (Design 5) [19]. The SCCS design is well suited to screening because it includes only persons who experienced the outcome while taking the object. This makes this design highly computationally efficient and thus more amenable to high-throughput analysis than the cohort or nested case–control designs. Because of the large number of candidate precipitants that they examined, the investigators used a semi-Bayesian shrinkage approach for multiple comparisons adjustment [30], an approach that limits the variability of the resulting measures of association and controls the type I error rate.

The Future

Given the continued development of new drugs, repurposing of old drugs, the rising frequency of polypharmacy, and the aging of the population, the clinical and public health importance of DDIs will continue to grow. The increasing use of healthcare data from larger populations, including data accessed using distributed data models (see Chapter 25), that characterizes pharmacoepidemiology in general promises to be particularly important for studying the health effect of DDIs. This is because studying the effects of multiple drugs in combination necessitates larger population databases than does studying the effects of individual drugs. The settings in which the health effects of DDIs are characterized are likely to expand from the current predominance of studies of community-dwelling persons to those set in hospitals, nursing homes, and other settings.

A wide variety of data and approaches are now being used to screen for potentially clinically important DDIs, including animal models, healthcare data, spontaneous reporting data (see Chapter 10), physiologically based pharmacokinetic models (see Chapter 2), physiologic and pharmacologic networks (see Chapter 2), and social media (see Chapter 27). As the use of screening increases, the number of hypothesized DDIs whose health effects need to be confirmed or refuted in etiologic studies will rise. Perhaps the most urgent need is to develop and test approaches to better incorporate the knowledge gained through studies of the health effects of DDIs into the healthcare system, thereby reducing the frequency of harmful effects of DDIs while allowing and perhaps even encouraging use of combinations that had been predicted to be harmful but were actually found to be safe. However, given the fragmented market for DDI knowledge bases and the surprising degree of lack of agreement among them [31], addressing this problem will be challenging.

The Pharmacoepidemiology of Medication Errors

Hanna M. Seidling[1,2] *and David W. Bates*[1]

Medications represent the most commonly used form of medical therapy today. For adults, 75% of office visits to general practitioners and internists are associated with the continuation or initiation of a drug [1]. For hospitalized patients, multiple medication orders tend to be written for each patient daily. Theoretically, medication errors can refer to selection of the wrong patient, the wrong drug, the wrong galenic formulation (e.g., tablets with immediate and sustained release), the wrong dosage or route of administration, or wrong time. Medication errors are frequent, but fortunately only a small proportion result in harm [2]. However, given the high prevalence of prescription medication use, preventable adverse drug events are one of the most frequent causes of preventable iatrogenic injuries. The IoM report "To Err is Human" suggested that at least 44 000–98 000 deaths occur in the US from iatrogenic injury [3]. One study estimated that about 7000 deaths are attributed to medication errors [4] and about 1 million injuries might result from medication use in general in the US per year.

Clinical Problems to Be Addressed by Pharmacoepidemiologic Research

Definition and Classification of Medication Errors

While the techniques of pharmacoepidemiology have most often been used to study the risks and benefits of drugs, they can also be used to study medication errors and their attendant adverse drug events. Medication errors have been defined as "any error in the process of ordering, dispensing, or administering a drug" regardless of whether an injury occurred or the potential for injury was present [5]. Mechanistically, medication errors may result from errors in planning actions – for example, not knowing the correct starting dosage for a medication (i.e., knowledge-based mistakes or rule-based mistakes) – or errors in executing correctly planned actions, like picking one sound-alike medication instead of another (i.e., action-based slips or memory-based lapses) [6].

Pharmacoepidemiology, Sixth Edition. Edited by Brian L. Strom, Stephen E. Kimmel and Sean Hennessy.

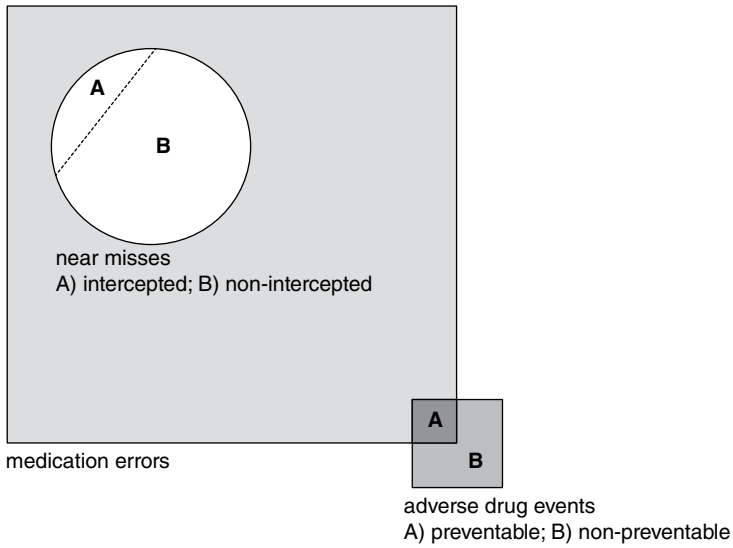

Figure 41.1 Relationship of medication errors and adverse drug events. About 1 in 10 medication errors is likely to result in patient harm [7], whereas about 25% of adverse drug events can be allocated to a medication error [2]. Near misses, both intercepted and nonintercepted, comprise those medication errors with potential for patient harm without resulting in actual harm.

In clinical practice, a medication error may occur at any stage of drug therapy, including drug prescribing, transcribing, manufacturing, dispensing, administering, and monitoring. Medication errors with potential for harm are called near-misses or potential adverse drug events; these errors may be intercepted before they reach the patient, or reach the patient without consequence. However, generally, about one in 10 medication errors results in patient harm [7]. An adverse drug event (ADE) would be considered preventable if a medication error is associated with the ADE (Figure 41.1). While ADEs have been defined as "any injury related to the use of the drug, regardless of whether a therapeutically appropriate dosage is used, although the causality of this relationship may not be proven" [8], an adverse drug reaction (ADR) can be defined as harm which is caused by a drug while appropriately used [9] (see also Chapter 1 for alternative definitions).

Detection of Medication Errors

Approaches for detecting medication errors include manual or automatic screening of claims data, administrative databases, medical records, electronic health records, or incident reports mostly by providers in hospitals, as well as patient monitoring or direct observation often by pharmacists. All approaches have inherent advantages and pitfalls and there is no single approach that is considered the gold standard for detecting medication errors or ADEs. Factors which might influence the identification of medication errors and ADEs include the setting (ambulatory vs inpatients; routine care vs research studies), the expected types of medication errors (prescribing vs administration errors), and the projected costs of detection [10]. In addition, the type of detection method influences which types of medication errors are found (e.g., only those resulting in patient harm) and with which frequency (see Chapters 8 and 10 for further discussions of detecting medication adverse events).

Screening of claims data, administrative databases, medical records, and electronic health records is used to evaluate large datasets, but is generally done retrospectively. The quality of the available information, however, varies between different data sources which limits

opportunities to comprehensively and systematically detect medication errors. Especially in the outpatient setting, claims data can be obtained for very large numbers of individuals. In the US, this represents tens and sometimes hundreds of millions of people, and in many other countries complete data for a population (such as the province of Ontario) may be available. Limitations of using claims data to detect medication errors include uncertainty regarding medication consumption and mischaracterization of the error if not linked to other information sources because clinical detail is often minimal (e.g., information on weight, actual drug dose or renal function might be missing). Since the focus of such data systems is on clinical outcomes and treatment, medication errors will be missed unless they result in patient injury severe enough to come to medical attention. Even then, it is usually not clear whether the injury was due to an error.

In the inpatient setting, manual chart review is a well-established method to detect ADEs and medication errors. With most relevant patient information at hand, the appropriateness of drug prescribing and administration can be assessed, although documentation may still be incomplete, especially for assessing issues such as appropriateness of the medication order. The main limitations with chart reviews are that they are time-consuming and expensive, with the average chart review costing approximately $20 per chart.

If electronic health records are available, the manual screening of paper-based information can be replaced by semi-automated approaches. However, the level of standardization and the extent to which clinical information is stored using controlled vocabulary determine the feasibility and effectiveness of automated, algorithm-based data analyses [11]. If electronic health records include electronic prescribing applications with clinical decision support (i.e., computerized physician order entry – CPOE), data from these applications can readily be used to detect many types of medication errors at the stage of prescribing. However, the specificity of the systems will also depend on the availability of information accessible via the electronic health records [12]. Specific types include overly high dosage, cumulative dose errors, and drug–drug interaction issues, among others.

Screening of incident reports (i.e., reports usually issued by personnel involved in the occurrence of an adverse event or a situation that might have led to an undesirable outcome) and *patient monitoring* (e.g., for specific symptoms) can each reveal medication errors that resulted in patient harm [13]. Screening of incident reports always grossly underestimates the incidence of errors (because of underreporting of events), but is relatively inexpensive because data are collected as a byproduct of routine care delivery. The major barrier for reporting medication errors is staff perception that reporting might be associated with disciplinary actions [14], even if the hospital pursues a nonpunitive policy [15]. One approach to increase reporting would be to only report near misses that help to identify which situations facilitate errors but also which actions might help to detect and prevent errors. These "critical incident reporting systems" typically belong to quality management systems in hospitals and are becoming more prevalent in the primary care setting. Predetermined patient monitoring for adverse drug events, while more time- and cost-intensive, has been successful, and can identify more adverse drug events than chart review [13].

Spontaneous reporting of medication errors (described in Chapter 10) is comparatively easy to implement and to maintain, both in inpatient and outpatient settings. However, both ADEs and medication errors are substantially underreported (see Chapter 10). Nevertheless, spontaneous reporting is useful for obtaining samples of errors. However, this method cannot be used to assess the underlying rate of medication errors in a sample [16].

Direct observation is typically conducted during research studies and offers a comprehensive assessment of medication dispensing and administration errors. While being both cost- and personnel-intensive, direct observation has been successfully and reliably used to classify complex medication errors [17], and is particularly useful at stages that are not sensitive to other detection methods (e.g., drug preparation or drug administration) [18].

Methodologic Problems to Be Addressed by Pharmacoepidemiologic Research

Pitfalls in the Detection of Medication Errors

The reliable and systematic detection of medication errors has many methodologic challenges, including the definition of what constitutes a medication error and the availability and appropriate interpretation of clinical data.

With respect to definition, examples of complexities include whether there was harm or potential for harm, and the decision about whether to include errors that are intercepted before reaching the patient.

Identification of medication errors remains challenging as general standards are lacking. For instance, the detection of "wrong timing errors" (i.e., giving a drug within a timeframe) requires the definition of a threshold value above which the medication is delayed. In the inpatient setting, this threshold value might be two or four hours, depending on the institution. However, sometimes patients are away from their inpatient rooms (e.g., getting diagnostic tests), in which case decisions need to be made about whether to use a singular threshold value.

Using the example of hazardous prescription of interacting drugs, a potential approach to detect a medication error involves the comparison of the prescribed medications with a drug–drug interaction (DDI) knowledge base. However, the content of such knowledge bases varies widely, in terms of both included drug pairs and specific information linked to a drug pair (e.g., severity of the DDI) [19] – see Chapter 40. Especially in the outpatient setting, comprehensive and reliable data on the patient's medication list may be missing. Furthermore, prescribing and dispensing data are seldom jointly available and determining actual patient adherence is even more difficult. Even patient surveys may not give adequate information. While patients might be nonadherent to some prescribed drugs, they might also consume over-the-counter drugs with potential for DDIs (e.g., St John's wort) that they do not report [20].

To evaluate the appropriateness of a medication for a specific patient, knowledge of the patient's characteristics is mandatory. For example, many medications are contraindicated in pregnancy, with notable examples being thalidomide, isotretinoin, and warfarin. In this context, the greatest difficulty lies in assessing whether the patient is pregnant at the time of the exposure. Information on whether a woman is pregnant or not at the time of prescribing is challenging to obtain and most information systems do not have good approaches for tracking this. In retrospective analyses, identification of the date of birth and backward calculation under the assumption of a term pregnancy might be feasible, though this process can still be subject to misclassification (e.g., if the pregnancy was not full term) and can be complex since such information is not readily stored in one location.

Another important piece of clinical information, especially in pediatrics (though also for the administration of chemotherapy and some other situations), is the patient's weight. Most pediatric medications use weight-based dosing. Standardized documentation of this information can be challenging to obtain, hindering not only analyses of pediatric dosing but also actual prescribing by pediatricians. Obtaining accurate

weight is also essential for many oncology patients, as certain intravenous chemotherapy drugs use weight-based dosing. However, this issue is further complicated in obese patients who may require dosing using body surface area (BSA) or ideal body weight (IBW).

Finally, information on the patient's medication allergy status is infrequently and inconsistently available [21,22]. It is important that true allergies (e.g., a rash related to penicillin) be differentiated from medication sensitivities or intolerances (nausea from codeine) through coded information rather than free text. It is particularly important that severe reactions, such as anaphylaxis, are clearly coded and identifiable. The eventual aim is to have one universal medication allergy list in an electronic format for each patient, rather than multiple disparate lists.

Measuring Incidence of Medication Errors

Especially because of the different approaches used in detection of medication errors, the assessment of medication error incidence remains challenging. Comparison of medication error incidence rates among different studies has substantial limitations. This is related to disparate detection approaches and using different methods to ascertain numerators (i.e., the medication errors) and denominators (i.e., the sample from which the medication errors arise). Thus, medication error rates from different studies can be difficult to compare unless the same, or similar, methods were used. Other factors to consider are the setting studied and the patient population. In addition, spontaneous reporting typically lacks information to calculate incidence (see Chapter 10).

Comparing Medication Error Rates Across Settings

Most medication error and ADE studies have been performed in the *hospital* setting. In the inpatient adult setting, patients are vulnerable to medication errors due to their medical acuity, the complexity of their disease process and medication regimens, and their age (e.g., the elderly are particularly susceptible). The medication error rate may differ depending on the type of hospital and may be higher in nonuniversity hospitals. A review from 2007 indicates that medication errors occur in about 5.1% (range 0.038–26%) of medications dispensed in university hospitals and 13.7% (range 3.5–49%) in nonuniversity hospitals [7]. Studies of ADE rates in hospitals have found rates ranging from 2 to 15 per 100 admissions [5,23,24].

In *intensive care units* (ICUs), the rates of medication errors appear higher than on general care units. This may result from the administration or ordering of many more medications that may also be associated with higher levels of toxicity. Beyond the increased incidence of medication errors in ICUs, the nature and causes of medication errors are different and the risk that a medication error will result in patient harm is also higher compared to general inpatient wards [25], with 7.4% of patients experiencing an ADE resulting from a medication error [26].

In *nursing homes* and especially in the *ambulatory setting* [13], assessment of medication error incidence is challenging because the individual steps in the medication process are rarely jointly documented (e.g., administration), and there are often substantial time lags between them. Sometimes estimation of frequency of medication errors has relied on spontaneous reporting of medication errors [27] or documentation of ADEs in charts, which misses both many ADEs and nearly all medication errors. In a recent review of medication errors in nursing homes, medication errors were reported for 16–27% of the residents. Most errors were associated with mild effects and only 0–1% resulted in severe effects [28].

In the ambulatory setting, patients live in their homes and take their medications independently,

which makes detection of medication errors and ADEs challenging. In one review, medication error rates ranged from 12% to 59%, with even higher numbers in elderly patients with complex medication regimes [29]. Thereby, errors can also be committed by a third person such as a caregiver who is also responsible for drug administration [30]. In addition, the incidence of medication error-related ADEs may be estimated by direct patient surveys in the outpatient setting, for example by calling patients or mailing or emailing them a survey. Using this kind of approach, ADE rates ranged from 25% of patients (as self-reported in a survey) [13] to 5% (of hospital admissions) [31]. For medication errors related to the prescription process, the error rate was 7.6% of all prescription orders in one study [32]. Medication error rates stratified for different specializations or dentists have not been studied in detail [33].

Another issue is what happens at the interfaces of care, for example when a patient is discharged home from the hospital. Many studies have shown that discrepancies in drug treatment at transitions of care are frequent and often these discrepancies are unintentional, facilitating substantial risk for patients [34,35]. For example, at the interface between primary and tertiary care [36], and especially in the elderly population, the incidence of problems with the drug prescription regime are frequent after discharge (in about one-third of elderly, discharged patients) and contribute to higher rehospitalization rates [37].

Comparing Medication Error Rates Across Different Patient Populations

Most early studies on medication errors and ADE have been done in *adults*. Medication errors were common, occurring at a rate of 5 per 100 medication orders in inpatients [2]. Seven in 100 medication errors had significant potential for harm, and 1 in 100 actually resulted in an injury [2].

In primarily the inpatient setting, medication error rates in *pediatric patients* have been estimated to be as high as 5–27% of all medication orders [38]. In neonatal intensive care units, error rates have been reported to be in similar ranges [39]. In the outpatient setting in cancer patients, medication error rates were three times higher in pediatric patients (18.8% of patients) than in adult patients (7.1% of patients) [40].

Medication error-related ADE rates have also been reported for the elderly; as many as 35% of elderly outpatients per year may experience an ADE [41], and as much as 30% of hospital admissions are ADE related in the elderly [42]. In elderly patients, many medication error studies have focused on the prescription of inappropriate drugs, especially using the Beers criteria (a list of drugs specified through expert consensus that should be avoided in elderly patients in general or under consideration of specific cofactors including co-morbidity or dosage) [43],although the utility of these criteria has been challenged [44].

Comparing Medication Error Rates Across Detection Methods

The incidence of medication errors may vary as much as 100-fold depending on the detection method. While direct observation is the most cost-intensive approach (about $5 per evaluated medication), it will yield the most accurate estimation of medication error incidence for dispensing and administration errors [45]. When aiming to detect the same set of medication errors by chart review or incident report review, costs substantially decrease but so do numbers of detected events, from the actual incidence rate of 11.7% (direct observation) to 0.7% (chart review) and 0.04% (incident report review). Moreover, the reported incidence will depend on the training and profession of the person who conducts the detection [45].

Medication error incidence rates are grossly underestimated if voluntary reporting methods

are applied [46]. To promote reporting, non-punishment policies as well as anonymous reporting have been established. Moreover, it is especially crucial to invite all individuals in the healthcare system who might be confronted with a medication error to report the error. For example, in the outpatient setting, where patients tend to see several physicians but get their medications from a single pharmacy, medication errors may be discovered in the pharmacy rather than during doctor's consultation. Thus, pharmacists should be invited to report medication errors to improve the systematic collection methodology [47].

Measuring Impact on Health-Related Outcome

As noted earlier, in one study 7 in 100 medication errors had significant potential for harm, and 1 in 100 actually resulted in an injury [2]. More recent literature indicates that in hospitalized patients, even 1 in 10 medication errors might result in an ADE [7]. However, the risk of whether a medication error results in harm varies. For example, the susceptibility to suffer an ADE is higher in geriatric wards as well as ICU patients compared to general care units (12% vs 6%) [25]. On the other hand, in one study pediatric patients had similar rates of ADEs compared to adults but a threefold higher rate of near misses [48]. Incidence rates of ADE in hospitalized patients are reported with a median overall frequency of 6.1% of patients [7]. Again, the detection method used substantially influences the estimation of the incidence, with highest numbers found by patient monitoring [7]. In about 2.9% (range 0.14–5%) of the patients experiencing an ADE, the ADE was fatal [7]. Nonfatal ADEs might prolong the hospital stay or increase the risk of rehospitalization. In another study, 13% of patients experienced an ADE after discharge, and of these 24% were preventable and 38% ameliorable [49]. In addition, ADEs occurring in the outpatient setting can contribute to hospital admissions, with 4.5 preventable ADEs per 1000 person-months [50].

Identifying Risk Factors

The search for risk factors for medication errors has been challenging, as some appear to occur relatively randomly in the medication process. Robust systems need to detect and prevent even errors occurring randomly [51]. Substantial research has been conducted on error nascence (i.e., the origin of the medication error) and it is important to understand and acknowledge the underlying causes on system and workflow or process level facilitating error nascence [52].

To subsequently assess these causes, it can be helpful to determine:

- at what stage of the treatment process medication errors are occurring
- by which person involved in the treatment process (e.g., the physician, the nurse, the pharmacist, the patient, or an informal care person) the error might be committed or potentially intercepted
- what the patient's characteristics are, including age, co-morbidities, and other medications they are taking
- what the clinical setting is.

These factors can be grouped into the categories of system level, patient level, and medication characteristics.

Well-defined factors influencing the risk for medication errors on a *system level* include organization policies or the general safety culture of an institution. On a workflow or process level, risk factors comprise poor communication, heavy workload or inadequate procedures [52]. Also *patient factors* such as renal dysfunction and old age increase error risk. Setting is also important, ICU patients having an especially high risk, because they are more seriously ill and are exposed to large numbers of medications. Settings with only limited monitoring options such as home care appear also risky [53].

In all settings, being administered the wrong dose is the most frequent type of medication error, especially overdosage [54]. Dosage errors may occur at the stage of administration (e.g., accidental intake of two tablets), the stage of manufacturing or dispensing (e.g., misreading the brand name), or, most frequently, at the stage of prescription. To select the appropriate dose for each patient, the physician has to consider a number of *patient characteristics* (age, weight) as well as *drug characteristics*. The individual exposure to a drug is subject to changes in the elimination organ function (e.g., renal or liver disease), pharmacokinetic interacting comedication, and genetic polymorphisms. Moreover, required dosages will depend on age-related pharmacodynamic changes and vary between disease conditions. They might also be higher or lower both at the beginning or the end of the therapy. The physician needs to have all such information at hand once he/she decides to prescribe a certain drug for a specific patient – and a lack of information might result in underdosage or, more often, in overdosage.

Any drug or drug formulation can be associated with a medication error. However, there are *medication characteristics*, including active ingredients, that are associated with an increased risk for medication errors. Predisposing factors include:

- a sophisticated way of prescribing (e.g., complex dosage adjustments), administration (e.g., usage of administration devices), or monitoring (e.g., therapeutic drug monitoring)
- a substantial dose-dependent toxicity which increases the likelihood that a medication error will result in patient harm
- a prescription frequency which is high enough that the error will occur during the study period but low enough that detection can be challenging.

The drug class with the highest prescription frequency is cardiovascular drugs. Consistent with the prevalence of prescribing, cardiovascular drugs have often been associated with an increased risk of medication errors and ADEs [55]. The prescription of antibiotics also has often resulted in ADEs, most often because known allergies were ignored [55]. Medication errors with fatal outcomes, however, are often associated with drugs which are less frequently used but complicated in their mode of administration. For instance, accidental intrathecal injection of vincristine has caused many deaths [56] despite extensive error prevention measures [57]. Similarly, intravenous administration of amphotericin B is complex and carries a high risk of harm; for intravenous administration, amphotericin is used both in an aqueous and a liposomal drug formulation with 3–4-fold higher maximum recommended doses for the liposomal preparation. Erroneous administration of aqueous amphotericin B solution in dosages appropriate only for the liposomal preparation has resulted in a number of cases of renal toxicity and death [58].

Most often, drugs frequently reported in medication error studies have more than one predisposing factor. Examples include warfarin, for which treatment must be closely monitored by adapting dosages to measured INR values to maintain effectiveness and prevent ADEs such as bleeding. In one inpatient study [59], about 30% of reported ADEs were caused by inappropriate anticoagulant use. In elderly patients, drugs associated with medication errors often affect the central nervous system and required dosage adjustments are often neglected [60].

In ambulatory care, specific drug formulations with complex handling requirements promote drug administration errors. For instance, on average, about one in three patients incorrectly self-administers the inhalation device for chronic asthma treatment [61].

Examples by Setting

In adult *inpatients*, administering the wrong dosage is the most frequent medication error. Patients with multiple co-morbidities may

require a dosage adjustment. In pediatric inpatients, wrong dosage often results from dose calculation errors, including 10-fold errors [62]. Moreover, less severe medication errors often result from incomplete drug orders (i.e., not specifying the route of administration if only one route is applicable). However, especially in developed countries, most potential medication errors are intercepted by hospital pharmacists while processing the order.

In the outpatient setting, many medication errors happen at the stage of drug monitoring (e.g., neglecting a required check-up of laboratory values) because patients tend to see their physicians only irregularly. Moreover, they will generally see several physicians concurrently who most often are only partially aware of the actions of their colleagues. Among elderly patients treated in the outpatient setting, the number of physicians seen by a patient was found to be an independent risk factor for a medication error-related ADE [63]. Because patients might often receive drugs from several physicians and additionally purchase over-the-counter drugs, the documentation of an actual and complete medication list is challenging to maintain. Thus, prescription of interacting drugs is frequent and drug–drug interactions contribute to 6% of ADE-related hospital admissions [31]. Compared to the inpatient setting, in the outpatient setting, prescription errors are less likely to be intercepted, so the patient must play a more active role in their medical treatment and assume some degree of responsibility for appropriate drug administration. Two major factors might impede appropriate drug administration: (1) patient nonadherence to prescribed drugs (see also Chapter 38), and (2) inadequate patient knowledge regarding administration, increasing the likelihood of administration errors (e.g., for asthma inhalers).

Moreover, due in part to the fact that information on drug prescription, dispensing, and administration may not be linked, dispensing errors are also important. In a large outpatient study, incidence rates were reported to be about four errors per 10 000 items dispensed [64]. Additionally, inappropriate splitting of tablets was found to be the source of some medication errors [65].

In the *ICU*, critically ill patients are characterized by rapidly changing clinical conditions, receive close and intensive patient monitoring, and require rapid adaptations of their drug therapies. Due to the large number of necessary medications, the frequency of DDIs is particularly high, with about two-thirds of patients having at least one DDI and 44% suffering from a DDI-related ADR in one study [66]. Moreover, a substantial fraction of drugs is given intravenously (IV), potentially using identical IV lines. In one study including 50 ICU patients, 5.8% of concurrently given IV medications were incompatible [67].

In the *long-term care* setting, relatively few data are available [68]. However, medication errors appear to be concentrated in a few different drug classes, most often involving drugs affecting the central nervous system or analgesics [59]. Pharmacotherapy in the elderly occurs in a patient population that is in general multimorbid, polymedicated, and with physiological changes requiring complex dosage adjustment. Therefore, prescribing errors involving inappropriate drug choice as well as inappropriate dosages are frequent [69].

In conclusion, a multitude of different combination of risk factors is possible and these factors must be carefully considered in designing and analyzing pharmacoepidemiology research on medication errors.

Currently Available Solutions

Developing Prevention Strategies

Medication error prevention strategies may address the persons involved in the medication process, the products used, or the process

organization itself. Most often, a prevention strategy might also cover several or all categories; for example, a workflow change will typically include education and training of the staff. Obviously, the best prevention strategies for medication errors will depend on the setting and the nature of the medication errors involved. Slips and lapses in executing correct planned actions can be addressed by workflow changes including skill training and monitoring (e.g., coworker confirmation, checklists) [70]. In contrast, mistakes might be prevented by providing relevant knowledge at the time it is required. Approaches might include educational training as well as provision of paper- or computer-based information at the point of care.

With the majority of errors being knowledge based and occurring during drug prescribing, the implementation of electronic prescribing systems (CPOE) with integrated clinical decision support systems (CDSS) assumes a key role in medication error prevention [71]. Implementation of such systems might eliminate several types of errors, such as transcribing errors [72], and reduce others. Their impact on ADEs in research studies has been less pronounced [73], partly due to the fact that most studies using this approach have been underpowered. However, a metaanalysis from 2014 suggested that implementing CPOE is associated with a greater than 50% decline in the preventable ADE rate [74]. Nearly all CPOE applications in use now were commercially developed, while many of the early studies were done on internally developed systems. In one study, commercial applications in the ICU setting were found in a metaanalysis to be associated with an 85% reduction in the prescribing medication error rates, and a 12% reduction in ICU mortality [75]. Another vulnerable area is intravenous admixture [76]; this is another place where technology is likely to help in the future.

Electronic solutions have been developed to safeguard against drug dispensing or administration errors. For example, barcoding systems are currently used to prevent medication administration to the wrong patient. Electronic medication administration records can be used to electronically monitor drug administration and effectively reduce errors of omission [77]. In the US, CPOE data linked with decision support and barcoding data have become the norm in over 90% of hospitals.

Outcome Assessment

The outcome of prevention strategies is often reported as changes in the frequency of medication errors. However, such information will imperfectly apply as a predictor for health-related outcome. Indeed, in studies assessing both medication errors and patient outcomes, a reduction in medication errors would not necessarily be accompanied by an improvement in patient outcomes. For example, a computer-assisted disease management system might enhance the number of guideline-conformed screenings but the disease severity would not be ameliorated [78]. The assessment of patient outcomes, either by measuring surrogate endpoints (e.g., lab values, disease monitoring parameters) or by assessment of clinical endpoints (e.g., ADE rates, mortality rates), is therefore preferable to estimate the impact of a prevention strategy.

Evaluation of Intervention Strategies

Most prevention strategies are evaluated in a before vs after implementation setting and only scarcely evaluated in randomized trials. Therefore, neglecting of confounding variables can substantially bias the results. In 2005, Han *et al.* reported that the implementation of a CPOE system was an independent factor associated with increasing mortality rates of pediatric inpatients (odds ratio 3.28; 95% confidence interval 1.94–5.55) [79]. However, in this study, the analysis did not control for workflow or policy changes that coincided with the

implementation of the CPOE. Nevertheless, the implementation of prevention strategies might potentially be associated with the introduction of new, "e-iatrogenic" errors [80,81], due to potential changes in workflows. Implementation of CPOE should therefore follow a stepwise roll-out after careful testing and be accompanied by close monitoring [82].

The Future

In the past decades, a multitude of small and several large-scale studies have been conducted in order to assess the frequency and nature of medication errors as well as to evaluate the impact of different prevention strategies. While all studies have found that medication errors happen with considerable frequency during drug therapy, variation in detection approaches makes it hard to narrowly define their incidence and severity. The frequency, best detection approaches, and prevention methods vary by setting and patient population. To allow comparison among study results, careful consideration of the study methodology is especially important. Especially in large-scale studies using only administrative data, information relevant to reliably identifying medication errors is often not systematically available. Key factors in conducting valid research related to medication errors include the consistent use of definitions and classifications of medication errors, and attempts to merge large medication databases with electronic data on patient's clinical information. Another area is refining the decision support in commercial applications.

But perhaps the major current research gap is to develop better approaches for and studies of detection and prevention in the ambulatory care setting – the setting in which the main part of drug treatment takes place. However, additional research is needed in all settings, especially in special populations such as psychiatry and pediatrics.

Patient Engagement and Patient-Reported Outcomes

Esi M. Morgan

Department of Pediatrics, Division of Rheumatology, Cincinnati Children's Hospital Medical Center, and University of Cincinnati College of Medicine, Cincinnati, OH, USA

Patient engagement reflects the effective participation of patients in their own healthcare. A historical view of the relationship of patient to clinician (physician, provider, etc.), may have positioned the patient in the role of a provider of medical history and symptoms, and subsequently a recipient of a "healthcare product," the product being clinician-generated information, advice, treatment prescription, and instructions that the patient was expected to follow. The outcome of care was thus a factor of the quality of the advice and treatment recommendations as well as the ability and inclination of the patient to carry out this advice.

The influential 2001 report by the Institute of Medicine on reforming and improving healthcare in the US named patient-centeredness as one of six guiding aims for healthcare, which should also be safe, effective, timely, efficient, and equitable [1]. It has been argued that healthcare is better conceived of as a service rather than a product provided to patients, and as such achievement of best patient outcomes may hinge on taking a co-production approach to care. In this service-oriented (rather than transactional) view, the patient (service user) and clinician (service professional) are in a collaborative relationship with shared creation of the healthcare service and shared responsibility for outcomes. Effectively, the healthcare service is "co-produced" [2]. Self-management support is a key component of effective chronic illness care management that is patient centered [3]. Concepts such as effective communication, shared decision making and monitoring of health outcomes to support successful self-management become important and essential goals for co-production of patient-centered care, particularly for chronic conditions (see Chapter 39).

The reframing of the patient–clinician relationship as co-producers of a healthcare service elevates the importance of measuring PROs in healthcare delivery. By extension, it increases the utility of PRO use in observational studies and clinical trials in order for patients to be able to translate expected benefit of study medications to expected experience in real-world use based on meaningful clinical outcome assessments. Broader use of standardized PRO measures in healthcare also increases the feasibility of conducting comparative effectiveness research with observational clinical data.

Patient engagement in comparative effectiveness research more generally, with patients moving from the role of study subject to becoming partners in prioritizing research questions

Pharmacoepidemiology, Sixth Edition. Edited by Brian L. Strom, Stephen E. Kimmel and Sean Hennessy.

and contributing to study design, has become a phenomenon over the past few decades due to patient advocacy efforts. The Patient Centered Outcomes Research Institute (PCORI), which has been funding research since 2012, has promoted engagement of multiple stakeholders (patients, clinicians, payers, healthcare institutions, etc.) in the conduct of clinical research and is systematically studying the impact of patient engagement on the research processes. Patient stakeholders on research teams may influence research topics towards patient priorities and clinical relevance, contribute to study design including selection of outcome measures, help with study materials including consent forms, participate in recruitment and retention efforts, reduce missingness in data collection, and provide important perspectives when interpreting study results. Given the brief period of time that patient-centered approaches to research have been emphasized, it is too early to assess the impact of patient engagement on study completion or uptake of findings into clinical practice [4].

Patient-reported outcomes (PROs) are defined as "any report of the status of a patient's health condition that comes directly from the patient, without interpretation of the patient's response by a clinician or anyone else" [5]. PROs enable patients to directly communicate information about their status with respect to various domains of health, such as symptoms, function, quality of life and participation, as well as health behaviors and experience with care, in a structured format that translates the patient experience into data. Use of PROs recognizes that the health concerns of the patient may not be adequately perceived by the clinician unless there is direct and structured inquiry of what is bothering the patient. As a consequence of failing to elicit direct patient input, clinicians may prioritize other health topics less valued by the patient. Incorporation of PROs into clinical care has the potential to enrich clinician–patient communication as the patient voice is systematically and routinely collected, as well as providing data in the form of meaningful scores to which clinical decisions and interventions can be anchored and that may be complementary to lab tests or physical exam. Building a system around incorporation of PROs into the practice of medicine supports patient engagement.

Advances in measurement theory and the use of item response theory (IRT) models in scale development have enabled development of modern PRO measures that are both more efficient (shorter) and have more precision in scoring [6] than questionnaires developed with classic test theory. In support of the clinical research enterprise, the National Institutes of Health supported the development and distribution of various IRT-based PROs, including the Patient Reported Outcomes Measurement Information System (PROMIS®) which started as a cooperative network in 2004 to develop unidimensional measures of physical, mental, and social health domains available as short forms, item banks, and computer adaptive tests. PROMIS measures were designed to be generic and used across chronic conditions to support clinical research [7], and the use case evolved to support outcomes assessment in clinical care. Numerous examples of other PROs have been widely used in research studies, and increasingly in clinical care.

Conceptualization of PROs as an essential component to patient engagement in healthcare has the power not only to influence and improve outcomes, but potentially to transform the relationship of patients to the perception of their own health and agency, and their communication and relationship with their healthcare professionals [8]. The vision is compelling but the reality of implementation, interpretation, use, and evaluation poses practical and methodologic challenges. This chapter will explore these challenges in the context of integration of PROs into pharmacoepidemiology research, including clinical trials and observational studies.

Patient-Reported Outcomes in Clinical Trials

It is increasingly recognized that including the perspective of the patient end-user is important during development of new medication or medical products. Capturing the patient perspective as a clinical trial outcome may take the form of a PRO. PROs can be rating scales, symptoms reports, or questionnaires completed by self-report or completed in the form of a structured or unstructured interview, provided there is no modification of the patient's response by the interviewer. Whereas only PROs can be used to capture symptoms and other unobservable domains of health, PROs can also be used to capture and include the patient viewpoint on observable domains (e.g., functional ability, counts of events). Methodologic challenges in longitudinal measurement and interpretation of PROs are discussed later.

In addition to PROs, there are three other forms of clinical outcome assessments for use in trials: clinician-reported outcomes, observer-reported outcomes, and performance outcomes. *Clinician-reported outcomes* are measurements completed by healthcare professionals based on their evaluation of the patient's health condition. By definition, these are observable and include physical findings and report of clinical events or interpretation of clinical data supporting occurrence of such events (lab or other physiologic tests). *Observer-reported outcomes* are also based on observable signs, events or behaviors related to the patient's health condition; however, they do not require interpretation or report by a healthcare professional but rather, observation can be by a caregiver, such as a parent. Examples could include event counts or behavior rating scales. Last, *performance outcomes* are based on patient completion of tasks as directed by a healthcare professional, for example, timed walking distance (gait speed) or tests of cognition/memory (word recall) [9]. These measurements are valued in part when they are understood by medical decision makers, clinicians and patients to be clinically meaningful endpoints [10].

Patient-reported outcomes serve a variety of functions in new product development. They can help better understand the impact of a medical condition on the patient, such as in the realm of physical, mental, or social health, and also uncover if there are (unmet) medical needs to be addressed by a new medication [11]. PROs can also be used to enable estimation of the benefit to the patient of use of a medication during the clinical trial (e.g., by estimating the minimal clinically important treatment effect or minimal clinically important difference [MCID]), and by extension, can be used to characterize the expected benefit to the end-user in the clinical setting. Adverse effects of treatment, or an estimate of risks of use, may also be captured from the patient perspective [5,10]. The Food and Drug Administration (FDA) as part of the 2012 reauthorization of the Prescription Drug User Fee Act (PDUFA V) has been including patient input on the impact of chronic illness to inform which aspects of illness would be most meaningful to target from the patient perspective. Ascertaining such information from cohorts of patients with chronic conditions and compiling perspectives on meaningful clinical impact that is desired from new products require a systematic approach and robust methods to interpret and use the information to inform drug development [11].

After clinical outcomes that are meaningful drug targets from the patient perspective are identified, it becomes important to be able to determine whether the drug/treatment/intervention under investigation exerts a clinically meaningful effect on the relevant clinical outcome. Although a statistically significant change in outcome measure scores may be achieved, achieving statistical significance may not correspond to a clinically meaningful benefit. Determination that a change is of clinical meaningfulness rests on the idea that the outcome being measured is of relevance and importance

to the patient to begin with, and that the degree of change exerted creates a clinically appreciable benefit (reduction in symptoms, increase in function, greater wellbeing, etc.). Understanding how to estimate clinically meaningful change in PROs is an area of active methodological research [12,13].

Patient-Reported Outcomes in Routine Care

A current challenge to use of PROs as outcomes in observational studies is that such measures are not typically available, especially when compared to measuring other outcomes such as clinical events or death. However, PRO measures are growing in use in clinical care in part due to the push for patient engagement to provide patient-centered care and improve healthcare value [14,15]. Conceptually, capturing PROs in clinical care could be seen as a method to include the patient voice in outcome estimation. In practice, incorporation of PROs is starting to effect meaningful healthcare improvement. Over the past decade, there has been a growing body of published evidence on the benefits of incorporating PROs in clinical care, including both process and outcomes improvement. A number of technical solutions for full integration into the electronic health record, used alongside the electronic health record or hybrid approaches, have been described [16]. User's guides have been published with step-by-step instructions for health systems considering adoption of PROs to facilitate incorporation into clinical care [16,17].

Better collection and understanding of PROs can also lead to interventions to improve outcomes. Published reports of integration of PROs into clinical care have over time evolved from description of acceptability and feasibility [18], to demonstration of improved care processes [19] and communication, to preliminary evidence of increased clinician satisfaction and even improved outcomes. When PROs are collected and reviewed, patients perceive the clinician to have increased awareness of their symptoms, which otherwise might go unrecognized and unaddressed [20]. Clinicians may be better able to identify and diagnose patient conditions, including mental health concerns, if PRO results are routinely collected [8]. Use of PROs may result in increased clinician awareness of the impact of the health condition on the patients' health-related quality of life and facilitate patient–clinician discussions [21]. Communication [22], shared decision making, and collaborative treatment planning are enhanced when PROs are incorporated into patient and clinician conversations [15,18]. Until recently, despite theoretical support for the incorporation of PROs in clinical practice to improve outcomes, there has been scant evidence of demonstrable benefit to outcomes. As PROs become more established and reliably implemented in routine clinical practice, researchers are moving beyond studies of process improvement to studies of the impact of PROs on outcomes of care.

Much of the literature on the effective use of PROs in clinical medicine has come from the fields of oncology and surgery. A recent compelling report from an oncology randomized trial of PRO use during routine cancer treatment showed that integration of PROs in the form of electronic symptom monitoring into care of patients with metatastic cancer was associated with increased survival [23]. The authors postulate that this could be a consequence of expedited medical care team response to patient symptoms, which could result in two potential benefits. First, averting potential adverse events with clinical interventions including adjustments to chemotherapy dose, and second, administering chemotherapy for a relatively longer duration which was possible due to reduction in adverse symptoms [24] prompted by early ascertainment and response to the symptoms. This brief research letter [23] illustrates a compelling account of the potential

benefit of PROs in improved management of patient symptoms and survival; however, the impact on alleviating adverse symptoms and reduction of suffering is meaningful in itself. Bringing increased survival into the calculus enhances the urgency of integration of PRO assessment – review of scores and taking appropriate action – into delivery of healthcare.

Recently, payers have been encouraging PRO collection [25], including the use of financial incentives for tracking PRO data. For example, PROs are used to evaluate the impact and trajectory for improvement of surgical interventions in the case of Medicare reimbursement for elective joint replacement [26]. The availability of such data can enhance observational studies by providing prospectively collected information on PROs.

Patient-Reported Outcomes as Motivation to Develop New Therapeutic Strategies

From a therapeutic perspective, incorporation of PROs may contribute to a more targeted conversation on issues of concern for the patient that might otherwise go unaddressed. It may help to quantify the discomfort a patient feels and subsequently trigger the use of a therapeutic intervention. Information on disease control status, such as number of asthmatic episodes, can focus the visit on topics of most relevance and be a useful measure of disease burden. Having prespecified and agreed-upon PRO score thresholds that trigger specific evidence-based interventions facilitates action by the clinician. Alternatively, aggregate patient-reported data on symptoms, function, quality of life, or experience related to an intervention can be shared with an individual patient as part of a shared decision-making discussion [26]. Several examples are provided here.

Self-management support is a key component of the Chronic Care Model, a framework that has been useful in driving health system improvement [3]. Patient engagement, with informed, activated patients, is key to productive patient–clinician relationships which effect clinical outcome improvement. Successful self-management support programs have the following elements:

- clinicians communicate the expectation for the central role of the patient in managing their condition
- patients' self-management skills, confidence in management ability, barriers and supports are assessed regularly
- trained staff employ behavior change interventions
- patients co-develop with healthcare professionals their own individualized treatment plans and support is available on an ongoing basis if the patient needs it [27].

Self-management support is a patient-centered, iterative, and ongoing process. Experience from a quality improvement collaborative on implementing self-management support revealed that the most successful care teams received relevant training, adopted a philosophy of patient-centered care and collaborative goal setting, integrated components into the care delivery system, and assigned accountable staff [27]. Due to the fact that the majority of chronic illness care occurs outside the medical office in the interval (days to months) between office visits, PRO assessment has the potential to become an effective facilitator of between-visit communication between patients and clinicians and may allow patients to better manage their health conditions.

Since medical care at outpatient office visits occurs at relatively infrequent intervals while health events occur on an ongoing basis, the trajectory of illness may not be adequately captured at clinic visits due to factors such as – on the patient side – the failings of memory (recall), the lack of a way to accrue and organize data, and perhaps – on the clinician side – failure to inquire (particularly in the case where PROs are not assessed). As a result, medical decision

making may not incorporate all relevant health information into treatment decisions. Imagine the situation where Patient A begins a new medication, Drug A, and experiences rapid improvement in signs and symptoms of disease which gradually return to baseline over time. Patient B experiences gradual improvement following the initiation of Drug B, then rapid worsening before the condition returns to baseline by the time of the follow-up visit. Both patients have roughly the same disease activity level at the follow-up visit. In this scenario, information is lost about the relative lack of effectiveness and negative impact Patient B experienced being on Drug B, as more time was spent in a flare state than with Patient A who took Drug A.

Technology can enable the capture and transmission of both patients' unique experience to the clinical team. Data can be collected at home, either as PRO questionnaires on computer or mobile devices, or as technology-enabled patient-generated data (e.g., physiologic monitors), and then shared with the clinical team. Data collection from wearable devices requires little or no effort from the patient perspective. This opens the possibility for patient data from in-between patient visits to serve action-oriented interventions. However, numerous potential barriers exist to such a system: availability of optimal technology platform to house and transmit data, cost of technology, and patient having access to a reliable and persistent Wi-Fi connection. From the clinician perspective, additional considerations include the interoperability of the technology with the electronic health record, providing training to use the system and interpret results, allocating staff to review the results and integrating this process into the clinical workflow. Patients who transmit data will have the expectation that results are reviewed, so workflows will need to be optimized to allow for reliability of review, and prompt response if deterioration in status or other change is identified.

Such a system is currently being tested in pediatric chronic illness care, with, for example, the Orchestra mobile health technology platform and care model intervention in cystic fibrosis and inflammatory bowel disease [28]. The concept, currently being piloted, is of a mobile health (mHealth) technology platform that enables clinicians and patients to work collaboratively together to co-produce healthcare. It does so in part by allowing symptom tracking with real-time data visualization on a platform that is shared with patients and clinicians, allowing for continuation of patient–clinician interaction outside the office visit. Furthermore, the system contains automated symptom surveillance detection software which generates alerts when potentially important changes in health status are detected. Other features supporting patient engagement include previsit planning support and opportunities to participate in research. For example, patients may be recruited to participate in a study of the impact of new medications, other interventions such as lifestyle changes on PROs, or other measures being tracked [28].

There are other insights to be gained from the operationalization of the mHealth technology, including study of the optimal way to integrate such a system into clinical workflow and evaluate the system in terms of feasibility, acceptance, and completion rates. Considering a culture shift is necessary to embrace the co-production model, internal (clinical team) and external (patient) stakeholder engagement and training are required – as are social contracts. Ultimately, the success of the system may be measured in terms of increased patient engagement and self-efficacy (i.e., belief in one's ability to perform activities necessary to achieve health goals), improved outcomes, and appropriate healthcare utilization [28]. The concept is potentially transformative in the ability of patients to self-manage care, including supporting development of individualized treatment plans and customized treatment trials, N-of-1 studies, with care being optimized based on a patient's own PRO data.

Clinical Problems to Be Addressed by Pharmacoepidemiologic Research

Patient-reported outcomes are directly relevant to pharmacoepidemiology research insofar as they capture information central to the estimation of benefit and potential adverse effects of medication that may elude physical exam or lab testing, such as symptoms like fatigue, cognitive impairment, or pain. Clinical trials have restricted sample size and duration of use compared to real-world consumption of medications. Routine and systematic collection of PROs as part of clinical care can help us better understand the epidemiology of disease and, importantly, also the impact of medications on symptoms and quality of life as part of postmarket surveillance. The value of the information is contingent on the reliability of data collection from a representative population, and ability to access the data for research. While PRO collection has benefit for pharmacoepidemiology research, the rationale behind incorporation of the patient voice into clinical care via the use of PROs is to identify unmet needs of patients and help identify gaps in healthcare. Once such a need is identified, ideally an action or response would occur, such as change in medication, referral for treatment, or development of an individualized action plan for lifestyle or behavior change as part of a self-management support. Motivating the move from recognition and identification of the problem to action is a major area for attention.

Ensuring PRO Completion and Results Review

In order to generate valid estimates of treatment effectiveness or impact on quality of life from analysis of PROs in clinical observational data, it is essential that clinical processes are in place to secure research quality data. As the primary motivation for PROs collection may be delivery of optimal patient-centered care and better health outcomes, with the ability to use the data for research as secondary, the clinical team – and patients – must be aligned in perceiving the value of quality PRO data collection. To be most useful clinically, and to allow valid inferences in research, PROs must be collected routinely (reliably at regular intervals), uniformly (in a consistent manner), completely (able to be scored), and correctly (patients understand the questions and answers reflect their health status).

Once a decision is made to incorporate PROs into clinical care, there must be a means to achieve reliable review of the results by the clinical team. This review may not always occur, as reflected in an example from a leading institution in which a discordance was noted between symptom documentation by self-report for signs of heart disease and lack of clinician documentation [29]. If clinicians do not understand the PRO measure, the way it is scored, do not feel it relevant to their specialty, or feel there is no intervention or action that can impact the PRO, they may not be inclined to discuss it [30]. The solution may be cultural and social, and require a clinical champion to motivate colleagues and gain agreement on selection of PROs (more on this later). Or it may require a solution similar to the idea of setting a social contract, noted in the Orchestra co-production example [28]. Barriers may be technical, related to location and ease of viewing of the reports in the medical record, in which case this may require an information technology solution. Another solution may leverage quality improvement methods and hinge on building a workflow in which discussion of PRO completion is an expected part of the clinic visit and is included into process of care quality measures.

There are significant consequences of clinicians not reviewing PROs completed by patients. When clinicians do not review PROs, it becomes a threat to co-production of care,

risks the patient feeling their time and input were not valued, and may result in a decreased willingness for PRO completion at subsequent visits; it is also a missed opportunity to check the reliability of the system for PRO administration (i.e., whether the patient even received the PRO to complete from the staff). Nonreview of PRO results is therefore a threat to patient satisfaction with care, their perceived trust in PROs, and a missed opportunity to improve functional outcomes.

Review of PRO results enables verification of patient understanding of the instrument and that it reflects their health status, increases recognition of areas for health intervention, and provides positive feedback that encourages completion of PROs at subsequent visits.

PRO Selection, Score Interpretation and Interventions

As noted earlier, instrument selection is vitally important for both clinical and research applications to ensure the measure is of clinical relevance, addresses an outcome of interest, and is brief and practical to administer. These and other considerations such as ease of understanding, ability to foster patient–clinician communication, and value in identifying unmet needs should be reviewed with representative patients and clinicians for input and agreement on importance. In addition, the basic prerequisites of adequate psychometric properties such as reliability, validity, and responsiveness should be met [17,25]. A comparison study of various PRO measures in oncology patients with feedback from patients and clinicians helped to highlight the importance of reviewing and selecting PROs specific and useful for the intended application in clinical practice [31].

In order to be actionable, scores on measures for a specific health condition should be known, including the normal range versus when to intervene for an abnormal score. There is need for consensus and standard-setting processes on threshold scores to trigger interventions. In order to track longitudinal change, it is helpful if the minimal clinically important difference for improvement or worsening has been determined (discussed further in methodologic considerations later). Ensuring these scores and thresholds for action are known, and identifying evidence-based interventions or, where such evidence does not exist, gaining consensus agreement amongst practice clinicians and patient stakeholders on recommended interventions will facilitate clinicians and patients moving from simple review and discussion of PROs to taking effective action and co-producing treatment plans based in part on PRO scores which are meaningful to them.

Considerations when selecting PROs for clinical use are likewise important for research applications. Using PROs with known clinically meaningful endpoints will facilitate longitudinal observational studies of effectiveness of medications or interventions.

Patient Engagement and Individualized Assessment and Treatment Plans

Mobile health tracking systems such as described in the Orchestra example [28] offer the possibility of customized measurement (choice of PROs, timing of administration), and use of individualized measures which may be of great importance in pharmacoepidemiology outcome studies [8]. In addition, use of PROs for in-between clinic visit care for continuous monitoring and data feedback, with customized reporting and means to detect signals of health status change in a personalized system, lends itself to N-of-1 trials. In this type of study, an individual can make planned changes to treatment or lifestyle modification, then track changes in symptoms to evaluate for possible effectiveness. By keeping daily journals or other means of annotation, patients can see if other triggers or environmental factors may have led to changes in their health status [28]. This structured type of intervention allows

study of the impact of medications with relatively rapid onset and dissipation of effects (e.g., pain medications). In addition, one can study whether patients who are given access to their outcome data become more engaged in their health such as being more prepared for clinic visits and involved in shared decision making and treatment planning.

Barriers to Measuring PROs in Clinical Practice and Using PROs to Guide Interventions

Barriers to PRO use are varied and start with garnering institutional resources to obtain, store, and update electronic data collection tools. Designing integration of PROs into clinical workflow is a necessary step which first requires gaining clinician consensus on the purpose and value of adding PRO capture and review to the clinical encounter. Clinicians must understand how the use of structured PROs adds value over simply asking the patient how they feel [15]. Frontline staff training on the importance of PRO collection and distribution of questionnaires or collection devices is required for reliable PRO collection.

Clinician training is required on how to use PROs to facilitate high-quality communication with patients. This requires training on how to interpret PRO results and how to communicate about the results with patients. The process could be facilitated by orientating the patients themselves to use of PROs and their role in their clinical care. For PROs to help facilitate co-production of care may in some circumstances necessitate reframing of the patient–clinician relationship, a complex endeavor in culture and behavior change [2].

Buy-in may become easier to obtain as more convincing data become available on PRO integration into care resulting in improved outcomes, as barriers to logistics of PRO collection are lowered, as graphical displays become more intuitive, and as interpretation of data and action steps become more familiar and supported with decision aids [15]. Clinicians may have higher interest in use of PROs if they receive feedback on their own patients' scores, relating to outcomes or experience with care (satisfaction) and recognize they can take steps to improve performance [30].

As use of PROs in clinical trials and pharmacoepidemiology research becomes more prevalent, PRO endpoints may become more widely accepted goals to measure and monitor treatment efficacy. This may serve as positive reinforcement to PRO use for monitoring treatment effectiveness in clinical practice settings.

Methodologic Problems to Be Solved by Pharmacoepidemiologic Research

Just as patient engagement and PROs inform the discussion in the clinical practice setting, they similarly play an increasing role in the research setting. For example, including patient-relevant outcomes in clinical trials has become a priority of the FDA [5,11] and fostering patient engagement in all stages of research has been the genesis of the PCORI and its significant funding portfolio [32]. However, there are methodologic challenges with incorporating PROs into clinical research, including issues of discordance in perception between raters and measurement of within-person change over time.

Discordance in Perspectives Between Patients, Clinicians, and Researchers

With respect to differences in rater perspectives, there are examples of discrepancies between perceptions of clinicians and patients regarding level of disease activity, and about whether there has been improvement or deterioration in the condition. There may also be lack

of concordance between composite measures of disease activity used to assess efficacy in clinical trials and measures that use PROs.

Examples from the field of rheumatology include the comparison of composite indices used in rheumatoid arthritis clinical trials (e.g., complete joint counts, laboratory values, physician global assessment), which tend to be lengthy to complete compared to PROs, which are shorter and more feasible for use in clinical practice. Composite indices are helpful to reduce the presentation of information from multiple measures into a single summary score. This is most informative when the measures included in an index are highly correlated. When a measure does not correlate or track well with others, to include it in a composite index would result in lost or obscured information. While there is a correlation between the results from composite indices and PROs, studies have found that the results from PROs do not always track with the composite indices. When PROs are independent predictors of treatment response, PRO results should be reported separately rather than included in a composite score [33]. In one study, composite indices were better at detecting flare states though worse at describing states of low disease activity [34]. This supports the inclusion of PROs in clinical studies along with established composite indices.

The same investigators also studied disparate perspectives about the change in clinical status between clinicians and patients with rheumatoid arthritis. In this study, patients required a greater improvement in their condition to show improved satisfaction with the change compared to physicians. Likewise, patients required less deterioration to show dissatisfaction with their condition compared to clinicians. Clinicians valued a change in the disease activity score of equal magnitude – better or worse – to reflect improvement or deterioration. However, patients required more disease reduction to consider it an improvement and less worsening to trigger dissatisfaction. There was only about 60% concordance between patients and clinicians in judgment of disease activity. Perception of improvement/worsening has been shown in other studies to vary from the vantage point of clinician, patients, and caregivers [35]. This is an area needing additional study. Examples of discordance can vary depending on type of study, measures used, and how perspectives are elicited.

Composite measures upon which clinicians base their assessment of improvement or deterioration may not necessarily include key aspects of the disease that matter to the patient. For instance, in the DAS-28 (disease activity score) assessment of rheumatoid arthritis, 28 joints are assessed for tenderness or swelling, but this count does not include the feet or ankles. Therefore, if patients have foot involvement, which can be very painful, it is possible they may not be satisfied with the degree of improvement noted on the DAS-28 because it excludes an important element of their disease experience. Using the DAS-28 as an outcome in pharmacoepidemiology studies could therefore miss outcomes important to patients and result in biased measures of association. Further, composite disease activity measures may not always translate to decision making based on the experience of an individual patient [36]. As a matter of patient engagement, the viewpoint of the patient must be considered in collaborative treatment decisions, and it may not always be aligned with outcomes assessed in research studies [37].

Measuring Within-Person Change

Understanding how to estimate clinically meaningful change using PROs is important to be able to determine the effectiveness of a treatment or intervention. Determining clinically meaningful change is complex; there is no consensus on the best approach and the topic represents an area of active methodological research. Although there are standard statistical

approaches to understanding and analyzing the change in PRO scores over time, detection of a statistically significant difference may not reflect a meaningful clinical difference. As noted above, there may be differences in defining a meaningful clinical difference depending on the respondent (e.g., patient, caregiver, clinician). It may depend on the health condition being studied, and also whether a patient is experiencing improvement or deterioration at the time of measurement. Additional considerations that make classification of meaningful clinical change challenging include instability of intrarater judgment, temporal changes related to disease stage, progress, and severity (see Chapter 37). Perception, or recall, of progress compared to an earlier state of disease may also be subject to bias. The context of measurement or the consequence of declaring a change meaningful (e.g., resulting in a treatment change) could influence the study results and decisions about clinical approaches (see Chapter 39).

Statistical Methods

Patient-reported outcome scores may change in response to an intervention, but just because a PRO is responsive and a change in score is statistically detectable does not mean the change is important. The *minimal important difference* (MID) represents the smallest change in score that could be determined important [12]. The *minimal clinically important difference* (MCID) is determined based on clinical anchors [12], and is generally regarded as the smallest difference in score that would prompt a change in patient management [38]. In practice, the terms MID and MCID are sometimes used interchangeably, but there may be differences between statistically derived estimations and those anchored on clinical parameters. MID and MCID estimates vary according to the population being studied and context of measurement. The MID is a useful calculation to help determine responsiveness to change of a PRO measure, which is part of construct validity.

Anchor-based methods such as the MCID use external indicators considered to be clinically relevant to the PRO, such as clinical measures (lab tests, clinician ratings) or patient measures (global rating of change), and place subjects on a continuum based on the size of change in the anchor (large negative change, small negative change, no change, small positive change, large positive change). Estimating what is considered a small versus medium, or other, change on a given clinical measure may require a consensus process [39]. Ideally, multiple relevant anchors should be used across multiple samples to confirm responsiveness of the PRO measure. Patients who made small changes that were considered meaningful should be included in the exercise [12] to try and reduce the likelihood of picking statistical but not clinically important differences. Another anchor-based technique to estimate MID uses receiver operating characteristic (ROC) curves to evaluate group-level criteria for improvement or worsening of clinical status [40,41].

Distribution-based methods are more strictly based on statistics, without requirement for a clinical anchor. The distribution-based approach uses scores from a sample to express the effect in terms of standard deviation units or standard error of measurement [39]. Distribution methods can be used if anchor methods are not available, or to assess if anchor-based measures are reasonable estimates [12].

Bookmarking and Scale Judgment of IRT-Based Measures

Alternative approaches to measuring meaningful within-patient change have been developed based on techniques from the field of educational testing applicable to PRO measures developed using IRT methods. The general approach is for the development of clinical vignettes representing a continuum of IRT-based scores, presenting these vignettes to a representative panel of stakeholders (e.g., patients, caregivers, clinicians) and having the

panel identify thresholds between scores (delineated by the vignettes), where they place a "bookmark" separating different levels of severity. Imagine, for example, the case of physical function; vignettes would be presented of patients having no physical limitation through severe disability. The panel would order the cards according to physical function described by the vignette, then set thresholds between categories of patients with "no problem," "mild problem," "moderate problem," and "severe problem." Such exercises help to identify clinically meaningful cut-points between scores [42]. Similar qualitative work with panelists can be used to identify minimal clinically meaningful differences by presenting PRO items to stakeholders and asking them to note how much response to an item (or items on a scale) would need to change for a change in status to be considered clinically meaningful [35].

Another approach, the "scale judgment" method, entails raters comparing prefilled IRT-based PRO questionnaires (for example, considering before and after an intervention) and indicating whether or not the person who completed the questionnaires had experienced an important difference [43]. These types of approaches require qualitative work with patient and other stakeholders across different patient populations (age, demographics, health conditions) and considering direction of improvement and worsening of PROs. Research is needed into the impact of different stakeholder roles and perspectives on agreement on severity thresholds and MCIDs, and how to understand and reconcile discordance particularly in the arena of clinical decision making.

Change in perspective

Another factor which may complicate the assessment of within-person health state change is the situation when a person's perception and valuation of the domain being measured change over time. This phenomenon, termed *response shift*, is defined as:

> a change in the meaning of one's self-evaluation of a target construct as a result of: a) a change in the respondent's internal standards of measurement (scale recalibration); b) a change in the respondent's values (i.e., the importance of component domains constituting the target construct), or c) a redefinition of the target construct (i.e, reconceptualization) [44].

For example, this could occur if a psychological intervention resulted in a change in thinking about a person's condition and the impact on their life or if patients adapt to disease progression, get used to medication toxicities, etc. Response shifts could potentially alter estimates of treatment effect over time. There are both statistical and qualitative methods to assess for response shift, and guidelines for investigators to evaluate objective change and changes in internal valuation [44]. The phenomenon of response shift in the quality of life appraisal process of the patient respondent may also be at root when their global rating of change differs from what might be expected based on PROs or other assessments [45].

Currently Available Solutions

Practical Guides for Selection of PROs and Implementation into Practice

With the proliferation in interest and adoption of PROs, there are publications offering guidance on training clinicians in use of PROs, as well as a number of studies on presentation of PRO scores to patients and clinicians. Recommendations for training clinicians on PRO use include eliciting local barriers and concerns to address during the training (such as how to deal with patient symptoms/concerns outside the specialty, concern about visit time constraints, how to interpret results), inclusion of the stakeholders in PRO selection and format for presentation, keeping the

training relatively brief, making training problem based and experiential with video examples and case studies, and including relevant treatment decision aids and decision support tools in the training [46].

Experience on considerations for graphical display and communication of PRO scores has also been published. Display format preferences tend to vary by audience characteristics such as age, education, and role (clinician vs patient) [47]. Some studies have identified preferences for line graphs [48], others for bar graphs [49]. Patients tend to prefer simpler formats, and clinicians prefer more data [47,48]. Directionality of data has been shown to matter, with better health being portrayed as higher on the chart, and including lines indicating threshold values for normal versus abnormal found to be helpful [50]. There are published examples, and depending on EHR vendor there may be preprogrammed displays. As the field matures, additional resources and guidance are anticipated to become available.

Overcoming perceived barriers to PRO adoption in clinical care may take a cultural shift, including acceptance of co-production as a means to transform healthcare delivery and improve chronic illness care. For some, it may help to view PROs as a tool in the data arsenal for enhanced signal detection of the health of an individual gone awry, or as a communication tool for more efficient and accurate exchange of information. As evidence mounts on the side of increased quality of care and improved outcomes resulting from interventions supporting co-production, the tide may shift to embrace PROs use in clinical care.

There are a host of useful publications providing guidance for integrating PROs into clinical practice, including considerations for selection of PROs use in performance measurement, and guidance on integration of PROs into electronic health records. Example references are publicly available and the reader is also referred to the following resources:

- A useful reference to find information about publicly available PRO measures developed and evaluated with National Institutes of Health (NIH) funding is the Health Measures website. This is a repository of official information about PROMIS® (Patient-Reported Outcomes Measurement Information System), which has a suite of person-centered measures across multiple domains of physical, mental, and social health for adult and pediatric populations. This repository serves as a distribution center for other NIH-funded measures such as Neuro-QoL, NIH Toolbox®, and ASCQ-Me®, in addition to PROMIS. www.healthmeasures.net/explore-measurement-systems/promis

The Future

Patient engagement in research, advances in PRO measurement, and recognition of the importance of garnering direct patient input will result in increased inclusion of the patient voice

in the calculus of medication efficacy in clinical studies [4–6]. PROs are increasingly used at the point of clinical care, and there are now prototypes for capturing data between clinical or study visits to enhance co-production of care [28]. There is growing evidence that electronic PROs, or at least symptom monitoring, may increase not only quality of care of processes, but also outcomes [23], and use of PROs may become a reflection of, and an instrument for, improving quality of care. PROs may become increasingly used in comparative effectiveness research, with patient engagement in study design leading to more meaningful incorporation of PRO measures. PRO capture is being incorporated in learning networks and registries [51]. As more is understood about PRO development, effective use, interpretation and potential applications, the use and new use cases for PROs can be expected to continue to grow.

There is increasing interest in using PRO data from clinical settings and captured in electronic health records as structured outcomes assessment for inclusion in comparative effectiveness research. This could be a powerful data source when combined with other sources of electronic data [52,53] (see Part IIIb). PROs in EHRs may be of particular use when there are no standardized outcomes assessments provided by clinicians in the clinical note. The complexities of analysis and interpretation of longitudinal PRO data require continued study to best leverage such data to make valid inferences. Cross-cutting PRO measures that could be used across conditions and contexts may confer advantages such as anticipating from clinical trials results the expected outcomes in clinical practice. Such PROs when collected in a clinical setting – or with technology to support in-between visit data collection – could be used such that clinical data registries could be combined with administrative claims data to support comparative effectiveness research.

An area of future development in medicine applicable to study and use of PROs is the use of wearable devices with health monitors. Previously used as sports fitness trackers, there is now the ability to track heart rhythms with electrocardiograms transmitted to medical facilities, and blood glucose monitoring may eventually be an option. Medical device companies and technology are making substantial investments in this arena. Coupling physiologic data with PRO data will be informative in understanding clinically relevant change in scores. For example, a patient may be able to better calibrate a worsening feeling of fatigue (quantified in PRO score) to corresponding physiologic worsening, keeping individual patients more in tune with how symptoms and function may reflect underlying physiology.

There are open research questions related to analysis and interpretation of measures used longitudinally. There are interesting and exciting case examples, and it remains to be seen which model will be scalable and generalizable to more settings. Ideally, the culture of co-production, patient engagement, and self-management will continue to take root, perhaps strengthened by demonstration of outcomes improvement, and support the shift towards PRO measurement for meaningful application, evidence generation, and shared decision making.

Acknowledgment

The author thanks Wendy Engstrom Gerhart, Director, Quality Outcomes and Evidence, Cincinnati Children's Hospital, as a colleague in implementation of patient-reported outcomes measures in clinical care and for her critical review and edits to the chapter.

The past two decades have witnessed an explosion of methodological advances in the design and analysis of epidemiologic studies. Some of these contributions have been fundamental to the field of epidemiology in general while others have arisen specifically from questions posed by pharmacoepidemiologic applications. Several of these advances have already played an important role in the conduct of research on drug effects, and will take an even greater place in future applications. In this chapter, we introduce some of these approaches with a focus on confounding control, one of the major methodologic challenges in drug safety and effectiveness research with noninterventional studies.

We start out by describing a robust study design that will exemplify several aspects of confounding control and other biases and point out critical decision points in the choice of study designs. Second, we describe efficient sampling strategies within cohort studies (case–control, case–cohort, and two-stage sampling) and self-controlled designs (case–crossover and case–time–control designs) and how they will help reduce confounding bias. Third, we introduce several analytic methods that have gained wider use in pharmacoepidemiologic studies and others that only recently have made inroads into pharmacoepidemiology.

Clinical Problems to Be Addressed by Pharmacoepidemiologic Research

Pharmacoepidemiologic analyses are in principle no different from analyses in any other subject area within epidemiology. They are concerned with valid estimation of associations between an exposure and outcome, and methods to minimize systematic and random error that may cloud causal conclusions. Some issues specific to pharmacoepidemiology stem from the constraints of the frequently used secondary data sources, in particular large electronic longitudinal healthcare databases from insurance health plans, electronic medical records systems, or registries (see Chapters 11–14). Another difference is the often unusually direct interdependency of treatment choice with health status, severity of disease, and prognosis that may lead to strong, sometimes intractable confounding by indication (see Chapter 3) [1].

Pharmacoepidemiology, Sixth Edition. Edited by Brian L. Strom, Stephen E. Kimmel and Sean Hennessy.

Pharmacoepidemiologists try to reduce biases by appropriate choices of study design and analytic strategies. Challenges arise if not all confounder information is captured in the available data. This chapter provides an overview of selected options that fit typical pharmacoepidemiologic data sources and study questions.

Methodologic Problems to Be Addressed by Pharmacoepidemiologic Research

The ready and relatively cheap availability of large longitudinal patient-level healthcare databases make the new-user cohort design a natural design choice as a starting point that mimics the classic parallel group controlled trial, except of course for the randomized treatment assignment (Figure 43.1) [2]. Efficient sampling designs within such cohorts, including case–control, case–cohort, and two-stage sampling designs, are important extensions to assess additional covariate or outcome information in a subset of patients. Such sampling usually provides no advantage if secondary data are the only source for exposure, covariate, or outcome assessment because there is no additional cost or time to analyze the entire dataset rather than a subsample [3].

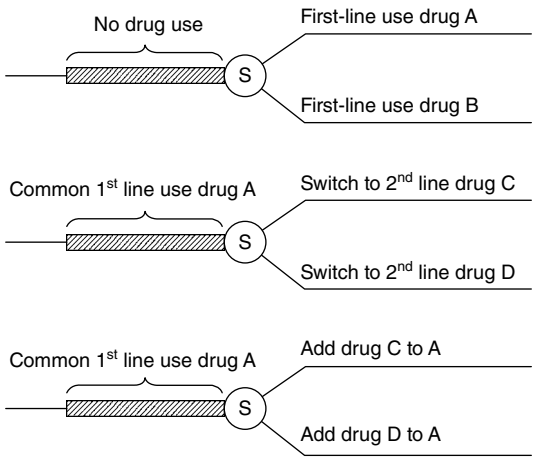

Figure 43.1 Principle of the new user design and its variations when studying second-line therapies. *Source:* Reproduced from Schneeweiss [3] with permission from John Wiley & Sons.

Bias can be reduced by appropriate design choices. Considerations about the sources for exposure variation will lead to fundamental decisions on the appropriate study design. In a causal experiment, one would theoretically expose a patient to an agent and observe the agent's effect on his or her health, then rewind time, leave the patient unexposed, and keep all other factors constant to establish a counterfactual experience. Since this experiment is impossible, the next logical expansion of the experiment is to randomly introduce or observe exposure variation within the same patient but over time (Figure 43.2). If we observe sporadic drug use resulting in fluctuations of exposure status within a patient over time, if that drug has a short washout period, and if the adverse event of interest has a rapid onset, then we may consider a case-crossover design or related approaches (see later). For most pharmacoepidemiologic studies, we will utilize variation in exposure between individual patients, and we will therefore apply a cohort study design. Any exposure variation among higher-level entities (provider, region, etc.) can be exploited using instrumental variable analyses (described later in the chapter) if unrelated to patient characteristics either directly or indirectly [4].

In a cohort design, there are several advantages to identifying patients who start a new drug and begin follow-up after initiation, similar to a parallel group randomized controlled trial that establishes inception cohorts. As patients in both the study group and the comparison group have been newly started on medications, they have been evaluated by physicians who concluded that these patients might benefit from the newly prescribed drug. This makes treatment groups more similar in characteristics that might not be observable in the study database if medication use is not new.

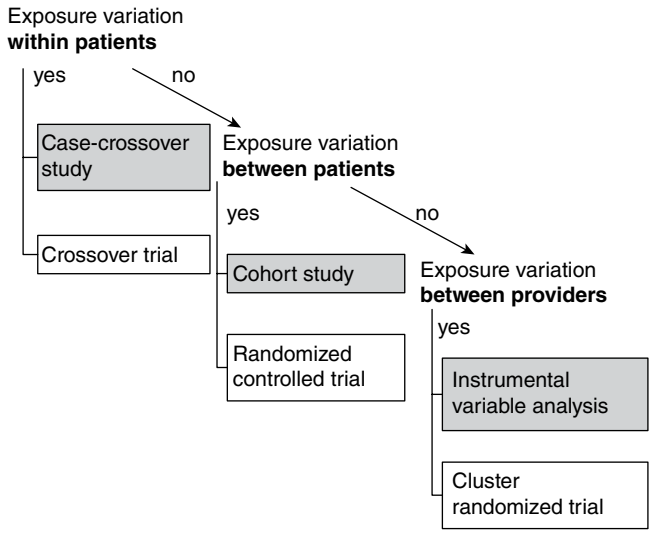

Figure 43.2 Study design choice by source of exposure variation. Shaded boxes indicate noninterventional study designs while clear boxes are the randomized design versions. *Source:* Reproduced from Schneeweiss [3] with permission from John Wiley & Sons.

The clear temporal sequence of confounder measurement before treatment initiation in an incident user design also avoids mistakenly adjusting for consequences of treatment (intermediates) rather than predictors for treatment, a possible reason for "overadjustment" [5]. Comparing two active treatment groups further reduces the chances of immortal time bias, a mistake that most frequently emerges if future information is used to define earlier exposure status in healthcare databases, particularly when defining a "nonuser" comparison group [6]. A common example of immortal time bias is to define nonusers as patients who have not used the study medication during the first six months of follow-up. By definition, these nonuser patients cannot die during the first six months of follow-up, and therefore their inclusion can bias the findings. Because of the well-defined starting point of inception cohorts, it is possible to assess whether and in what form hazards vary over time by stratifying on duration of treatment. Studying new users is also useful when studying newly marketed medications; the incident user design avoids comparing populations predominantly composed of first-time users of a newly marketed drug with a population predominantly composed of prevalent users of the old drug. Such a comparison would be prone to bias because patients who stay on treatment for longer may be less susceptible to the event of interest [7].

A common criticism of the incident user design is that excluding prevalent users will restrict and thus reduce the study size, in some cases substantially [8]. While this is true, researchers should be aware that by including ongoing (prevalent) users, they might gain precision at the cost of validity [9]. Screening and identifying incident users in secondary databases is not costly except for a bit more computing time. In some situations, particularly studies of second-line treatments in chronic conditions, we can only study patients who switch from one drug to another, as very few patients will be treatment naive. Such switching is often not random, but rather is determined by progressing disease and treatment failure or by side effects that may be related to the study outcome. A fairer treatment comparison may be achieved by comparing new switchers to the study drug with new switchers to a comparison drug (see Figure 43.1). Consequently, prevalent new-user cohort designs are being developed to minimize bias when one needs to include as many new users of the study drug as possible.

Even with appropriate designs, however, all observational pharmacoepidemiologic studies still must consider carefully how to approach the problems of potential confounding, in order to prevent bias. Approaches to addressing these methodologic challenges, and their limitations, will be the primary focus of this chapter.

Currently Available Solutions

The solutions available to minimize confounding in pharmacoepidemiologic database studies can be broadly categorized into (1) approaches that collect more information on potential confounders and apply efficient sampling designs to reduce the time and resources it takes to complete the study, and (2) analytic approaches that try to make better use of the existing data with the goal of improved control of confounding.

Efficient Sampling Designs Within a Cohort Study

In any cohort study, the cost, time, and resources necessary to collect data on all cohort members can be prohibitive. Even with cohorts formed from computerized databases, there may be a need to supplement and validate data with information from hospital records, medical records, and physician or patient interview questionnaires, with the goal of improved confounding control. When the cohort size is considerable, such additional data gathering can become a formidable task. Moreover, even if no additional data are needed, the data analysis of a cohort with multiple and time-dependent drug exposures can become technically unfeasible, particularly if the cohort size and number of outcome events are large. For example, a study of the long-term effect of antihypertensive drugs and the risk of cancer involved a cohort of over 1.1 million patients where 41 059 developed cancer during 14 years of follow-up, a size that necessitated sampling within the cohort [10]. Finally, there are situations with multiple confounding factors that may require accurate matching rather than simply modeling adjustment.

To counter these constraints, designs based on sampling subjects within a cohort have been proposed and applied successfully in pharmacoepidemiology. These designs are based on the selection of all cases with the outcome event from the cohort, but differ in the selection of a small subset of "noncases." Generally, they permit the precise estimation of relative risk measures with negligible losses in precision. Below, we discuss structural aspects of cohorts and present three sampling designs within a cohort the nested case–control, the multi-time case–control, and case–cohort designs.

Structures of Cohorts

Figure 43.3 illustrates graphically a cohort of 21 newly diagnosed diabetics over the period 1995 to 2010. This cohort is plotted in terms of calendar time, with subjects ranked according to their date of entry into the cohort, which can correspond to the date of disease diagnosis or treatment initiation. Such *calendar-time cohorts* depict the natural chronological nature of the cohort accrual. An alternative depiction of this same cohort could be based on duration of disease (i.e., follow-up time from diagnosis or first

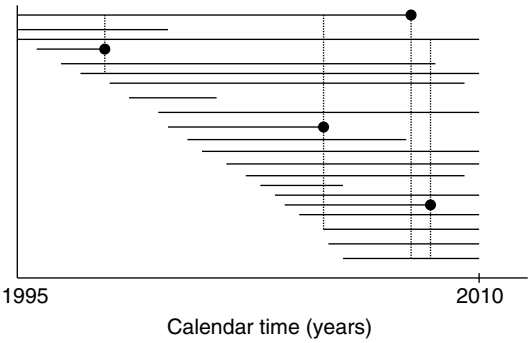

Figure 43.3 Illustration of a *calendar-time* cohort of 21 subjects followed from 1978 to 1990 with four cases (●) occurring and related risk-sets (---).

exposure to a drug), which may be more relevant to the drug effect under study. In this instance, the illustration given in Figure 43.4 for the same cohort, using follow-up time as the new time axis, is significantly different from the previous one. In these *follow-up-time cohorts*, the same subjects are ranked according to the length of follow-up time in the study with zero-time being the time of diagnosis or treatment start.

The question of which of the two forms one should use for the purposes of data analysis rests on one's judgment of the more relevant of the two time axes, essentially the one for which the risk varies most over time, called the primary time axis, with respect to risk and drug exposure. This decision is important, since it affects the demarcation of "risk-sets," which are fundamental to the analysis of data from cohorts and consequently the sampling designs within cohorts. A risk-set is formed by the members of the cohort who are at risk of the outcome event at a given point in time; namely they are free of the outcome event and are members of the cohort at that point in time, called the index date. Drug exposure measures are then anchored at this index date. It is clear that Figures 43.3 and 43.4 produce distinct risk-sets for the same cases in the same cohort, as illustrated by the different sets of subjects crossed by the vertical broken line for the same case under the two forms of the cohort. In Figure 43.3, for example, the first chronological case to occur has in its risk-set only the first six subjects to enter the cohort, while in Figure 43.4, all 21 cohort members belong to its risk-set at the time that the first case arises. While the second form based on disease duration is often used, because in pharmacoepidemiologic drug exposure can vary substantially over calendar time, the first form may be as relevant for the formation of risk-sets and data analysis as the second form. Regardless, an advantage of having data on the entire cohort is that the primary time axis can be changed according to the study question, using calendar time for one analysis, duration of disease or drug exposure for another, with respective adjustment in the analysis for the effect of the other time axis.

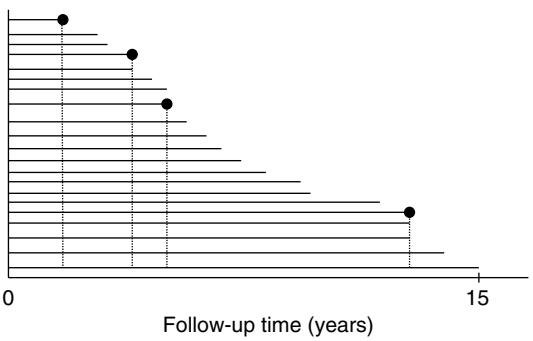

Figure 43.4 Illustration of *follow-up-time* cohort representation after rearranging the cohort in Figure 43.3, with the new risk-sets (---) for the four cases.

The Nested Case–Control Design

The notion of a nested case–control design within a cohort was first introduced by Mantel [11], who proposed an unmatched selection of controls and called it a synthetic retrospective study. It was developed further and formalized by Liddell *et al.* [12] in the context of a cohort study of asbestos exposure and the risks of lung cancer and mortality. The modern nested case–control design involves four steps:

1) defining the cohort time axis, as above
2) selecting all cases in the cohort, i.e., all subjects with an outcome event of interest
3) forming a risk-set for each case and
4) *randomly* selecting one or more controls from each risk-set.

Figure 43.5 illustrates the selection of a nested case–control sample from a cohort, with one control per case (1:1 matching). It is clear from the definition of risk-sets that a future case is eligible to be a control for a prior case, as illustrated in the figure for the fourth case (the circle occurring last in time), and that a subject may be selected as a control more than once. A bias

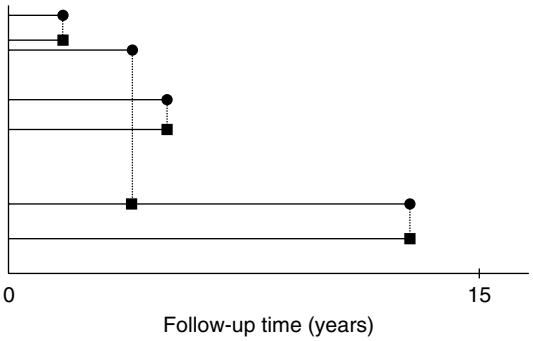

Figure 43.5 Nested case–control sample of one control (■) per case (●) from cohort in Figure 43.4.

is introduced in the estimation of the relative risk if controls are forced to be selected only from the noncases and subjects are not permitted to be used more than once in the nested case–control sample, since the control exposure prevalence will be slanted to that of longer term subjects who do not become cases during the study follow-up [13]. The magnitude of the bias depends on the frequency of the outcome event in the cohort; the more frequent the event, the larger the potential for bias.

This property leading to subjects possibly being selected more than once in the sample may be challenging when the exposure and covariate factors are time dependent, particularly when the data are obtained by questionnaire where the respondent would have to answer questions regarding multiple time points in their history. This issue arose in a study of the risks of severe adverse events in asthma associated with the use of inhaled beta-agonists [14]. A cohort of 12 301 asthmatics spanning the period 1978–87 was identified from the Saskatchewan Health computerized databases, of whom 129 were cases (death or near-death from asthma). A nested case–control approach was needed to permit the collection of additional data from hospital charts and questionnaires sent to all physicians who saw these patients. These additional data were time dependent, focusing on the two-year period prior to the index (risk-set) date. A standard nested case–control sample of six controls per case, as described above, would have likely produced some case and control subjects who contributed multiple times as controls in the sample. This would have added complexity to the questioned physicians who, for example, would have had to respond to questions about the same patient's asthma severity in different two-year periods, a potentially confusing data collection scheme. In part to circumvent this difficulty, the cohort was stratified according to various potential confounding factors, namely age, area of residence, social assistance, prior asthma hospitalization and calendar date of entry into the cohort. This fine stratification resulted in 129 mutually exclusive subcohorts, one leading to each case, and between two and eight controls per case (some risk-sets contained only two eligible controls). Since each subcohort contained a single risk-set (only one case) and the subcohorts were mutually exclusive, a selected subject was guaranteed to appear only once in the nested case–control sample.

The analysis of data from a nested case–control study must preserve the matched nature of the selection of cases and controls, particularly if the risk of the event changes with disease duration and drug exposure varies in calendar time. The method of analysis is identical to that of a conventional matched case–control study, not nested within a cohort. The conditional logistic regression method for this design is appropriate, as it uses the risk-set as the fundamental unit of analysis, in agreement with the proportional hazards model of the full cohort [15]. Simple formulae exist to estimate the relative risk for 1:1 matching [16].

The question of the required number of controls per case is important (see also Chapter 4). Although selecting one control per case will greatly simplify the data analysis, a large number of cases will be required to attain an acceptable level of power. Since the number of cases in the cohort is fixed and cannot be increased to

satisfy this requirement, the only remaining alternative is to increase the control-to-case ratio. Tables for determining the power for given numbers of controls are given in Breslow and Day [17], and Appendix A in this book. It can be readily seen from these sample size tables that the gain in power is significant for every additional control up to four controls per case, but becomes negligible beyond this ratio. For example, if we consider an exposure prevalence in the controls to be 30% and we target detecting a relative risk of 2 with 5% significance and 80% power, the required numbers of cases are 122, 90, 74, 65, and 62, respectively, for 1:1, 2:1, 4:1, 10:1, and 20:1 control-to-case ratios. These translate to total study sizes (cases and controls combined) of 244, 270, 370, 715, and 1302, with clear cost implications and related optimality decisions. Of course, the number of cases in a cohort is frequently fixed *a priori* by the study constraints, thus eliminating this option to increase the number of cases.

However, although this general rule of an optimal 4:1 control-to-case ratio is appropriate in the majority of instances, one should be prudent when exposure to the drug under study is infrequent, or when several factors or other drugs are being assessed simultaneously. In these situations, the ratio could easily be required to increase to 10 or more controls per case. This was the case in two recent nested case-control studies, within a cohort of over 40 000 patients with rheumatoid arthritis, where 100 controls per case were used to obtain sufficiently stable estimates of the rate ratios of serious hepatic events (n=25 cases) and interstitial lung disease (n=74 cases) associated with the use of disease-modifying antirheumatic drugs (DMARD) [18,19].

The appropriate method to perform external comparisons using data from a nested case–control design has been described [20]. It uses knowledge about the sampling structure to yield an unbiased estimate of the outcome event rate in the full cohort, thus permitting the estimation of the necessary standardized relative measure with respect to the selected external population.

Finally, the "nested case–control" label has led to some misunderstandings, including the usual presentation of data as a comparison between "cases" and "controls" rather than by exposure, as well as the convoluted way that forward-looking associations from exposure to outcome extracted from backward-looking data. Moreover, the nested case–control approach provides estimates of the odds ratio, not a rate difference. However, the fact that it is nested within a clearly defined cohort with known sampling fraction allows estimation of risks and rates [21]; the quasi-cohort approach utilizes this property to address these concerns [22]. A quasi-cohort approach was used to assess the risk of pneumonia associated with inhaled corticosteroids in patients with asthma [23].

The Multi-time Case–Control Design

The multi-time case–control design has been introduced recently as an alternative strategy to improve the precision of the odds ratio in a case–control study with transient time-varying exposures, in a setting where increasing the number of control subjects is too costly. This approach is based on increasing the number of observations per control subject, by measuring drug exposure at many different points in time. Indeed, several case–control studies will collect extensive data on time-dependent exposures but use only a portion of these data in estimating the rate ratio.

For example, the International Agranulocytosis and Aplastic Anemia Study (IAAAS) assessed the risk of agranulocytosis associated with the use of analgesics using a case–control study of 221 cases of agranulocytosis and 1425 controls [24]. While the study collected data on exposure for four weeks prior to the index date, only one week's worth of data was used in the analysis. The multi-time case–control approach allows the use of all available exposure data during the four weeks (i.e., four control person-moments)

rather than only one week (i.e., one control person-moment) to improve the precision of the odds ratio estimate, which must however be corrected for within-subject correlation.

This design increases the number of control observations per case, thus potentially also increasing the power of the study without adding additional subjects [25]. For example, in a nested case–control study within a cohort of 12 090 patients with chronic obstructive pulmonary disease (COPD), there were 245 incident cases of acute myocardial infarction (AMI) that occurred during follow-up, for whom one and 10 controls per case were identified [25]. The rate ratio of AMI associated with use of antibiotics in the month prior to the index date was 2.00 (95% confidence interval [CI] 1.16–3.44) with one control per case. The precision (as reflected in the confidence intervals) was improved by increasing to 10 controls per case with a rate ratio of 2.13 (95% CI 1.48–3.05). Alternatively, keeping only one control patient per case but increasing the number of control time windows per subject from one to 10 (taken as 10 control exposure measures, one for each of the 10 months prior to the index date) also improved the precision with a rate ratio of 1.99 (95% CI 1.36–2.90).

The Case–Cohort Design

The first recognized application of a sampling design we currently call case–cohort was made by Hutchison [26], in performing external comparisons of leukemia rates in patients treated by radiation for cervical cancer. It was ultimately developed and formalized by Prentice [27], who coined the name "case–cohort." Although recent, this design has already been used effectively in some drug risk studies [28–31]. The case–cohort design involves two steps:

1) selecting all cases in the cohort, i.e., all subjects with an adverse event; and
2) randomly selecting a sample of predetermined size of subjects from the cohort, irrespective of case or control status.

Figure 43.6 depicts the selection of a case–cohort sample of six subjects from the illustrative cohort. Note that it is possible that some cases selected in step 1 are also selected in the step 2 sample, as illustrated in the figure for the third case.

The case–cohort design resembles a reduced version of the cohort, with all cases from the full cohort included. It can also be perceived as an unmatched version of the nested case–control design, with all cases compared with a random sample of the cohort used as controls though not at a specific person-moment. Although these aspects suggest a possible resemblance of the data analysis approach with either the established cohort or case–control methods, the techniques are in fact distinct, each requiring specific software. The analysis of case–cohort sampled data is complex, as it must take into account the overlap of cohort members between successive risk-sets induced by this sampling strategy [32].

The first advantage of the case–cohort design is its capacity to use the same sample to study several different types of events. Indeed, the cases can be split into several subcategories and each can be analyzed with the same "control" subcohort [33]. In contrast, the nested case–control design requires different control groups for each type of event because the selection

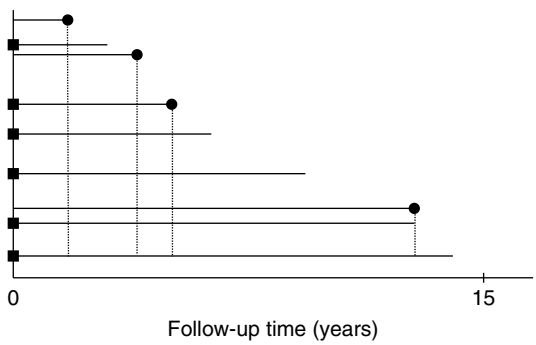

Figure 43.6 Case–cohort sample with six controls (■) from cohort in Figure 43.4.

depends on event times. For example, the beta-agonist risks nested case–control study had two distinct control groups, one of size 233 for the 44 asthma deaths, the other of size 422 for the 85 asthma near-deaths [14]. Another useful advantage is that the case–cohort design permits one to change the primary time axis of analysis from calendar to disease time and vice versa, depending on either the assumed model or the targeted outcome. This is not possible with the nested case–control study, where the primary time axis must be set *a priori* to permit the risk-set construction. This is less of a problem in pharmacoepidemiology, however, where the cohort can be divided into subcohorts of successive calendar time, as was discussed earlier. Yet another example is its simplicity in sampling, which has advantages in both comprehensibility and computer programming. Finally, external comparisons are simple to perform with the case–cohort approach [34].

The nested case–control design does have some advantages over the case-cohort design. The first is the simplicity of power calculation, or equivalently sample size determination. The nested case–control design is independent of the size of the cohort, while for the case–cohort design knowledge about overlap in risk-sets is essential, thus greatly complicating these calculations. Second, data on time-dependent exposure and covariates need only be collected up to the time of the risk-set for the nested case–control study, while the collection must be exhaustive for the case–cohort. Finally, despite the accessibility of software for data analysis of case–cohort data, these can quickly become surpassed and even infeasible with some of the huge sample sizes in some databases and multiple time-dependent exposures. In this situation, the nested case–control design, with its single risk-set per case, is not only advantageous but also the only solution. A study of benzodiazepine use and motor vehicle crashes, initially designed as a case–cohort study, had to be analyzed as a nested case–control study because of technical limitations of the case–cohort analysis software and hardware [35].

An obvious practical consideration is that the case–cohort sampling design can be used to study multiple endpoints in a single analysis (in contrast to case–control sampling) while the case–control study can easily consider many exposures. Depending on the clinical context, one might have strong preferences. As pointed out earlier, in database analyses the main use of cohort sampling designs is when additional information is needed that is time consuming or expensive to collect. If, for example, one engages in outcome validation via expensive chart review, a case–control analysis is often embedded in a cohort study [36]. On the other hand, if baseline biomarkers need to be obtained to determine patient subgroups or improve confounding control the case–cohort design is more suitable [37].

Prevalent New-User Designs

A common situation in pharmacoepidemiology involves the study of the effect of a new drug entering the market, with the best comparator being an older drug. Most often, patients prescribed the new drug will have been switched from the older comparator drug. An incident new-user cohort design based on incident new users of the study and comparator drugs, including only patients who were treatment naive to both drugs, would be optimal. However, it would exclude the possibly large number of subjects who switched from the older to the new drug, a clinically relevant subset. The prevalent new-user design provides an approach to include these switchers [38].

A prevalent new-user cohort is formed from the base cohort of all users of the comparator drug and of the drug under study, which inherently includes the subjects who switched from the comparator to the study drug those who initiated the study drug *de novo*. These latter subjects can directly be matched to contemporaneous initiators on covariates or propensity scores (see

below). For the subjects who switched from the comparator to the study drug, comparators can be selected from the base cohort by matching conditional on exposure sets. Time-based exposure sets can be defined, within the base cohort, by the time from the first prescription of the comparator drug up to the point of switching, while prescription-based exposure set are defined by the number of prescriptions of the comparator drug received up to the point of switching. Because of the granularity of the time scale, time-based exposure sets must be defined with a time interval (such as ±1 month) where all patients with a comparator prescription in the time interval belong to the exposure set and the set is defined by each patient's prescription date. Thus, with either type of exposure set, each switcher to the study drug will belong to an exposure set that includes subjects of similar duration or prescription history with a dispensing of the comparator drug. The importance of the exposure sets is that a visit occurred where the physician decided to either continue the comparator treatment or switch to the new study drug. The exposure set provides equivalent time points in the disease course at which confounding patient characteristics can be measured and controlled for.

To identify, within the exposure sets, the comparator drug users most similar to the patients who switched to the study drug, time-conditional propensity scores (TCPS) can be used [38]. The time-dependent Cox proportional hazards model can be used to compute the "propensity" of switching to the study drug, versus continuing on the comparator drug, as a function of the time-varying patient characteristics measured at the point of the exposure set, thus conserving the matching induced by the exposure set and avoiding adjusting for causal intermediates. The model is used to compute the time-conditional propensity scores within each exposure set, thus identifying their matched comparator as the one with the closest value to that of the switcher. For the purposes of the positivity assumption, the time-conditional propensity score of the switcher should lie within the range of the time-conditional propensity scores of the members of the corresponding exposure set. To emulate the randomized trial, the selection process can be initiated with the first chronological index study drug subject and repeated sequentially. Additionally, once a patient has been selected into the comparator group, they are not considered any longer in subsequent exposure sets as potential comparators. Thus, each subject who initiated the study drug will have a comparator user, matched on the time-conditional propensity score. Cohort entry is taken as the date of the first prescription of the study drug and the corresponding date for the matched comparator. If the exposure sets are too large to compute the time-conditional propensity scores by the time-varying Cox model, an alternative is to select random samples of prescriptions from each exposure set using conditional logistic regression, matching on the exposure set, with the relative odds estimating the relative hazards. The computed propensity odds score for the index switcher is used to identify the corresponding matched patient as the subject with the closest value from all members of the exposure set, not only the sampled ones.

This approach is useful for studies having a "nonuse" comparator, by using a physician visit or prescription for any drug other than the study drug as the comparator. Several questions remain regarding this design [38]. In particular, potential bias from using the prevalent users as comparators should be investigated by stratification on the incident/prevalent new-user status.

Within-Subject Designs

When dealing with the study of transient drug effects on the risk of acute adverse events, Maclure asserts that the best representatives of the source population that produced the cases would be the case subjects themselves; this is

the premise of the case–crossover design [39]. This is a design where comparisons between exposures are made within subjects, thus significantly attenuating the problem of confounding. An extension to the case–crossover design, the case–time–control design, has been proposed and is also presented here.

Case-Crossover Design

The case–crossover study is simply a crossover study *in the cases only*. The subjects alternate at varying frequencies between exposure and nonexposure to the drug of interest, until the adverse event occurs, which happens for all subjects in the study sample, since all are cases by definition. With respect to the timing of the adverse event, each case is investigated to determine whether exposure was present within the predetermined effect period, namely within the previous four hours in our example. This occurrence is then classified as having arisen either under drug exposure or nonexposure on the basis of the effect period. Thus, for each case, we have either an exposed or unexposed status, which represents for data analysis the first column of a 2 × 2 table, one for each case. Since each case will be matched to itself for comparison, the analysis is matched and thus we must create separate 2 × 2 tables for each case.

With respect to control information, the data on the average drug use pattern are necessary to determine the typical probability of exposure during the time window of effect. This is done by obtaining data for a sufficiently stable period of time. In our example, we may find out the average number of times a day each case has been using beta-agonists (two inhalations of 100 μg each) in the past year. Note that there are six four-hour periods (the duration of the effect period) in a day. Such data will determine the proportion of time that each asthmatic is usually spending time in the effect period and thus potentially "at risk" of ventricular tachycardia. This proportion is then used to obtain the number of cases expected on the basis of time spent in these "at-risk" periods, for comparison with the number of cases observed during such periods. This is done by forming a 2 × 2 table for each case, with the corresponding control data as defined above, and combining the tables using the Mantel–Haenszel technique as described in detail by Maclure [39].

To carry out a case–crossover study, three critical points must be considered. First, the study must necessarily be dealing with an acute adverse event that is alleged to be the result of a transient drug effect. Thus, drugs with chronic or regular patterns of use which vary only minimally between and within individuals are not easily amenable to this design. Nor are latent adverse events, which only occur long after exposure. Second, since a transient effect is under study, the effect period (or time window of effect) must be precisely determined. For example, in a study of the possible acute cardiotoxicity of inhaled beta-agonists in asthmatics, this effect period can be determined to be four hours after having taken the usual dose of two inhalations of 100 μg of the product. An incorrect specification of this time window can have important repercussions on the risk estimate, as we will show in the example below. Third, one must be able to obtain reliable data on the usual pattern of drug exposure for each case, over a sufficiently long period of time (as discussed further below). For our example, we could seek the frequency of use of beta-agonists during the year preceding the adverse event.

We generated data for a hypothetical case–crossover study of 10 asthmatic patients who experienced ventricular tachycardia. These were all queried (also hypothetically) regarding their use of two puffs of inhaled beta-agonist in the last four hours and on average over the past year. The data are displayed in Table 43.1. The fact of drug use within the effect period for the event classification is straightforward. The usual frequency of drug use per year is converted to a ratio of the number of "at-risk" periods to the number of "no-risk" periods, the total number of

four-hour periods being 2190 in one year. Thus, for example, the content of the 2 × 2 table for the first case, who is not found to have been exposed in the prior four-hour period, is (0,1,365,1825), while for the second case, who is exposed, it is (1,0,6,2184). Using the Mantel–Haenszel technique to combine the 10 2 × 2 tables, the estimate of relative risk is 3.0 (95% CI 1.2–7.6).

This method is sensitive to the specification of the time window of effect. For example, if this effect period is in fact only two hours, then the data of Table 43.1 would be affected in two ways: some cases may not be considered exposed any more, and the exposure probabilities will change. By considering as unexposed cases 2 and 4, for instance, who may have been exposed three hours before ventricular tachycardia, and recalculating the appropriate exposure probabilities, the relative risk becomes 2.0 (95% CI 0.3–12.0). On the other hand, if this effect period is in fact six hours long, then the data of Table 43.1 would be affected in two ways: some new cases may now be considered exposed, and the exposure probabilities will change. By considering as exposed cases 3 and 5, for instance, who may have been exposed five hours before ventricular tachycardia, and recalculating the appropriate exposure probabilities, the relative risk becomes 5.0 (95% CI 2.0–12.2). The difference in the magnitude of the risk and the corresponding statistical significance between the various scenarios is indicative of the importance of the need for an accurate specification of the length of the effect period.

This method is valuable when studying an acute adverse event that is alleged to be the result of a transient drug effect. Consequently, it excludes the study of drugs with regular patterns of use that vary minimally within individuals or adverse events which can only result from long extended exposure. Moreover, the case–crossover design requires precise knowledge about the effect period (or time window of effect), although the latter can be varied to investigate the optimum window to use. The design is also very useful when the selection of controls in the usual sense is uncertain. A significant advantage of this design is that it elimi-

Table 43.1 Hypothetical data for 10 subjects with ventricular tachycardia included in a case–crossover study of the risk of ventricular tachycardia in asthma associated with the four-hour period after beta-agonist exposure.

Case #	Beta-agonist use in last 4 hours[a] (E_i)	Usual beta-agonist use in last year	Periods of exposure (N_{1i})	Periods of no exposure (N_{0i})
1	0	1/day	365	1825
2	1	6/year	6	2184
3	0	2/day	730	1460
4	1	1/month	12	2178
5	0	4/week	208	1982
6	0	1/week	52	2138
7	0	1/month	12	2178
8	1	2/month	24	2166
9	0	2/day	730	1460
10	0	2/week	104	2086

nates the problem of confounding by factors that do not change over time. It cannot, however, easily address the problem of confounding by factors that do change over time. In this instance, time-dependent data will be required for such confounders, a possibly difficult task.

The case–crossover design is automatically free of control selection bias, which occurs when controls are not representative of the base population from which the cases arose. However, the case was inevitably different during the time period when they took the drug, from the time period when they did not take the drug. Thus, in this design, confounding by indication (see Chapter 33) can be severe. Although such control selection bias (in the usual control sense) is eliminated, case selection bias could be present if case selection is related to the exposure under study. Information bias resulting from the differential quality of recent and past drug exposure data can be a concern but less so if one uses drug exposure data from computerized databases. However, this design requires very precise knowledge of when a drug was actually taken, often a very difficult task in computerized databases, especially with drugs that are taken intermittently, exactly when this design could be useful.

Finally, the case–crossover design is intended to be used with transient exposures; otherwise estimates will be biased towards the null, as was shown empirically in a case–crossover study of the effects of long half-life benzodiazepines and the risk of motor vehicle crashes (MVC) in the elderly [40]. There were 5579 cases of MVC identified from the Province of Quebec, Canada, computerized databases. The case–crossover approach applied to all cases did not show any effect (OR 0.99; 95% CI 0.83–1.19). However, among the cases restricted to subjects with four or fewer prescriptions filled in the previous year (transient use), the odds ratio was 1.53 (95% CI 1.08–2.16]. Thus, it is important to verify this assumption of transient exposure, which may not be met in practice for drug therapies that are given for chronic conditions. This approach has been used successfully in several studies [41–45]. It has also been adapted for application to the risk assessment of vaccines (see Chapter 20) [46].

Case–Time–Control Design

One of the limitations of the case–crossover design is the assumption of the absence of a time trend in the exposure prevalence. An approach that adjusts for such time trends is the case–time–control method. By using cases and controls of a conventional case–control study as their own referents, the *case–time–control design* attempts to limit the biasing effect of unmeasured confounding factors, such as drug indication, while addressing the time trend assumption [47]. The method is an extension of the case–crossover analysis that uses, in addition to the case series, a series of control subjects to adjust for exposure time trends.

The approach is illustrated with data from the Saskatchewan Asthma Epidemiologic Project [14], a study conducted to investigate the risks associated with the use of inhaled beta-agonists in the treatment of asthma. Using a cohort of 12 301 asthmatics followed during 1980–87, 129 cases of fatal or near-fatal asthma and 655 controls were identified. The amount of beta-agonist used in the year prior to the index date was used for exposure. Table 43.2 displays the data comparing low (12 or fewer canisters per year) with high (more than 12) use of beta-agonists. The crude odds ratio for high beta-agonist use was 4.4 (95% CI 2.9–6.7). Adjustment for all available markers of severity, such as oral corticosteroids and prior asthma hospitalizations as confounding factors, lowers the odds ratio to 3.1 (95% CI 1.8–5.4), the "best" estimate one can derive from these case–control data using conventional tools.

To apply the case–time–control design, exposure to beta-agonists was obtained for the one-year current period and the one-year reference period prior to the current period. First, a

Table 43.2 Illustration of a case–time–control analysis of data from a case–control study of 129 cases of fatal or near-fatal asthma and 655 matched controls, and current beta-agonist use.

			Controls			
Cases	**High**	**Low**	**High**	**Low**	**OR**	**95% CI**
Current beta-agonist use (case–control)	93	36	241	414	3.1[b]	1.8–5.4
Discordant[a] use (case–crossover)	29	9			3.2	1.5–6.8
Discordant[a] use (control–crossover)			65	25	2.6	1.6–4.1
Case–time–control	29	9	65	25	1.2	0.5–3.0

case–crossover analysis was performed using the discordant subjects among the 129 cases, namely the 29 who were current high users of beta-agonists and low users in the reference period, and the nine cases who were current low users of beta-agonist and high users previously. This analysis is repeated for the 655 controls, of which there were 90 discordant in exposure; that is, 65 were current high users of beta-agonists and low users in the reference period, and 25 were current low users of beta-agonists and high users previously. The case–time–control odds ratio, using these discordant pairs frequencies for a paired-matched analysis, is given by (29/9)/(65/25) = 1.2 (95% CI 0.5–3.0). This estimate, which minimizes the effect of unmeasured confounding by disease severity, indicates a very small risk for these drugs.

The case–time–control approach can provide an unbiased estimate of the odds ratio in the presence of confounding by indication, despite the fact that the indication for drug use (in our example, intrinsic disease severity) is not measured, because of the within-subject analysis. It also controls for time trends in drug use. Nevertheless, its validity is subject to several assumptions, including the absence of time-dependent confounders, such as increasing asthma severity over time (an important problem, since new drugs may be more likely to be implemented when disease is most severe), so that caution is recommended in its use [48,49]. This approach has been used successfully in several studies [50–55].

Analytic Approaches for Improved Confounding Control

Balancing Patient Characteristics

Confounding caused by imbalance of patient risk factors between treatment groups is a known threat to validity in nonrandomized studies of treatment effects. A litany of options for reducing confounding is available to epidemiologists [56,57]. Several approaches fit key characteristics of longitudinal healthcare databases well and address important concerns in pharmacoepidemiologic analyses.

Propensity Score Analyses

Propensity score analysis has emerged as a convenient and effective tool for adjusting large numbers of confounders. In an incident user cohort design, a propensity score (PS) is the estimated probability of starting medication A versus starting medication B, conditional on all observed pretreatment patient characteristics. Such prediction of treatment choice based on preexisting patient characteristics fits the structure of the incident user cohort design.

Propensity scores are known as a multivariate balancing tool that balance large numbers of covariates in an efficient way even if the study outcome is rare, which is frequent in pharmacoepidemiology [58]. Estimating the propensity score using logistic regression is uncomplicated. Strategies for variable selection (i.e., the variables to include in the logistic regression model to estimate the propensity score) are well described [59]. Variables that are only predictors of treatment choice but are not independent predictors of the study outcome will lead to less precise estimates and in some extreme situations to bias [60]. Selecting variables based on *P* values is not helpful as this strategy depends on study size, and different variables would be selected or unselected for confounding adjustment if the study size changes, although the confounding effect of each variable may remain unchanged. Once a propensity score is estimated based on observed baseline covariates, there are several options to utilize it in a second step to adjust confounding. Typical strategies include adjustment for quintiles or deciles of the score with or without trimming, regression modeling of the PS, or matching on propensity scores [61]. Matching illustrates the working of propensity scores well.

Fixed ratio matching on propensity scores like 1:1 matching has several advantages that may outweigh its drawback of not utilizing the full dataset in situations where not all eligible patients match. Several matching algorithms are frequently used [62]. They have in common that for each exposed patient with a specific propensity score, one or multiple comparator patients will be picked with a propensity score that is similar within a defined caliper [63]. They vary in how they identify the best matches. Such matching will exclude patients in the extreme PS ranges where there is little clinical ambivalence in treatment choice; we therefore see little or no overlap in data (Figure 43.7). The tails of the PS distribution often harbor extreme patient scenarios caused by unobserved patient characteristics often in patients who are not representative for the majority in clinical practice. Keeping them in the analyses may lead to clinically less relevant

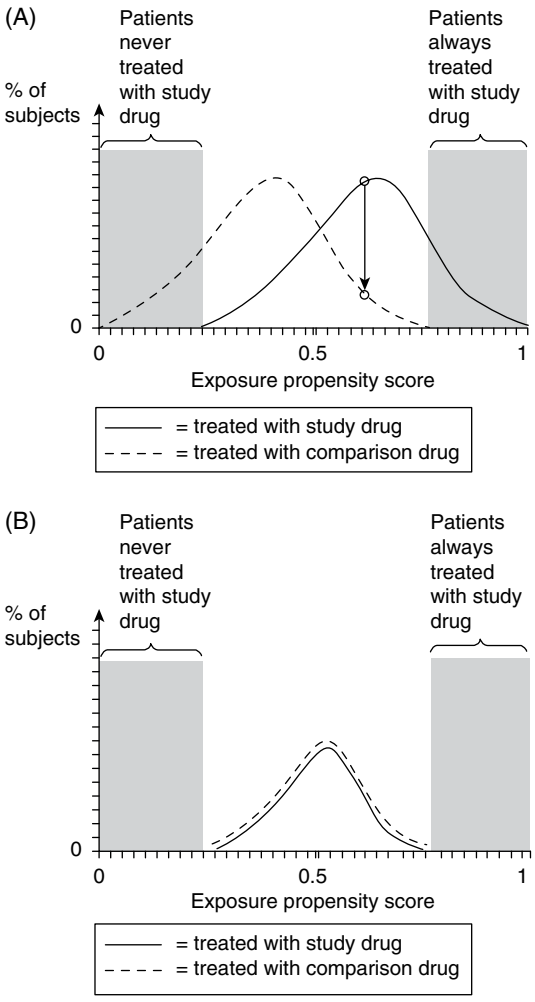

Figure 43.7 Two hypothetical propensity score distributions before and after matching. (A) Before matching: two propensity score distributions partially overlap, indicating some similarities between the comparison groups in a multivariate parameter space. (B) After 1:1 matching on propensity score: not all patients found matches that were similar enough in their multivariable characteristics. Areas of nonoverlap between PS distributions drop out entirely.

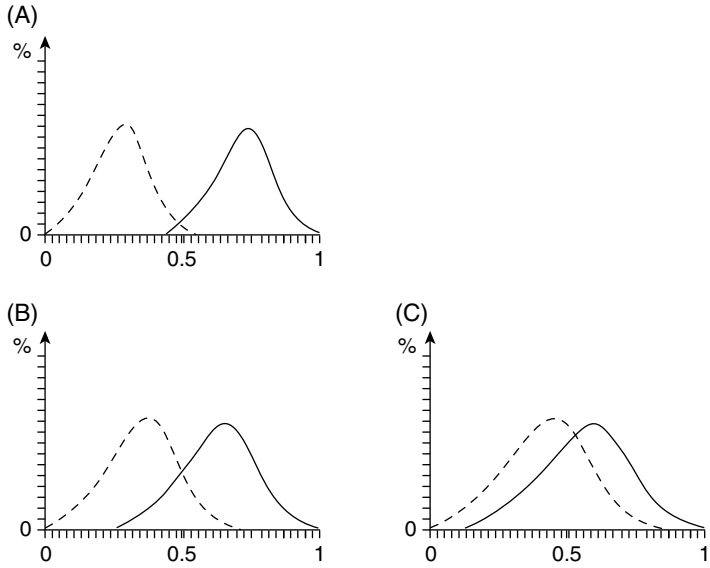

Figure 43.8 Multivariate propensity score distributions with varying degrees of overlap (A, low; B, moderate; C, high) as a diagnostic tool.

findings [64,65]. Trimming the extremes of the propensity score distributions is a data restriction strategy that generally will increase internal validity of findings [66]. Another advantage is that the multivariate balance of potential confounders can be demonstrated by cross-tabulating observed patient characteristics by actual exposure status after fixed ratio matching. 1:1 matching in cohort studies does not require matched analyses, which simplifies the effect estimation to a bivariate analysis. 1:1 matching allows inclusion of all overlapping comparator patients within a defined caliper in the analysis. However, in a variable ratio matching design the matching sets need to be preserved in the analysis to avoid bias. Analytic techniques that condition on the matching sets and may be used in this setting include conditional logistic regression or stratified Cox regression, depending on the data model.

It has been shown that on average, multivariate covariate balance will be achieved between treatment groups when matching on propensity score [67]. If a rational treatment decision process can be modeled well with observed patient characteristics, a resulting propensity score may lead to substantial or even full separation of treated and untreated patients (Figure 43.8A) [68]. This means that for patients initiated on a study drug, very few patients initiated on a comparison drug could be identified who had the same propensity for treatment given the observed patient characteristics. This would leave few comparable patients for analysis. In other words, treatment choice would be almost deterministic; little random treatment choice or empirical equipoise would be left in the prescribing decision that could be exploited for inference about the drug effect.

Consider the comparison of a fixed combination of ezetimibe and simvastatin versus simvastatin alone and their effect on coronary events as an example of such a situation. Assume that a health plan that provides the study data covers the ezetimibe/simvastatin combination only if LDL and HDL levels have crossed certain thresholds: every patient below those thresholds will use simvastatin alone. The LDL and HDL levels therefore become strong if not perfect determinants of treatment choice, and

including them in the propensity score estimation will lead to substantial or complete separation of the PS distributions of the two treatment groups. As the ezetimibe/simvastatin combination continues to be marketed, it will be used less selectively by more and more patients. Consequently, as the prescribers' treatment decisions are less disease state determined (e.g., not driven by LDL/HDL levels in the ezetimibe vs simvastatin example) and increasingly preference based, the propensity score distributions will overlap more and more as a sign that more patients are subject to treatment equipoise (Figure 43.8B,C).

If strong separation of PS distributions is observed, it indicates that the specific comparison cannot be made validly in the study population. In the above example, all ezetimibe and simvastatin users have high LDL level and hardly any simvastatin users have a comparable LDL level. Therefore, very few comparable patients are available for valid inference. This is not a limitation of the method, but rather a very insightful multivariate diagnostic describing the limitations inherent in a study population. The corresponding effect estimates from conventional multivariate outcome models will have substantial imprecision, reflecting the fact that few patients contribute to the estimation despite a large study size. Investigators may want to reconsider the comparison agent and choose a more comparable drug or use another study population where there is less treatment separation in clinical practice.

In summary, propensity score analyses are convenient tools to adjust for many covariates when study outcomes are rare. Extensive confounding adjustment is central in most pharmacoepidemiologic applications and in secondary healthcare databases we can often define many covariates in an effort to reduce the limitation of unobserved or misclassified patient characteristics. As such, PS analyses fit the needs of pharmacoepidemiologists working with longitudinal claims data well. In contrast to traditional outcome models, PS analyses allow the investigator to demonstrate the covariate balance achieved in the final study sample. Postmatching c-statistics or standardized differences of covariates have gained popularity in PS matching analyses [63,69]. PS estimation is well developed for comparing two agents using logistic regression to predict treatment choice. When more than two agents or several dose categories are compared, polytomous regression models are used to estimate the propensity score [70] and either pragmatic pairwise matching to a common reference group or multidimensional matching is applied [71]. Of importance, PS analyses adjust for measured variables, although they can be used to adjust for many at the same time some of which will be proxies for unobserved confounders [72]. Further, one loses the ability to see the effects of adjusting for one variable at a time.

In situations where exposure is rare, disease risk scores, an alternative to propensity score analysis, might be more suitable [73,74]. They estimate the association between patient factors and the study outcome in an unexposed population using multivariate regression and summarize the relationship in each patient's estimated probability of the outcome independent of exposure.

Focusing on the Analysis of Comparable Patients

Restriction is a common and effective analytic tool to make drug user groups more comparable by making populations more homogeneous, which leads to less residual confounding. Some restrictions are quite obvious since they are made by explicit criteria, for example, limiting the study population to elderly patients with dementia to study the safety of antipsychotic medications used to control behavioral disturbances in this population. Other restrictions, like PS matching, are more implicit and blur the line between design choices and analytic strategies to reduce confounding. It is important for pharmacoepidemiologists to understand the

reasons for specific restrictions and their implications for the generalizability of findings.

Choice of Comparator Group

Picking a comparator group is arguably the most fundamental choice in a pharmacoepidemiologic study design and may influence results substantially. Ideally, we want to restrict the comparison population to patients who have the identical indication as the users of the study agent in routine care. Rosiglitazone and pioglitazone are such a medication pair. They were marketed around the same time, were both indicated for second-line treatment of diabetes, come from the same class of compound, and in the early marketing phase were thought to have similar effectiveness and safety profiles. This should make treatment choice largely random with regard to patient characteristics and treatment groups comparable by design, resulting in almost overlapping propensity score distributions and little confounding (see Figure 43.8C). In individual situations, it may be that rosiglitazone-preferring physicians may treat less sick patients or independently produce better health outcomes in comparable patients. However, these physicians may or may not average out with similar pioglitazone-preferring physicians in this setting of treatment equipoise. As indications are usually recorded unreliably and frequently go beyond the labeled indications, picking a comparison drug that implicitly has the identical indication, if available, is usually more fruitful.

Limiting to Incident Users

By restricting the study population to new users of the study agent or a comparator agent, we implicitly require that both groups have been recently evaluated by a physician. Based on this evaluation, the physician has decided that the indicating condition has reached a state where a pharmacologic treatment should be initiated. Therefore, such patients are likely to be more similar in observable and unobservable characteristics than comparing incident users versus nonusers or versus ongoing users of another drug.

Matching on Patient Characteristics

Multivariate propensity scores demonstrate areas of nonoverlap where no referent patients with comparable baseline characteristics can be identified. It is recommended to remove those patients from the analysis as they are not contributing to the estimation and may introduce bias. Such a restriction can be achieved by trimming these patients from the study population [66] or by matching patients on the propensity score or on specific key patient characteristics of importance.

While restriction is an important tool to improve internal validity, it will reduce generalizability of findings. However, in pharmacoepidemiology we usually place higher value on internal validity even if that comes at the price of reduced external validity. Investigators will need to be aware of this trade-off and justify their choices accordingly.

Unobserved Patient Characteristics and Residual Confounding

Once a study is implemented, strategies to reduce confounding further are limited to observable disease risk factors. Secondary data, like electronic healthcare databases, often lack critical details on health state and risk factors, which leads to residual confounding if left unadjusted.

Proxy Adjustment

Longitudinal electronic healthcare databases are as much a description of medical sociology under financial constraints as they are records of delivered healthcare and can be analyzed as a set of proxies that indirectly describe the health status of patients [75]. This status is presented through the lenses of healthcare providers recording their findings and interventions with or without the help of professional coders and operating under the constraints of a specific healthcare system. On several steps along the

way, weighing of medical evidence and treatment options occurred; these are not observable in claims data but collectively resulted in a measurable action. A measured action like the filling of a medication has a clear interpretation but such interpretations are not always possible. In fact, in most cases we cannot determine the exact interpretation, but an exact interpretation may not be required for effective confounder adjustment. For example, old age serves as a proxy for many factors including co-morbidity, frailty, and cognitive decline; use of an oxygen canister is a sign of frail health; having regular annual check-ups is indicative of a health-seeking lifestyle and increased adherence. Adjusting for a perfect surrogate of an unmeasured factor is equivalent to adjusting for the factor itself [76].

The degree to which a surrogate is related to an unobserved or imperfectly observed confounder is proportional to the degree to which adjustment can be achieved [77,78]. Frequently used proxies in pharmacoepidemiologic analyses are the number of prescription drugs dispensed, the number of physician visits, and hospitalizations before the index drug exposure. Such measures of healthcare utilization intensity are useful proxies for general health, access to care, and surveillance. They have been shown to meaningfully help adjust for confounding [79].

Proxy adjustment can be exploited by algorithms that systematically search through recorded codes for diagnoses, procedures, equipment purchases, and drug dispensings to identify potential confounders or proxies thereof [72]. The hundreds of proxies that will be identified can then be adjusted for in a large propensity score model. Collinearity may likely occur in such large models. It will not affect estimation validity as the individual parameters estimated in the large propensity score regression will not be interpreted but only used for predicting treatment [58]; however, it may reduce precision [60]. This high-dimensional propensity score approach has been empirically shown to improve confounding adjustment in many settings over and above investigator-selected covariates [72,80–83].

While the semi-automated high-dimensional PS approach is remarkably robust, issues may arise in small studies with few exposed and rare outcomes [84,85]. Generally in such settings PS stratification is more robust [86] and variance estimates may be inflated [87]. Although adjusting for variables that are only related to the exposure and not to the outcome (an instrumental variable) could theoretically increase bias [60], in practical scenarios the advantage of adjusting for potential confounders outweighs the risk of adjusting for the rare instrument according to a recent simulation study [88]. A challenge remains that, empirically, it is very difficult to know with enough certainty whether a variable is a confounder or an instrument.

Exploiting Random Aspects in Treatment Choice Via Instrumental Variable Analysis

As explained earlier, we are interested in identifying residual random exposure variation after adjusting for observable confounders in order to more completely account for residual confounding. However, in secondary data such as longitudinal claims databases, electronic medical records, or registries, not all clinically relevant risk factors of the outcome may be recorded. To attempt to address this limitation, we can try to identify naturally occurring quasi-random treatment choices in routine care. Factors that determine such quasi-random treatment choices are called instrumental variables (IVs), and IV analyses can result in unbiased effect estimates even without observing all confounders if several assumptions are fulfilled (discussed further later).

An instructive example of an instrument is a hospital drug formulary. Some hospitals list only drug A for a given indication and other hospitals list only drug B. It is a reasonable assumption that patients do not choose their preferred hospital based on its formulary but rather on location and recommendation. Therefore, the

choice of drug A versus drug B should be independent of patient characteristics in the hospitals with these restricted formularies. Thus, comparing patient outcomes from drug A hospitals with patient outcomes from drug B hospitals should result in unbiased effects of drug A versus drug B, using the appropriate analytic tools. An example of such a study is one on the risk of death from aprotinin, an antifibrinolytic agent given to reduce bleeding during cardiac surgery [89]. The study identified surgeons who always used aprotinin and compared their outcomes to surgeons who always used aminocaproic acid, an alternative drug. If physician skill level and performance are on average equal between institutions, independent of drug use, this will result in valid findings. On the other hand, of course, such an assumption may not be valid, for example if academic hospitals allow less restrictive formularies, are more likely to see sicker patients, and have skilled physicians, all of which may be true.

Instrumental variable analyses rely on the identification of a valid instrument, a factor that is assumed to be related to treatment, but neither directly nor indirectly related to the study outcome. As such, an IV is an observed variable that causes (or is a marker of) variation in the exposure similar to random treatment choice. Typically, the following three assumptions need to be fulfilled for valid IV estimation: 1) an IV should affect treatment or be associated with treatment choice by sharing a common cause – the strength of this association is also referred to as the instrument strength; 2) an IV should be a factor that is as good as randomly assigned, so that it is unrelated to patient characteristics; and 3) an IV should not be related to the outcome other than through its association with treatment. As such, an IV analysis sounds very much like a randomized trial with noncompliance. The flip of a coin determines the instrument status (treat with A vs treat with B) and the amount of random noncompliance determines the strength of the instrument. In nonrandomized research, however, identifying valid instruments is difficult and successful IV analyses are infrequent. In principle, treatment preference can be influenced by time if treatment guidelines change rapidly and substantially. A comparison of patient outcome before versus after a sudden change in treatment patterns may then be a reasonable instrument [90,91]. Table 43.3 summarizes a list of some published IV analyses in healthcare.

More commonly, IV analyses utilize individual, local, or regional treatment preferences. For example, Brookhart *et al*. used physician prescribing preference to study the effect of analgesic treatment with COX-2 selective inhibitors (coxibs) versus nonselective NSAIDs (nsNSAID) on the risk of upper gastrointestinal (GI) bleed [93]. Many variations in defining this preference were tested and a reasonable instrument implementation turned out to be the same physician's analgesic prescription (IV status = coxib vs nsNSAID) to the previous patient who needed an analgesic [97]. The authors could demonstrate that such preference is a fairly strong instrument compared to instruments often used in economics. However, despite additional adjustment for observed patient characteristics and general quality of care [98,99], sicker patients may still cluster in coxib-preferring practices and be associated with GI bleed, which would invalidate the IV analysis. Stuckel et al. [94] used regional variation in the rate of cardiac catheterization (IV status = high vs low rate) to estimate its effect on post-MI mortality. While this regional preference instrument was weaker than the physician prescribing preference, it was argued that the instrument was more valid as it is less likely that patients would move to another region to receive the preferred care rather than simply switching their physician.

An IV analysis is technically fairly straightforward once all IV assumptions are fulfilled. In the case of a dichotomous instrument (Z) and exposure (X), the classic IV estimator is:

$$\beta_{IV} = \frac{E[Y \mid Z=1] - E[Y \mid Z=0]}{E[X \mid Z=1] - E[X \mid Z=0]}$$

Table 43.3 Selected examples of instrumental variable analyses in clinical epidemiology.

Instrument group	Instrument type	Examples
Sudden changes in treatment preference over time	Regulatory or coverage interventions	Johnston *et al.:* Beta-blocker use after heart failure hospitalization before and after 1998 [90]
	Innovations and rapid adoption	Juurlink *et al.:* Triamterene use in patients with hypertension before and after the RALES trial [91]
Provider treatment preference	Distance to specialist provider	McClellan *et al.:* Distance to cardiac cath lab facility in patients with acute myocardial infarction (MI) [92]
	Physician prescribing preference (PPP)	Brookhart *et al.:* Physician's treatment initiation choice to the preceding patient [93]
	Regional treatment preference	Stukel *et al.:* Variation of cardiac catheterization rates in 530 US regions in patients with MI [94]
	Hospital formulary/ surgeon treatment preference	Schneeweiss *et al.:* Cardiac surgeons who always use aprotinin as antifibrinolytic agent [89]
	Medication co-payment level	Cole *et al.:* Medication co-payment level in patients with heart failure and adherence [95]
	Dialysis center preference	Thamer *et al.:* Epo dosing by nonprofit vs for-profit dialysis centers [96]

where Y is the study outcome and β is a measure of the effect of X on Y [100]. The numerator of this estimator is the effect of the instrument status (coxib-preferring physician vs not) on the outcome measured as a risk difference. The denominator is the association between instrument status and actual treatment and is a measure of the strength of an instrument. In the case where the instrument perfectly predicts the treatment (e.g., in the example of a restrictive hospital formulary), then the denominator is 1 and the IV estimator will be identical to the naive risk difference estimate. As the instrument gets weaker, the denominator shrinks and the IV estimator increases relative to the naive risk difference estimate. The denominator is sometimes called a rescaling parameter as it scales up the naive risk difference estimate.

In practice, IV analyses use two-stage regression models that allow additional adjustment for multiple observed characteristics. These can be linear models to estimate risk differences or nonlinear models for risk ratio estimation [101]. Brookhart *et al*. have suggested several empirical tests to investigate the quality of an instrument in healthcare effectiveness research [4]. However, such strategies cannot test all assumptions and only help to rule out unsatisfactory IVs rather than confirm valid IVs. Fundamentally, the price of potentially unbiased estimation in IV analyses is the ultimately untestable assumptions that the authors will have to argue based on substantive knowledge and some empirical data. Because of the two-stage estimation, IV analyses are generally less precise which can, in some situations, severely reduce their utility for decision making. Users should also be cautioned that IV inference is based on those "marginal" patients whose treatment decision is influenced by the IV status. This concept is somewhat similar to propensity score analyses where only patients in the overlapping area of propensity score distributions contribute to the multivariate analysis. The IV analyses make an assumption of random treatment choice based on the nature of the healthcare system while

propensity score estimation is trying to utilize unexplained random treatment variation that is left after adjusting for all measured confounders.

Supplementing Database Studies with Clinically Rich Data on Potential Confounders

Resources and time permitting, another strategy to mitigate residual confounding is to identify a subsample and observe among a small number of patients detailed information on potential confounders (see sections earlier). A common version thereof is the nested case–control design or the case–cohort design where only a sample of controls or a sample of exposed and unexposed will be used to collect detailed confounder information. Eng *et al.* demonstrated the use of a case–cohort design embedded in a much larger claims-based analysis [102]. The two-stage sampling approach samples patients according to their exposure and outcome status simultaneously and then reweights findings [103]. Collet *et al.* demonstrated two-stage sampling in a Canadian healthcare database [104]. Increasingly, it is possible to link information-rich electronic health records or registry data in subsets of patients of large claims data studies. It is used to demonstrate that balance had been achieved in patient characteristics that were not observable in claims data [102]. In a new-user cohort study of oral antidiabetic medications with propensity score matching, it was demonstrated that laboratory test results, BMI, and duration of diabetes were well balanced although these parameters were only observable in the subset of EHR-linked patients and not part of the claims data analysis [105]. Such a process is less resource intensive and can be routinely applied in the right data environment.

From the perspective of secondary database studies, all these approaches can be described as internal validation studies, as patients are identified within the underlying study cohort and then contacted to retrieve more details on patient characteristics [106]. The advantage of these approaches is that they are tailored towards the specific question at hand, that is, the sampling as well as the confounder information of interest can be defined by the investigator. However, these approaches are operationally not necessarily efficient ways to collect information. They are often time-consuming since patients need to be identified and information needs to be collected.

An alternative approach is to utilize detailed confounder information that was already collected and then can be tied into the adjusted analysis of the main study cohort. If additional information is available elsewhere, such as a routinely conducted survey of a representative sample of the main database study, such external data sources can be used for reducing residual confounding under certain assumptions [107,108]. For example, each year the Medicare Current Beneficiary Survey routinely studies a representative sample of Medicare beneficiaries to measure a wide variety of characteristics that are not captured in Medicare claims data, for example limitations in activities of daily living [109], cognitive impairment, and physical impairments [110]. If such surveys are truly representative of the study cohort and data are already collected then such external adjustment has the advantage of being much faster and less costly. As the exact study question is not known when the external survey is conducted, it is recommendable to include a wide battery of patient characteristics in the questionnaire.

The available algebraic methods for such external adjustment [108] are limited to single binary confounders and cannot consider the joint confounding arising from several factors. These methods were recently extended to adjustment for multiple confounders of any scale using propensity score calibration (PSC) [111]. The basic concept of PSC is to estimate two multivariate propensity scores in the information-rich survey. One PS mimics the information available in the main study and is seen as an error-prone PS. The second PS uses all available information and is called the complete PS. By regressing the error-prone PS on the complete PS, a calibration factor can be estimated.

With this factor, the error-prone PS-adjusted result in the main study will be calibrated to produce results that are adjusted for the additional factors only available in the more detailed survey data using established regression calibration techniques [112]. Simulation studies have demonstrated good performance of PSC assuming that the relevant confounders were captured in the survey and the survey is representative of the main study [113]. PSC methods can be extended to other than survey data, including electronic medical records or disease registries.

Sensitivity Analyses

A series of sensitivity analyses can help investigators to better understand how robust a study's findings are to implicit and explicit assumptions. Some of the sensitivity analyses suggested below are generic and others are specific to database analyses.

An important but underutilized diagnostic tool for the impact of unobserved confounders on the validity of findings in nonrandomized studies is quantitative sensitivity analyses. Basic sensitivity analyses of residual confounding try to determine how strong and how imbalanced a confounder would have to be among drug categories to explain the observed effect. Such an "externally" adjusted relative risk (RR_{adj}) can be expressed as a function of the unadjusted relative risk (RR_{unadj}), the independent RR of the unmeasured confounder on the disease outcome (RR_{CD}), and the prevalence of the confounder in both drug exposure categories ($P_{C|E}$) [16]:

$$RR_{adj.} = \frac{RR_{unadj}}{\left[\frac{P_{C|E=1}\left(RR_{CD}-1\right)+1}{P_{C|E=0}\left(RR_{CD}-1\right)+1}\right]}$$

A recent cohort study could not find the expected association between use of TNF-alpha inhibitors, an immunomodulating agent, in treating rheumatoid arthritis, and the incidence of serious bacterial infections. There was a concern that physicians may have prescribed the agent selectively in patients with more progressive disease. A sensitivity analysis demonstrated the direction and strength of any such bias and concluded that it would be unlikely to change the clinical implications of the study [114]. This type of sensitivity analysis is particularly helpful in database studies, but is underutilized. Spreadsheet software is available for easy implementation of such sensitivity analyses (drugepi.org) [115]. Lash and Fink proposed an approach that considers several systematic errors simultaneously, allowing sensitivity analyses for confounding, misclassification, and selection bias in one process [116].

When using retrospective databases, it is usually cumbersome or impossible to contact patients and ask when they began using a drug for the first time in order to implement an incident user cohort design. Therefore, incident users are identified empirically by a drug dispensing that was not preceded by a dispensing of the same drug for a defined time period. This washout period is identical for all patients. A typical length is six months. In sensitivity analyses, this interval could be extended to nine and 12 months. In a study on the comparative safety of antidepressant agents in children in British Columbia, this interval was extended from one year to three years to ensure that the children in the study were treatment naive before their first use, which helped balance comparison groups and reduce confounding [117]. Although increasing the length of the washout increases the likelihood that patients are truly incident users, it also reduces the number of patients eligible for the study. This trade-off is particularly worth noting in health plans with high enrollee turnover.

There is often uncertainty about the correct definition of the exposure risk window based on the clinical pharmacology of the study agent. This is further complicated in healthcare databases, since the discontinuation date is imputed through the days' supply of the last dispensing/prescription. Varying the exposure risk window

is therefore insightful and easy to accomplish in cohort studies [118].

Another set of sensitivity analyses concerns the potential for informative censoring. Patients change and discontinue treatment because they lack a treatment effect or experience early signs of a side effect. The more strongly such nonadherence (i.e., drug switching or discontinuation) is associated with the outcome, the more an as-treated analysis, which censors at the point of discontinuation, will be biased. A cumulative risk analysis follows all patients for a fixed time period, carrying forward the initial exposure status and disregarding any changes in treatment status over time. Because this analysis disregards informative nonadherence, it will not suffer bias as a consequence of censoring, but it will suffer bias as a consequence of exposure misclassification. Such misclassification increases with a longer follow-up period and a shorter average time to discontinuation. In most cases, though not all, such misclassification will bias effects towards the null, similar to intention-to-treat analyses in randomized trials. Viewed separately, these two analysis types trade different biases but together, they give a range of plausible effect estimates. Adjusting for nonadherence in an analysis of a drug effect requires information about the predictors of treatment discontinuation [119,120], which is often not available with sufficient accuracy in pharmacoepidemiologic studies.

The Future

Minimizing confounding in nonrandomized pharmacoepidemiologic research is an ongoing development. While great progress has been made in analyzing longitudinal healthcare databases, much remains to be improved in order to reliably achieve unbiased estimates that will carry the weight of medical decision making. Several developments are promising. One is the use of instrumental variable analyses utilizing the multilevel structure of healthcare systems. Another is the expanded use of propensity score methods, including its combination with data-mining activities for high-dimensional proxy adjustment. A development that is gaining importance is the enrichment of existing data environments with supplemental clinical data linked from electronic medical records, disease registries, patient surveys, and/or laboratory test result repositories. While this information will provide an opportunity for improved confounding adjustment, it comes with equally large methodologic challenges, as information is collected in routine care and may have been requested/recorded selectively in patients who were thought to benefit most. Clearly, there is still plenty of work to be done to find satisfactory solutions for the control of confounding in the broad range of pharmacoepidemiologic research.

> *We should all be concerned about the future because we will have to spend the rest of our lives there.*
>
> (Charles Franklin Kettering, 1949)

Speculating about the future is at least risky and possibly foolish. Nevertheless, the future of pharmacoepidemiology seems apparent in many ways, judging from past trends and recent events. Interest in the field by the pharmaceutical industry, government agencies, new trainees, and the public continues to grow, as does realization of what pharmacoepidemiology can contribute. Indeed, international attention on drug safety remains high, important safety questions involving widely used drugs continue to emerge, and questions concerning the effectiveness of systems of drug approval and drug safety monitoring remain.

As the functions of academia, industry, and government have become increasingly global, so has the field of pharmacoepidemiology. The number of individuals attending the annual International Conference on Pharmacoepidemiology has increased from approximately 50 in the early 1980s to over 1800 in 2019. The International Society for Pharmacoepidemiology (ISPE), established in 1991, has grown to approximately 1500 members from over 60 countries. It developed a set of guidelines for Good Epidemiologic Practices for Drug, Device, and Vaccine Research in the United States in 1996 [1], and updated these guidelines most recently in 2016 as the ISPE Guidelines for Good Pharmacoepidemiology Practices [2]. Many national pharmacoepidemiologic societies have been formed as well. The journal *Clinical Pharmacology and Therapeutics*, the major US academic clinical pharmacology journal, actively solicits pharmacoepidemiologic manuscripts, as did the *Journal of Clinical Epidemiology*. The major journal devoted to the field, *Pharmacoepidemiology and Drug Safety*, ISPE's official journal, is indexed on Medline and achieved an impact factor of 2.314 in 2018, remarkably high for a niche field. Other journals have been formed to copy and compete with it.

The number of individuals seeking to enter the field continues to increase, as does their level of training. The number of programs of study in pharmacoepidemiology is increasing in schools of medicine, public health, and pharmacy. While in the 1980s the single summer short course in pharmacoepidemiology at the University of Minnesota was sometimes cancelled because of

Pharmacoepidemiology, Sixth Edition. Edited by Brian L. Strom, Stephen E. Kimmel and Sean Hennessy.

insufficient interest, later the University of Michigan School of Public Health summer course in pharmacoepidemiology attracted 10% of all students in the entire summer program, and now McGill University, Erasmus University Rotterdam, Utrecht University, and the Johns Hopkins Bloomberg School of Public Health all conduct summer short courses in pharmacoepidemiology. Several other short courses are given as well, including by ISPE itself which has seen a massive increase in preconference courses offered over the years. Regulatory bodies around the world have expanded their internal pharmacoepidemiologic programs. The number of pharmaceutical companies with their own pharmacoepidemiologic units has also increased, along with their support for academic units and their funding of external pharmacoepidemiologic studies. Requirements that a drug be shown to be cost-effective (see Chapter 34) have been added to many national and provincial healthcare systems, and managed care organizations, either to justify reimbursement or even to justify drug availability. Drug utilization review is being widely applied (see Chapter 19), and many hospitals are becoming mini-pharmacoepidemiologic practice and research laboratories.

The US Congress has recognized the importance of pharmacoepidemiology, requiring the FDA to build a new data resource, containing at least 100 million lives, for evaluating potential adverse effects of medical products (see Chapter 25), and most recently passing the 21st Century Cures Act, encouraging the wide use of "real-world evidence." The latter has been deemed to range from traditional pharmacoepidemiology data sources like claims and medical record databases, and even *ad hoc* pharmacoepidemiology studies (see Part III), to novel data sources like e-health tools, m-health tools, and other wearable devices, as well as pragmatic trials using traditional pharmacoepidemiology databases to collect outcomes (see Chapter 32). The future is likely to see a marked expansion of these novel, technology-driven approaches.

Thus, from the perspective of those in the field, the trends in pharmacoepidemiology are remarkably positive, although many important challenges remain. In this chapter, we will briefly give our own view on the future of pharmacoepidemiology. Following the format of Part II of the book, we explore this future from the perspectives of academia, the pharmaceutical industry, regulatory agencies, and then the law.

The View from Academia

Scientific Developments

Methodologic Advances

Methodologically, the array of approaches available for performing pharmacoepidemiologic studies will continue to grow. Each of the methodologic issues discussed in Part V can be expected to be the subject of further research and development. The future is likely to see ever more advanced ways of performing and analyzing epidemiologic studies across all content areas, as the field of epidemiology continues to expand and develop. Some of these new techniques will, of course, be particularly useful to investigators in pharmacoepidemiology (see, for example, Chapter 43). The next few years will likely see continued expanded use of propensity scores, instrumental variables, the trend-in-trend design, sensitivity analysis, and novel methods to analyze time-varying exposures and confounders. In addition, we believe that we will see increasing application of pharmacoepidemiologic insight in the conduct of clinical trials, as well as increased use of the randomized trial design to examine questions traditionally addressed by observational pharmacoepidemiology (see Chapter 32), especially given the controversies resulting from inconsistencies between nonexperimental studies and experimental studies, and given the emerging field of comparative effectiveness research (see Chapter 26).

Drug regulators have enthusiastically embraced therapeutic risk management (see Chapter 24). Yet, this field is still very much in its infancy, with an enormous amount of work needed to develop new methods to measure, communicate, and manage the risks and benefits associated with medication use. Rigorous studies (i.e., program evaluations) of the effectiveness of risk management programs remain the exception rather than the rule. Development of this area will require considerable effort from pharmacoepidemiologists as well as those from other fields.

We may see developments in the processes used to assess causality from individual case reports (see Chapters 10 and 29). Data mining approaches will be used increasingly in spontaneous reporting databases to search for early signals of adverse reactions (see Chapter 27). Hopefully, we will see studies evaluating the utility of such approaches. The need for newer methods to screen for potential adverse drug effects, such as those using healthcare claims or medical record data and data from social media, is also clear.

We are likely to see increasing input from pharmacoepidemiologists into policy questions about drug approval (see Chapter 8), with new attention to applying pharmacoepidemiology in the study of the growing opiate epidemic (see Chapter 28). We anticipate that emphasis will shift from studies evaluating whether a given drug is associated with an increased risk of a given event to those that also examine patient- and regimen-specific factors that affect risk [3] (see also Chapters 24, 26, and 42). Such studies are crucial because, if risk factors for adverse reactions can be better understood before a safety crisis occurs, or early in the course of a crisis, then the clinical use of the drug may be able to be repositioned, avoiding the loss of useful drugs (see Chapters 24, 30, 35, and 39).

With recent developments in molecular biology and bioinformatics, and their application to the study of pharmacogenetics, the ability of researchers to identify biologic factors that predispose patients to adverse drug reactions has increased [4] (see Chapter 30). However, few of these discoveries have yet been shown useful in improving patient care, and new studies and methods must be pursued to determine the clinical utility of genetic testing. Pharmacogenetics has evolved from studies of measures of slow drug metabolism as a contributor to adverse reactions [5] to the study of molecular genetic markers [6–9]. This has been aided by the development of new, noninvasive methods to collect and analyze biosamples, making population-based genetic studies feasible. We believe that clinical measurement of biologic factors will ultimately complement existing approaches to tailoring therapeutic approaches for individual patients. However, it is unlikely that genotype will be the only, or even the major, factor that determines the optimal drug or dose for a given patient.

Future years are likely to see much more of this cross-fertilization between pharmacoepidemiology and molecular biology, and newer forms of "-omics" such as the microbiome. From a research perspective, we can easily envision pharmacogenetic studies added to the process of evaluating potential adverse reactions. We also anticipate the availability of genotypic information for members of large patient cohorts for whom drug exposures and clinical outcomes are recorded electronically, and even for selected patients from electronic data systems, such as those described in Part IIIb of this book.

New Content Areas of Interest

In addition, there are a number of new content areas that are likely to be explored more. Studies of drug utilization will continue to become more innovative (see Chapter 18). Particularly as the healthcare industry becomes more sensitive to the possibility of overutilization, underutilization, and inappropriate utilization of drugs, and the risks associated with each, one would expect

to see an increased frequency of and sophistication in drug utilization review programs, which seek to improve care (see Chapter 19), potentially incorporating techniques from molecular pharmacoepidemiology (see Chapter 30).

The US Joint Commission on Accreditation of Healthcare Organizations revolutionized US hospital pharmacoepidemiology through its standards requiring adverse drug reaction surveillance and drug use evaluation program in every hospital [10,11]. Hospitals are also now experimenting with different methods of organizing their drug delivery systems to improve their use of drugs, for example through use of computerized clinical decision support and the addition of pharmacists to patient care teams [12] (see Chapter 41).

Interest in the field of pharmacoeconomics, that is, application of the principles of health economics to the study of drug effects, is continuing (see Chapter 34). Society is realizing that the acquisition cost of drugs is often a very minor part of their economic impact, and that their beneficial and harmful effects can be vastly more important. Further, more governments and insurance programs are increasingly requiring economic justification before permitting reimbursement for a drug. As a result, the number of studies exploring this is increasing. As the methods of pharmacoeconomics become increasingly sophisticated, and its applications clear, this could be expected to continue to be a popular field of inquiry.

More nonexperimental studies of beneficial drug effects, particularly of drug effectiveness, can be expected, as the field becomes more aware that such studies are possible (see Chapter 33). This is being encouraged by the rapid increase in the use of propensity scores to adjust for measured covariates, although investigators using this method often place more confidence in that technique than is warranted, some not recognizing that its ability to control for confounding by indication remains dependent on one's ability to *measure* the true determinants of exposure (see Chapter 43). It is also being encouraged by the development of comparative effectiveness research (see Chapter 26). Other approaches to controlling for confounding are similarly likely to become more common as they are further developed (see Chapter 43). New analytic approaches, like machine learning, artificial intelligence, and cognitive computing, are also likely to make their way into pharmacoepidemiology studies.

We will also see more use of pharmacoepidemiologic approaches prior to drug approval, for example to understand the baseline rate of adverse events that one can expect to see in patients who will eventually be treated with a new drug (see Chapter 7).

Recent years have seen an explosion in the worldwide use of herbal and other complementary and alternative medications. These are essentially pharmaceuticals sold without conventional standardization, and with no required premarketing testing of safety or efficacy. In a sense, for these products, this is a return to a preregulatory era. Therefore, it is quite likely that the next few years will see an analogous set of safety concerns associated with their use, and society will turn to pharmacoepidemiologists to help evaluate the use and effects of these products. Of course, if regulatory oversight is decreased in some countries, as has been suggested in the US, the same could occur with traditional medications.

Research interest in the entire topic of patient nonadherence with prescribed drug regimens goes back to about 1960, but little fruitful research could be done because methods for ascertaining drug exposure in individual ambulatory patients were grossly unsatisfactory [13]. This problem has been mitigated greatly by advances in incorporating time-stamping microcircuitry into pharmaceutical containers, which records the date and time whenever the container is opened [14]. Perhaps as a consequence of its inherent simplicity and economy, electronic monitoring is increasingly emerging

as the *de facto* gold standard for compiling dosing histories of ambulatory patients, from which one can evaluate the extent of adherence to the prescribed drug regimen. Future years are likely to see a continuing increase in the use of this technique (see Chapter 38) in research, and perhaps in clinical practice. Perhaps equally importantly, new methods of measuring adherence that do not rely on purchasing and using alternative sources of drug dispensing, such as smartphone-based measures of pill taking, may expand our ability to measure adherence in real-world epidemiology studies.

The next few years are also likely to see the increasing ability to target drug therapy to the proper patients. This will involve increasing use of both statistical methods and laboratory techniques from other biological sciences, as described above. Statistical approaches will allow us to use predictive modeling to study, from a population perspective, who is most likely to derive benefit from a drug, and who is at greatest risk of an adverse outcome. Laboratory science will enable us to measure individuals' genotypes, to predict responses to drug therapy (i.e., molecular susceptibility). From the perspective of preapproval testing, these developments may allow researchers to target specific patient types for enrollment into their studies, those subjects most likely to succeed with a drug. From a clinical perspective, it will enable healthcare providers to incorporate biological factors in the individualization of choice of regimens.

The past few years have seen the increased use of surrogate markers, presumed to represent greater risk of rarer serious adverse effects when drugs are used in broader numbers of patients. These range from mild liver function test abnormalities, used as predictors of serious liver toxicity, to electrocardiographic QTc prolongation as a marker of risk of suffering the arrhythmia torsades de pointes, which can lead to death. Indeed, some drugs have been removed from the market, or from development, because of the presence of these surrogate markers. Yet the utility of these markers as predictors of serious clinical outcomes is poorly studied. The next few years are likely to see the increased use of both very large observational studies and large simple trials after marketing, to study important clinical outcomes (see Chapters 32 and 36).

In addition, with the growth of concerns about patient safety (see Chapter 41), there has been more attention to simultaneous use of pairs of drugs that have been shown in pharmacokinetic studies (see Chapter 2) to cause increased or decreased drug levels. Yet population studies informing the clinical importance and pharmacologic aspects of drug–drug interactions have only been performed in the past few years (see Chapter 40). The next few years are likely to see the emergence of more studies to address such questions.

Finally, in the last few years, society has increasingly turned to pharmacoepidemiology for input into major policy decisions. For example, pharmacoepidemiology played a major role in the evaluations by the Institute of Medicine of the US National Academy of Sciences of the anthrax vaccine [15] (deciding whether the existing vaccine was safe to use and, thereby, whether the military vaccine program should be restarted) and the smallpox vaccine program (deciding the shape of the program intended initially to vaccinate the entire US population) [16]. This is likely to occur even more often in the future.

Logistical Advances

Logistically, with the increased computerization of data in society in general and within healthcare in particular, and the increased emphasis on using electronic databases for pharmacoepidemiology [17] (see Part IIIb), some data resources will disappear (e.g., the Rhode Island Drug Use Reporting System and the inpatient databases discussed in prior editions of this book have disappeared, with new ones added,

and Group Health of Puget Sound has become less commonly used as a data resource, as much larger databases have emerged), and a number of new computerized databases have emerged as major resources for pharmacoepidemiologic research, such as commercial insurance databases (see Chapter 12), inpatient databases (see Chapter 14), and the databases from Ontario and Denmark (see Chapter 12). The importance of these databases to pharmacoepidemiology is now clear: they enable researchers to address, quickly and relatively inexpensively, questions about drug effects in different settings that require large sample sizes, with excellent quality data on drug exposures. Registries (see Chapter 16) will also become increasingly important for pharmacoepidemiologic research. With the initiation of US Medicare Part D in 2006, which provides prescription drug coverage to US Medicare recipients, the availability of this data resource is potentially "game changing" for hypothesis testing studies, as it is so large relative to other resources; nearly 27 million Medicare beneficiaries were already subscribed to Part D coverage in 2009 [18] (see Chapter 12). It has created an enormous new data resource for pharmacoepidemiology, as well as increased interest from the US government in what pharmacoepidemiology can do. The development of the FDA's Sentinel Initiative [19] (see Chapter 25) has similarly provided a vast new data resource, initially intended for hypothesis generating, and more recently used for hypothesis strengthening and testing.

Nevertheless, even as the use of databases increases, it is important to keep in mind the importance of studies that collect data *de novo* (see Chapter 16). Each approach to pharmacoepidemiology has its advantages and its disadvantages, as described in Part III. No approach is ideal in all circumstances, and often a number of complementary approaches are needed to answer any given research question (see Chapter 17). To address some of the problems inherent in any database, we must maintain the ability to perform *ad hoc* studies as well (see Chapter 16). Perhaps better, less expensive, and complementary approaches to *ad hoc* data collection in pharmacoepidemiology will be developed. For example, a potential approach that has not been widely used is the network of regional and national poison control centers. In particular, poison control centers would be expected to be a useful source of information about dose-dependent adverse drug effects.

Of critical importance, there is increasing concern about patient privacy in many countries. The regulatory framework for human research is actively changing in the process, such as Europe's new data protection law. As discussed in Chapter 31, this is already beginning to make pharmacoepidemiologic research more difficult, whether it affects access to medical records in database studies or access to a list of possible cases with a disease to enroll in *ad hoc* case–control studies. This will be an area of great interest and rapid activity over the next few years as electronic health records become much more commonplace, and one in which the field of pharmacoepidemiology will need to remain very active or risk considerable interference with its activities.

It is likely that new types of research opportunities will emerge. For example, as the US finally implemented a drug benefit as part of Medicare, its health program for the elderly, US government drug expenditures suddenly increased by $49.5 billion in 2007 [20]. Outside the US, many different opportunities to form databases are being developed. There is also increased interest in the importance of pharmacoepidemiology in the developing world. Many developing world countries spend a disproportionate amount of their healthcare resources on drugs [21], yet these drugs are often used inappropriately [22]. There have been a number of initiatives in response to this, including the World Health Organization's development of its list of Essential Drugs [23,24].

Funding

For a number of years, academic pharmacoepidemiology suffered from limited research funding opportunities. In the early 1980s, the only available US funding for the field was an extramural funding program from the FDA with a total of $1 million/year. Industry interest and support were similarly limited. With growing interest in the field, this situation appears to be changing rapidly. The FDA has expanded its internal pharmacoepidemiology program and the US National Institutes of Health (NIH) is funding pharmacoepidemiologic studies. In the US, other funding now comes from the Agency for Health Care Research and Quality (AHRQ), and from the Patient-Centered Outcomes Research Institute (PCORI), created as part of the Affordable Care Act. Much industry funding is available, as the perceived need for the field within industry grows (see below). This is likely to increase, especially as the FDA more often requires industry to perform postmarketing studies, and with the legislative mandate for the FDA to pay more attention to "real-world evidence."

There is, of course, a risk associated with academic groups becoming too dependent on industry funding, in terms of both choice of study questions and credibility. Fortunately, in the US, the AHRQ has begun to fund pharmacoepidemiologic research as well, as part of an initiative in pharmaceutical outcomes research. In particular, the AHRQ Centers for Education and Research on Therapeutics (CERTs) program provided federal support for ongoing pharmacoepidemiologic activities (see Chapter 6). While still small relative to industry expenditures on research, it was large relative to the US federal funding previously available for pharmacoepidemiology. Similar programs have now been started in Europe and Canada. Unfortunately, the CERTs program has ended and the future of the AHRQ itself is always in question.

Even the US NIH now funds pharmacoepidemiologic projects more often. The NIH is the logical major source for such support, as it is the major funding source for most basic biomedical research in the US. Its funds are also accessible to investigators outside the US, via the same application procedures. However, the NIH's current organizational structure represents an obstacle to pharmacoepidemiologic support. In general, the institutes within the NIH are organized by organ system.

Earlier in the development of pharmacoepidemiology, the National Institute of General Medical Sciences (NIGMS) provided most of the US government support for our field. It remains, conceptually, perhaps the most appropriate source of such support, since it is intended to fund projects that are not specific to an organ system, and it is the institute that funds clinical pharmacologic research. However, over the past few years there has been limited funding from the NIGMS for epidemiologic research. A notable exception was the NIGMS-funded Pharmacogenetics Research Network (PGRN), which has now been disbanded. In the meantime, NIH funding continues to be available if one tailors a project to fit an organ system or in some other way fits the priorities of one of the individual institutes, such as the National Institute on Aging or the National Institute of Child Health and Human Development.

Personnel

With the major increase in interest in the field of pharmacoepidemiology, accompanied by an increased number of funding opportunities, a major remaining problem, aggravated by the other trends, is one of inadequate personnel resources. There is a desperate need for more well-trained people in the field, with employment opportunities available in academia, industry, and government agencies. Some early attempts were made to address this. The Burroughs Wellcome Foundation created the Burroughs Wellcome

Scholar Award in Pharmacoepidemiology, a faculty development award designed to bring new people into the field. This program did not provide an opportunity for fellowship training of entry-level individuals but was designed for more experienced investigators. Unfortunately, it is no longer active.

Outside government, training opportunities are limited. In the US, the NIH is the major source of support for scientific training but as noted above, the NIGMS, which funds training programs in clinical pharmacology, now supports one program in pharmacoepidemiology, while the National Heart, Lung and Blood Institute supports another. The National Institute of Child Health and Human Development also has funded limited training in pediatric pharmacoepidemiology. However, pharmacoepidemiologic training is still too dependent on nonfederal sources of funds, especially at a time when such funding is becoming harder to obtain.

There is a growing number of institutions now capable of carrying out such training, for example universities with faculty members interested in pharmacoepidemiology, including those with clinical research training programs supported by, for example, an NIH Clinical and Translational Science Award and organ system-specific training grants. Young scientists interested in undergoing training in pharmacoepidemiology, however, can only do so if they happen to qualify for support from such programs. No ongoing support is normally available from these programs for training in pharmacoepidemiology *per se*. This was addressed in the past primarily through the leadership and generosity of some pharmaceutical companies. Much more is needed, however. Fortunately, with the rapid rise in interest in comparative effectiveness research (see Chapter 26), additional training support emerged from both the NIH and AHRQ/PCORI, but this is now in question going forward. Further, the focus on comparative effectiveness research (see Chapter 26) and patient engagement and patient-reported outcomes (see Chapter 42) triggered by the PCORI are in doubt now, as PCORI was created by the Affordable Care Act which is itself at risk.

The View from Industry

It appears that the role of pharmacoepidemiology in industry is expanding rapidly. All that was said above about the future of pharmacoepidemiology scientifically, as it relates to academia (see Chapter 6), obviously relates to industry as well (see Chapter 7). The necessity of pharmacoepidemiology has become apparent to many of those in industry. In addition to being useful for exploring the effects of their drugs, manufacturers are beginning to realize that the field can contribute not only to identifying problems but also to documenting drug safety and developing and evaluating risk management programs. An increasing number of manufacturers are mounting pharmacoepidemiologic studies "prophylactically," to have safety data available in advance of when crises may occur. Proper practice would argue for postmarketing studies for all newly marketed drugs used for chronic diseases, and all drugs expected to be either pharmacologically novel or sales blockbusters, because of the unique risks that these situations present. Pharmacoepidemiology also can be used for measuring beneficial drug effects (see Chapter 33) and even for marketing purposes, in the form of descriptive market research and analyses of the effects of marketing efforts.

Perhaps most importantly for the industry's financial bottom line, pharmacoepidemiologic studies can be used to protect the major investment made in developing a new drug against false allegations of adverse effects, protecting good drugs for a public that needs them. Further, even if a drug is found to have a safety problem, the legal liability of the company may be diminished if the company has, from the outset, been forthright in its efforts to learn about that drug's

risks. Finally, as noted in Chapter 1 and above, the FDA now has new authority to require postmarketing pharmacoepidemiologic studies, and a new charge to focus on "real-world evidence," so one can expect to see much more required of industry by regulators.

Industry is always interested in predictability. With that, there is increased interest in developing a formulaic approach to risk–benefit assessment (see Chapter 35). The next few years are likely to see considerable additional work in this area.

In light of these advantages, most major pharmaceutical firms have formed their own pharmacoepidemiologic units. Of course, this then means that industry confronts and, in fact, aggravates the problem of an insufficient number of well-trained personnel. Many pharmaceutical companies increased their investment in external pharmacoepidemiologic data resources, so that they will be available for research when crises arise. This has been declining, however. A risk of the growth in the number of pharmacoepidemiologic studies for industry is the generation of an increased number of false signals about harmful drug effects. This is best addressed by having adequately trained individuals in the field, and by having personnel and data resources available to address these questions quickly, responsibly, and effectively, when they are raised.

The View from Regulatory Agencies

It appears that the role of pharmacoepidemiology in regulatory agencies is also expanding (see Chapter 8). Again, all of what was said above about the future of pharmacoepidemiology scientifically, as it relates to academia, obviously relates to regulatory agencies as well. In addition, there have been a large number of major drug crises, many described throughout this book. Many of these crises resulted in the removal of the drugs from the market. The need for and importance of pharmacoepidemiologic studies have become clear. Again, this can be expected to continue in the future. It has even been suggested that postmarketing pharmacoepidemiologic studies might replace some premarketing Phase III studies in selected situations, as was done with zidovudine [25]. As noted, regulatory agencies are being given increased authority to require such studies after marketing. They are also expanding their pharmacoepidemiologic staffing, and seeking training in pharmacoepidemiology for those already employed by the agencies.

We are also seeing increasing governmental activity and interest in pharmacoepidemiology, outside the traditional realm of regulatory bodies. For example, in the US, pharmacoepidemiology used to play an important role within the AHRQ, the Centers for Disease Control and Prevention, PCORI, and the NIH, and there has been for nearly 40 years intermittent debate about the wisdom of developing an independent new Center for Drug Surveillance [26–29].

As noted above, the use of therapeutic risk management approaches (see Chapter 24) has been aggressively embraced by regulatory bodies around the world, and there has been considerable discussion about risk–benefit assessments of medical products (see Chapter 35). This will continue to change regulation as more experience with it is gained.

There is considerable regulatory interest in getting important new drugs onto the market quickly, using mechanisms such as the FDA's initiatives on orphan drugs, expanded access programs, compassionate use programs, fast track regulations, accelerated approval, priority review, breakthrough drug designation, and use of "real-world evidence," and analogous initiatives elsewhere. On the other hand, efforts like the Right to Try Act may compromise the scientific rigor of the normal regulatory approach. The future is likely to see continued creative regulatory initiatives toward maintaining this balance.

There is also increased interest in encouraging the use of generic drugs, reducing costs, and reducing regulatory obstacles to the availability of generically equivalent drugs, once patents expire.

As much of drug development expands from just small molecules to include biologics, and as these mature on the market, regulators have had to develop a new framework to regulate biosimilars (see Chapter 23). The next few years are likely to see considerable new efforts in this vein.

Finally, there is an enormous increase in attention to drug safety, for example driven by drug safety issues identified with COX-2 inhibitors and even traditional nonsteroidal antiinflammatory drugs, and then by the thiazolidinediones, used for treatment of diabetes. The net result has been major regulatory change, and even new legislation. Between 2009 and 2012, for example, the FDA approved 110 new drugs and biologics for 120 indications, and only 13 of them did not have any postmarketing requirements [30].

The View from the Law

Finally, the importance of pharmacoepidemiology to the law has also been growing. The potential financial risk to drug manufacturers posed by lawsuits related to adverse drug effects is very large. Some financial payments have been enormous, and indeed put large multinational companies at risk. It is clear that the interest in the field and the need for more true experts in the field will increase accordingly.

Conclusion

> *There are no really "safe" biologically active drugs. There are only "safe" physicians.*
> (Harold A. Kaminetzsky, 1963)

All drugs have adverse effects. Pharmacoepidemiology will never succeed in preventing them. It can only detect them, hopefully early, and thereby educate healthcare providers and the public, which will lead to better medication use. Pharmacoepidemiology can also lead to safer use of medications through a better understanding of the factors that alter the risk/benefit balance of medications. The net results of increased activity in pharmacoepidemiology will be better for industry and academia but, most importantly, for the public's health. The next drug disaster cannot be prevented by pharmacoepidemiology but it can minimize its adverse public health impact by detecting it early. At the same time, it can improve the use of drugs that have a genuine role, protecting against the loss of useful drugs. The past few decades have demonstrated the utility of this new field. They also have pointed out some of its problems. With luck, the next few years will see the utility accentuated and the problems ameliorated.

$\alpha = 0.05$ (two-tailed); $\beta = 0.20$ (power = 80%); control : case ratio = 4 : 1. The sample size listed is the number of subjects needed in the case group. Quadruple this number would be included in the control group.

Appendix B

Glossary

Accuracy of a measurement is the degree to which the measurement approximates the truth.

Active surveillance is surveillance carried out via a continuous, defined process in a specific population, using one of several approaches. Active surveillance can be medical product based, identifying adverse events in patients taking certain products; setting based, identifying adverse events in certain healthcare settings where patients are likely to present for treatment (e.g., emergency departments); or event based, identifying adverse events likely to be associated with medical products (e.g., acute liver failure).

Actual knowledge, in a legal sense, is defined as literal awareness of a fact. Actual knowledge can be demonstrated by showing that the manufacturer was cognizant of reasonable information suggesting, for example, a particular risk.

Ad hoc studies are studies that require primary data collection.

Adverse drug event, **adverse drug experience, adverse event, or adverse experience** is an untoward outcome that occurs during or following clinical use of a drug. It does not necessarily have a causal relationship with this treatment. It may or may not be preventable.

Adverse drug reaction is an adverse drug event that is judged to be caused by the drug.

Studies of adverse effects examine case reports of adverse drug reactions, attempting to judge subjectively whether the adverse events were indeed caused by the antecedent drug exposure.

Adversomics is the study of vaccine adverse reactions using immunogenomics and systems biology approaches.

Agreement is the degree to which different methods or sources of information give the same answers. Agreement between two sources or methods does not imply that either is valid or reliable.

Analyses of secular trends examine trends in disease events over time and/or across different geographic locations, and correlate them with trends in putative exposures, such as rates of drug utilization. The unit of observation is usually a subgroup of a population, rather than individuals. Also called ecologic studies.

Analytic studies are studies with control groups, such as case–control studies, cohort studies, and randomized clinical trials.

Anticipated beneficial effects of drugs are desirable effects that are presumed to be caused by the drug. They usually represent the reason for prescribing or ingesting the drug.

Pharmacoepidemiology, Sixth Edition. Edited by Brian L. Strom, Stephen E. Kimmel and Sean Hennessy.

Anticipated harmful effects of drugs are unwanted effects that could have been predicted on the basis of existing knowledge.

Association is when two events occur together more often than one would expect by chance.

Autocorrelation is where any individual observation is to some extent a function of the previous observation.

Bias is any systematic (rather than random) error in a study.

Biologic inference is the process of generalizing from a statement about an association seen in a population to a causal statement about biologic relationships.

Case–cohort studies are studies that compare cases with a disease to a sample of subjects randomly selected from the parent cohort.

Case–control studies are studies that compare cases with a disease to controls without the disease, looking for differences in antecedent exposures.

Case-crossover studies are studies that compare cases at the time of disease occurrence to different time periods in the same individuals, looking for differences in antecedent exposures.

Case reports are reports of the experience of individual patients. As used in pharmacoepidemiology, a case report usually describes a patient who was exposed to a drug and experienced a particular outcome, usually an adverse event.

Case series are reports of collections of patients, all of whom have a common exposure, examining what their clinical outcomes were. Alternatively, case series can be reports of patients who have a common disease, examining what their antecedent exposures were. No control group is present.

Exposure causes a health event when it truly increases the probability of that event in some individuals. That is, there are at least some individuals who would experience the event given the exposure who would not experience the event absent the exposure.

Changeability is the ability of an instrument to measure a difference in score in patients who have improved or deteriorated.

Channeling bias is a type of selection bias, which occurs when a drug is claimed to be safe and therefore is used in high-risk patients who did not tolerate other drugs for that indication. It is sometimes used synonymously with *confounding by indication.*

Clearance is the proportion of the apparent volume of distribution that is cleared of a drug in a specified time. Its units are volume per time, such as liters per hour. The total body clearance is the sum of clearances by different routes, e.g., renal, hepatic, pulmonary, etc.

Clinical pharmacology is the study of the effects of drugs in humans.

Cohort studies are studies that identify defined populations and follow them forward in time, examining their frequencies (e.g., incidence rate, cumulative incidence) of disease. Cohort studies generally identify and compare exposed patients to unexposed patients or to patients who receive a different exposure.

Combination-triggered drug–drug interaction is, in a potential drug–drug interaction, the scenario in which both the object drug and precipitant drug are initiated simultaneously.

Confidence interval can be conceptualized to represent a range of values within which the true population value lies, with some probability.

Confidentiality is the right of patients to limit the transfer and disclosure of private information.

Confounding by indication can occur when the underlying diagnosis or other clinical features that affect the use of a certain drug are also related to the outcome under study.

Confounding variable, or confounder, is a variable other than the risk factor and outcome variable under study that is related independently both to the risk factor and to the outcome. A confounder can artificially inflate or reduce the magnitude of association between and exposure and outcome.

Constructive knowledge, from a legal perspective, is knowledge that a person did not have, but could have acquired by the exercise of reasonable care.

Construct validity refers to the extent to which results from a given instrument are consistent with those from other measures in a manner consistent with theoretical hypotheses.

Cost is the consumption of a resource that could otherwise be used for another purpose.

Cost–benefit analysis of medical care compares the cost of a medical intervention to its benefit. Both costs and benefits must be measured in the same monetary units (e.g., dollars).

Cost-effectiveness analysis of medical care compares the cost of a medical intervention to its effectiveness. Costs are expressed in monetary units, while effectiveness is determined independently and may be measured in terms of any clinically meaningful unit. Cost-effectiveness analyses usually examine the additional cost per unit of additional effectiveness.

Cost-identification analysis enumerates the costs involved in medical care, ignoring the outcomes that result from that care.

Criterion validity refers to the ability of an instrument to measure what it is supposed to measure, as judged by agreement with a reference (gold) standard.

Cross-sectional studies examine exposures and outcomes in populations at one point in time; they have no time sense.

Data mining is exploratory data analysis for hypothesis generation. As part of a knowledge discovery process, data mining looks to uncover patterns or correlations in the dataset with no or limited presupposition, with the intent of more rigorous testing of any emerging hypothesis tailored to the issue at hand.

Defined daily dose (DDD) is the usual daily maintenance dose for a drug for its main indication in adults.

Descriptive studies are studies that do not have control groups, namely case reports, case series, and analyses of secular trends. They are contrasted with analytic studies.

Detection bias is an error in the results of a study due to a systematic difference between the study groups in the procedures used for ascertainment, diagnosis, or verification of disease.

Differential misclassification occurs when the degree of misclassification of one variable (e.g., drug usage) varies according to the level of another variable (e.g., disease status).

Direct medical costs of medical care are the costs that are incurred in providing the care.

Direct nonmedical costs are nonmedical care costs incurred because of an illness or the need to seek medical care. They can include the cost of transportation to the hospital or physician's office, the cost of special clothing needed because of the illness, and the cost of hotel stays and special housing (e.g., modification of the home to accommodate the ill individual).

Discriminative instruments are those that measure differences among people at a single point in time.

Disease registries are registries characterized by inclusion of subjects based on diagnosis of a common disease or condition.

Drug is any exogenously administered substance that exerts a physiologic effect.

Drug–drug interaction is the phenomenon in which one or more drugs affects the pharmacokinetics and/or pharmacodynamics of one or more other drugs.

Drug utilization, as defined by the World Health Organization (WHO), is the "marketing, distribution, prescription and use of drugs in a society, with special emphasis on the resulting medical, social, and economic consequences."

Drug utilization evaluation (DUE) programs are ongoing structured systems designed to improve drug use by intervening when inappropriate drug use is detected. See also drug utilization review programs.

Drug utilization evaluation studies are *ad hoc* investigations that assess the appropriateness of drug use. They are designed to detect and quantify the frequency of drug use problems.

Drug utilization review programs are ongoing structured systems designed to improve drug use by intervening when inappropriate drug use is detected.

Drug utilization review studies are *ad hoc* investigations that assess the appropriateness of drug use. They are designed to detect and quantify any drug use problems. See also drug utilization evaluation programs.

Drug utilization studies are descriptive studies that quantify the use of a drug. Their objective is to quantify the present state, the developmental trends, and the time course of drug usage at various levels of the healthcare system, whether national, regional, local, or institutional.

Ecologic studies examine trends in disease events over time or across different geographic locations and correlate them with trends in putative exposures, such as rates of drug utilization. The unit of observation is a subgroup of a population, rather than individuals. See also analyses of secular trends.

Effect modification occurs when the magnitude of effect of a drug in causing an outcome differs according to the levels of a variable other than the drug or the outcome (e.g., sex, age group). Effect modification can be assessed on an additive and/or multiplicative scale. See interaction.

Study of drug effectiveness is a study of whether, in the usual clinical setting, a drug in fact achieves the effect intended when prescribing it.

Study of drug *efficacy* is a study of whether, *under ideal conditions*, a drug has the ability to bring about the effect intended when prescribing it.

Study of drug *efficiency* is a study of whether a drug can bring about its desired effect at an acceptable cost.

Enriched or hybrid study designs draw on both primary and secondary data, with some data collected *de novo*, specifically for the purposes of the study and other study-specific data collected via probabilistic or deterministic linkage with other data sources, such as electronic health records, administrative claims and billing data, vital records, and genetic information.

Epidemiology is the study of the distribution and determinants of disease or health-related states in populations.

Evaluative instruments are those designed to measure changes within individuals over time.

Experimental studies are studies in which the investigator controls the therapy that is to be received by each participant, generally using that control to randomly allocate participants among the study groups.

Face validity is a judgment about the validity of an instrument, based on an intuitive assessment of the extent to which an instrument meets a number of criteria including applicability, clarity and simplicity, likelihood of bias, comprehensiveness, and whether redundant items have been included.

Fixed costs are costs that are incurred regardless of the volume of activity.

General causation, from a legal perspective, addresses whether a product is capable of

causing a particular injury in the population of patients like the plaintiff.

Generic quality-of-life instruments aim to cover the complete spectrum of function, disability, and distress of the patient, and are applicable to a variety of populations.

Half-life ($T_{1/2}$) is the time taken for the drug concentration to decline by half. Half-life is a function of both the apparent volume of distribution and clearance of the drug.

Hawthorne effect is when study subjects alter their behavior simply because of their participation in a study, unrelated to the study procedures or intervention.

Health profiles are single instruments that measure multiple different aspects of quality of life.

Health-related quality of life is a multifactorial concept which, from the patient's perspective, represents the end-result of all the physiological, psychological, and social influences of the disease and the therapeutic process. Health-related quality of life may be considered on different levels: overall assessment of wellbeing; several broad domains – physiologic, functional, psychologic, social, and economic status; and subcomponents of each domain – for example pain, sleep, activities of daily living, and sexual function within physical and functional domains.

Human research subject, as defined in US regulations, is "a living individual, about whom an investigator (whether professional or student) conducting research obtains either: (1) data through intervention or interaction with the individual, or (2) identifiable private information" [1].

Hybrid or enriched study designs draw on both primary and secondary data, with some data collected *de novo*, specifically for the purposes of the study, and other study-specific data collected via probabilistic or deterministic linkage with other data sources, such as electronic health records, administrative claims and billing data, vital records, and genetic information.

Hypothesis-generating studies are studies that give rise to new questions about drug effects to be explored further in subsequent analytic studies.

Hypothesis-strengthening studies are studies that reinforce, although do not provide definitive evidence for, existing hypotheses.

Hypothesis-testing studies are studies that evaluate in detail hypotheses raised elsewhere.

Inception cohort design is a cohort study that is restricted to new users of the exposure(s) of interest.

Incidence/prevalence bias, a type of selection bias, may occur in studies when prevalent cases rather than new cases of a condition are selected for a study. A strong association with prevalence may be related to the duration of the disease rather than to its incidence, because prevalence is proportional to both incidence and duration of the disease.

Incidence rate of a disease is a measure of how frequently the disease occurs. Specifically, it is the number of new cases of the disease which develop over a defined time period in a defined population at risk, divided by the number of people in that population at risk.

Indirect costs are costs that do not stem directly from transactions for goods or services, but represent the loss of opportunities to use a valuable resource in alternative ways. They include costs due to morbidity (e.g., time lost from work) and mortality (e.g., premature death leading to removal from the workforce).

Information bias is an error in the results of a study due to a systematic difference between the study groups in the accuracy of the measurements being made of their exposure or outcome.

Instrumental variable is a variable used to adjust for confounding that meets certain specific criteria: it should affect treatment or be associated with treatment choice by sharing a common cause; should be a factor that is as good as randomly assigned, so that it is unrelated to patient characteristics; and should not be related to the outcome other than through its association with treatment.

Intangible costs are those of pain, suffering, and grief.

Interaction, see effect modification.

Interrupted time-series designs include multiple observations of study populations before and after an intervention.

Knowledge, as used in court cases, can be actual or constructive; see those terms.

Large simple trials are randomized trials characterized by large sample sizes, broad entry criteria consistent with the approved medication label, randomization based on equipoise, minimal data requirements, objectively measured endpoints, follow-up that minimizes interventions or interference with normal clinical practice, follow-up of all patients regardless of whether they discontinue randomized medication, and intent-to-treat analysis.

Medication errors are any error in the process of prescribing, transcribing, dispensing, administering, or monitoring a drug, regardless of whether an injury occurred or the potential for injury was present.

Meta-analysis is a systematic, structured review of the literature and formal statistical analysis of a collection of analytic results for the purpose of integrating the findings. Meta-analysis is used to identify sources of variation among study findings and, when appropriate, to provide an overall measure of effect as a summary of those findings.

Microbiome includes the microorganisms, primarily bacteria in the gut, and their genes, harbored within each person.

Misclassification bias is the error resulting from classifying study subjects as exposed when they truly are unexposed, or vice versa. Alternatively, misclassification bias can result from classifying study subjects as diseased when they truly are not diseased, or vice versa.

Molecular pharmacoepidemiology is the study of the manner in which molecular biomarkers alter the clinical effects of medications.

N-of-1 RCT is a randomized controlled trial (RCT) within an individual patient, using repeated assignments to the experimental or control arms.

Near misses are medication errors that have high potential for causing harm but did not, either because they were intercepted prior to reaching a patient, or because the error reached the patient who fortuitously did not have any observable untoward sequelae.

Negative control precipitant drug is, in a study of a potential drug–drug interaction, a drug that is used in similar clinical circumstances as the potential precipitant under study, yet by virtue of the control precipitant's pharmacology is not believed to interact with the study object.

Negative control object drug is, in a study of a potential drug–drug interaction, a drug that is used for similar indications as the object under study, but is not believed to interact pharmacologically with the study precipitant.

Nondifferential misclassification occurs when the misclassification of one variable does not vary by the level of another variable. Nondifferential misclassification usually results in bias toward the null.

Nonexperimental studies are studies in which the investigator does not control the therapy, but observes and evaluates the results of ongoing medical care. The study designs that are used are those that do not involve random allocation, such as case reports, case series,

analyses of secular trends, case–control studies, and cohort studies.

Object drug is, in a drug–drug interaction, the drug(s) whose pharmacokinetics or pharmacodynamics are affected by the other drug(s).

Object-triggered drug–drug interaction is, in a study of a potential drug–drug interaction, the scenario in which the object drug is started in a person already taking the precipitant drug.

Observational studies (or nonexperimental studies) are studies in which the investigator does not control the therapy, but observes and evaluates the results of ongoing medical care. The study designs that are used are those that do not involve randomization, such as case reports, case series, analyses of secular trends, case–control studies, and cohort studies.

Odds ratio is the odds of exposure in the diseased group divided by the odds of exposure in the nondiseased group. When the underlying risk of disease is low (about 10% or lower), it is an unbiased estimator of the relative risk. It is also an unbiased estimate of the rate ratio in a nested or population-based case–control study in which controls are selected at random from the population at risk of disease at the time that the case occurred.

One-group, post-only study design consists of making only one observation on a single group which has already been exposed to a treatment.

Opportunity cost is the value of a resource's next best use, a use that is no longer possible once the resource has been used.

Patient-reported outcomes are any report of the status of a patient's health condition that comes directly from the patient, without interpretation of the patient's response by a clinician or anyone else.

Pharmacodynamics is the study of the relationship between drug level and drug effect. It involves the study of the response of the target tissues in the body to a given concentration of drug.

Pharmacoeconomics is the study of how the price of pharmaceutical products and their economic impact health and the healthcare system.

Pharmacogenetic epidemiology is the study of the effects of genetic determinants of drug response on outcomes in large numbers of people.

Pharmacoepidemiology is the study of the use of and the effects of drugs in large numbers of people. It is also the application of the research methods of clinical epidemiology to the content area of clinical pharmacology, and the primary science underlying the public health practice of drug safety surveillance.

Pharmacogenetics is the study of genetic determinants of responses to drugs. Although it is sometimes used synonymously with pharmacogenomics, it often refers to a candidate-gene approach as opposed to a genome-wide approach.

Pharmacogenomics is the study of genetic determinants of responses to drugs. Although it is sometimes used synonymously with pharmacogenetics, it often refers to a genome-wide approach as opposed to a candidate-gene approach.

Pharmacokinetic compartment is a theoretical space into which drug molecules are said to distribute, and is represented by a given linear component of the log-concentration versus time curve. It is not an actual anatomic or physiologic space, but is sometimes thought of as a tissue or group of tissues that have similar blood flow and drug affinity.

Pharmacokinetics is the study of the relationship between the dose administered of a drug and the concentration achieved in the blood, in the serum, or at the site of action. It includes the study of the processes

of drug absorption, distribution, metabolism, and excretion.

Pharmacology is the study of the effects of drugs in a living system.

Pharmacotherapeutics is the application of the principles of clinical pharmacology to rational prescribing, the conduct of clinical trials, and the assessment of outcomes during real-life clinical practice.

Pharmacovigilance is the identification and evaluation of drug safety signals. More recently, some have also used the term as synonymous with pharmacoepidemiology. The WHO defines *pharmacovigilance* as the science and activities relating to the detection, assessment, understanding and prevention of adverse effects or any other possible drug-related problems [2]. Mann defines pharmacovigilance as "the study of the safety of marketed drugs under the practical conditions of clinical usage in large communities" [3].

Pharmionics is the study of how patients use or misuse prescription drugs in ambulatory care.

Population-based databases or studies refer to whether there is an identifiable population (which is not necessarily based in geography), all of whose medical care would be included in that database, regardless of the provider. This allows one to determine incidence rates of diseases, as well as being more certain that one knows of all medical care that any given patient receives.

Positive control precipitant drug is, in a study of a potential drug–drug interaction, a precipitant drug known to produce an association with an outcome in patients receiving the object drug of interest.

Postmarketing surveillance is the study of drug use and drug effects after release onto the market. This term is sometimes used synonymously with "pharmacoepidemiology," but the latter can be relevant to premarketing studies as well. Conversely, the term "postmarketing surveillance" is sometimes felt to apply only to those studies conducted after drug marketing that systematically screen for adverse drug effects. However, this is a more restricted use of the term than that applied in this book.

Potency refers to the amount of drug that is required to elicit a given response. A more potent drug requires a smaller milligram quantity to exert the same response as a less potent drug, although it is not necessarily more effective.

Potential adverse drug events are medication errors that have high potential for causing harm but did not, either because they were intercepted prior to reaching a patient, or because the error reached the patient who fortuitously did not have any observable untoward sequelae.

Power (statistical power) of a study is the probability of detecting a difference in the study if a difference really exists (either between study groups or between treatment periods).

Pragmatic clinical trials typically fall somewhere between a typical randomized trial and a simple and a large simple trial, where the goal is to introduce one or more pragmatic elements into the design, but with substantial protocol-required follow-up and testing outside of usual care practice.

Precipitant drug is, in a drug–drug interaction, the drug that affects the pharmacokinetics or pharmacodynamics of the other drug(s).

Precipitant-triggered drug–drug interaction is, in a study of a potential drug–drug interaction, the scenario in which the precipitant drug is started in a person already taking the object drug.

Precision is the degree of absence of random error. Precise estimates have narrow confidence intervals.

Precision medicine has been defined by the National Institutes of Health (NIH) in the US

as an "approach to disease prevention and treatment based on people's individual differences in environment, genes and lifestyle" [4].

Pre–post with comparison group design includes a single observation both before and after treatment in a nonrandomly selected group exposed to a treatment (e.g., physicians receiving feedback on specific prescribing practices), as well as simultaneous before-and-after observations of a similar (comparison) group not receiving treatment.

Prescribing errors refer to issues related to underuse, overuse, and misuse of prescribed drugs, all of which contribute to the suboptimal utilization of pharmaceutical therapies.

Prevalence of a disease is a measurement of how common the disease is. Specifically, it is the number of existing cases of the disease in a defined population at a given point in time or over a defined time period, divided by the number of people in that population.

Prevalence study bias is a type of selection bias that may occur in studies when prevalent cases rather than new cases of a condition are selected for a study. A strong association with prevalence may be related to the duration of the disease rather than to its incidence, because prevalence is proportional to both incidence and duration of the disease.

Privacy, in the setting of research, refers to each individual's right to be free from unwanted inspection of, or access to, personal information by unauthorized persons.

Procedure registries are registries characterized by inclusion of subjects based on receipt of specific services, such as procedures, or based on hospitalizations.

Product registries are registries characterized by inclusion of subjects based on use of a specific product (drug or device) or related products in a given therapeutic area.

Propensity scores are an approach to controlling for confounding that uses mathematical modeling to predict exposure based on observed variables, and uses the predicted probability of exposure as the basis for matching or adjustment.

Prospective drug utilization review is designed to detect drug-therapy problems before an individual patient receives the drug.

Prospective studies are studies performed simultaneously with the events under study; namely, where patient outcomes have not yet occurred at the outset of the study.

Proteomics is, within the context of pharmacoepidemiology, the study of how proteins are responsible for variability in medication response.

Protopathic bias is interpreting a factor to be a result of an exposure when it is in fact a determinant of the exposure, and can occur when an early sign of the disease under study led to the prescription of the drug under study.

Publication bias occurs when publication of a study's results is related to the study's findings, such that study results are not published or publication is delayed because of the results.

P value is the probability that a difference as large as or larger than the one observed in the study could have occurred purely by chance if no association truly existed.

Qualitative drug utilization studies are studies that assess the *appropriateness* of drug use.

Quality of life is the description of aspects (domains) of physical, social, and emotional health that are relevant and important to the patient.

Quantitative drug utilization studies are descriptive studies of *frequency* of drug use.

Random allocation is the assignment of subjects who are enrolled in a study into study groups in a manner determined by chance.

Random error is error due to chance.

Random selection is the selection of subjects for a study from among those eligible in a manner determined by chance.

Randomized clinical trials are studies in which the investigator randomly assigns patients to different therapies, one of which may be a control therapy.

Recall bias is an error in the results of a study due to a systematic difference between the study groups in the accuracy or completeness of their memory of their past exposures or health events.

Referral bias is error in the results of a study that occurs when the reasons for referring a patient for medical care are related to the exposure status, e.g., when the use of the drug contributes to the diagnostic process.

Registries are organized systems that use observational study methods to collect uniform data (clinical and other) to evaluate specified outcomes for a population defined by a particular disease, condition, or exposure, and that serves one or more predetermined scientific, clinical, or policy purposes. Registries can be thought of as both the process for collecting data from which studies are derived, as well as referring to the actual database.

Regression to the mean is the tendency for observations on populations selected on the basis of an abnormality to approach normality on subsequent observations.

Relative rate is the ratio of the incidence rate of an outcome in the exposed group to the incidence rate of the outcome in the unexposed group. It is synonymous with the terms *rate ratio* and *incidence rate ratio*.

Relative risk is the ratio of the cumulative incidence of an outcome in the exposed group to the cumulative incidence of the outcome in the unexposed group. It is synonymous with the term *cumulative incidence ratio*.

Reliability is the degree to which the results obtained by a measurement procedure can be replicated. The measurement of reliability does not require a gold standard, since it assesses only the concordance between two or more measures.

Reporting rate in a spontaneous reporting system is the number of reported cases of an adverse event of interest divided by some measure of the suspect drug's utilization, usually the number of dispensed prescriptions. This is perhaps better referred to as a *rate of reported cases*.

Reproducibility is the ability of an instrument to obtain more or less the same scores on repeated measurement of patients who have not changed.

Research, as defined in US regulations, is any activity designed to "develop or contribute to generalizable knowledge" [5].

Research subject is "a living individual, about whom an investigator (whether professional or student) conducting research obtains either: 1) data through intervention or interaction with the individual, or 2) identifiable private information" [6].

Responsiveness is an instrument's ability to detect change.

Retrospective drug utilization review compares past drug use against predetermined criteria to identify aberrant prescribing patterns or patient-specific deviations from explicit criteria.

Retrospective studies are studies conducted after the events under study have occurred. Both exposure and outcome have already occurred at the outset of the study.

Risk is the cumulative probability that something will happen.

Risk evaluation and mitigation strategy (REMS) is a pharmacovigilance assessment plan in the US, approved by regulators in advance of implementation, to ensure that the benefits of a drug or biologic product outweigh its risks.

For a **risk management plan** in the EU, pharmacovigilance legislation explicitly requires the active monitoring of the outcome of risk minimization activities it contains, placing the obligation on manufacturers and regulatory authorities for this activity.

Judgment about **safety** is a personal and/or social judgment about the degree to which a given risk is acceptable.

Safety signal is a concern about an excess of adverse events compared to what is expected to be associated with use of a product (drug or device).

Sample distortion bias is another name for selection bias.

Scientific inference is the process of generalizing from a statement about a population, which is an association, to a causal statement about scientific theory.

Selection bias is error in a study that is due to systematic differences in characteristics between those who are selected for the study and those who are not.

Self-controlled designs are studies that include only persons who experienced the outcome, using each person as their own control, and include self-controlled case series and case-crossover designs.

Self-controlled case series (SCCS) design is a self-controlled design that is analogous to the cohort design. It includes only individuals who experienced the outcome, and examines the rate of the outcome during exposed vs. unexposed periods within those individuals.

Sensibility is a judgment about the validity of an instrument, based on an intuitive assessment of the extent to which an instrument meets a number of criteria including applicability, clarity and simplicity, likelihood of bias, comprehensiveness, and whether redundant items have been included.

Sensitivity is the proportion of persons who truly have a characteristic, who are correctly classified by a diagnostic test as having it.

Sensitivity analysis is a set of procedures in which the results of a study are recalculated using alternate values for some of the study's variables, in order to test the sensitivity of the conclusions to altered specifications.

Serious adverse experience is any adverse experience occurring at any dose that results in any of the following outcomes: death, a life-threatening adverse experience, inpatient hospitalization or prolongation of existing hospitalization, a persistent or significant disability/incapacity, or congenital anomaly/birth defect.

Service registries are registries characterized by inclusion of subjects based on receipt of specific services, such as procedures, or based on hospitalizations.

Signal is a hypothesis that calls for further work to be performed to evaluate that hypothesis.

Signal detection is the process of looking for or identifying signals from any source.

Signal generation, sometimes referred to as data mining, is an approach that uses statistical methods to identify a safety signal. No particular medical product exposure or adverse outcome is prespecified.

Signal refinement is a process by which an identified safety signal is further evaluated to determine whether evidence exists to support a relationship between the exposure and the outcome.

Specific causation, from a legal perspective, addresses whether the product in question actually caused an alleged injury in the individual plaintiff.

Specificity is the proportion of persons who truly do *not* have a characteristic, who are correctly classified by a diagnostic test as not having it.

Specific quality-of-life instruments are focused on disease or treatment issues specifically relevant to the question at hand.

Spontaneous reporting systems are maintained by regulatory bodies throughout

the world and collect unsolicited clinical observations that originate outside of a formal study.

Statistical inference is the process of generalizing from a sample of study subjects to the entire population from which those subjects are theoretically drawn.

Statistical interaction, see effect modification.

Statistically significant difference is a difference between two study groups that is unlikely to have occurred purely by chance.

Steady state, within pharmacokinetics, is the situation when the amount of drug being administered equals the amount of drug being eliminated from the body.

Systematic error is any error in study results other than that due to random variation.

Therapeutic ratio is the ratio of the drug concentration that produces toxicity to the concentration that produces the desired therapeutic effect.

Therapeutics is the application of the principles of clinical pharmacology to rational prescribing, the conduct of clinical trials, and the assessment of outcomes during real-life clinical practice.

Type A adverse reactions are those that are the result of an exaggerated but otherwise predictable pharmacologic effect of the drug. They tend to be common and dose related.

Type B adverse reactions are those that are aberrant effects of the drug. They tend to be uncommon, not dose related, and unpredictable.

Type I statistical error is concluding there is an association when in fact one does not exist, i.e., erroneously rejecting the null hypothesis.

Type II statistical error is concluding there is no association when in fact one does exist, i.e., erroneously accepting the null hypothesis.

Unanticipated beneficial effects of drugs are desirable effects that could not have been predicted on the basis of existing knowledge.

Unanticipated harmful effects of drugs are unwanted effects that could not have been predicted on the basis of existing knowledge.

Uncontrolled studies refer to studies without a comparison group.

Unexpected adverse experience means any adverse experience that is not listed in the current labeling for the product. This includes an event that may be symptomatically and pathophysiologically related to an event listed in the labeling, but differs from the event because of greater severity or specificity.

Utility measures of quality of life are measured holistically as a single number along a continuum, e.g., from death (0.0) to full health (1.0). The key element of a utility instrument is that it is preference based.

Vaccinovigilance is all methods of assessment and prevention of adverse events following immunizations.

Validity is the degree to which an assessment (e.g., questionnaire or other instrument) measures what it purports to measure.

Variable costs are costs that increase with increasing volume of activity.

Apparent **volume of distribution** (V_D) is the apparent volume that a drug is distributed in after complete absorption. It is usually calculated from the theoretical plasma concentration at a time when all of the drug was assumed to be present in the body and uniformly distributed. This is calculated from back extrapolation to time zero of the plasma concentration time curve after intravenous administration.

Voluntariness is the concept in research ethics that investigators must tell subjects that participation in the research study is voluntary, and that subjects have the right to discontinue participation at any time.
