A panel reactive antibody (PRA) screen is performed to determine the level of antibodies to red blood cell antigens from prior blood transfusions. Highly sensitized patients (allosensitization) are those who have a PRA >10%. Cardiac transplantation for highly sensitized patients has increased morbidity and mortality [102]. The use of cryopreserved allograft material for prior congenital heart surgery also induces a HLA immune response.

High levels of antibodies to specific antigens may prevent transplant from a donor with those antigens, and a "virtual cross-match" is performed for donor and recipient red cell antigens before accepting the organ. A strongly positive cross-match for specific antigens may prevent transplantation from a donor with those antigens. Other strategies for patients with high PRA titers include preoperative plasmapheresis, thymoglobulin, and cyclophosphamide treatment to reduce titers [110]. HLA prospective cross-matching is not routinely performed because of time constraints and limited availability of donor organs.

Psychosocial assessment of patient and family

This includes the capacity to comply with the complicated regimens needed for ongoing care [111]. Although substance abuse, psychosocial problems, and non-compliance have been associated with increased morbidity and mortality after adult heart transplantation, there are limited studies to assess its impact in pediatric patients [103]. Developmental delay is also commonly encountered in pediatric transplant patients, especially those with CHD. Consensus opinion is that the selection of these patients for heart transplant listing should be considered on a case-by-case basis rather than arbitrary denial [103].

United Network for Organ Sharing waiting list

In the United States, organ donation and allocation is managed by UNOS [112]. UNOS maintains the waiting lists for each type of transplant, and determines the rules for organ allocation, which depend on patient status and, to some extent, proximity to the donor. Once listed for transplant, the patient is designated a status dependent on priority for transplant (Table 30.15) [113]. The median waiting time for pediatric heart transplant is 60–80 days [113]. Wait-list mortality in pediatric heart transplant remains significant and can be as high as 23% in infants 6 months after listing for transplant [114,115]. Other factors associated with increased wait-list mortality include the need for extracorporeal membrane oxygenation (ECMO) or mechanical ventilation, status 1A listing, diagnosis of CHD, the need for dialysis, and weight <3 kg [104,114,115].

Table 30.15 Status designation for pediatric heart transplantation. Status 7 refers to a listed patient who is temporarily off the transplant list, i.e. for infection or other reversible cause, who can be reinstated once the condition is treated

Status 1A (at least one of the criteria below)	Status 1B (at least one of the criteria below)	Status 2
Continuous mechanical ventilation and is hospital inpatient	Needs one or more inotrope infusions but does not qualify for 1A	<18 years old at time of listing but does not meet requirements for 1A or 1B
Ductal-dependent systemic or pulmonary circulation and is hospital inpatient	Has hypertrophic cardiomyopathy or restrictive cardiomyopathy *and* is <l year old	
Hemodynamically significant congenital heart disease and is an inpatient on multiple inotropes or high-dose single inotrope		
Dependent on mechanical circulatory support		
NB status 1A must be recertified every 14 days	*Can remain IB for unlimited period without recertification*	*Status 2 does not need recertification*

Source: Adapted from Organ Transplant and Procurement Network [113].

KEY POINTS: HEART TRANSPLANT RECIPIENT SELECTION

- Evaluation of four main areas (cardiovascular anatomy and hemodynamics, other organ dysfunction, HLA sensitization, and psychosocial assessment of patient and family) is required prior to listing for heart transplant
- Most centers require a PVR <6 WU prior to transplant listing. High PVRs should be reactive to pulmonary vasodilator therapy
- Highly sensitized patients with a PRA >10% have a higher transplant morbidity

Anesthesic management

Pre-bypass period

The basic anesthetic considerations for transplantation do not differ from the normal preparation for congenital cardiac surgery (see Chapter 27 for a detailed discussion of pathophysiology). A summary of intraoperative considerations for pediatric cardiac transplantation is presented in Box 30.5. A thorough preoperative evaluation and consultation with the patient and family and explanation of the anesthetic procedures is performed. The preoperative condition may vary from a deconditioned, hospitalized, status 1A patient dependent on multiple inotropes or ventricular assist devices to status 1B patients called in from home. The timing of entrance into the operating room (OR) must be planned and communicated with frequent updates due to difficulties in coordinating harvesting teams and donor hospital OR time. It is preferable to err on the side of having the patient in the OR too early than too late; prolonged ischemic time will affect graft function and 1-year survival [102,104]. Allowing adequate time to place invasive vascular access lines and extensive surgical dissection for multiple re-entry sternotomies must be considered when deciding an OR time. At Lucille Packard Children's Hospital, Stanford we organize a multidisciplinary huddle hours before bringing the patient into the OR. This involves discussion between the heart failure team, transplant surgeon, cardiovascular ICU, and anesthesia team and reviews the patient's current medical condition, any anticipated perioperative problems such as vascular access, rescue plans for cardiopulmonary decompensation, renal protection, and immunosuppressive regimens.

Patients presenting for cardiac transplantation have limited cardiopulmonary reserve and the anesthesia induction should be tailored to the condition and the specific physiology of the patient. While most patients will require some form of anxiolysis the timing, route, and location should be determined by the patient's cardiorespiratory state. The timing of immunosuppressive regimens varies between institutions – some start soon after arrival to the OR and others after separating from cardiopulmonary bypass (CPB) when bleeding is controlled. Although having invasive arterial monitoring in place prior to induction is ideal, this is not always possible for younger patients where standard non-invasive monitoring for induction may have to suffice. Continuous transthoracic echo monitoring during induction can also be considered provided there are skilled and dedicated personnel to obtain and interpret the images. Transthoracic echo monitoring may be useful for monitoring function, left ventricular outflow tract obstruction, and PVR changes during anesthesia induction. Most pretransplant patients are at significant risk of developing dysrhythmias or cardiovascular collapse with the induction of general anesthesia and positive pressure ventilation. Therefore, methods of resuscitation must be immediately at hand to support the patient. This includes pharmacological agents, defibrillator, and the ability to rescue the patient with emergent CPB. Intravenous induction can often be accomplished with gradual titration of midazolam 0.05–0.1 mg/kg per dose, and fentanyl 1–5 μg/kg per dose, followed by muscle relaxation. Another option for intravenous induction includes etomidate 0.1–0.3 mg/kg, which has little or no hemodynamic effect [116]. Ketamine 1–2 mg/kg IV can also be used. However, one should be aware of the potential for direct myocardial depression with the use of ketamine in patients receiving continuous infusions of β-adrenergic agonists where the patient's endogenous catecholamine stores may be depleted [117,118]. Bolus propofol should generally be avoided because of its venous and arterial vasodilating properties.

Assisted mask ventilation is assumed, taking care to limit intrathoracic pressure and minimize changes to the PVR. Among patients with pulmonary hypertension, increases in pulmonary arterial pressure can be minimized by the use of

Box 30.5: Summary of intraoperative anesthetic considerations for pediatric cardiac transplantation

Pre-bypass period
- Consider pathophysiology of congenital heart disease and/or reduced myocardial function (see Chapter 27)
- Induction and maintenance agents to preserve function
- Maintain preoperative inotropes, increase doses preinduction if needed
- Mechanical circulatory support (MCS): MCS specialist, preinduction arterial line, and NIRS if non-pulsatile
- Resuscitation drugs, bypass machine, and perfusionist and surgeon immediately available
- Interrogate/convert pacemaker/ICD functions as indicated (DOO pacing, defibrillator off)
- Efficient vascular access with ultrasound: arterial, central venous, large-bore peripheral IV lines; minimize ischemic time
- Prepare for possible emergency femoral vessel cannulation for bypass
- Adequate blood products and heparin in OR
- Antifibrinolytic agents: tranexamic acid or ε-aminocaproic acid
- Thromboelastography/elastometry for coagulation monitoring
- TEE to assess function, filling, air, and postoperative anatomy

Bypass period
- Exchange transfusion as bypass initiated for ABO-incompatible or high panel reactive antibody patients
- Cooling on bypass will depend on surgical needs; usually moderate hypothermia
- Deep hypothermic bypass or circulatory arrest may be necessary for aortic arch reconstruction or pulmonary vein repair in congenital heart disease
- Left atrial and aortic anastomosis done with aortic cross-clamp. A donor ischemic time of <5 h is desirable
- Lidocaine, magnesium sulfate, or amiodarone may be needed for ventricular fibrillation
- Inotropic support varies; low-dose epinephrine, milrinone, and low-dose isoproterenol are commonly used
- Inhaled nitric oxide for elevated pulmonary vascular resistance
- Atrial and ventricular pacing wires for heart rate support in denervated heart

Post-bypass period
- Significant bleeding with repeat sternotomy or VAD patients: platelets, cryoprecipitate/fibrinogen concentrate, and fresh frozen plasma/coagulation factor concentrate/activated factor VII are often necessary
- TEE to assess anastomoses and cardiac function
- Maintain inotropic support, pacing, and iNO as needed
- Usually will not extubate in OR, but stable patients can be extubated in 12–24 h
- Full hand-over report from anesthesia/surgical team to ICU team

DOO, asynchronous atrial/ventricular pacing; ICD, implantable cardiac defibrillator; ICU, intensive care unit; iNO, inhaled nitric oxide; IV, intravenous; NIRS, near-infrared spectroscopy; OR, operating room; TEE, transesophageal echocardiography; VAD, ventricular assist device.

larger doses of opioids, 100% oxygen, and mild hyperventilation prior to tracheal intubation. If a pulmonary hypertensive crisis develops, treatment with systemic vasopressors and pulmonary vasodilators, including inhaled nitric oxide, is immediately undertaken.

In addition to invasive monitoring (arterial and central venous), adequate large-bore access should be secured especially for repeat sternotomy patients. Some complicated re-entry sternotomy patients may require predissection arterial and venous access via femoral or neck vessels that could be used to rapidly transition to extracorporeal support if needed.

Many patients especially those with CHD may have implantable pacemakers or cardioverter-defibrillators in place and these should be reprogrammed appropriately prior to incision and the use of surgical diathermy.

Almost a third of pediatric heart transplant patients are on a form of mechanical circulatory support (MCS) (see section "Bridge to transplant"), most often a left ventricular assist device (LVAD). The anesthesiologist must be familiar with the many types of devices in current use; the presence of an MCS specialist is essential to operate and troubleshoot the device. Patients on a continuous flow ventricular assist device may have reduced or no cardiac and arterial pulsatility, rendering conventional pulse oximetry and oscillometric blood pressure monitoring non-functional. A preinduction arterial line with ultrasound guidance, or near-infrared spectroscopy, combined with maintaining ventricular assist device flow parameters in normal ranges, is often necessary in these patients.

Additional monitoring includes TEE to assess post-transplant cardiac function and integrity of cardiac and great vessel anastomoses. We routinely utilize near-infrared spectroscopy measurement of cerebral oxygen saturation because of the high risk of cerebral oxygen desaturation from a low cardiac output state in these patients. Early detection and treatment of cerebral oxygen desaturation may lead to improved neurological outcomes. Although patients with poor cardiac function undergoing transplant are at higher risk for anesthesia awareness, processed electroencephalographic monitoring for depth of anesthesia will not reliably prevent this significant problem and is not recommended for use in this situation, particularly in young children [119].

Because many of these patients have undergone previous sternotomies and are at greater risk for intra- and postoperative hemorrhage, antifibrinolytic agents are often utilized. These include EACA or tranexamic acid. Antibiotic prophylaxis, often cefazolin in uncomplicated transplants, is given 30–60 min before incision, repeated after institution of bypass, and every 3–4 h thereafter while in the OR.

Patient positioning, preparation, draping, and sternotomy are accomplished as efficiently as possible. The mediastinal,

heart, and great vessel dissection and preparation is then undertaken prior to donor organ arrival in order to minimize donor ischemic time. Pre-bypass anesthetic management is carried out according to the pathophysiology of the patient's underlying cardiac disease and response to surgical and anesthetic interventions. Maintenance of anesthesia is often achieved with large doses of opioids such as fentanyl, and amnestic agents such as midazolam. Low doses of volatile anesthetic agents are often employed and there are some data that suggest isoflurane may preserve cardiac output better than other volatiles [120,121].One should also consider using a trigger-free anesthetic regimen, when possible, for patients with neuromuscular disease (e.g. Duchenne or Becker muscular dystrophy) who may be at risk for malignant hyperthermia-type symptoms or anesthesia-induced rhabdomyolysis.

Bypass period

Standard CPB techniques are used for cardiac transplant, including heparin 300–400 units/kg for anticoagulation, and anticoagulation monitoring with celite activated clotting time, and heparin level assay or TEG/thromboelastometry, according to institutional practice. Aorto-bicaval cannulation is utilized. General principles of bypass management for CHD are followed (see Chapter 26 for further details). Recent data suggest that pH stat blood gas management, and maintaining higher hematocrits of 30–35%, result in better long-term neurological outcomes [122]. Maintaining full flow CPB of 150 mL/kg/min for patients under 10 kg, and 2.4–2.8 L/min/m^2 for those over 10 kg, may improve outcomes as well [123]. Moderate hypothermia to 25–28°C is commonly employed and deep hypothermic (<22°C) circulatory arrest (DHCA) is avoided; however, complex reconstruction of pulmonary venous or aortic anatomy may require DHCA. If possible, DHCA periods should be limited to less than 30 min; reperfusing for a short period and then reinstituting DHCA may be required, utilizing cerebral oximetry to guide the bypass [123–127]. Ultrafiltration on CPB is very useful to achieve hematocrit goals and to remove excess fluid and inflammatory mediators. Alternatively, modified ultrafiltration after CPB can be used to achieve the same goals.

In patients where high levels of PRAs are measured, or in ABO-incompatible transplants (see later in this chapter), an exchange transfusion is performed when CPB is initiated. A double CPB prime volume is prepared, with packed red blood cells and FFP. Upon institution of CPB, the patient's calculated blood volume is drained into a separate collection bag, bypassing the venous reservoir, and discarded. This process will reduce the red cell antibody concentration, and limit the possibility of acute rejection [128].

The most common surgical technique involves orthotopic transplantation [129], where the donor heart is completely excised except for a cuff of left atrial tissue containing all four pulmonary veins (Fig. 30.10) [130]. Donor weight is ideally 80–160% of the recipient's weight. It is important for the surgical team to know the details of the donor's demise (while appropriately preserving patient confidentiality), donor cardiac function (ejection fraction) and inotropic support, and any donor structural abnormalities such as atrial septal defect or patent foramen ovale. The entire right atrium is removed, leaving the superior and inferior vena cavae for anastomosis. After arrival of the donor heart, the ABO and rH type of both the donor and recipient are checked and independently verified by two people including the transplant surgeon. The donor heart is typically preserved with a solution such as crystalloid cardioplegia or Celsior® and stored on ice at 4°C. The heart is placed in the mediastinum, and the left atrial anastomosis is performed first. Then, the aortic anastomosis is performed. The aortic cross-clamp is usually removed at this point to minimize the donor heart ischemic time and to allow sufficient time for donor heart reperfusion. Donor ischemia time is the time from donor heart cross-clamp during retrieval until the cross-clamp is removed during recipient implantation. Ideally, an upper limit of 5 h of donor ischemic time is desired. This limits donor organ transport time to 3.5–4 h. Although transplantation of hearts with longer ischemic times are reported, it is believed that after 5 h of ischemia, graft function worsens, and long-term graft function may be compromised [101,102]. After the aortic cross-clamp is removed, the donor heart commonly experiences ventricular fibrillation due to ischemia and/or electrolyte imbalance, and must be defibrillated (initial energy 2–10 J) until sinus rhythm is achieved. Lidocaine, 2 mg/kg into the CPB circuit, is given 5 min before aortic cross-clamp removal, and a repeat dose of 1 mg/kg can be given if more than 1–2 defibrillations are required. Magnesium sulfate 25–50 mg/kg is often helpful, as is a lidocaine infusion at 20–40 μg/kg/min. Rarely, amiodarone 5 mg/kg load, repeated up to two additional doses, may be required. With the cross-clamp removed and the heart beating, the bicaval anastomoses and the pulmonary artery anastomoses are completed. The surgeon must pay particular attention to the anatomy of CHD recipients. There may be a need for extensive aortic arch reconstruction, requiring a long length of donor aorta in patients with hypoplastic left heart syndrome, or the need for a long length of donor superior vena cava in the case of single-ventricle patients with cavopulmonary anastomoses.

With the establishment of sinus rhythm and completion of the anastomoses, rewarming is accomplished. Additional intravenous anesthetics and muscle relaxant are administered. During this period inotropic support is instituted, according to institutional preference, taking into account ischemic time, systemic and pulmonary vascular resistance, and appearance of the myocardial function on visual inspection and TEE. Low-dose epinephrine, 0.03–0.05 μg/kg/min, is a common choice in this setting. Milrinone, 0.25–0.75 μg/kg/min, with or without a loading dose of 25–75 μg/kg over 15–30 min, is also useful in this situation for its inotropic and pulmonary and systemic vasodilator properties, as well as low propensity for arrhythmogenicity. Because the denervated heart has limited capacity to alter heart rate, and sinus node discharge of the donor heart often slows with edema, inflammation, or hypothermia, an isoproterenol infusion in low doses of 0.01–0.03 μg/kg/min is often very useful to maintain adequate heart rate. Some institutions opt for temporary atrial pacing to augment heart rate instead of pharmacotherapy. Recipients with pulmonary hypertension, and situations where the donor is smaller than the recipient (the donor right heart may have insufficient ability to overcome the recipient PVR), the right heart can be supported with milrinone, or inhaled nitric oxide, at 10–20 ppm [131]. Additional transthoracic monitoring catheters, such as right and left atrial lines,

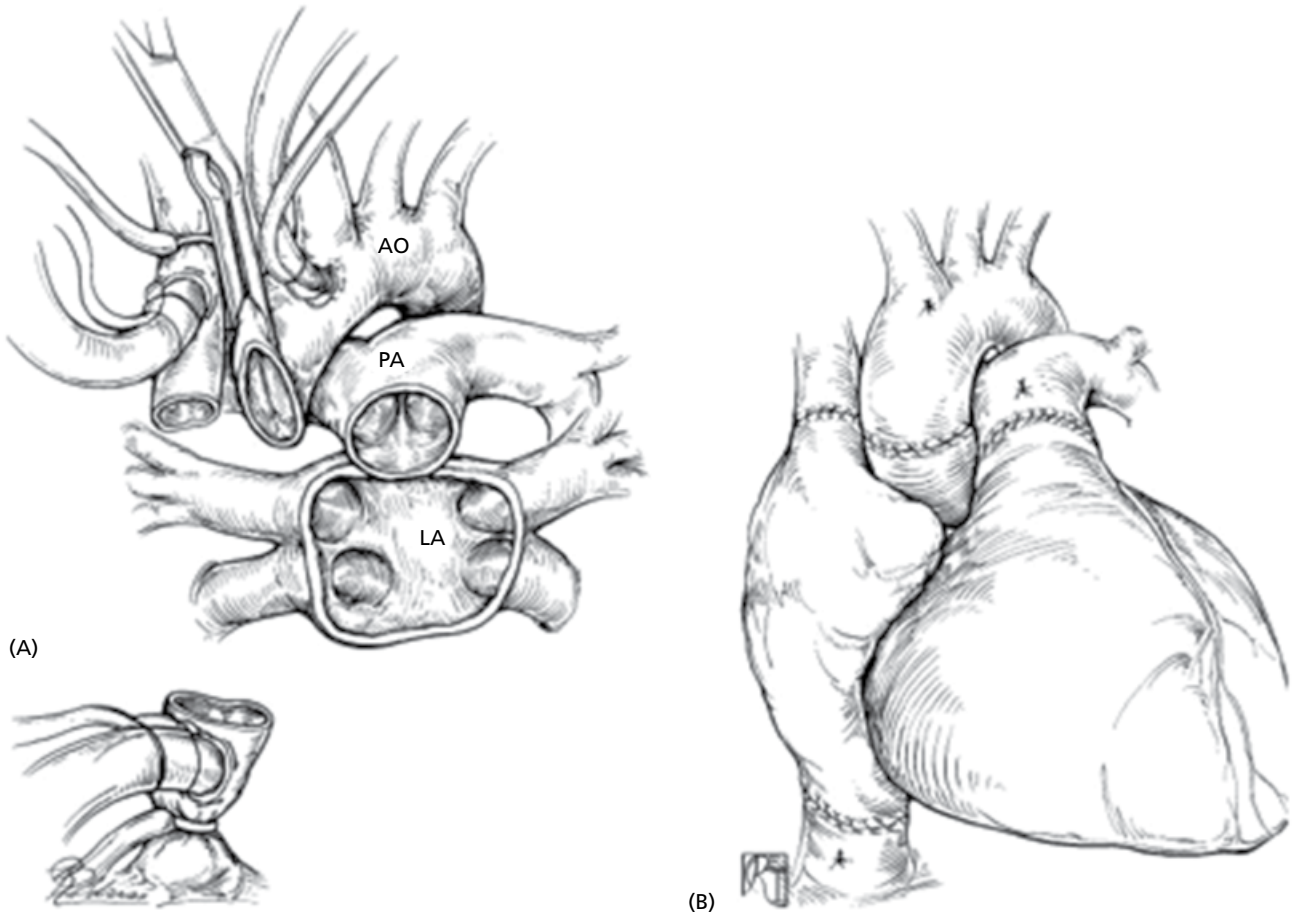

Figure 30.10 Surgical technique for "bicaval" cardiac transplantation. (A) The recipient cardiectomy has been completed. Note that the entire recipient right atrium has been removed. (B) The completed implant. The sequence of anastomoses is: (1) left atrial (LA), (2) aortic (Ao) (cross-clamp removed and heart perfused), (3) inferior vena cava, (4) pulmonary artery (PA), and (5) superior vena cava. *Source*: Reproduced from Rossano et al [130] with permission of John Wiley and Sons.

and occasionally pulmonary artery lines, are placed by the surgeon, along with temporary atrial pacing wires, which may be needed to support the denervated heart. Ventilation is commenced with 100% oxygen, designed to produce mild hypocarbia with a $PaCO_2$ of 32–35 mmHg. Once heart rate and rhythm, hematocrit, ventilation, and electrolytes are optimized, CPB is weaned slowly with gradual volume loading of the heart, using TEE monitoring to assess for intracardiac air, as well as biventricular function. After separation from CPB, cardiac function is assessed with TEE, as is the status of the anastomoses of the aorta, pulmonary artery, vena cava, and left atrium, with particular attention to any pulmonary venous obstruction. After ensuring a period of adequate hemodynamics and cardiac function, protamine 1–1.3 mg per mg of heparin in the original dose is administered, to neutralize the anticoagulation. The TEE probe is removed if no longer needed, and surgical hemostasis is achieved. Platelets and cryoprecipitate (rich in fibrinogen) are often required to achieve hemostasis, particularly with repeat sternotomy and complicated great vessel reconstruction [132]. Patients who are supported with ventricular assist devices before heart transplant are typically on intensive preoperative anticoagulation to prevent thrombosis and embolization, and this group of patients more commonly develop uncontrollable hemorrhage after bypass. There appears to be an increasing trend for the use of prothrombin complex concentrates to control refractory bleeding after cardiac surgery although the data in the pediatric population are limited.

Post-bypass period

In a few unstable patients, particularly small infants, the sternum may be left open for a period of 24–48 h to allow bleeding and myocardial performance to improve; these patients must have the sternum closed as soon as possible to reduce the risk of infection in the immunosuppressed patient. After bypass, attention is directed to the need for additional antibiotic or corticosteroid/immunosuppressive medications. Extubation of pediatric cardiac transplant patients in the OR is typically avoided, as many patients have an ongoing risk for myocardial dysfunction, arrhythmias, bleeding, and pulmonary hypertension. If the patient is stable, tracheal extubation can often be achieved in 12–24 h after ICU admission. Upon transfer to the ICU, a thorough patient hand-over report is given, including the surgical team discussing surgical issues, the anesthesia team giving a complete perioperative report to the attending ICU physician, and bedside nurses and the heart failure team clarifying the patient's postoperative immunosuppressive therapy. A standardized hand-over note, verbal communication, along with an opportunity to answer any questions, is recommended practice for the effective transfer of care in these complicated patients.

KEY POINTS: HEART TRANSPLANT PERIOPERATIVE MANAGEMENT

- Successful perioperative outcomes are dependent on careful multidisciplinary discussion, communication, and planning
- Many pretransplant patients are at high risk for cardiovascular collapse and therefore plans for resuscitation and extracorporeal support should be clearly organized
- Perioperative complications include massive bleeding, cardiac dysfunction, and arrhythmias
- In pediatric patients, 30% are bridged to transplant with MCS and are more prone to perioperative bleeding and vasoplegia

Post-transplant rejection surveillance

The mainstay of post-transplant surveillance for rejection is myocardial biopsy, with the first biopsy often performed 7–10 days after transplant to assess for acute rejection. Biopsies are performed most frequently in the first year after transplant, often every 3 months for uncomplicated cases. Thereafter, biopsy every 6 months is usually performed, along with thermodilution cardiac output measurement. Coronary angiography is added to the yearly regimen after 1–2 years, to assess the development of coronary artery vasculopathy. Five to seven biopsies of the right ventricle are obtained, and rejection is usually assessed according to the International Society for Heart and Lung Transplantation (ISHLT) scale according to the degree of lymphocytic infiltration and myocyte damage in the specimen [133]. Rejection is classified as either cellular, primarily lymphocyte infiltration, or humoral, a predominance of antibody–antigen and complement complexes, which is often observed in patients with high PRA titers. Signs of acute rejection can range from low-grade fever and malaise, and gastrointestinal symptoms, to poor myocardial function and cardiovascular collapse. Treatment for acute rejection often begins with large doses of corticosteroids, and higher doses of maintenance immunosuppressants. Other agents such as antithymocyte globulin, antilymphocyte globulin, or interleukin-2 receptor antagonists may also be added according to institutional practice. Plasmapheresis may be used for humoral rejection to reduce the antibody titers until immunosuppressants have an effect. Patients in acute rejection may need additional therapy, including inotropic and ventilatory support, or even MCS with ventricular assist devices or ECMO. If all of these measures fail to reverse the rejection, retransplant is the only remaining treatment option.

Morbidity and mortality after cardiac transplant

The median survival post transplant is 22.3 years in infants less than 1 year old and 13.1 years for those aged 11–17 (Fig. 30.11) [102]. The decreasing median survival in older patients is thought to be multifactorial, including a relatively immature immune system in infants with a lack of preformed antibodies, increased sensitization in older children from previous cardiac surgeries, and increased risk taking behavior in older children such as poor medication compliance [104].

The highest mortality rate remains during the first year post transplant [102] (Fig. 30.11) and improvements in 5-year survival over different eras (Fig. 30.12) are primarily due to improvements in early survival in the first year [101,102]. Early mortality is significantly increased for patients on ECMO, those with a CHD diagnosis, those undergoing retransplantation, and those requiring ventilatory support immediately prior to transplant (Fig. 30.13) [102]. Continuous risk factors associated with 1-year mortality include donor ischemic time, donor–recipient height difference, estimated glomerular filtration rate, and pediatric center volume (Table 30.16). The leading causes of death in the first 30 days are: graft failure in 35%, infection in 15%, and multiorgan failure and acute rejection in 12% each. Categorical risk factors for 5-, 10-, and 15-year mortality include CHD, ECMO, and PRA >10%. Continuous risk factors for late mortality are also displayed in Table 30.16.

The leading cause of late mortality is graft failure, responsible for 30–40% of deaths beyond 3 years after transplant (Fig. 30.14) [102]. Retransplantation is most commonly

performed because of severe coronary artery vasculopathy (CAV) or graft failure, and carries a higher risk of mortality, with a 5-year survival of about 67% in the modern era versus 77% for primary transplantation [134].

Morbidities in cardiac transplant recipients at 5 years after transplant include hypertension in 63% (primarily associated with corticosteroid use), hyperlipidemia in 26%, CAV in 11%, and renal dysfunction in 9% [101,102]. Thus a substantial number of these patients will be taking antihypertensive medications, and some will be taking statins or other cholesterol-lowering drugs. Renal function requires assessment before anesthetic, to avoid or minimize the use of agents with primary renal excretion, in appropriate patients. Infection and lymphoma are seen in a very small percentage of pediatric cardiac transplant recipients. Early CAV in the first 3 years after transplant is associated with a significantly higher risk of rejection.

KEY POINTS: HEART TRANSPLANT MORTALITY

- The highest mortality rate occurs during the first year post transplant
- Mortality risk factors include pretransplant ECMO or mechanical ventilation, CHD, retransplantation, renal dialysis, PRA >10%, and donor ischemic time
- The leading cause of early mortality is graft failure and of late mortality is coronary artery vasculopathy

Anesthetic management

Endomyocardial biopsy

All cardiac transplant recipients require myocardial biopsy. Access is gained either via the right internal jugular vein or

Table 30.16 Multivariable analysis of continuous risk factors for mortality after pediatric cardiac transplantation

Variable	p value
1-year mortality (transplants: January 2004 to June 2015)	
Ischemic time	0.0003
Recipient body mass index	0.0072
Donor body surface area	0.0038
Donor–recipient height difference	0.0119
Recipient estimated glomerular filtration rate	0.0117
Center volume: number of pediatrie transplants in previous year	0.0004
Recipient total bilirubin	0.0170
5-year mortality (transplants: January 2001 to June 2011)	
Recipient age	0.0002
Donor age	0.0434
Ischemic time	0.0048
Recipient weight	0.0403
Recipient estimated glomerular filtration rate	0.0006
Center volume: number of pediatrie transplants in previous year	0.0026
10-year mortality (transplants: January 1996 to June 2006)	
Recipient age	0.0010
Donor age	0.0006
Recipient height	0.0023
Recipient estimated glomerular filtration rate	0.0143
Transplant center volume	0.0084
15-year mortality (transplants: January 1990 to June 2001)

the femoral vein. One advantage of jugular vein access is a faster post-biopsy recovery without a mandatory "lying flat" period, whereas femoral vein access may simplify the anesthetic and sedation management because the access site is remote from the airway. Some older teenage patients are mature and cooperative enough to receive intravenous sedation and local anesthesia to the access site without requiring the presence of an anesthesiologist. However, many older patients are very anxious due to the lifelong nature of their medical interventions, and require higher doses of sedative medications and associated deeper sedation in order to perform the catheterization. In stable outpatients without signs or symptoms of rejection or CAV, moderate or deep IV sedation with a variety of agents can be used, including benzodiazepines, opioids, and propofol. Patients with known or suspected rejection or CAV must be approached with great care. These patients may have significantly compromised cardiac function, or very severe CAV with marginal myocardial perfusion. They have very limited reserves if the myocardial oxygen supply–demand balance is upset. Whatever technique is used, these patients should not be subjected to significant reductions in preload or afterload as myocardial perfusion depends on blood pressure. Bolus administration of agents such as propofol or thiopental should be avoided, blood pressure monitored closely, and hypotension treated immediately. Tachycardia should also be avoided. If general anesthesia is chosen, positive pressure ventilation must be instituted carefully so as not to excessively decrease venous return. Airway and oxygenation may be supported with nasal cannulae, facemask, laryngeal mask airway, or endotracheal intubation.

Non-cardiac surgery

Cardiac transplant recipients may undergo surgical and diagnostic procedures, unrelated to the transplant. In addition to the assessment of cardiac and non-cardiac problems, the anesthesiologist should determine the results of the most recent cardiac biopsy, cardiac output, signs of rejection, and whether there is a suspicion of CAV. Ideally there should be a cardiology evaluation, including an echocardiogram, within 6 months of the procedure. The hemodynamic goals noted

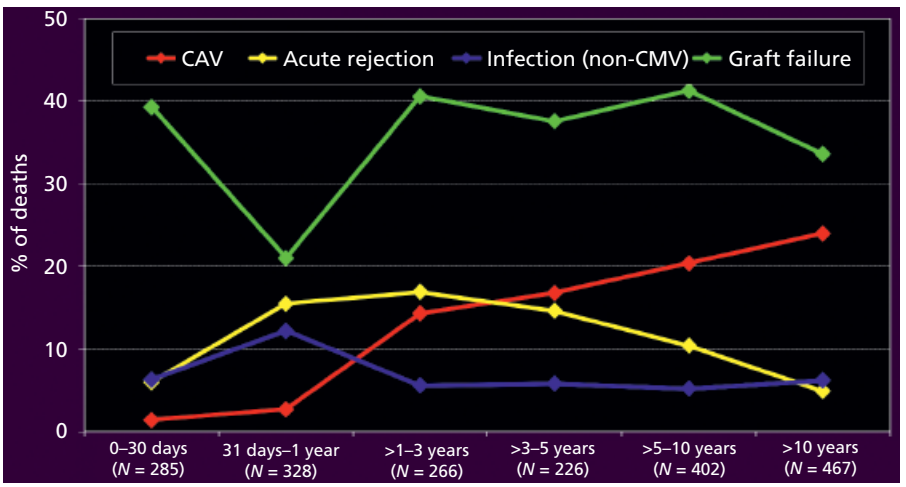

Figure 30.14 Relative incidence of leading causes of death in pediatric heart trasnsplants, 2004–2016. CAV, coronary artery vasculopathy; CMV, cytomegalovirus. *Source*: Reproduced from Rossano et al [102] with permission of Elsevier.

above for endomyocardial biopsy are the same for non-cardiac surgery. The denervated heart does not respond to vagolytic agents, so bradycardia requires treatment with a direct acting β1-agonist such as isoproterenol or epinephrine. Infective endocarditis prophylaxis guidelines have been significantly revised, and limit the need for prophylaxis to transplant recipients who develop valvulopathy and undergo dental and airway procedures where the respiratory mucosa is breached.[135]. Prophylaxis is no longer recommended for gastrointestinal and genitourinary procedures unless there is active infection. Care should be taken with the reversal of non-depolarizing muscle relaxants using neostigmine. Variable parasympathetic reinnervation, along with humoral or cellular rejection, may produce unpredictable responses to neostigmine and glycopyrrolate, which have been reported to produce severe sinus bradycardia and asystole [136]. Stress dose corticosteroids should be administered as appropriate for significant surgical procedures, where adrenal suppression is suspected.

ABO-incompatible transplantation

The number of infants listed for cardiac transplantation exceeds the number of donors by approximately 3:1, and there is significant mortality for infants waiting for transplant. Many infant heart transplant recipients who survive the first year after transplant are remarkably free of rejection. In 2001 West and colleagues described a series of infant cardiac transplants in patients up to age 14 months, with ABO-incompatible donors [128]. Anesthetic and surgical management of the transplant does not differ, except that an exchange transfusion, as described earlier, is performed upon institution of CPB. In addition, transfused blood products are selected to avoid antibodies to the donor heart. Midterm survival and rejection rates were not different to those of ABO-compatible transplants, and the waiting list mortality was reduced from 58% to 7% for infant transplants [128]. This technique has been adopted by more institutions, as evidence develops that overall survival of infants listed for transplant improves in the long term [137,138]. UNOS recently changed the priority listing for ABOi heart transplants to give them equal organ priority to ABO-compatible listed patients [111,112]. In recent years the ABO-incompatible approach has been extended to patients less than 2 years of age, with similar outcomes as for ABO-compatible transplants [139]. Many programs now offer these transplants, and the ABO-incompatible approach has now been reported in pediatric lung, liver, and kidney transplantation.

Bridge to transplant

Due to the shortage of donor organs, an increasing number of pediatric patients (approximately 30%) undergo MCS as a bridge to transplant (Fig. 30.15) [102]. In the past 10–15 years this has been the biggest change in the field of pediatric cardiac transplantation; the percentage of transplant patients on a ventricular assist device (VAD) has approximately tripled, while the percentage on ECMO support has declined significantly with improvement in techniques and devices for VAD support. Recent data show a similar overall survival in pediatric patients bridged to transplant with a VAD or total artificial heart (TAH) compared with no MCS (Fig. 30.16) [102]. However, patients bridged to transplant with ECMO had a significantly worse survival when compared to those bridged with VAD/TAH or those without MCS. The greatest risk of death in the ECMO group occurred in the first 6 months post transplant [102]. In 2011, the PediMACS registry was developed as a comprehensive registry of temporary and durable VADS in pediatric patients. Durable devices include pulsatile flow devices such as the Berlin Heart Excor® and continuous flow devices such as the HeartMate® (Thoratec, Pleasanton, CA, USA) and HeartWare™ (Medtronic, MA, USA) devices. Overall pediatric survival on a durable device is approximately 72% at 6 months [140]; ranging from 47% in patients <1 year to 81% in patients 11–19 years of age. Approximately 50% all patients were transplanted by 6 months on a device; 81% of patients were supported with LVAD alone whereas 15% required biventricular support. Common adverse events post-VAD implantation include bleeding, infection, device malfunction, and neurological events [140]. The frequency of MCS varied significantly according to the indication for transplant [102]. From 2009 to 2015, 47% of patients with DCM

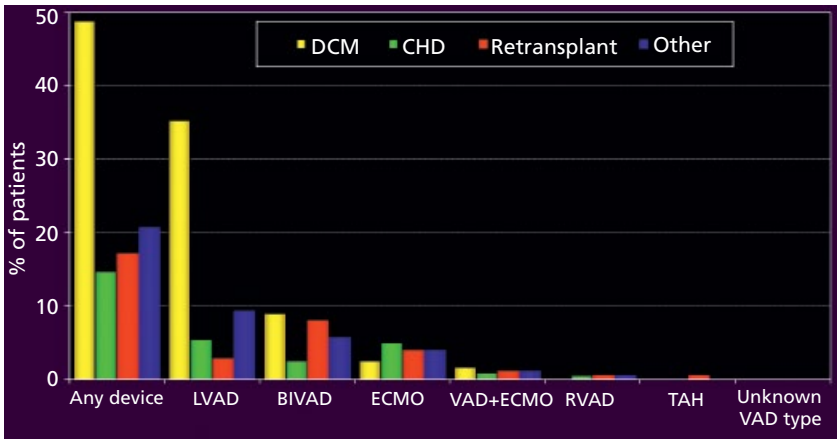

Figure 30.15 Pediatric heart transplant recipients bridged with mechanical circulatory support by diagnosis, 2009–2016. required some form of MCS as a bridge to transplant, with the majority of cases being LVADs. ECMO as the primary support modality decreased from 42% of the MCS cases in 2005 to 9% in 2015 [102]. Perhaps, in the future, as technology advances and MCS survival and morbidity improves, implantable devices will be regarded as more of a long-term therapeutic option rather than just a bridge to transplant.

Lung transplantation

History

The first human lung transplant was performed on an adult in 1963 by James Hardy at the University of Mississippi [141]. This was followed by adult lobar (Shinoi, 1966) and pediatric heart–lung transplantation (Cooley, 1968) but outcomes were uniformly dismal. Advances over the next decade included the introduction of cyclosporine, better surgical techniques, and improved donor organ preservation, leading to the first long-term success with an adult heart–lung transplant by Reitz at Stanford in 1981 [142]. Cooper and colleagues in Toronto demonstrated that bronchial omentopexy enhanced the vascularity and integrity of the bronchial anastamosis and subsequently reported the first long-term successful adult (1983) and pediatric (1987) lung transplants [99]. Living donor lobar transplantation was first performed at Stanford by Starnes in 1990.

Data about lung and heart–lung transplantation from many centers around the globe are updated regularly by the ISHLT and can be viewed at their website (www.ishlt.org/registries; accessed April 2019). The ISHLT registry report in 2017 for the period 1988–2015 included 2326 pediatric lung transplant and 728 pediatric heart–lung transplant procedures [143]. Of note, heart–lung transplant procedures peaked in the late 1980s to early 1990s, at 50–60/year in the ISHLT registry. Over the last 10 years, only 5–10 heart–lung transplants are performed annually due to historically poor survival, especially in infants.

Forty to 50 centers have reported pediatric lung transplant procedures to the ISHLT over the last 10 years. Of these, only 1–3 centers report between 10 and 19 transplants per year over the past 10 years, 3–5 centers report 5–9 transplants per year, and the vast majority (35–40) of centers report <5 transplants per year (Fig. 30.17) [143]. Annually, an average of 100–120 children received lung transplant surgery over the past 10 years. Most patients were adolescents; the number of infant transplants has remained low at about 5–10 annually over the past 10 years (Fig. 30.18) [143].

In addition to the specific challenges inherent in caring for children, pediatric lung transplantation has many unique aspects, including a diverse spectrum of pulmonary and non-pulmonary diseases, donor–recipient matching, and growth of the transplanted organs. Children receiving transplantation undergo many surgical and diagnostic interventions and frequently require sedation or general anesthesia. Provision of safe perioperative care requires familiarity with the relevant issues, including pulmonary pathophysiology and the conduct and consequences of lung transplantation.

Indications

Generally, lung transplant surgery is considered for children with any end-stage lung disease for whom there is no medical treatment [144]. For all children less than 18 years of age, the common primary diagnoses leading to lung transplantation are cystic fibrosis (56%) and pulmonary hypertension, either idiopathic (10%) or related to CHD (5%) [143], whereas the common primary diagnoses in adults are chronic obstructive pulmonary disease or interstitial lung diseases. Indications for transplantation differ by age with cystic fibrosis the predominant indication for children aged 6 years or older (Table 30.17).

Cystic fibrosis

Respiratory failure is the commonest cause of death in these children. Many variables, like rate of decline in forced expiratory volume in 1 s (FEV_1), elevated pCO_2 (>50 mmHg), falling pO_2 (<55 mmHg), deteriorating nutritional status, frequency of hospitalizations, and the 6 min walk test are considered before listing the patient for lung transplant [145]. Perioperative management should address non-pulmonary

manifestations of cystic fibrosis such as severe malnourishment, chronic infection, pancreatic insufficiency, diabetes mellitus, cholelithiasis, hepatic cirrhosis, distal intestinal obstruction syndrome, sinusitis, nasal polyps, osteoporosis, and genitourinary problems [146,147]. Pretransplant mechanical ventilation was predictive of poor 1-year survival after lung transplantation [148]. There are reasonably compelling data documenting the beneficial impact of lung transplantation on functional status, hemodynamics, and quality of life but demonstration of a survival benefit for children remains controversial [149,150]. Newer treatments for cystic fibrosis such as dornase alpha and ivacaftor (an oral cystic fibrosis transmembrane conductance regulator (CFTR) potentiator that improves chloride transport in cells expressing certain CFTR gating mutations), have contributed to sustained improvements in pulmonary function, weight gain, life expectancy, and delay in age of lung transplantation [151,152].

Pulmonary hypertension

During the Fourth World Symposium on Pulmonary Hypertension held in Dana Point, California in 2008, a reclassification of pulmonary hypertension based on clinical evolution, histopathology, and response to therapy was proposed. A diagnosis of primary (or idiopathic) pulmonary arterial hypertension is made when no known risk factor is identified. Familial pulmonary arterial hypertension has been linked to mutations in receptors in the transforming growth factor β superfamily, such as BMPR2 (bone morphogenetic protein receptor 2) and ALK-1 (activin-like kinase 1) which affect vascular intimal proliferation. Pulmonary arterial hypertension associated with CHD constitutes a heterogenous group of conditions and has been classified based on circulatory pathophysiology [153].

Transplantation options for pulmonary hypertension include lung transplantation, heart–lung transplantation, or lung transplantation in combination with repair of the underlying cardiac defect. Survival rates for these strategies have been reviewed [154]. In Eisenmenger syndrome secondary to ventricular septal defect, there was a survival benefit of heart–lung over lung transplantation [155]. Transplantation may improve the quality of life of patients with Eisenmenger syndrome but may not improve survival because most unrepaired Eisenmenger patients will survive beyond their 40th birthday [156]. Many children with pulmonary hypertension will be receiving agents such as endothelin receptor antagonists, phosphodiesterase inhibitors, prostacyclin analogs and nitric oxide. For idiopathic pulmonary hypertension, contemporary guidelines recommend referral to lung transplantation centers for evaluation of patients who are in World Health Organization (WHO) functional class III or IV on optimized medical therapy or who have rapidly progressive disease [157].

Disorders of surfactant metabolism

Pediatric interstitial lung disease syndrome is an uncommon indication for lung transplantation and includes diseases of surfactant metabolism [158]. Surfactant proteins B, C, and ABCA3 transporter are necessary for surfactant homeostasis, and mutations in the genes encoding these proteins lead to surfactant dysfunction, giving rise to both lethal and chronic respiratory disease in infants. Patients may require lung transplantation in early infancy because of severe respiratory failure.

Miscellaneous disorders

Lung transplant surgery has also been performed in children for a variety of other indications like bronchopulmonary dysplasia, congenital diaphragmatic hernia, hemosiderosis, bronchiolitis obliterans, and emphysema.

Criteria for listing and contraindications

The criteria for listing children for lung transplant surgery are based on the natural history of the disease, functional status, and expected improvement in quality of life. Generally, a clear diagnosis with a life expectancy of less than 2 years is necessary for listing the child for the lung transplant. However, it is hard to develop survival models for relatively rare diseases.

Contraindications to lung transplantation are listed in Table 30.18 [144]. Mechanical ventilation is a risk factor for morbidity and mortality in older children but not infants. Children with cystic fibrosis who are colonized with multidrug-resistant organisms like *Burkholderia cenocepacia* and *B. gladioli* do poorly and most centers consider this a strong contraindication. Children with liver disease secondary to cystic fibrosis may be candidates for combined liver–lung transplant surgery and have good survival rates. Patient and parental psychosocial issues can be particularly challenging and may become a significant contraindication if child and family consistently fail to meet agreed-upon expectations for care and follow-up [13].

Perhaps the most difficult decision for pediatric lung transplant physicians is determining the appropriate time to accept organs because there is wide variation in the natural history of the primary diseases (Table 30.19) and the 5-year survival rate after lung transplantation is only about 50% [13]. Most pediatric centers consider multiple factors, including waiting list survival estimates (when available), growth and nutrition status, frequency of hospitalizations, and potential for improvement in overall quality of life before committing a child to lung transplant.

Table 30.18 Contraindications to pediatric lung transplantation

Absolute	Relative
Active malignancy	Pleurodesis
Sepsis	Renal insufficiency
Active tuberculosis	Markedly abnormal body mass index
Severe neuromuscular disease	Mechanical ventilation
Documented, refractory non-adherence	Scoliosis
Multiple organ dysfunction	Poorly controlled diabetes mellitus
Acquired immunodeficiency syndrome	Osteoporosis
Hepatitis C with histological liver disease	Hepatitis B surface antigen positive
	Fungal infection/colonization
	Chronic airway infection with multiply resistant organisms

Table 30.19 Recommendations regarding timing of referral to lung transplant center

Specific disease	Timing of referral
Surfactant deficiencies	Patients with SP-B deficiency and ABCA3 deficiency with refractory respiratory failure should be referred immediately Patients with SP-C deficiency and less severe forms of ABCA3 deficiency may respond to medical therapy and should be referred when unrelenting progression of disease develops
Primary pulmonary hypertension	Patients who present in NYHA class III or IV or have evidence of right heart failure should be referred immediately Patients who fail to respond adequately to vasodilator therapy should also be referred
Eisenmenger syndrome	When the trajectory of pulmonary hypertension appears to be worsening with impaired exercise tolerance and worsening quality of life
Other pulmonary vascular disorders (pulmonary vein stenosis, alveolar capillary dysplasia)	These patients should be referred immediately since they typically do not respond to medical management and are at risk for sudden death
Cystic fibrosis	Patients with percent predicted FEV_1 values less than 30%, frequent hospitalizations, refractory hypoxemia or hypercapnia should be referred for transplant
Bronchopulmonary dysplasia	Patients with recurrent or severe episodes of respiratory failure or evidence for progressive pulmonary hypertension
Diffuse parenchymal lung disease	Patients without evidence for systemic disease that could affect outcome should be referred early

Donor selection, availability, and the lungs allocation system

Like other organ transplant surgeries, donor availability has been a limiting factor. Only about 15% of cadaveric donors have lungs that are considered acceptable for transplantation [159]. The OPTN implemented a new lungs allocation system in 2005 that used medical urgency as the primary determinant of organ allocation and discouraged the use of waiting time [160]. Under this system, a lung allocation score is calculated for every patient >12 years of age using multiple variables like age, functional status, forced vital capacity, and oxygen requirement. The new policy also mandated that the donor lungs from pediatric donors be preferentially given to pediatric patients. Recent data from adult and pediatric patients suggest that implementation of the lung allocation score system has decreased waiting times and increased the annual number of lung transplant surgeries performed [160].

However, children younger than 12 years of age still received organs based on the waiting time accrued on the transplant list. Recognizing that infants carry the highest waiting list mortality rate among all transplant candidates, the OPTN recently approved proposals to preferentially direct organs from donors under 11 years old to younger children [161].

Donor lungs are selected after thorough medical screening and multiple laboratory tests. In younger children, comparable age and height (<20% discrepancy) are considered acceptable for matching lung volume. Selection criteria are relatively subjective. An ideal donor is younger than 55 years, a nonsmoker, and has no history of cardiopulmonary or significant neurological disease. The donor lungs should produce good gaseous exchange (PaO_2 >350 mmHg with FiO_2 of 1.0) on a moderate amount of ventilatory support. The chest radiography and bronchoscopy should rule out any significant infection, consolidation, and tumor. An expected ischemic time of <6 h is preferred. Optimal donor lung management has been reviewed [162]. To increase the number of potential donors, some centers have advocated acceptance of longer ischemic times and "marginal" donors with reversible mild lung pathology [163]. Biochemical markers in the bronchoalveolar lavage fluid from the donor lungs (e.g. interleukin (IL)-8, IL-6, and IL-1b), are being evaluated as predictors of early and late graft dysfunction [164]. Additionally, using lung donation after cardiac death is another option that has been being considered to alleviate organ shortage [165].

The process of harvest includes systemic heparinization of the donor and infusion of prostaglandin E1 into the main pulmonary artery. A number of preservation solutions have been tried but currently Euro-Collins solution is used by most centers. Lungs are inflated with an FiO_2 of less than 0.4 to an airway pressure less than 20 cmH_2O. Lungs are removed en bloc with the thoracic aorta, left atrial cuff, and main pulmonary artery [162].

KEY POINTS: INDICATIONS, CONTRAINDICATIONS, AND LISTING FOR LUNG TRANSPLANTATION

- Cystic fibrosis and pulmonary hypertension are the leading indications for lung transplantation
- Contraindications include active malignancy, sepsis, colonization with multidrug resistant bacteria or fungus, and severe neuromuscular disease
- Life expectancy of less than 2 years is generally necessary before listing for lung transplant

Preoperative assessment and preparation

Candidates for lung transplantation undergo an extensive medical and psychosocial evaluation. Imaging studies of major thoracic systemic and pulmonary vessels may be required for patients with CHD because abnormal vasculature can alter the conduct of organ harvest and transplantation surgery. Children with pulmonary hypertension undergo a diagnostic cardiac catheterization to quantify hemodynamics and test for reactivity to pulmonary vasodilator therapy. After listing, the child's clinical progress is monitored regularly and an anesthetic consultation obtained. Many children can be living at home with minimal oxygen supplementation while others, especially infants, are on chronic ventilatory or

extracorporeal hemodynamic support. Recently, extracorporeal devices that facilitate respiratory exchange have been utilized as a bridge to lung transplant [166–168]. In addition, there are now a number of reports of "awake" venovenous ECMO in older pediatric patients awaiting lung transplant [169–171]. This strategy allows oral intake, physical therapy, and even ambulation and may improve preoperative transplant status.

Anesthetic management

Box 30.6 summarizes the intraoperative management of pediatric lung transplantation. Like other solid organ transplants, time of surgery is unpredictable. Most families are provided a hospital pager and have been anticipating the surgery for a long period of time. Patients are often excited and frightened. Anxiolytics such as midazolam can be safely given to most children but discretion and monitoring are advised because of the potential for compromise to upper airway control, respiratory effort, and hemodynamic stability.

When relevant, the patient and family should be informed preoperatively that surgery may possibly not proceed to transplantation if the donor lungs are deemed unsuitable. Good communication between the donor and recipient teams is vital, with all parties having a clear understanding of the expected time of anesthesia induction and donor organ arrival. Anesthesia preparations are similar to those for pediatric hypothermic open heart surgery. Anesthesiologists often work under considerable time pressure because of concerns about extending the donor organ ischemic time.

Standard NPO guidelines are followed to minimize the risk of aspiration and contamination of the new lungs. The method of anesthesia induction and choice of agents will depend on the patient's clinical and NPO status. The hemodynamic goal is to preserve stability without increasing PVR. Both volatile and intravenous anesthetic agents are acceptable. Propofol is safe for hemodynamically stable children (e.g. many cystic fibrosis patients) but ketamine or etomidate may be the preferred drug for patients who have poor cardiac reserve and/or pulmonary hypertension. Anesthetic depth can be maintained

Box 30.6: Summary of intraoperative considerations for pediatric lung transplantation

Pre-bypass period

- Consider pathophysiology of lung disease: CF, pulmonary hypertension, congenital heart disease, others
- Maintain all pulmonary vasodilator therapy on schedule
- Administer immunosuppressant induction agents and antibiotics according to preoperative plans
- Standard single-lumen endotracheal tube for most cases. Plan with surgeon for tracheostomy management
- Vascular access: arterial line (consider femoral if arms up for clamshell incision), CVP, large-bore peripheral intravenous catheters
- Discuss surgical approach: BSLT (clamshell incision, separate bronchial anastomoses), versus en bloc technique with bronchial revascularization (sternotomy, single tracheal anastomosis)
- Ventilate to baseline $PaCO_2$ values (e.g. hypercarbia common)
- ICU ventilator or HFOV may be required for infants
- Maintain pulmonary toilet pre-bypass: suction, bronchodilators
- Prepare for possibility that donor lungs are unsuitable after visualization (limit fixed agents, reverse muscle relaxant, awaken patient, remove lines)

Bypass period

- Normally mild to moderate hypothermic bypass
- Repair any congenital cardiac lesions, e.g. atrial septal defect
- Normally no aortic cross-clamp
- Instill antibiotics into trachea for CF patients
- Prepare bronchoscope to visualize bronchial/tracheal anastomoses, suction/irrigate blood, mucus, clot
- Ideally ischemic time goal is <6 h until lungs are reperfused (completed pulmonary artery anasotomoses)

Postbypass period

- Separate from bypass on ventilator settings that minimize volutrauma, barotrauma, oxygen toxicity: 6–7 mL/kg (donor weight), peak pressure <25 cmH_2O), PEEP 5 cmH_2O, FiO_2 0.4–0.5 or less
- Inhaled nitric oxide 20 ppm, epoprostenol frequently used
- Limit fluid administration (no lymphatic drainage): CVP 4–6
- Milrinone, vasopressors (vasopressin, phenylephrine) as needed
- Significant bleeding treated with platelets, cryoprecipitate/fibrinogen concentrate, and fresh frozen plasma/coagulation factor concentrate/activated factor VII
- Usually no TEE unless intracardiac repair
- Early graft dysfunction (hypoxemia, pulmonary edema) treated with increased FiO_2, PEEP, inhaled nitric oxide to maintain SpO_2 in low 90s; venovenous ECMO if needed
- Usually will not extubate in operating room; but stable patients can be extubated in 12–24 h
- Full hand-over report from anesthesia/surgical team to ICU team
- Pain management via opioid infusion, dexmedetomdine, and patient/nurse-controlled analgesia

CF, cystic fibrosis; BSLT, bilateral sequential lung transplantation; CVP, central venous pressure; ECMO, extracorporeal membrane oxygenation; FiO_2, fraction of inspired oxygen; HFOV, high-frequency oscillatory ventilation; ICU, intensive care unit; $PaCO_2$, partial pressure of CO_2 in arterial blood; PEEP, positive end-expiratory pressure; SpO_2, peripheral capillary oxygen saturation; TEE, transesophageal echocardiogram.

with opioids and benzodiazepines, and supplemented with inhalational or intravenous agents [172]. Nitrous oxide is best avoided because of concerns about myocardial depression, pulmonary hypertension, air embolism, and the requirement for high concentrations of inspired oxygen. The combination of anesthesia, right ventricular diastolic dysfunction, and positive pressure ventilation may unmask a relative intravascular volume deficiency that can be corrected by IV fluid infusion.

Most often, pediatric lung transplants are performed with the assistance of CPB and the airway is secured with a single-lumen endotracheal tube because lung isolation is not required. Occasionally, patients have a tracheostomy, and airway management needs to be planned with the surgeon; i.e. intubate the trachea from above and temporarily seal the stoma, endotracheal tube in the stoma for improved airway access, or utilize the existing tracheostomy (see Chapter 16). Frequent toilet of the airway is advised, particularly in patients who have cystic fibrosis. Bronchodilator therapy should be available. Effective oxygenation and carbon dioxide elimination may be difficult during the pre-CPB period, and permissive hypercapnia is acceptable. Ventilation should be adjusted to minimize air trapping because lung hyperinflation can impede venous return to the heart. Strategies to limit airway pressure are advised for patients at increased risk of barotrauma, such as those with restrictive lung disease or chronic obstructive pulmonary disease. Occasionally, especially in infants, a sophisticated pediatric intensive care ventilator may be required in the OR. Many patients who have end-stage lung disease have a chronic compensatory metabolic alkalosis. Enthusiastic hyperventilation to normal $PaCO_2$ values induces an iatrogenic alkalotic blood pH level that increases cerebral vasoconstriction and leads to relative cerebral ischemia.

Invasive monitoring appropriate for surgery with CPB is established. At many institutions, continuous monitoring of pulmonary pressure with pulmonary artery catheter is limited to adolescents with the pretransplant diagnosis of pulmonary hypertension [173]. The pulmonary artery catheter is introduced through a sheath in the internal jugular vein and advanced to the pulmonary artery after the patient has been weaned from CPB. For smaller children, a transthoracic catheter can be placed directly into the pulmonary artery by the surgeon. Intraoperative TEE is useful for assessing cardiac anatomy and function, pulmonary hypertension, and to rule out pulmonary venous obstruction [174,175].

Anesthesiologists must ensure that the non-anesthetic drugs like immunosuppressants and preoperative antibiotics are administered at appropriate times. For children with pulmonary hypertension, selective vasodilators like nitric oxide and prostacyclins must be maintained throughout the pre-bypass period to avoid rebound pulmonary hypertension.

Children undergoing lung transplantation are at increased risk for perioperative bleeding because of coagulopathies associated with CPB and cyanosis, and bleeding from chest wall adhesions (infections, previous surgery) or abnormal vessels (venovenous or arteriovenous collaterals). Antifibrinolytic prophylaxis with the lysine analogs may help reduce blood loss but there is insufficient information about their efficacy and safety in young children.

The function of the implanted lungs could be adversely affected by donor pathology, ischemia-reperfusion injury, CPB, blood product transfusions, denervation, lymphatic stasis, positive pressure ventilation, oxygen toxicity, and hyperacute rejection. Ischemia-reperfusion injury contributes to primary graft dysfunction (PGD) and can increase the risk of acute and perhaps chronic rejection. Oxygen is readily available to the metabolically active endothelium of lung allografts during the ischemic period and this allows production of free radicals, making lungs more susceptible to graft failure than other solid organs. Reperfusion injury appears to occur in two distinct phases. The first phase, seen immediately after the reperfusion, is initiated by donor macrophages and includes the release of superoxide anions and inflammatory cytokines, with mast cell degranulation and complement activation. These damage the vascular endothelium causing movement of fluid to the interstitial and alveolar space [176]. The delayed phase of PGD starts a few hours later when the recipient's neutrophils are recruited by cytokines to the injured endothelium. These neutrophils produce reactive superoxide anions and greatly amplify the initial injury. Strategies to minimize reperfusion injury include improvements to the lung preservation solution, gentler reperfusion techniques, protective ventilation strategies, and inhaled nitric oxide [177]. Ultrafiltration during and after CPB can ameliorate the inflammatory response. However, modified ultrafiltration increases right ventricular volume load and may precipitate right heart failure in the presence of pulmonary hypertension [178].

Before weaning from CPB, a bronchodilator may be administered by metered dose inhalation or nebulization, and the lungs are carefully re-expanded to check for bronchial air leaks and ventilation is then resumed. Ventilator parameters are guided by the donor weight. Tidal volume and airway pressures are adjusted so that all atelectatic areas are expanded but not over distended. Volutrauma caused by overdistension of the new lungs can increase endothelial permeability and potentiate primary graft dysfunction. Typically, flexible bronchoscopy is performed to assess the bronchial anastomosis, and to remove blood and secretions from each lung under direct visualization. If possible, inspired oxygen concentrations should be lowered because of concern about oxygen toxicity and free-radical damage [179]. Restriction of fluid infusions is advocated because the lung allograft is very sensitive to pulmonary edema but trials substantiating this practice are lacking.

Inhaled selective pulmonary vasodilator therapy (e.g. nitric oxide, epoprostenol) is initiated when pulmonary artery pressures are increased. Some centers routinely administer intravenous prostacyclin or prostaglandin E1 to reduce pulmonary artery pressures and preserve right heart function. Pulmonary hypertension must be anticipated and managed carefully [180,181]. Inhaled nitric oxide before and after transplantation may improve allograft function [182]. Right ventricular dysfunction can be supported by intravenous inotropes. Milrinone is a common choice because of its lusitropic and vasodilator effects.

Cardiopulmonary bypass

Although controversial, there is some evidence that CPB is an independent or contributing factor for PGD [183]. Therefore, most adult bilateral lung transplant centers perform lung transplantation using single-lung ventilation through dual-lumen

endotracheal tubes. However, most children are physically too small to accommodate a double-lumen tube. Additionally, some children are too tenuous clinically to tolerate a prolonged period of single-lung ventilation. CPB allows the resection of both diseased lungs simultaneously, thus minimizing the risk of cross-contamination of the new lungs. Also, it provides stable hemodynamics during the extensive surgical dissection, greatly simplifies the anesthetic and surgical management, and consequently reduces lung ischemic times. Therefore, most pediatric lung transplants are performed using CPB. A large single-center comparison of the incidence of PGD in pediatric and adult lung transplant found no difference suggesting that CPB did not carry additional risk in children [184].

Surgical technique

Most children undergo bilateral sequential lung transplantation through a trans-sternal, clamshell incision (Fig. 30.19) [185]. Very few pediatric single-lung transplants are performed because the primary disease usually affects both lungs. Beating heart CPB with moderate hypothermia (28–32°C) is employed. Aortic cross-clamping and cardioplegia may be necessary if co-existing intracardiac defects require repair. Once CPB is established, both lungs are removed and the recipient's tracheal stump is irrigated with an antibiotic solution. Meanwhile, a second surgical team prepares the donor lungs that are then implanted using end-to-end bronchial anastomoses. Since the surgery compromises the bronchial vasculature, peribronchial tissue is sutured loosely around the anastomoses to provide blood flow by new vessel ingrowth. The donor pulmonary artery is attached to the native main pulmonary artery. The pulmonary veins are reconnected to the recipient's left atrium en bloc, using the donor's atrial cuff. This method not only reduces the surgical time but also minimizes the risk of developing pulmonary vein stenosis.

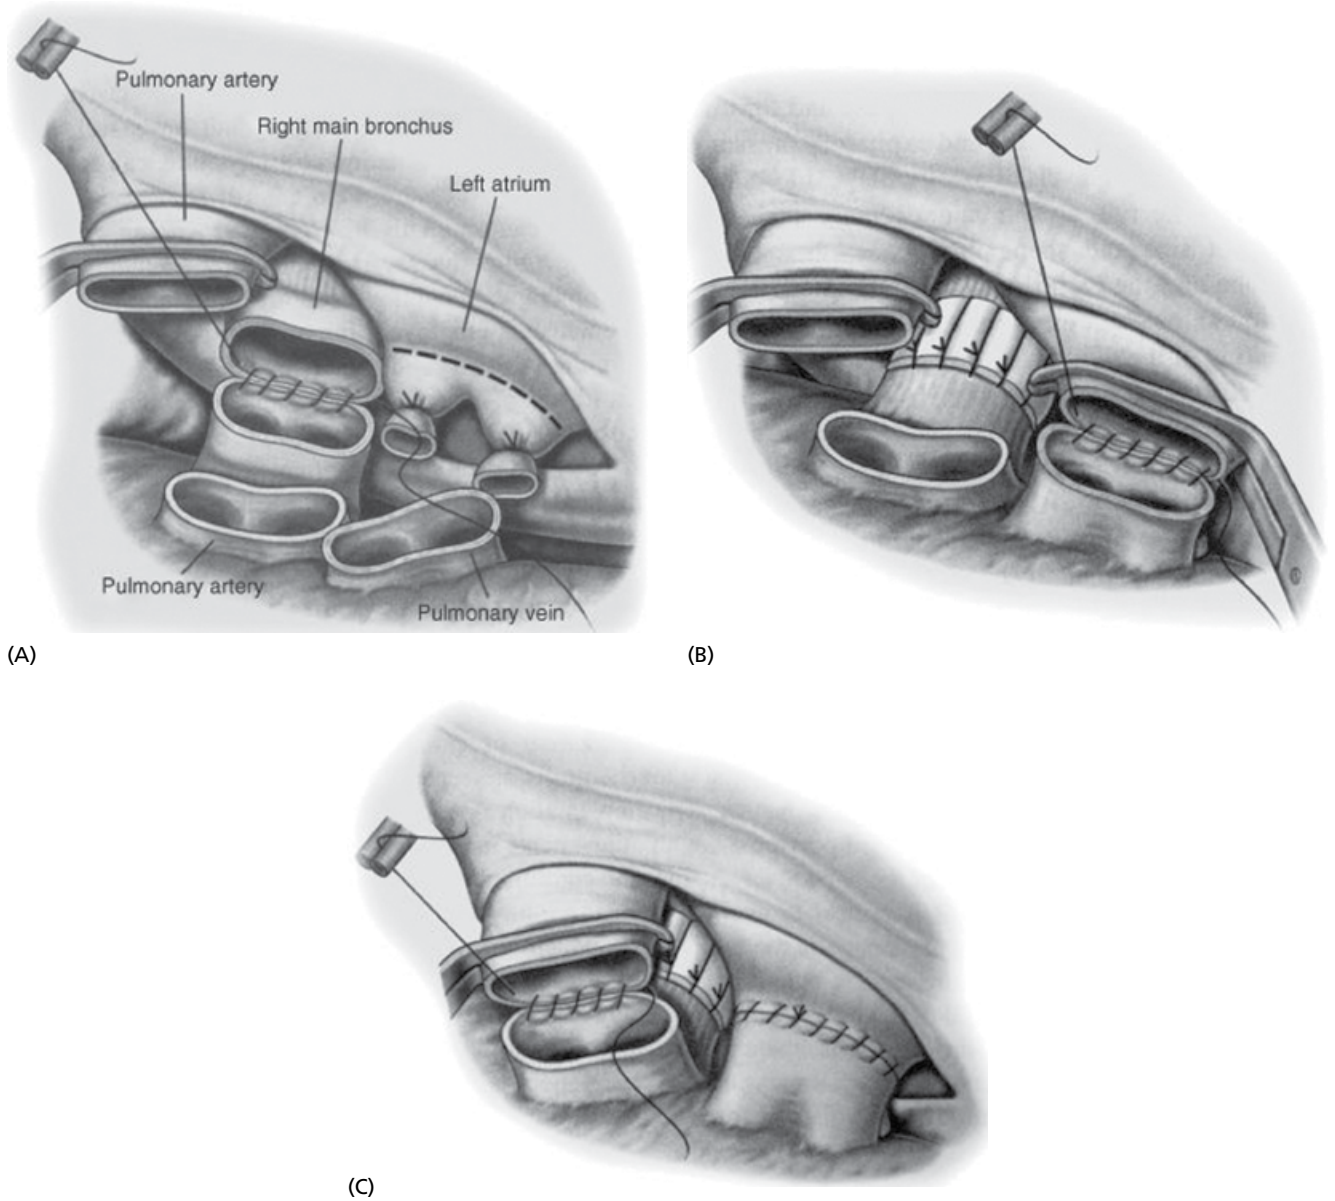

Figure 30.19 (A) End-to-end right bronchial anastomosis. (B) End-to-end right pulmonary vein anastomosis. (C) End-to-end right pulmonary artery anastomosis. *Source*: Reproduced from Ren et al [185] with permission of John Wiley and Sons.

Another surgical approach is the en bloc technique with a single tracheal anastomosis, and bronchial artery revascularization using a using a cuff of donor aorta [186]. The theoretical advantage of this technique is much improved perfusion to the graft because the bronchial artery circulation normally provides 50% of the airway's dual blood supply. This in turn may reduce airway and infectious complications, and delay the onset of bronchiolitis obliterans syndrome, which can have an ischemic etiology. The descending aorta is clamped with a partial occlusion clamp, and the bronchial artery button is anastomosed to this area (Fig. 30.20). After reperfusion of the bronchial arteries, bleeding will be observed from the cut edge of the trachea, and blood return is often identified in the pulmonary arteries and veins. This theoretically limits further graft ischemia. A single end-to-end tracheal anastomosis is completed, followed by flexible bronchoscopy by the anesthesiologist for removal of bloody secretions. During aortic cross-clamp, a single left atrial anastomosis is performed, and other intracardiac anomalies may be addressed. After removal of the aortic cross-clamp, an end-to-end main pulmonary artery anastomosis is performed. Another advantage of this technique is that it can be done through a median sternotomy, reducing pain and facilitating early tracheal extubation. In a single institution comparison study of 88 bilateral sequential lung transplants and 31 en bloc transplants with bronchial artery revascularization, there was no difference in ischemic or bypass times, early or longer term survival, graft dysfunction, or cellular rejection scores. Bilateral sequential lung transplant was associated with higher ischemic injury and non-airway complications.

Living donor lobar transplant (LDLT) involves two living donors, each providing a lower lobe to the recipient. LDLT has often been used to provide organs rapidly to children with cystic fibrosis who have undergone an unexpected rapid progression of their disease. Although outcomes can be comparable to deceased donor transplant [187] and there is some evidence to suggest that the incidence of bronchiolitis obliterans is lower in LDLT recipients [188], the procedure is resource intensive and has ethical implications because 10–20% of donor lobectomy surgeries have serious complications [189,190]. The 2017 ISHLT report noted the number of LDLT surgeries in pediatric recipients peaked in 1998–1999

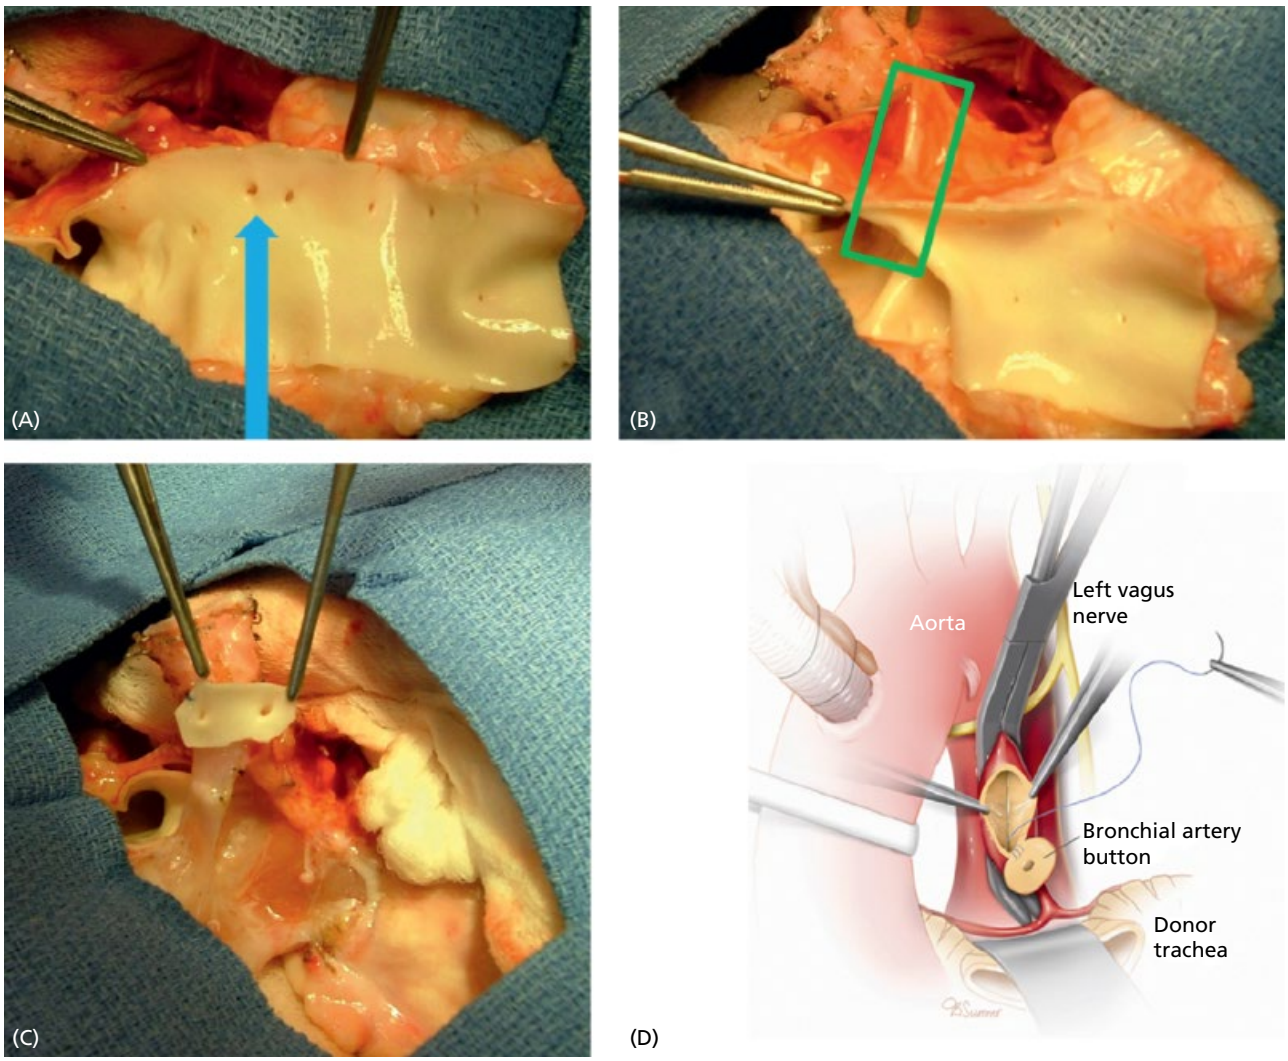

Figure 30.20 Key operative aspects involving bronchial artery revascularization technique. (A) The descending donor thoracic aorta is opened longitudinally. and since then has decreased substantially, and none were reported in 2013–2015 [143].

When the recipient's chest is too small to accommodate the donor lungs, the donor lungs can be reduced in size. Options include lobectomy (typically, the right middle lobe or lingula), wedge resection using a linear stapler, single lobe transplant, or split lung "bipartitioned" transplant (in which two smaller "lungs" are created from a single deceased donor lung). Reports suggest that outcomes in pediatric recipients of reduced-size organs can be comparable to recipients of full-sized grafts [191].

KEY POINTS: PREOPERATIVE CONSIDERATIONS AND ANESTHETIC MANAGEMENT FOR LUNG TRANSPLANT

- Extensive pretransplant evaluation and preparation is necessary; preoperative condition ranges from stable outpatients, to ventilated inpatients, and even ambulatory ECMO
- Most pediatric transplants are bilateral sequential lung transplant on CPB via a clamshell incision
- Careful attention to volutrauma and barotrauma, oxygen toxicity, fluid overload, and acute graft dysfunction are necessary for anesthetic care

Early postoperative management

Patients are sedated and on ventilator support when admitted postoperatively for intensive care. The duration of mechanical ventilation has to be individualized for each child but many can be extubated within 12 h of the surgery. Infants often have complex clinical problems and are critically ill before surgery; they required ventilation for longer (average 24 days) than older patients with cystic fibrosis (average 3 days) [192].

Some programs elicit the help of pediatric pain service specialists for postoperative pain management. Many centers provide patient-controlled anesthesia and opioid infusions. There are no pediatric studies of postoperative analgesia after lung transplantation comparing epidural and intravenous techniques. Regional anesthesia via an epidural catheter has been frequently used in adults and some older children when transplantation was performed without CPB. A report of 58 pediatric patients who underwent epidural insertion before surgery and CPB, showed no apparent complications from this technique and a median time to extubation of 19 h [193]. Epidural analgesia was less effective in adult patients undergoing unilateral and bilateral lung transplantation than in patients undergoing a thoracotomy for other indications, perhaps due to the extensive clamshell incision [194]. A survey of adults found the occurrence of moderate to severe persistent pain after lung transplantation was low (5–10%) [195].

Physiological changes and growth of the transplanted lungs

The allograft lungs are denervated but this produces few clinically significant effects on airway reflexes, mucociliary movement, and bronchial hyper-reactivity [196]. Lack of afferent stimuli to the respiratory center in transplanted patients results in poor coordination between the thoracic and abdominal muscles, and a subnormal increase in the minute ventilation with carbon dioxide challenge was noted in adult patients [197]. Loss of lymphatic drainage makes the transplanted lungs more susceptible to interstitial edema, increased water content, and lower compliance [198].

It is uncertain whether transplanted lungs grow. Although spirometry measurements (i.e. FEV_1 and forced vital capacity) after lung transplant may be in the normal range in infants [197] and older children [199], these measurements may indicate increased volume of each alveolar unit rather than alveolar tissue growth or increased surface area for gas exchange. Animal studies demonstrated lung tissue growth, and serial imaging studies in humans showed airway growth [200]. The measurement of diffusing capacity for carbon monoxide (DLCO) provides an estimate of gas exchange surface area. A single-center study of the DLCO in pediatric recipients of cadaveric and living donor transplants did not show an appreciable increase in DLCO, thereby suggesting the increase in lung volume seen in mature lobes is secondary to hyperinflation [201].

Complications of lung transplantation

Common complications are summarized in Table 30.20 [143]. Hypertension is diagnosed in as many as 70% of lung transplant survivors at 5 years.

Airway complications

A single-center study involving 470 bronchial anastomoses at risk reported 42 (9%) airway complications (stenosis, $n = 36$; dehiscence, $n = 4$; malacia, $n = 2$) requiring interventions. Most (90%) complications were diagnosed within the first 3 months after transplantation. Associated risk factors were preoperative infection with *Pseudomonas cepacia*, postoperative fungal lung infection, and prolonged mechanical ventilation [202]. Infants are prone to developing tracheobronchomalacia and dynamic airway obstruction. Often the problem resolves without surgical intervention but patients may need prolonged ventilatory support [203]. Airway stenosis is usually treated successfully with repeated mechanical balloon dilation through a rigid bronchoscope. Stents are generally avoided in children with potential for airway growth; the devices are difficult to remove and can cause problems with exuberant granulation tissue growing through the wire mesh.

Vascular complications

A perfusion scan is typically performed early after surgery to quantify the distribution of pulmonary blood flow. Vascular complications are infrequent, with pulmonary vein obstruction being the commonest problem. Cardiac catheterization is indicated if a vascular abnormality is suspected. Any significant obstruction to pulmonary blood flow requires urgent treatment either by surgery or interventional cardiac catheterization [204].

Nerve injuries

Early re-exploration of the chest was performed in 11% of cases in one series, most commonly for bleeding [204]. Phrenic

Table 30.20 Cumulative morbidity rates in pediatric lung transplant survivors, 1994–2015

Outcome	Within 1 year	Total *N* with known response	Within 5 years	Total *N* with known response	Within 7 years	Total *N* with known response
Renal dysfunction:	9.7%	(*N* = 815)	29.6%	(*N* = 291)	42.0%	(*N* = 169)
Abnormal creatinine ≤2.5 mg/dL	6.4%		22.7%		30.8%

nerve injury (typically the right) occurred in 22% of cases and previous thoracotomy was a risk factor. Hoarseness from left recurrent laryngeal nerve injury was noted in 10% of patients. Most of these nerve injuries resolved in the first several months after transplantation, but some patients required diaphragm plication because of poor respiratory function [204,205].

Injury to the vagus nerve frequently leads to gastropharyngeal reflux and gastric paresis. Gastroesophageal reflux disease and resulting recurrent silent aspiration has been implicated in deteriorating graft function and bronchiolitis obliterans syndrome [206]. The incidence of severe gastroesophageal reflux is high (50%), particularly in the young [207]. Patients with deteriorating pulmonary function have been shown to benefit from surgical treatment of gastroesophageal reflux [208].

Arrhythmias

Arrhythmias encountered that require therapy include atrial flutter (11% of pediatric transplants), atrial fibrillation, and supraventricular tachycardia [209]. Most can be controlled with drug therapy. The left atrial suture line is the presumed source.

Primary graft dysfunction

Primary graft dysfunction represents a severe form of acute injury to the allograft and is characterized by patchy pulmonary infiltrates, a low ratio of arterial oxygen to the fraction of inspired oxygen, diminished lung compliance, and pathological findings of diffuse alveolar damage [210,211]. There are many opportunities for lung damage during the processes of donor death, organ harvesting, allograft preservation, and transplantation. PGD is the net product of these insults, with ischemia-reperfusion injury being a major contributor [212]. Interestingly, primary pulmonary hypertension is a recipient risk factor independently associated with the development of PGD [213], presumably from right ventricle dysfunction. PGD may contribute to nearly half of the short-term mortality after lung transplantation [214]. Survivors of PGD even have increased risk of death extending beyond the first post-transplant year and PGD is associated with the subsequent development of bronchiolitis obliterans syndrome [214,215].

Once PGD develops, patients are managed with aggressive cardiopulmonary support involving mechanical ventilation or non-invasive ventilation in the prone position [216], inotropes, and occasionally with the use of venovenous ECMO. Early use of nitric oxide reduces the early mortality [217]. In most patients PGD resolves over several days. Children who need extracorporeal support have significantly higher mortality.

The preventive strategies to reduce the incidence of PGD include minimizing reperfusion injury, reducing ischemic time, improving donor management, and avoiding volu- and barotrauma. Surgeons routinely allow the ejection of small amounts of blood into the pulmonary artery immediately after establishing vascular supply to the first lung. Prostaglandin E1 and prostacyclin may reduce the incidence and severity of the reperfusion injury [218]. The value of prophylactic nitric oxide is questionable [219].

Rejection

Hyperacute rejection

This rare complication may lead to early graft failure and results from circulating, preformed, recipient serum antibodies binding to donor tissue antigens and causing complement-mediated graft injury. Endothelial cells lining the blood vessels of the new organ are the principal targets. Preformed antibodies directed at HLA or endothelial antigens are generally attributed to prior blood transfusions, a previous transplant, or pregnancy. To evaluate the risk for this complication, testing for PRAs is performed during the assessment process. PRAs include a mix of 60–100 different samples that express a wide range of antigens tested with the recipient serum. Sensitized patients with high PRA scores may qualify for specialized therapies such as intra- and postoperative plasmapheresis, thymoglobulin, and intravenous immunoglobulins [177].

Acute rejection

Acute cellular rejection is T-cell mediated and is common in the first year after lung transplantation, especially during the first 3 months. Clinically, it may be difficult to differentiate from an acute respiratory infection and the histopathological findings are not always helpful. Often the diagnosis of acute rejection is made on clinical suspicion and confirmed by the

response to therapy. Some patients are asymptomatic and the acute rejection is detected by airflow limitation (a 10% decrease from baseline in FEV_1 is considered significant). Others present with dyspnea and hypoxia and have infiltrates on chest radiograph. Infants and toddlers have immature immune systems and a lower incidence of acute rejection compared with older children [220]. Also, patients who receive lung–liver transplants have lower rates of acute rejection and bronchiolitis obliterans [221]. A pathological diagnosis of acute cellular rejection is based on the presence of perivascular and interstitial mononuclear cell infiltrates in the lung biopsy samples. Histology is classified as follows: acute rejection (A0–A4); lymphocytic bronchitis (B0–B2R, Bx); and obliterative bronchitis (C0–C1) [222]. Lymphocytic bronchiolitis represents airway-directed rejection. In adults, acute rejection and lymphocytic bronchitis have consistently been identified as strong risk factors for chronic rejection [223] but the evidence is less convincing for pediatric lung transplant recipients [224]. It is unclear to what extent humoral rejection, which is antibody mediated, occurs among lung transplant recipients [222].

Methylprednisolone pulse at 10 mg/kg/dose daily for 3 days followed by augmented oral prednisone is the treatment of acute cellular rejection. Overall, the response to this treatment is improvement of symptoms and pulmonary function test results within several days. Management of steroid-resistant acute rejection is currently controversial. Treatment options for humoral rejection include plasmapheresis for antibody removal and immunoglobulin infusion.

Chronic rejection

Chronic rejection is the primary obstacle to better long-term outcomes after lung transplantation (Fig. 30.21) [143]. It manifests as obliterative bronchiolitis, which is characterized histologically by fibroproliferative tissue remodeling with extracellular matrix deposition and results in small airway occlusion with sparing of the alveoli. Because the pathology has a patchy distribution, diagnosis by transbronchial biopsy has low sensitivity and specificity. Therefore, a clinical surrogate – the bronchiolitis obliterans syndrome – was created and is defined as a progressive deterioration in pulmonary function tests (Table 30.21) [222,225]. Measurement of lung function in young children can be challenging. Changes in lung function tests are likely late manifestations of obliterative bronchiolitis but other diagnostic modalities, including imaging and exhaled biomarkers, have not proven useful.

The etiology of bronchiolitis obliterans syndrome is unclear. Identified risk factors include late or recurrent refractory acute rejection, lymphocytic bronchiolitis, cytomegalovirus (CMV) infection, ischemia-reperfusion injury (longer ischemia times), HLA mismatches, infection, and gastroesophageal reflux with aspiration. Young children, LDLT recipients, and liver–lung recipients have a lower risk of bronchiolitis obliterans syndrome.

To date, there is no effective treatment of bronchiolitis obliterans syndrome. Therapies attempted include pulse steroids, methotrexate, cyclophosphamide, cytolytic therapy, inhaled cyclosporine, total lymphoid irradiation, photophoresis and switching to a different immunosuppression protocol [226]. Azithromycin and other macrolides may be useful [227]. Antireflux surgery may reverse the decline in pulmonary function in some patients and statins have beneficial potential because they induce apoptosis in fibroblasts. Retransplantation is considered in relatively few patients; the risk of post-surgical death within 1 year is nearly 50% [143].

Table 30.21 Classification of bronchiolitis obliterans syndrome

Stage	Definition
BOS 0	FEV_1 >90% of baseline and FEF25–75% >75% of baseline
BOS 0-p	FEV_1 = 81–90% of baseline or FEF25–75% ≤75% of baseline
BOS 1	FEV_1 = 66–80% of baseline
BOS 2	FEV_1 = 51–65% of baseline
BOS 3	FEV_1 ≤50% of baseline

BOS, bronchiolitis obliterans syndrome; FEF25–75%, forced expiratory flow between 25% and 75% of vital capacity; FEV_1, forced expiratory volume in 1 se. Baseline: the average of the two highest measurements at least 3 weeks apart after transplantation.

Immunosuppression

Higher doses of immunosuppressant agents are administered for pediatric lung transplantation than for other solid organ transplantation. Induction immunosuppression is currently used in approximately half of recipients, with about 10% receiving polyclonal antilymphocyte globulin and 40% receiving IL-2 receptor antagonists [143]. Most patients are given triple drug therapy for maintenance immunosuppression. This consists of a calcineurin inhibitor (tacrolimus more commonly than cyclosporine), cell cycle inhibitors like azathioprine or mycophenolate mofetil, and prednisone. Sirolimus (target of rapamycin inhibitor) is seldom administered during the first year post-transplant, but is more common at 5-year follow-up. Virtually all patients receive long-term maintenance corticosteroids [143].

Infection

Infections occur in 60–90% of recipients. The risk of infection is largely determined by the interaction of three factors: (1) technical/anatomical factors that involve the transplant procedure itself, and the perioperative aspects of care such as the management of vascular access, drains, and the endotracheal tube; (2) environmental exposure to pathogens; and (3) the patient's net state of immunosuppression [228]. Bacterial infections are most common but fungal and viral infections result in higher mortality. Hypogammaglobulinemia post-transplant was associated with increased infections [229].

Respiratory viral infections are associated with decreased 1-year survival after transplantation [230]. Common pathogens included adenovirus, rhinovirus, respiratory syncytial virus, and parainfluenza virus. Fungal infections were independently associated with a decreased 1-year post-transplant survival [231,232] and most centers routinely administer antifungal prophylaxis. Lung transplant patients are also at increased risk for invasive mold infections [233].

CMV after lung transplantation is a serious infectious complication, especially in CMV-negative recipients receiving CMV-positive donor lungs (i.e. mismatch). Pediatric patients are at increased risk for mismatch because they are more likely to be CMV negative and their incidence of CMV disease was 30% [234]. CMV disease was associated with increased mortality after pediatric lung transplantation. Usually it presents as pneumonitis but can also involve the liver, small bowel, and retina. Antiviral prophylaxis (e.g. ganciclovir) is beneficial although the optimal duration of prophylaxis is uncertain. Surveillance blood testing to measure the viral load is recommended.

KEY POINTS: COMPLICATIONS OF LUNG TRANSPLANTATION

- Early postoperative graft dysfunction is managed with mechanical ventilation, nitric oxide, and possibly veno-venous ECMO
- Acute rejection is usually treated with increased doses of corticosteroids
- Chronic rejection includes bronchiolitis obliterans syndrome; onset of this syndrome carries a high mortality within 1–2 years

Surveillance

Lung transplant recipients are closely monitored for rejection and other complications. Routine monitoring for rejection includes daily home spirometry, regular pulmonary function testing, chest radiographs, bronchopulmonary lavages, and transbronchial lung biopsies (a typical biopsy schedule would be at 2 and 6 weeks, and 3, 6, 9, and 12 months after transplant) [177]. Transbronchial biopsies are the mainstay of rejection surveillance in young children because spirometry is not feasible [235]. Infant pulmonary tests (peak expiratory flow rate) using thoracoabdominal compressions can be done but require anesthesia and are not part of the bronchiolitis obliterans syndrome criteria. Sometimes it is difficult to obtain sufficient tissue via transbronchial biopsy in small children and an open lung biopsy may be necessary [13,199,236].

Outcome

Lung transplant

Survival after lung transplantation is similar in children and adult recipients and has improved in recent years. Children transplanted between 2008 and 2015 had a 1-year survival of 84.1% and a 5-year survival of 56.7% [143]. These outcomes are

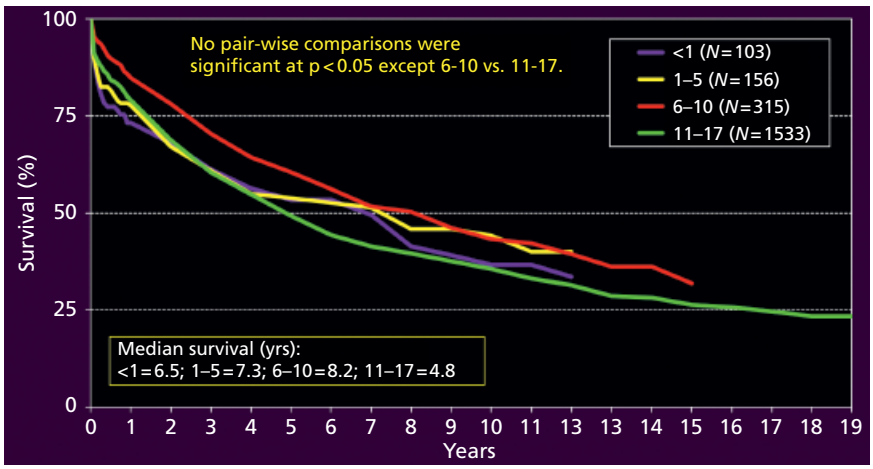

Figure 30.22 Pediatric lung transplant survival by recipient age group, 1990–2015. *Source*: Reproduced from Rossano et al [102] with permission of Elsevier.

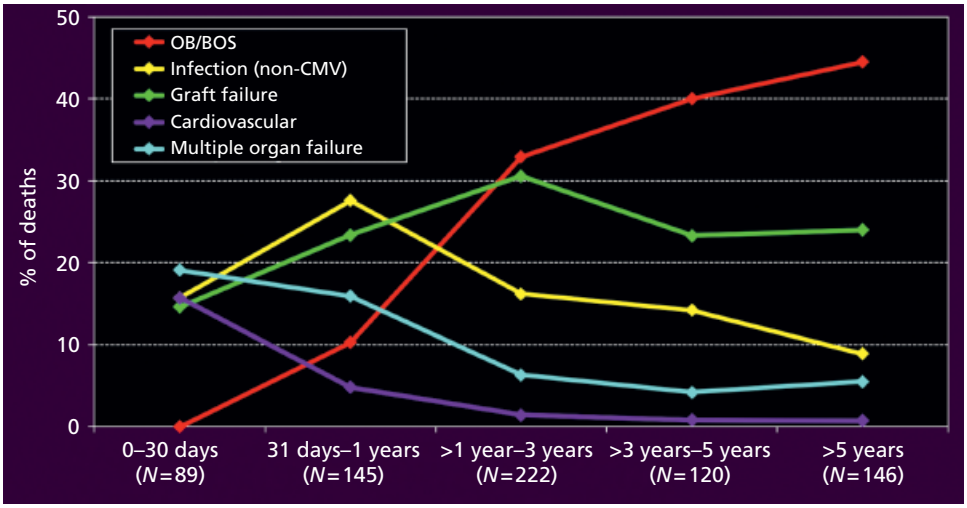

Figure 30.23 Relative incidence of leading causes of death in pediatric lung transplantation, 2000–2016. BOS, bronchiolitis obliterans syndrome; CMV, cytomegalovirus; OB, obliterative bronchiolitis. *Source*: Reproduced from Rossano et al [102] with permission of Elsevier.

inferior to those for other pediatric solid organ transplantation. Children in the 6–10-year age group have better long-term outcomes than adolescents (Fig. 30.22). Significant risk factors for mortality include preoperative ventilatory support, earlier era of transplant, center volume of <5 pediatric lung transplants per year, and adolescent age group. The poor long-term outcome of adolescents is ascribed to the propensity for poor adherence to medical therapies [237]. Children with tetralogy of Fallot and pulmonary atresia had a worse outcome after lung transplantation than patients with Eisenmenger syndrome or pulmonary vein stenosis [238]. Graft failure, technical issues, cardiovascular failure, and infection are common causes of death in the early post-transplant period, whereas infection, graft failure, and bronchiolitis obliterans syndrome are common causes of late death (Fig. 30.23) [143]. Children undergoing repeat lung transplant have a worse outcome (42% 5-year survival).

Heart–lung transplant

Fewer than 15 heart–lung transplants are reported per year to the ISHLT [143]. About 90% of procedures are for congenital heart disease with pulmonary hypertension, primary pulmonary hypertension, or cystic fibrosis. A higher proportion of younger children undergo heart–lung transplantation compared with lung transplantation but the majority of procedures are performed in adolescents. Survival after heart–lung transplantation is slowly improving, with a 5-year survival of 50% in the 193 transplants from 2000 to 2015. Infants <1 year in age have worse survival than older children; there have been no heart–lung transplants in this age group reported to the ISHLT since 2007.

Intestinal, multivisceral, and pancreatic transplantation

Indications

Successful transplantation of liver, kidneys, hearts, and lungs has led transplant surgeons to attempt to treat other illnesses affecting infants and children. The etiology of intestinal failure in children is most often the short-gut syndrome, which results from necrotizing enterocolitis, intestinal malrotation, and volvulus, or congenital defects (intestinal atresia, abdominal wall defects), and leads to dependence on total parenteral nutrition (TPN) (Table 30.22) [239]. The long-term sequelae of TPN include steatotic liver disease and eventual hepatic failure and the complications of long-term venous access. Isolated small bowel transplants, combined small bowel–liver transplants, and extensive multivisceral transplants (liver, pancreas, gastrointestinal tract from stomach to colon) have been performed in an attempt to manage short-gut syndrome (Fig. 30.24) [239]. The results of intestinal transplantation have improved over the past decade. Transplantation of the intestine before liver failure improves early outcomes [240]. In 2016, the results of 2887 intestinal transplant procedures (from 82 centers in 19 countries) were summarized in the report of the International Intestinal Transplant Registry [239]. The most recent cohort (transplanted after 2009) demonstrated 76% overall 1-year patient survival and over 80% 1-year

Table 30.22 Causes of intestinal failure in children

Short bowel syndrome	Congenital
	Surgical
	Necrotizing enterocolitis

survival in those recipients who received induction therapy combined with tacrolimus. Recently a single-center series reported 1- and 5-year patient and graft survival to be 78–85% and 56–61%, respectively, despite divergent immunosuppression protocols [241]. More than 80% of transplant recipients who survive attain freedom from parenteral nutrition and resume normal daily activities. Intestinal transplant procedures peaked in 2008 with130 children reported to the International Intestinal Transplant Registry. There has been a significant decline in recent years to 50–60 annually; the reason is likely from improved long-term intestinal rehabilitation protocols reducing the need for transplantation [239].

Pancreas transplantation has been utilized most commonly as combined renal and pancreas transplantation for the treatment of ESRD in diabetics with other end-organ dysfunction (retinopathy, neuropathy). Because of the interval between the development of insulin-dependent diabetes in children and end-organ complications, few reports of pancreas transplantation have been reported in children, apart from the multivisceral procedures described above. The number of pancreas transplants peaked in 2004, and steadily declined through 2008. Even though pancreas transplantation of diabetic patients has stabilized or improved their nephropathy, retinopathy, and neuropathy, immunological failures of the transplant has led to the abandonment of isolated pancreas transplants and only combined kidney and pancreas transplants are now performed in children [242].

Anesthetic management

The exact form of intestinal transplantation (i.e. isolated, combined liver–small bowel, or multivisceral transplantation) depends upon the cause of intestinal failure and associated extraintestinal organ involvement. Following identification of an appropriate donor, the recipient undergoes a regimen designed to purge and decontaminate the intestinal tract. Routine premedication is avoided, but may be required and administered under appropriate monitoring situations. Rapid-sequence induction of general anesthesia and tracheal intubation is planned. Despite normal or slightly impaired hepatic function, there is a potential for extensive blood loss and hemorrhage in most of these cases. Previous abdominal surgery and extensive dissection and evisceration of the native organs prolong the dissection period and increase blood loss. Venous access sites, particularly around the central circulation, may be limited because of previous TPN catheters. However, central venous access is essential for management. Arterial blood pressure and CVP should be monitored directly. Intraoperative management is similar to liver transplantation: hemodynamic stability may require rapid infusion of crystalloid, colloids, or blood products; and maintaining metabolic homeostasis requires frequent arterial blood gases and electrolyte concentration determinations.

In multivisceral transplantation and combined pancreatic renal transplantation, particular attention is required to maintain normoglycemia. Tight intraoperative control of the glucose concentration may result in improved pancreatic allograft function. To achieve glucose concentrations of 80–150 mg/dL requires frequent intraoperative determinations of glucose concentration, and titration of a regular insulin infusion. A period of hyperglycemia is common following reperfusion of the pancreatic graft and requires additional insulin administration.

Complications following transplant

Rejection

A common complication associated with all forms of allograft transplantation is the occurrence of rejection of the

transplanted tissue by the recipient. Rejection in the early post-transplant period may be a subtle process and difficult to assess by routine physical and laboratory examination. Clinical signs of rejection will vary by the transplanted organ, and are not likely to be specific. Therefore, there is need for early histological evaluation of the organ to diagnose acute rejection. Many transplant centers routinely biopsy the organ at weekly to monthly intervals to search for evidence of acute rejection. This generally requires an invasive procedure requiring anesthesia or sedation in children. Routine immunosuppression is altered in the face of acute rejection. Steroid administration is increased first, and then maintenance immunosuppressive therapy may be increased. See earlier specific discussions of heart and lung rejection and surveillance.

Infection

Immunosuppression leads to an increased risk of infection. Various forms of infection are more common at different time periods [228,243,244]. In the *1st month*, there are three major causes of infection: (1) infection that was present in the recipient before transplant; (2) infection conveyed with a contaminated allograft; and (3) typical postoperative infections also observed in immunocompetent patients, such as surgical wound infections, pneumonia, and infected lines or drains.

One to 6 months after transplantation is when more intense immunosuppression produces the greatest effect on the risk of infection. During this period, two major classes of infection predominate: chronic viral infections and opportunistic infections. Viral pathogens such as CMV, Epstein–Barr virus (EBV), human herpesvirus 6, and the hepatitis viruses B and C may be acquired from the donor, reactivated in the host, or the patient may become infected with a new strain of these viruses. During this 1–6-month post-transplant period opportunistic infections are also observed and include organisms such as *Listeria monocytogenes*, *Aspergillus fumigatus*, and *Pneumocystis jiroveci*.

Once patients are *more than 6 months* post-transplant, their infectious risk can be broken down into two categories of patients: those with a good result from transplant and a smaller group with a poor graft function. The majority of patients have good graft function, are on maintenance immunosuppression therapy, and are at greatest risk from typical community-acquired infections such as influenza, parainfluenza, and respiratory syncytial virus. The smaller group of patients with acute and chronic immunosuppression, poor allograft function, and, often, chronic viral infection remain at high risk for recurrent infections related to mechanical problems from surgery as well as opportunistic infections attributable to organisms like *Pneumocystis jiroveci*, *Listeria monocytogenes*, *Cryptococcus neoformans*, and *Nocardia asteroides*. Infectious risk and outcomes related to lung transplant are discussed earlier in the chapter.

Malignancy

The risk of developing cancer after solid organ transplantation is about 5–10-fold more than that of the general population. Children receiving transplants are at high risk of developing a malignancy during their lifetime. The cumulative risk of cancer increases with age and is >50% at 20 years after transplantation.

Post-transplant lymphoproliferative disease (PTLD) is the most common cancer observed in children following solid organ transplantation, accounting for half of all such malignancies [245]. The incidence is about 5–10%. PTLD results from the uncontrolled proliferation of lymphocytes in the immunosuppressed transplant recipient and is a major contributor to long-term morbidity and mortality in this population. Among children, most cases are associated with EBV infection. PTLD is an early event (i.e. within the first 2 years after transplant) in most cases, likely because of more intense immunosuppression used for induction therapy or the exposure of the EBV-naive host to the virus, often from EBV-infected passenger lymphocytes in the allograft. PTLD commonly affects the lung allograft, lymphoid tissues, gastrointestinal tract, and liver. Gastrointestinal involvement is associated with increased mortality [246]. Therapy for PTLD includes empirical reduction in immunosuppression antiviral drugs, monoclonal antibodies specifically targeting the B-lymphocyte antigen CD20 (e.g. rituximab), or chemotherapy, when appropriate [247]. Skin cancers and atypical solid tumors are also seen with significantly higher incidence than in the general population. Outcomes of treatment of these secondary malignancies are generally worse than in the general population.

Renal dysfunction

Renal dysfunction is one of the most common complications following solid organ transplantation. Ojo and colleagues found that the cumulative 5-year risk of chronic renal failure, defined as the need for either chronic dialysis or kidney transplantation, was 6.9–21.3% depending on type of organ transplanted. This study included more than 69,000 non-renal solid organ transplant recipients who were predominately adults. The risk of death increased more than fourfold with the onset of chronic renal failure, and the cost of care was dramatically increased [248]. Table 30.23 shows the risk of renal failure related to the type of organ transplant.

There are multiple factors that produce renal dysfunction following solid organ transplantation; however, the CNIs cyclosporine and tacrolimus are the major contributing factors. The CNIs produce both acute and chronic nephrotoxicity. Acute nephrotoxicity involves afferent arteriolar vasoconstriction and reduced renal plasma flow, and is associated with high trough levels. In contrast, chronic CNI-induced nephrotoxicity is not predicted by individual trough levels, and is characterized by potentially irreversible structural changes including arteriolopathy, tubulointerstitial fibrosis, and, eventually, glomerulosclerosis [249]. Strategies for management of post-transplant renal dysfunction have largely focused on CNI minimization, replacement, or avoidance.

Growth and developmental delay

Organ failure frequently leads to a poor nutritional state and growth failure. After organ transplant, most patients demonstrate catch-up growth, yet a large percentage of patients do not reach their predicted adult height and weight. Immunosuppression regimens that limit the use of steroids seem to be well tolerated and allow for better growth; however, the long-term effect of CNIs on growth is not well studied, and may also contribute to growth failure [250]. Growth

Table 30.23 Cumulative incidence of chronic renal failure according to type of transplanted organ

Type of organ	Cumulative incidence of chronic renal failure after transplantation (% ± SE)			Relative risk of chronic renal failure (95% CI)
	12 months	36 months	60 months	
Heart	1.9 ± 0.1	6.8 ± 0.2	10.9 ± 0.2	0.63 (0.61–0.66)

hormone can be used but there are theoretical concerns about the risk of triggering rejection [13].

Solid organ transplant recipients display a wide range of developmental outcomes, from normal development to significant delays. Factors that lead to poor developmental outcome likely include long-term hospitalization, chronic malnutrition in the pretransplant period, and surgical complications. Children who receive heart transplantation may have better cognitive outcomes than expected considering the results of older studies of children with cyanotic CHD. The cognitive outcomes of liver and kidney transplant recipients may also be improving, but many still require special educational resources. Infants requiring intestine or liver and intestine transplant are probably at the highest risk for cognitive delay, but there is a lack of longitudinal studies that affirm these delays [250]. In all cases neurological co-morbidities increase the risk of delay. Despite recent advances, a significant proportion of liver and heart recipients have serious developmental delay or neurological injury.

Cardiovascular side-effects

Immunosuppressive agents produce cardiovascular toxicity, causing an increased likelihood of hypertension, hyperlipidemia, hypercholesterolemia, and diabetes mellitus. Hypertension is found in 62–75% of pediatric patients (Table 30.24) [251]. Although both tacrolimus and cyclosporine can cause hypertension, cyclosporine appears to have a greater impact on blood pressure [252].

These side-effects are treated via an alteration of immunosuppressive regimen, or the addition of specific medications to address each risk factor or complication. Since steroids and CNIs provide the mainstay of immunosuppressive treatments, they generally cannot be eliminated. Steroid withdrawal or reduction as well as the use of tacrolimus over cyclosporine may decrease the risk of hypertension, dyslipidemia, or diabetes mellitus [249]. All classes of antihypertensive medications have been used and are ideally chosen based on the therapeutic profile. In addition to surveillance of tacrolimus levels, long-term monitoring of cardiac function may also be warranted in high-risk populations.

KEY POINTS: GENERAL COMPLICATIONS FOLLOWING TRANSPLANTATION

- Infection is a constant threat for transplant recipients; chronic viral infections such as CMV, EBV, and hepatitis B and C, and opportunistic infections such as *Aspergillus*, *Pneumocystis*, and *Listeria* are seen
- Secondary malignancy is seen in 5–10% of organ transplants; post-transplant lymphoproliferative disorder is most common
- Renal dysfunction, growth, and developmental delay, and hypertension are common in transplant recipients

Post-transplant surgery

Regardless of the transplant procedure, as transplant recipients age, they are likely to acquire diseases or conditions that require additional surgery. Prior to such procedures, the anesthesiologist must assess the function of the transplanted organ, review the status of the patient's immunosuppression, and perform a careful assessment of the other organ systems. Hypertension and chronic renal insufficiency are common findings in patients. Most patients will demonstrate evidence and findings of chronic steroid administration.

Quality of life

The functional status of most long-term survivors of solid organ transplantation is good, with more than 80–90% of 5-year survivors from kidney, liver, heart, and lung transplantation reporting no limitations in activity. Despite excellent function, children may experience psychological difficulties and an impaired quality of life [253]. Pediatric studies focusing on quality of life after transplantation remain scarce [253,254]. Research thus far shows improved overall quality of life after kidney, liver, heart, and lung transplantation; although the debate continues for patients with cystic fibrosis [150]. The quality of life after small bowel transplantation is probably equal to or better than quality of life on parenteral nutrition, and children report a quality of life similar to normal school children. A study that used qualitative interviews to examine psychosocial issues after lung transplantation in adolescents with cystic fibrosis reported that patients were able to develop long-term goals, and a wish to reclaim control over their lives as much as possible and adjust to a new lifestyle; yet common emotional responses included fear and anxiety over rejection, uncertainty over the future, and frustration with parental overprotectiveness [255]. It has been proposed that quality of life should be included in the assessment of transplantation benefit [256]. Presently, timing of transplantation relies primarily on estimates of survival benefit because comprehensive objective measures of quality of life for pediatric lung transplantation are not available.

CASE STUDY

History

A 14-year-old, 67 kg boy listed status 1A was scheduled for orthotopic heart transplant with an "in room" time of 0200. He was born with hypoplastic left heart syndrome and received a three-stage palliation to a Fontan circulation, which subsequently started failing 2 years ago. He was initially managed as an outpatient on oral heart failure medication (enalapril, furosemide, digoxin, and aspirin) but his clinical condition declined significantly over the past 6 months and despite modification to his oral heart failure regimen he was admitted to hospital 2 months ago for increasing fatigue, poor appetite, nausea, and ascites. He has been an inpatient for the past 1 month in the cardiovascular ICU (CVICU) dependent on milrinone and dopamine infusions.

Preoperative assessment

The patient was malnourished with moderate abdominal distention. His heart rate was 116 beats/min and blood pressure 80/42 mm Hg; SpO_2 was 86% on room air; respiratory rate was 28 breaths/min. He was alert and could speak but was short of breath with minimal exertion. His peripheries were cool to touch.

The most recent echocardiogram 5 days preoperatively revealed severely depressed right ventricular (RV) systolic function with moderate to severe tricuspid valve regurgitation. The Fontan pathway appeared unobstructed. Cardiac catheterization data from 1 month preoperatively (prior to starting inotropes) showed a Fontan pressure 23 mmHg, left pulmonary capillary wedge pressure of 16 mmHg, RV end-diastolic pressure of 16 mmHg, pulmonary vascular resistance index of 2.3 Wu, and a cardiac index of 1.9 L/min/m^2. Preoperative lab results included: Hgb 14 g/dL, Na 122 mEq/L, K 5.1 mEq/L, Cr 1.9 mEq/L, and INR 1.6.

He had a double-lumen percutaneously inserted central catheter (PICC) line in place with milrinone at 0.75 μg/kg/min and dopamine 5 μg/kg/mn. He also had an epicardial pacemaker implanted 5 years preoperatively for sick sinus syndrome. His last pacemaker interrogation 2 months prior to surgery showed 80% atrial-paced, ventricular-sensed rhythm and was set with a lower rate of 80 beats/min and an upper rate 120 beats/min. A CT scan performed for vascular mapping 2 months prior to transplant showed that all major vessels are patent but both femoral arteries appeared small from previous access.

Preoperative huddle

A multidisciplinary huddle occurred at 8 pm the evening prior to transplant and was attended by the attending cardiothoracic surgeon and fellow, cardiac anesthesia attending and fellow, CVICU attending, heart failure attending and fellow, and the perfusionist. Given the recipient's tenuous cardiovascular status and high risk of cardiovascular collapse during anesthesia induction it was decided that the patient would have a preinduction radial arterial line placed in the operating room and would be started on low-dose epinephrine at 0.02 μg/kg/min prior to anesthesia induction. It was also decided that because of small femoral arteries the neck would be the preferred site for emergency CPB cannulation should the patient decompensate during anesthesia induction or surgical dissection. The surgeon's preference was for the anesthesia team to place the right internal jugular central venous line using a high approach to allow him room lower down on the neck to perform a cut down if needed. A plan was also made to place a pigtail catheter in the abdomen to allow for controlled drainage of ascites soon after anesthesia induction.

The huddle discussions revealed that the donor was a good match for size with good cardiac function. The donor mode of death was status epilepticus and the organ was coming from a location with a 2.5 h total travel time and therefore an anticipated short ischemic cross-clamp time. The recipient was highly sensitized to blood cell antigens with a high panel reactive antibody titer, and would follow an immunosuppression protocol involving plasmapheresis on CPB with a 1.5 volume exchange in the OR just after CPB was initiated, followed by methylprednisolone post separation from CPB, IV immunoglobulin in the OR, and then thymoglobulin and tacrolimus post-op in the CVICU.

Because of the pre-existing renal dysfunction it was decided to follow the high-risk renal protective protocol that

had recently been instituted at the hospital, which involves perioperative aminophylline infusion in addition to maintaining a higher mean arterial pressure (60 mmHg) on CPB.

Intraoperative course

The patient was brought into the operating room at 2 am and standard ASA monitoring was instituted. Epinephrine infusion 0.02 μg/kg/min had been added to the inotropic regimen prior to transporting the patient. The patient received 2 mg of IV midazolam in divided doses for anxiolysis prior to placing a radial arterial line with ultrasound guidance. After placement of the arterial line the invasive blood pressure was 85/45 mmHg. A slow induction of general anesthesia was then started, carefully titrating fentanyl and etomidate bolus to effect, ensuring adequate time for the drugs to circulate (given the patient's low cardiac index) prior to giving subsequent doses. In total, 4 mg of midazolam, 250 μg of fentanyl, and 10 mg of etomidate was administered before the patient lost verbal communication and an eyelash response and required assisted ventilation. Then, 70 mg of rocuronium was given and positive pressure ventilation instituted taking care not to use high intrathoracic pressures or large tidal volumes that may impede Fontan flow and RV function, and also avoiding hypoxia, hypercarbia, and atelectasis. The patient was intubated easily with a 7.0 mm cuffed endotracheal tube and the hemodynamics remained stable throughout with a heart rate hovering between 115 and 120 beats/min and systolic blood pressure ranging between 80 and 85 mmHg. The surgeon then placed a pigtail catheter in the abdomen to allow for controlled drainage of the ascites prior to sternotomy and the anesthesia team inserted a 5 Fr triple-lumen 13 cm catheter in the right internal jugular vein using a high approach and ultrasound guidance. A 9 Fr 10 cm sheath was also placed in the left femoral vein using ultrasound and connected to a rapid infusing device (Belmont Rapid Infuser®; Belmont Instrument Company, Billerica, MA, USA). Two 14 G peripheral IV catheters were also placed in the upper extremities. Since the most recent pacemaker interrogation had revealed that the patient was pacemaker dependent with an 80% paced rhythm, the device was reprogrammed to an asynchronous (DOO) mode prior to incision to avoid any interference from surgical diathermy. Antibiotics and induction immunosuppressants were administered.

The chest, neck and right groin were prepped into the surgical field and the sternotomy was started. Dissection proved to be very difficult due to dense adhesions from prior cardiac surgeries and there was considerable microvascular oozing and bleeding from chest wall collaterals, which was managed by transfusing 2 units of FFP, 1 unit of platelets, and 1 unit of packed red cells in addition to a prophylactic aminocaproic acid infusion. After 2 h of careful surgical dissection the patient was ready to be cannulated for cardiopulmonary bypass. The ascending aorta, superior vena cava (SVC), and inferior vena cava (IVC) were cannulated and CPB instituted. Soon after institution of CPB the patient underwent plasmapheresis and cooled down to 32°C. A left atrial (LA) vent was inserted in the right upper pulmonary vein and after applying a cross-clamp on the ascending aorta, the recipient heart was removed while the donor heart was prepared on the back table. The recipient SVC was removed from the pulmonary arteries and patch augmentation of the pulmonary arteries performed. The donor heart was then implanted in the patient using LA anastomoses and then IVC, pulmonary artery, and aortic anastomoses. The donor heart was then de-aired, the cross-clamp removed after lidocaine and magnesium sulfate were administered, and rewarming commenced. While rewarming the SVC anastomoses was completed.

The donor ischemic time was 3 h and 10 min and the heart was reperfused for 1 h before separating from CPB – approximately one-third of the donor ischemic time, in accordance with the institution's standard practice. The patient subsequently separated from CPB on dopamine, epinephrine, calcium, and milrinone infusion and transesophageal echocardiography confirmed integrity of all the anastomoses without stenosis and adequate cardiac function of both ventricles. Heparin was reversed with protamine using a heparin-protamine titration system, and activated clotting time (ACT) to guide the dosage of protamine. There was significant bleeding post-CPB separation requiring 20 units of cryoprecipitate, 4 pheresis units of platelets, 3 units of red cell concentrate, and three 10 IU/kg doses of prothrombin complex concentrate. Once adequate hemostasis was achieved the sternum was closed and the patient transported to ICU where a comprehensive multidisciplinary sign-out occurred including cardiothoracic surgery, anesthesia, CVICU, heart failure, bedside nurses, and the respiratory therapist. The patient was successfully extubated the next day.

Conclusion

This case illustrates that, despite the increasing complexity of pediatric patients presenting for orthotopic heart transplant, involving complex congenital heart disease and multiorgan dysfunction, with careful multidisciplinary planning and communication, these cases can be managed successfully with good outcomes. Significant concerns include perioperative cardiovascular collapse with potentially limited rescue options, perioperative bleeding, and challenging pre-CPB dissection from previous multiple sternotomies and post-CPB RV dysfunction, pulmonary hypertension, and renal impairment.

Introduction

Anesthetics for abdominal surgical conditions are among the most common cases in the pediatric age group. They range from simple outpatient surgeries such as inguinal herniorrhaphy to extensive surgery, such as radical excision of neuroblastoma or hepatic tumors. The extensive adoption of laparoscopic surgery for many abdominal procedures has significantly changed the anesthetic approach for abdominal surgery, including postoperative analgesia. This chapter begins with a presentation of common abdominal surgical conditions, including intussusception, biliary atresia, malrotation and intestinal atresia, inflammatory bowel disease, abdominal tumors, inguinal hernia, pyloric stenosis, and appendicitis. Then, specific procedures such as gastrointestinal endoscopy, gastrostomy, Nissen fundoplication are discussed. Finally, laparoscopy, including physiological changes in response to gas insufflation and positioning are reviewed.

ABDOMINAL SURGICAL CONDITIONS

Intussusception

Intussusception is the most common cause of bowel obstruction in children less than 5 years of age [1]. The incidence is one in 2000 infants and children and it is always considered as a true pediatric emergency. Intussusceptions occur when a segment of bowel (the intussusceptum) invaginates into the distal bowel (the intussuscipiens), usually in an antegrade direction, resulting in venous congestion and bowel wall edema (Fig. 31.1) [2]. If not recognized and treated it could cause bowel necrosis and perforation. Overall mortality is less than 1% and the outcome is excellent if the condition is diagnosed early and treatment is instituted within the first 24 h.

Epidemiology

Intussusception occurs primarily in infants and toddlers. Males are affected twice as often as females. Peak incidence occurs between 5 and 9 months of age, with only 10–25% of cases occurring after 2 years of age [3]. Ninety percent of intussusception is idiopathic. Lymphoid hyperplasia has been suggested as the "lead point" in the pathogenesis of intussusceptions [4]. Incidence is higher during the fall and spring suggesting the possibility this might be a sequela following a preceding viral infection; adenovirus, rotavirus, and human herpesvirus 6 have all been associated with intussusceptions [5–7]. Other common lead points are Meckel diverticulum, intestinal polyps, lymphoma, and an inverted appendiceal stump. Patients with systemic conditions like Henoch–Schönlein purpura, Peutz–Jeghers syndrome, familial polyposis, nephrotic syndrome, and mesenteric nodes are predisposed to developing intussusceptions [7–9]. In 1999 the oral rotavirus vaccine was introduced in the US childhood immunization schedule, and was linked with intussusception among vaccine recipients. It was found to be greatest in the first 3–14 days after the first dose of rotavirus vaccine in infants older than 3 months [10]. Subsequently the vaccine was withdrawn from the market in 1999 [11].

Recurrent intussusceptions is uncommon but has been reported to occur in 1–3% after operative repair and 10–15% after hydrostatic reductions [12].

Gregory's Pediatric Anesthesia, Sixth Edition. Edited by Dean B. Andropoulos and George A. Gregory.

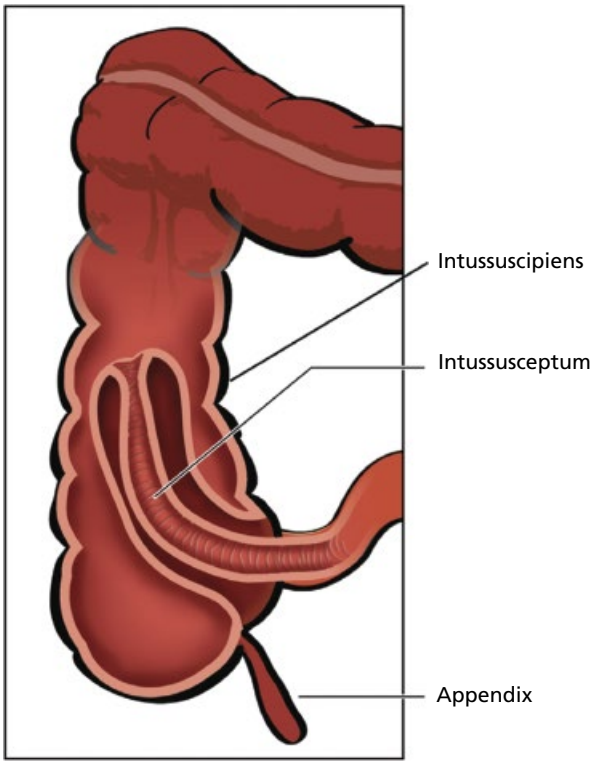

Figure 31.1 Ileocolic intussusception. *Source*: Reproduced from and Moses [2] with permission of Elsevier. Illustration by Colin Fahrion.

Pathophysiology

Ileocolic intussusception account for over 90% of cases. During the process the intussusceptum is propagated distally along the intestine and draws its blood supply with it. Initially the compression of the blood vessels causes venous congestion and bowel wall edema. As the obstruction progresses, the arterial supply may be compromised resulting in intestinal ischemia and infarction [3].

Clinical presentation

Intussusception has both typical and atypical presentations, but many present with non-specific sign and symptoms. The classic presentation is a young child with history of recent viral illness with vomiting and/or diarrhea. The classic clinical triad of intermittent abdominal pain, red currant jelly stool, and a palpable mass is found in 7.5–40% of children; 20% are pain free at their initial presentation, and 30% present with diarrhea leading to misdiagnosis of gastroenteritis [13,14]. On physical examination a palpable mass in the right upper quadrant is present, usually sausage shaped and ill defined, which may enlarge during episodes of pain. Some patients may present with syncope, sepsis, or hypovolemic shock. Recognition of hypovolemia and shock is an important priority for the surgical and anesthetic team.

Diagnosis

There is no reliable clinical model to accurately diagnose all patients presenting with intussusception. Imaging studies are essential in confirming the diagnosis. Plain abdominal films, ultrasound, or computed tomography (CT) scans have all been used to confirm the diagnosis, but in recent years ultrasound has become the preferred modality [2]. The classic finding is called the target sign, where concentric, alternating rings of low and high echogenicity are seen, corresponding to the layers of intestine and mesenteric fat (Fig. 31.2).

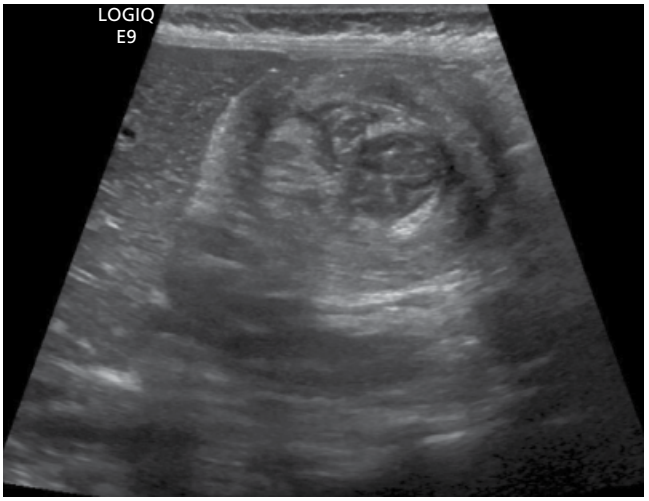

Figure 31.2 Ultrasound image of ileocolic intussusception demonstrating the target sign. *Source*: Reproduced from Padilla and Moses [2] with permission of Elsevier.

Management

In recent years, management of intussusception has changed significantly. Barium, aqueous, or air enemas have been used to reduce intussusception. Reduction rates with air range from 60% to 90%, and for barium/aqueous contrast from 60% to 80%. If non-operative reduction is not successful or is contraindicated, patients may require operative reduction. Sedation or anesthesia is rarely required for radiological reduction; but if non-operative reduction has failed, these patients may be significantly dehydrated. Aggressive fluid resuscitation is often necessary in the preoperative period; and antibiotic administration is essential [15,16].

The standard operative approach to intussusception reduction has been open laparotomy; although in recent years more surgeons are employing a laparoscopic approach. A recent retrospective review found a 71% success rate of laparoscopic intussusception reduction in 276 cases, with a very low complication rate [1].

Preoxygenation and rapid sequence intravenous induction using propofol and muscle relaxant using succinylcholine or rocuronium with endotracheal intubation is recommended to minimize the risk of regurgitation and aspiration. Maintenance of anesthesia is accomplished with isoflurane, sevoflurane, or an opioid-based anesthetic in critically ill patients. Careful attention to isotonic fluid replacement to compensate for often significant third-space losses from bowel manipulation and possible bowel resection is essential.

KEY POINTS: INTUSSUSCEPTION

- Intussusception is a common cause of bowel obstruction, with an incidence of one in 2000
- The classic clinical triad is of intermittent abdominal pain, red currant jelly stool, and a palpable mass
- On physical examination a palpable sausage-shaped mass is often present in the right upper quadrant

- Barium, aqueous, and air enemas are used for non-operative reduction; if this is not successful or is contraindicated patients may require operative reduction
- Aggressive fluid resuscitation in the preoperative period is often necessary

Biliary atresia

Biliary atresia is defined as the absence of patent extrahepatic bile ducts. It is the most common cause of jaundice in neonates and infants. If untreated it causes cirrhosis and liver failure within the first 2 years of life. The incidence ranges from one in 10,000 to one in 16,700 live births with a slight female preponderance [17,18]. There are three main types of biliary atresia: type I, atresia at the site of the common bile duct (11.9%); type II, atresia at the site of the hepatic duct, which is relatively less common (2.5%); and type III, atresia at the porta hepatis, which is the most common type (84.1%) [19]. Ten to 20% of patients with biliary atresia have associated congenital malformation, e.g. polysplenia, asplenia, inferior vena cava anomalies, bowel atresia, annular pancreas, and genitourinary anomalies [19,20].

Etiology

The exact cause of biliary atresia remains elusive, but there is some association between perinatal viral infections (reovirus type 3, rotavirus, cytomegalovirus, human papillomavirus, respiratory syncytial virus, and Epstein–Barr virus) and biliary atresia [21–25]. There may also be a genetic predisposition to its development. Defects in immune response, autoimmune disorders, and morphogenesis are other possible causes of biliary atresia. Evidence exists that these inciting factors, including viruses, toxins, and gene sequence variations in the etiology of biliary atresia, trigger a proinflammatory response that injures the biliary duct epithelium and results in a rapidly progressive cholangiopathy. This immune response also activates the expression of type 2 cytokines that promote epithelial cell proliferation and extracellular matrix proliferation by non-parenchymal cells [26]. This new information could lead to innovative medical therapies to lessen the severity of the liver disease.

Pathophysiology

Whatever the cause, the end result is complete obstruction of the lumen of the extrahepatic bile ducts and progressive cellular inflammation of the intrahepatic ducts. The degree of intrahepatic bile duct involvement is responsible for much of the morbidity encountered after hepatic portoenterostomy (Kasai procedure).

Clinical presentation

Most patients present with jaundice, acholic stools, dark urine, and an enlarged, firm liver within several weeks after birth – eventually leading to cirrhosis and splenomegaly. Coagulopathy and portal hypertension are often present. Malabsorption of fat-soluble vitamins often leads to anemia, malnutrition, and failure to thrive. Karrer et al reported a less than 10% 3-year survival in children who do not undergo a definitive biliary drainage procedure [17].

Diagnosis

No single test reliably diagnoses biliary atresia. However, a combination of physical examination, liver function tests, ultrasonography, and percutaneous liver biopsy is suggested in the diagnosis of the infant with suspected biliary atresia. Of these, percutaneous liver biopsy has an overall accuracy of more than 90%, and if the the patient is less than 60 days of age accuracy increases to over 95% [27]. Absolute definitive diagnosis requires surgical exploration.

Management

Currently, biliary atresia is managed in two phases [28].

- *Phase 1*: attempts are made to preserve the infant's own liver by performing a Kasai procedure, which involves excising all of the extrahepatic biliary structures at the liver hilus, which is then anastomosed to a Roux-en-Y jejunal limb. The microscopic biliary structures contained within the transected fibrous tissue drain into the intestinal conduit. Over time autoanastomosis occurs between the intestinal and ductal epithelial elements and provides biliary drainage.
- *Phase 2*: if the bile flow is not restored by the Kasai procedure or the cirrhosis worsens, the infant is considered for liver transplant (see Chapter 30).

Anesthetic management for infants with biliary atresia can be challenging since these patients are frequently malnourished. Preoperatively it is important to review all the laboratory and other diagnostic studies. Blood products should be available, especially packed red blood cells and fresh frozen plasma, since these patients may have a coagulopathy. There is also a potential for intraoperative blood loss due to surgery around the major intra-abdominal vascular structures, e.g. the inferior vena cava (IVC) and the hepatic artery. Depending on the infant's condition and the type of surgery, the procedure may be scheduled as same-day surgery or after admission to hospital prior to surgery.

Intravenous access can be difficult. Arterial and central venous access may be considered for ill patients, for close monitoring of arterial pressure, frequent blood draws, and secure venous access.

Anesthesia is usually induced with IV propofol and fentanyl; muscle relaxation is provided with rocuronium, vecuronium, or cisatracurium. Anesthesia is often maintained with either isoflurane or sevoflurane. It is preferable to have IV access in the upper extremity in case there is massive bleeding. Having a functioning arterial line during surgery is very helpful. Intraoperative hypotension is common with IVC compression by surgical instruments or with sudden blood loss. All replacement IV and irrigation fluids should be warmed. Plans are made before surgery for postoperative respiratory and pain management. Some children develop cholangitis after a Kasai procedure and are very ill.

KEY POINTS: BILIARY ATRESIA

- Biliary atresia is a common cause of cirrhosis and liver failure during the first 2 years of life
- Complete obstruction of the lumen of the extrahepatic bile ducts and progressive cellular inflammation of the intrahepatic ducts are common
- These patients present with jaundice, acholic stools, dark urine, and an enlarged, firm liver within weeks after birth
- Biliary atresia is managed in two phases: phase 1, the Kasai procedure; and phase 2, liver transplantation.

Malrotation of the bowel and intestinal atresia

Intestinal obstruction can occur at any age, but the etiology of obstruction varies according to the age of the patient. It is often embryological in origin, especially in children less than 1 year of age. The common congenital causes of bowel obstruction include bowel atresia/stenosis, malrotation of the bowel, Hirschsprung disease, imperforate anus, and meconium ileus. Congenital or acquired small bowel obstructions are more common in children than are large bowel obstructions. Hernias, intramural and extramural intestinal lesions, tumors, inflammatory bowel disease, intestinal volvulus, and adhesions are some of the common causes of pediatric bowel obstruction. Adhesions account for about 60% of all small bowel obstructions [29]. Early diagnosis of intestinal obstruction depends on early recognition of the symptoms, e.g. bilious vomiting, abdominal distension and tenderness, and radiographic findings.

Intestinal atresia

Jejunoileal atresia and stenosis are common causes of neonatal intestinal obstruction. Atresia is a congenital anomaly that completely occludes the intestinal lumen; this accounts for 95% of the cases of obstruction. Stenosis is defined as a partial intraluminal occlusion that incompletely obstructs the intestine. It is responsible for 5% of jejunoileal obstructions. Jejunoileal obstruction occurs in 0.7 per 10,000 livebirths. Intrauterine mesenteric vascular compromise is thought to be the etiology of jejunoileal atresia. On the other hand, mucosal atresia is thought to cause duodenal atresia.

Prenatal ultrasound is useful for diagnosing intestinal atresia in babies whose mothers have polyhydramnios. A history of maternal polyhydramnios, neonatal bilious vomiting, abdominal distension, and failure to defecate meconium on the first day of life is the usual clinical presentation [30]. The diagnosis is confirmed by radiographic examination. Thumb-sized intestinal loops and air–fluid levels are highly suggestive of neonatal intestinal obstruction.

Management of intestinal atresia consists of surgical resection of the atretic/stenotic section of bowel with reanastomosis. Common postoperative complications include obstruction at the anastomotic site and anastomotic leaks. Factors contributing to the morbidity and mortality of these patients include associated anomalies, respiratory distress, prematurity, and short bowel syndrome.

Malrotation of the bowel

Intestinal malrotation refers to abnormal rotation of the midgut around the superior mesenteric artery and abnormal fixation of the gut within the peritoneal cavity. Several types of malrotation occur and are caused by errors in growth, rotation, and position of the duodenum and the ligament of Treitz. These abnormalities in rotation range from non-rotation to reversed rotation (Fig. 31.3) [31,32]. The most common form of gut malrotation in children is due to incomplete rotation and narrow attachment of the mesentery of the midgut to the posterior abdominal wall, which predisposes to midgut rotation and volvulus. Rotational abnormalities commonly occur with heterotaxy, which in this case refers to abnormal attachments of the body organs. Major, complex cardiac anomalies and other gastrointestinal anomalies (e.g. malposition of the stomach, liver, and pancreas, asplenia, or polysplenia) are associated with heterotaxy [31].

Epidemiology

The exact incidence of malrotation of the gut is unknown, but it is thought to be about one in 500 livebirths [32]. The incidence is high in patients with heterotaxy (40–90%). There is no gender-specific preponderance for this lesion. Malrotation is also associated with other congenital or acquired lesions of the gastrointestinal tract (e.g. Hirschsprung disease, intussusceptions, and atresia of the jejunum, duodenum, and esophagus) [33]. These abnormal gut rotations and fixations can obstruct and strangulate the gut at any time between 10 weeks of intrauterine life and adulthood. Malrotation of the gut also occurs in patients with abdominal wall defects, e.g. omphalocele, gastroschisis, and diaphragmatic hernias.

Clinical presentation

Sixty percent of patients presenting with malrotation of the gut do so during the first month of life. Twenty percent present between 1 month and 1 year of age and the remainder present later. Some patients are asymptomatic and their lesion is found accidentally. The usual presenting symptoms of neonates are bilious vomiting or signs of midgut volvulus [34]. Beyond the neonatal period, the presenting symptoms vary from vomiting, intermittent colicky abdominal pain, failure to thrive, diarrhea, constipation, gastrointestinal hemorrhage (i.e. hematemesis or bloody stools), and acute intestinal obstruction [35]. Signs of abdominal distension and peritonitis are often found on physical examination.

Diagnosis

Diagnosis of malrotation is radiological. Making the diagnosis may be difficult if there is heterotaxy because the location of the liver, spleen, and stomach is often ambiguous. Plain radiographs of the abdomen are frequently non-diagnostic. Occasionally, however, there is a "double bubble" sign (i.e. two air-filled structures in the upper abdomen – the stomach on the left and the duodenum on the right – with little or no air seen distally). This finding is usually indicative of acute duodenal obstruction. On an upper gastrointestinal series, if the duodenojejunal flexure and loops of jejunum are on the right side of the abdomen and the cecum is above its normal position on a delayed film, this is diagnostic of malrotation. Abdominal ultrasound and CT scans can fail to rule out the diagnosis of malrotation.

Management

Preoperative management of malrotation requires fluid resuscitation with a balanced salt solution to correct vomiting-induced hypovolemia and dehydration. Attaching a nasogastric tube to suction can increase volume loss. Antibiotics should be administered early. Symptomatic patients with midgut volvulus must be managed urgently or emergently; delays can lead to irreversible intestinal ischemia, worsening sepsis, and

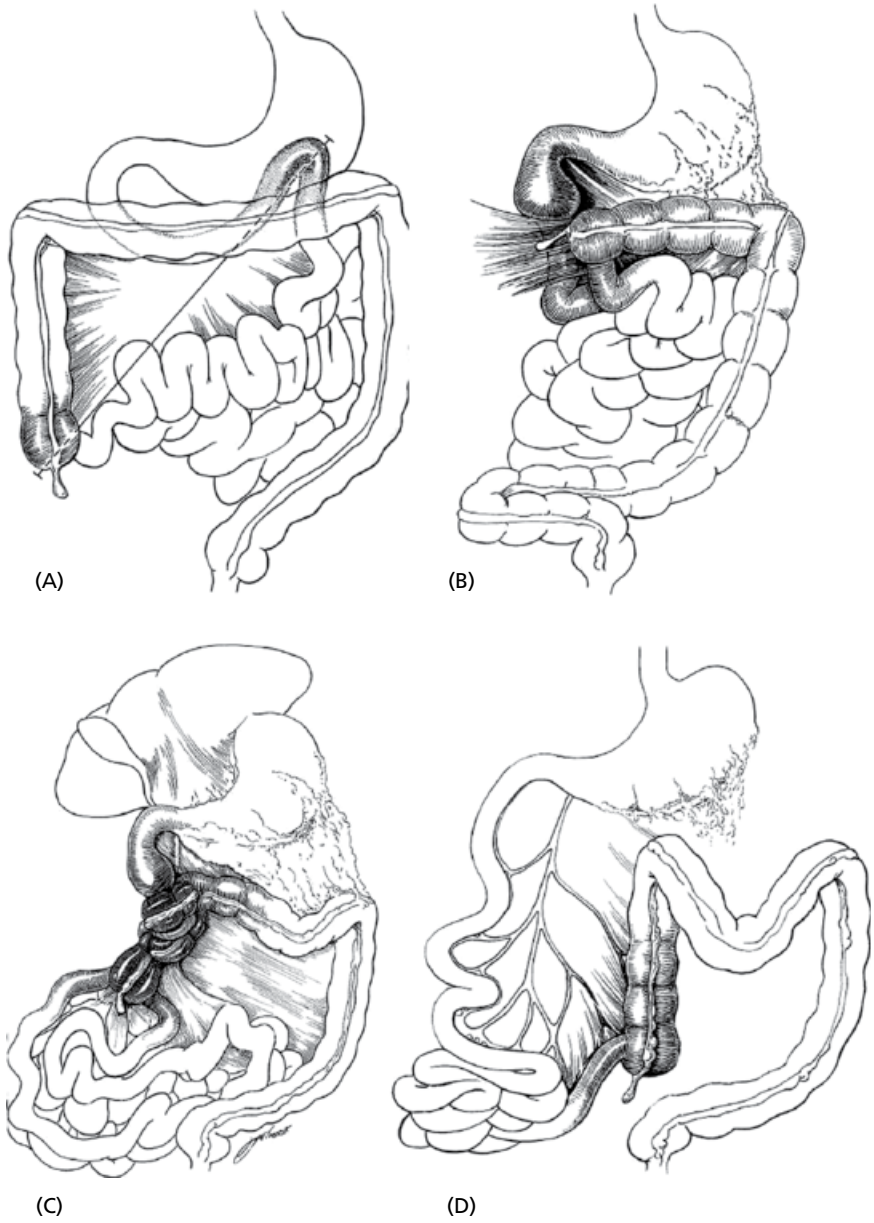

Figure 31.3 (A) Normal intestinal rotation. (B) Malrotation without volvulus. (C) Malrotation with volvulus. (D) Non-rotation. *Source*: Reproduced from Langer [32] with permission of Elsevier.

death. Some patients are severely acidotic from both hypovolemia and poor gut blood flow. If the acidosis is not corrected by fluid replacement, partial correction of pH with bicarbonate or tromethamine should be considered. Once the patient is normovolemic, a Ladd procedure is done, which includes derotation of the midgut volvulus, division of bands and adhesions when present, and an appendectomy. The small bowel is then placed in the right side of the abdomen and the colon on the left side (Fig. 31.4) [32].

These patients must be considered to have a full stomach. Before inducing anesthesia, all laboratory and other diagnostic studies should be reviewed and the degree of acid–base imbalance and electrolyte abnormalities corrected. Adequate venous and intra-arterial access is required. Just before the induction of anesthesia, the stomach is decompressed through an orogastric or nasogastric tube, and the lungs are preoxygenated. Rapid sequence induction of anesthesia is accomplished with intravenous propofol 2–3 mg/kg or etomidate 0.2–0.3 mg/kg and a non-depolarizing muscle relaxant, e.g. rocuronium 1–1.2 mg/kg or vecuronium 0.1–0.2 mg/kg, to facilitate rapid intubation. Intraoperatively, the patient's lungs are ventilated with a mixture of air and oxygen and low concentrations of sevoflurane or isoflurane. Intravenous opioids, e.g. fentanyl, are titrated to effect. The key to a good outcome is fluid resuscitation and replacement of extracellular fluid losses in the perioperative period. Occasionally, large volumes of colloids and blood are required. Circulatory support with vasopressors may be required, especially after derotation of the bowel. These infants frequently require intensive care after

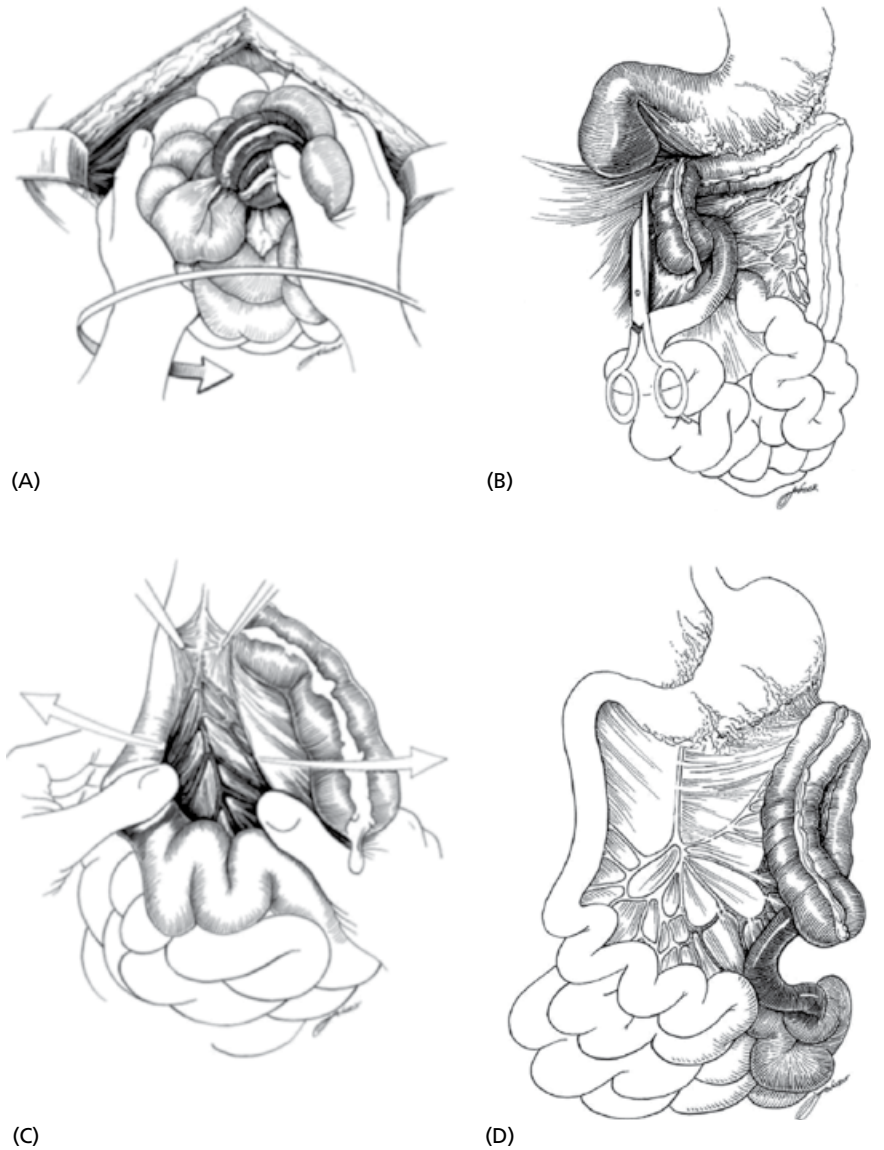

Figure 31.4 Operative steps of Ladd procedure. (A) The bowel is assessed and, if volvulus is present, gently detorsed in a counterclockwise direction (arrow). (B) Ladd bands attaching the colon to the liver, gallbladder, or retroperitoneum are divided sharply or with electrocautery. (C) Adhesions to the mesentery are divided (arrows) and the mesenteric pedicle widened, allowing the colon to be placed on the left side of the patient and the small bowel with a straightened duodenum on the right. (D) Final position of the bowel contents at the completion of the Ladd procedure. An appendectomy has been performed to avoid future confusion with the presentation of atypical appendicitis in the left abdomen. *Source*: Reproduced from Langer [32] with permission of Elsevier.

surgery. Depending on the stability of the patient, the magnitude of the surgery, and associated co-morbid conditions, some patients require postoperative mechanical ventilation. Delayed return of intestinal function often makes parenteral nutrition necessary for a period of time.

Management of asymptomatic patients with malrotation is controversial, with some authorities arguing for an elective Ladd procedure when diagnosed, and others preferring to observe for development of symptoms [36–38]. Laparoscopy may aid in determining the risk for volvulus, i.e. true malrotation with narrow mesenteric stalk, which confers high risk; repair can often be completed laparoscopically. Patients with complex, congenital, single-ventricle cardiac disease and heterotaxy with malrotation can be observed until after their initial cardiac surgery. Additional multicenter data addressing this issue are needed for more definitive recommendations.

Intestinal pseudo-obstruction

If the surgeons find no cause for the bowel obstruction, the patient may have intestinal pseudo-obstruction, a condition in which the signs and symptoms of intestinal obstruction are present but no mechanical lesion is found. Pseudo-obstruction is myopathical or neuropathical in etiology and is not limited to the small intestine. Box 31.1 lists the causes of intestinal pseudo-obstruction. These patients have recurrent attacks of variable duration and frequency that include nausea, vomiting, abdominal distension, diarrhea, and constipation. Treatment of intestinal pseudo-obstruction is difficult and is mainly medical. Erythromycin and octreotide have been used with some success to stimulate intestinal motility and contraction. New treatments that target intestinal serotonin receptors (e.g. alosetron) are in clinical trials. Surgery is only helpful for patients who have a short segment of intestinal dysmotility.

KEY POINTS: MALROTATION OF THE BOWEL AND INTESTINAL ATRESIA

- Jejunoileal atresia and stenosis are major causes of neonatal intestinal obstruction
- Abnormal intestinal rotation commonly occurs with heterotaxy, i.e. there is abnormal sidedness of the liver, spleen, and vascular structures
- Neonates with intestinal malrotation present with bilious vomiting or with signs of midgut volvulus
- Large volumes of crystalloids, colloids, and blood, as well as circulatory support with vasopressors, may be required. Acidosis is common and may necessitate blood volume expansion and alkali to correct it

- Tricyclic antidepressants
- Phenothiazines

Inflammatory bowel disease

Inflammatory bowel disease (IBD) includes two major forms of chronic intestinal inflammation: Crohn disease and ulcerative colitis. Both are associated with significant morbidity. Prompt and accurate diagnosis and appropriate treatment of IBD minimizes its short-term and long-term physical and psychological effects.

Epidemiology

The incidence of IBD is steadily increasing. Over 1 million Americans are afflicted with the disease, and 10–25% of them are children [39–41]. In pediatric patients, the incidence of Crohn disease ranges from two to seven per 100,000 per year compared with 1–4 per 100,000 per year for ulcerative colitis [42]. Males and females are equally afflicted. North America and northern Europe have the largest number of patients with IBD. Caucasians, especially in the Ashkenazi Jewish population, have the highest risk for the disease. However, the increased disease prevalence is occurring in diverse rural and urban populations alike and in people of different ethnic backgrounds.

Etiology

The etiology of IBD is unknown, but a number of risk factors appear to play a role in its development. There appears to be a genetic predisposition because pediatric IBD is familial in 19–41% of cases [42]. Monozygotic twins are more likely to have IBD than dizygotic twins. Environmental factors, infections, immune system disorders, and psychological stress play a role in the development of IBD. The gut microbiome has increasingly been studied and Crohn disease is associated with increased load of enteroinvasive *Escherichia coli* strains [42].

Pathophysiology

Ulcerative colitis is usually limited to the colon and rectum. However, the extent of the disease differs between children and adults. It is usually more extensive in children and may present as pancolitis. Microscopic changes of ulcerative colitis are limited to the mucosa and are continuous from the rectum upward [43]. Crohn disease, on the other hand, can affect any part of the gastrointestinal tract from the mouth to the anus. Children with Crohn disease usually have extensive lesions of the ileum and colon when first evaluated. The inflammatory lesions are focal, asymmetrical, and patchy in location and severity. In the colon, Crohn disease may be difficult to distinguish from ulcerative colitis. Patients with IBD also have extraintestinal manifestations and a higher than predicted risk of developing colorectal cancer.

Clinical presentation

The classic presentation of Crohn disease is abdominal pain, diarrhea, and weight loss. Bloody, mucoid diarrhea is classic for ulcerative colitis. Extraintestinal manifestations of IBD include anorexia, lethargy, pyrexia, arthralgia, arthritis, erythema nodosum, uveitis/iritis, and growth failure.

Diagnosis

The gold standard for diagnosing IBD is upper endoscopy, colonoscopy, and tissue histology. However, there is no substitute for a complete history and physical examination.

Laboratory screening tests include erythrocyte sedimentation rate (ESR), C-reactive protein (CRP) [44], and examination of the stool for bacteria and parasites. Fecal inflammatory markers are also helpful for screening and monitoring patients with IBD. Fecal markers include proteins released from activated neutrophils in the bowel mucosa (e.g. lactoferrin, calprotectin, polymorphonuclear-elastase, and lysozyme) [45].

Serological biomarkers include anti-*Saccharomyces cerevisiae* (ASCA) immunoglobulin A (IgA) and IgG, anti-*E. coli* outer membrane porin C, antiperinuclear antineutrophil IgG, anti-*Pseudomonas fluorescens* CD-related protein IgA, and anti-flagellin. It has been postulated that patients who have immune reactivity to antimicrobial antigens have a more severe form of disease [46]. Higher ASCA levels are associated with younger age at disease onset, structuring of the bowel, penetrating disease, and a need for surgery in both adults and

children with Crohn disease. Radiographic studies, CT scans, ultrasound, magnetic resonance imaging (MRI), and barium enemas are also used to detect disease and complications of the disease (e.g. abscess); however, use of these modalities is limited.

Management

Inflammatory bowel disease is quite debilitating. Therefore, the goals of management include induction and maintenance of disease remission to facilitate normal growth and development and improve the child's quality of life. Medical management consists of a combination of pharmacological agents, including administering corticosteroids for their anti-inflammatory properties to children who have moderate to severe active IBD. Sulfasalazine and 5-aminosalicylate are locally active medications that are useful for the induction and maintenance of disease remission [47]. Immunomodulators, such as 6-mercaptopurine (6-MP) and azathioprine, are the most commonly prescribed agents for these children. These drugs act by incorporating 6-thioguanine nucleotide metabolites of 6-MP in leukocyte DNA [48]. Methotrexate is a second-line immunomodulator that has significant corticosteroid-sparing effects when injected weekly in children with IBD [48]. Cyclosporin and tacrolimus effectively control severe fulminant ulcerative colitis and fistula formation in Crohn disease by blocking production of the potent proinflammatory cytokine interleukin-2 [49,50].

Biological therapy with infliximab, a chimeric monoclonal antibody (IgG1), is directed against tumor necrosis factor α (TNF-α) and is widely used in children with IBD [51]. More recently, adalimumab has been used to treat pediatric patients with IBD. [42]. Antibiotics/probiotics, especially ciprofloxacin (Cipro) and metronidazole (Flagyl), are used to prevent and treat infection, e.g. pouchitis [52]. Nutritional therapy with an elemental diet or total parenteral nutrition helps maintain nutrition and improve growth, which is important because poor nutrition is a major cause of growth failure in patients with IBD. Finally, fecal microbial transplant has been utilized in recent years for pediatric IBD and initial results have been promising [53].

Psychological problems are common in children with IBD due to demanding treatment regimens, frequent relapses of their disease, pain, diarrhea, fecal incontinence, and altered physical appearance. These children frequently do not discuss their problem with peers. Multidisciplinary help is often needed for both the children and their families to help them cope with the practical and psychological implications of IBD [54].

Patients with IBD have an increased risk of developing cancer. It is estimated that the risk of cancer in patients with ulcerative colitis increases 1% per year after the first 10 years of the disease [55]. Patients with total colonic disease have the highest risk. After having the disease for 8–10 years, yearly surveillance of the bowel should be done in all patients, regardless of whether they are symptomatic or asymptomatic. The incidence of surgery in these patients is declining due to better medical and nutritional management. Since surgery does not cure the disease, it is reserved for failures of medical management or for complications of the disease. Emergency surgery is indicated for fulminant disease that is refractory to medical management, including extensive rectal bleeding or toxic megacolon. In the past, proctocolectomy with ileostomy was standard treatment for ulcerative colitis. Since the 1970s restorative proctocolectomy with ileal–anal anastomosis has been practiced. Some patients develop strictures and require surgery to relieve them.

Anesthetic management of patients with IBD begins with a thorough history and physical examination. Particular attention is paid to the patient's fluid and electrolyte status. Optimizing the fluid and electrolyte status before elective surgery is crucial to a good outcome. Prophylactic steroid administration is recommended for patients who have been on long-term steroid therapy. Patients on total parenteral nutrition (TPN) require monitoring of their blood glucose and metabolic states during the perioperative period. Sudden discontinuation of a TPN solution that contains high glucose concentrations may lead to severe hypoglycemia. No one particular anesthetic technique is preferred. Combined general and epidural anesthesia should be considered for abdominal surgery, since the epidural will provide significant postoperative pain relief. The extent of the surgery determines how much intraoperative monitoring is necessary. If the patient requires extensive colonic resection, arterial and central venous lines are appropriate. Attention to intraoperative fluid replacement, blood loss, and correction of fluid, electrolyte, glucose, and hematological derangements is important.

Postoperative pain management can be challenging because many of these patients were receiving narcotics before surgery for their abdominal pain. Intravenous patient-controlled analgesia (PCA) and regional analgesia provide good pain relief and are used routinely. Anastomotic leaks and abscess formation are the most frequent complications encountered after surgery. Abscess drainage by an interventional radiologist often requires general anesthesia.

KEY POINTS: INFLAMMATORY BOWEL DISEASE

- Ulcerative colitis is usually limited to the colon and rectum
- Crohn disease can affect the entire gastrointestinal tract from the mouth to the anus
- Children with IBD and extraintestinal manifestations have a higher risk of developing colorectal cancer
- The gold standard for diagnosing IBD is upper endoscopy, colonoscopy, and tissue histology
- The goals of IBD management are induction and maintenance of disease remission
- Medical management combines pharmacological agents, corticosteroids, anti-inflammatory agents, and biologicals directed against TNF
- Emergency surgery is indicated for fulminant disease that is refractory to medical management or for extensive rectal bleeding or toxic megacolon

Abdominal masses: major abdominal/liver tumors and pheochromocytoma

Major abdominal tumors

Neuroblastomas, Wilms tumor, and hepatomas are the most common intra-abdominal tumors in children. Neonates and infants with these tumors often present with an abdominal

mass and abdominal distension. Box 31.2 lists the differential diagnosis of abdominal masses in children.

Laboratory, radiographic, and imaging studies are common diagnostic measures used to determine the cause of the child's problem. Box 31.3 lists useful studies for the initial evaluation of patients with an abdominal mass.

Neuroblastomas

Neuroblastomas arise from neural crest tissue. In the abdomen they arise from the adrenal glands and paraspinal sympathetic ganglia. Neuroblastoma is the most common neoplasm in infancy and the most common extracranial solid tumor during childhood. The behavior patterns of neuroblastomas are heterogeneous and range from complete regression to life-threatening progression despite treatment.

Epidemiology

Neuroblastomas account for more than 7% of malignancies in patients less than 15 years of age and around 15% of all pediatric oncology deaths [56]. Approximately 40% of cases are diagnosed by 1 year, 75% by 7 years, and 98% by 10 years of age [57]. More than half of the patients are younger than 2 years old when diagnosed. The incidence of neuroblastoma is slightly more common in boys than girls (ratio of 1.2:1.0) [57]. A familial history of neuroblastoma, with an autosomal dominant pattern of inheritance, has been reported in 1–2% of patients. The median age at diagnosis of familial neuroblastoma is 9 months, compared with 18 months for sporadic cases [56]. Maris et al found that 20% of patients with familial neuroblastomas have bilateral or multifocal tumors with evidence for a locus on chromosome 16p12-13 [58].

Approximately 75% of cases of abdominal neuroblastomas have metastasis at diagnosis, the most common sites being lymph nodes, bone marrow, liver, and skin. In the USA the overall incidence is one per 100,000, with approximately 700 new diagnoses annually. The overall survival is 65%, but most patients have high-risk metastatic disease at presentation, where survival rates are less than 50% despite intensified chemotherapy and invasive surgery [59]. In contrast to neuroblastoma diagnosed after the neonatal period, neonatal neuroblastoma, which accounts for less than 5% of cases, most often regresses spontaneously and may resolve completely without treatment. Many authorities advocate a watch and wait approach for low-risk neonates, and reduced therapy for some intermediate-risk patients to minimize exposure to toxic chemotherapy and to surgery [60].

- Toxic megacolon
- Retroperitoneal/intra-abdominal abscess

Other
- Impacted feces
- Mesenteric cysts
- Intussusception
- Volvulus

Box 31.3: Studies for the evaluation of abdominal masses

Laboratory studies
- Complete blood count with differential
- Serum chemistry
- Serum electrolyte levels
- Liver function tests
- Plasma catecholamine levels
- Serum β-chorionic gonadotropin
- Serum α-fetoprotein levels
- Urinalysis
- Uric acid and lactate dehydrogenase levels
- Urine for vanillylmandelic acid and catecholamine levels

Radiographic imaging studies
- Plain abdominal x-ray
- Abdominal sonogram
- CT scan or MRI of the abdomen
- MIBG (metaiodobenzyl guanidine) scan

Clinical presentation

The clinical presentation of neuroblastomas varies, depending on the site of the primary disease, the extent of metastasis, the size of the tumor, and any associated paraneoplastic syndromes. Patients in the early stage of the disease may have non-specific symptoms, such as pain and generalized malaise. Between 50% and 75% of patients present with an abdominal mass and may have abdominal pain and abdominal distension, weight loss, failure to thrive, fever, and anemia [57]. Tumors producing catecholamine cause hypertension in 25% of patients. Thoracic tumors may be discovered accidentally on a chest radiograph or when the patient shows signs of Horner syndrome (ptosis, miosis, enophthalmos, anhydrosis, and heterochromia of the iris) on the affected side. Patients with metastatic neuroblastomas can present with proptosis and periorbital ecchymosis, often referred to as "raccoon eyes." Infants with neuroblastomas can have hypokalemia and intractable diarrhea with watery, explosive stools. The diarrhea is thought to be the result of tumor-produced vasoactive intestinal polypeptide.

Diagnosis

Neuroblastomas are diagnosed by serological and urine examinations and by radiological and isotope studies. While there are no specific serum markers for neuroblastoma, high levels of ferritin, neuron-specific enolase, and lactate dehydrogenase are often present [61]; patients occasionally have high levels of serum and urinary catecholamines. Immunological analysis of serum and bone marrow is sensitive for detection of tumor cells. Radiographic examinations include plain x-rays of the abdomen, CT scan, helical (spiral) CT, MRI, and isotope bone scans. Once the diagnosis is made, the disease is staged according to the International Neuroblastoma Staging System (INSS). The INSS score is one

of the main clinical variables used to predict outcomes of patients with neuroblastomas. Increasingly, histopathological characteristics are used to determine patient risk and treatment strategies. Finally, genomic and biological features such as DNA ploidy, chromosomal alterations, and amplification of specific genes are now used for staging and risk assessment, and to determine treatment.[59]

Management

Surgery, chemotherapy, radiotherapy, and immunotherapy are the main treatment modalities for neuroblastoma. Surgery is beneficial for patients who have localized tumors. However, more than half of children with neuroblastomas present with metastatic, unresectable tumors. When this occurs, they are initially treated with chemotherapy followed by tumor resection. Children with high-risk neuroblastomas undergo multimodal therapy, including induction of chemotherapy, surgical resection of the primary tumor, radiotherapy, and consolidation chemotherapy.

Surgical resection of the tumor

When children with neuroblastoma present for surgery, a complete history and physical examination and preoperative consultation with the patient's primary physician are important. Evaluation of the complete blood count, serum electrolyte concentrations, echocardiography, and radiological studies is also important. Knowledge of the chemotherapeutic drugs and steroids used is important as both therapies can cause complications. Intraoperative anesthetic management consists of general anesthesia, tracheal intubation, and standard monitoring plus intra-arterial and central venous monitoring. Occasionally neuroblastoma resection is accompanied by significant blood pressure fluctuations like that seen with pheochromocytomas (see next section).

Pheochromocytomas

Pheochromocytomas arise from catecholamine-producing chromaffin cells and are of neuroectodermal origin. These cells are found anywhere in the sympathoadrenal system but arise most commonly from the adrenal medulla. Tumors arising from extra-adrenal sympathetic and parasympathetic paraganglia are classified as extra-adrenal paragangliomas. Pheochromocytomas and sympathetic paragangliomas secrete catecholamines, but most parasympathetic paragangliomas are non-secretory. Pheochromocytomas secrete large amounts of adrenaline, noradrenaline, and dopamine, plus various peptides and ectopic hormones: enkephalin, somatostatin, calcitonin, oxytocin, vasopressin, insulin, and adrenocorticotropic hormones [62]. Data on the etiology, diagnosis, and management of pheochromocytoma in children are limited.

Epidemiology

Pheochromocytomas are one-tenth as common in children as in adults (one in 500,000 children compared to one in 50,000 in adults) [63]. Approximately 10% of tumors are bilateral, 10% are extra-adrenal, 10% are malignant, and 10% are familial. In children, 70% of the tumors are bilateral and extra-adrenal, the majority of them benign [64]. Advances in molecular genetics have allowed mutations in germline cells to be identified in 59% of patients presenting at 18 or fewer years of age and in 70% of patients presenting before age 10 years. The inherited predisposition is related to mutation(s) in the von Hippel–Lindau (VHL) gene, which encodes the subunits B and D of succinate dehydrogenase and also the RET proto-oncogene that predisposes patients to the development of multiple endocrine neoplasia type 2 (MEN2) or neurofibromatosis type 1 (NF1). The VHL gene is the most commonly mutated gene in children who present with pheochromocytoma [65].

Though rare, pheochromocytomas may present in the neonatal period. However, they present more commonly in older, male children. There is a female preponderance for the disease during the reproductive years, suggesting a hormonal influence.

Clinical presentation

Patients with pheochromocytomas are thin, anorexic, and hypermetabolic. The most common symptoms include headaches, flushing, palpitations, hypertension, and sweating. Central nervous system manifestations include tremors, nervousness, anxiety, visual disturbances, and psychosis. Cardiovascular symptoms include hypertension, ventricular arrhythmias, cardiomyopathy, and cardiac failure. Some patients have symptoms of gastrointestinal disturbances.

Diagnosis

Pheochromocytoma is diagnosed by biochemical testing and imaging studies. Measurement of 24 h urinary vanillylmandelic acid, total metanephrine, and catecholamine concentrations is valuable [66]. Urinary metanephrine levels are increased in 95% of cases, and vanillylmandelic acid and catecholamine levels are increased in approximately 90% of patients [67]. Plasma catecholamine concentrations that exceed 2000 pg/mL during a hypertensive episode are diagnostic of pheochromocytoma; normal levels are not. Plasma catecholamine levels between 500 and 1000 pg/mL are suggestive of pheochromocytoma, but further work-up is required [68]. CT or MRI scans and ^{123}I-labeled metaiodobenzyl guanidine (MIBG) scintigraphy are all also helpful in making the diagnosis [69]. Abnormal neuroectodermal tissue takes up the isotope, which produces a focal area of increased uptake on the scan. These scans help localize extra-adrenal tumors. Positron emission tomography with ^{18}F fluorodeoxyglucose or hydroxyephedrine is also useful for localizing tumors [70].

Management

Surgical excision of the tumor is the definitive treatment, but this requires optimization of the patient's condition medically before surgery. The goals of medical management include normalization of the arterial blood pressure and heart rate, restoration of blood volume, and prevention of a hypertensive crisis and its subsequent consequences.

Preoperative preparation of the patient should begin at least 10–14 days before surgery. Initial treatment includes α-adrenoreceptor blockade to reduce catecholamine-induced vasoconstriction and its sequelae [71]. Phenoxybenzamine is a non-selective α1 and α2 non-competitive blocker that is administered orally in doses of 0.5–1 mg/kg twice a day. The dose is adjusted according to the patient's response to the drug. Phentolamine, a competitive non-selective α-adrenergic blocker, is also used as an adjunct. Adequate α-blockade is

demonstrated by the presence of normotension or by the presence of side-effects to the drug, such as orthostatic hypotension tachycardia, nasal congestion, and dizziness [71]. The unopposed β-stimulation following α-blockade causes tachycardia and arrhythmias, which are controlled by β-adrenergic receptor-blocking agents, such as propranolol or labetalol. β-receptor blockade should never be initiated until α-blockade is fully accomplished because a severe hypertensive crisis can occur due to unopposed α-stimulation. Occasionally, α-methyl-para-tyrosine (metyrosine), which competitively inhibits tyrosine hydroxylase, the rate-limiting step in catecholamine biosynthesis, is added to reduce catecholamine stores in the tumor [72].

Patients with pheochromocytomas are generally intravascular volume depleted and have circulating plasma volumes of about 15% below normal. Once adequate pharmacological blockade is established, volume resuscitation is required.

Anesthetic management of patients with pheochromocytomas consists of providing stable anesthesia and avoiding surges in catecholamines. In spite of optimal medical management, patients can and do have sudden blood pressure fluctuations during induction of anesthesia and tracheal intubation, during surgical manipulation of the tumor, and after ligation of the tumor's venous drainage. Premedication with oral midazolam is often used to treat patient anxiety. General tracheal anesthesia or combined general and epidural anesthesia have been used successfully for intraoperative management of these patients. Anesthesia is usually induced by mask with sevoflurane or with intravenous propofol or etomidate. Following induction of anesthesia, large-bore intravenous catheters and an arterial line are inserted. Muscle relaxation is achieved with a non-depolarizing muscle relaxant, such as rocuronium, vecuronium, or *cis*-atracurium. A central venous catheter is inserted if one is not already in place. Fentanyl, sufentanil, or a continuous infusion of remifentanil can be used.

Intraoperative hypertension is managed by infusion of sodium nitroprusside, a potent arteriovenodilator. Esmolol is often used to control tachycardia and hypertension. Hypotension may occur once the adrenal vein is ligated and the tumor is removed. The hypotension usually responds to fluid administration and discontinuation of vasodilators. Occasionally vasopressors, such as phenylephrine or norepinephrine, are required.

After surgery the patients are admitted to the intensive care unit (ICU) to monitor for and control hypertension, hypotension, and hypoglycemia. Once the tumor is excised, pancreatic β-cell suppression is removed and insulin levels increase, which may cause hypoglycemia. Lipolysis and glycogenolysis cease after tumor removal and α-blockade. Residual adrenergic blockade may mask the signs and symptoms of hypoglycemia. Consequently, blood glucose concentrations should be closely monitored. If hypertension persists postoperatively, it is likely that there is a second pheochromocytoma. Normalization of catecholamine levels should be confirmed in all patients. Long-term follow-up is required to detect subsequent development of metachronous tumors and to detect tumors at other sites.

Wilms tumor

Wilms tumor (nephroblastoma) is the most common renal neoplasm affecting children. Diagnosis and treatment of Wilms tumor are discussed in Chapter 32.

Liver tumors

Liver tumors account for 1% of all pediatric tumors. Hepatoblastoma and hepatocellular carcinomas are responsible for most hepatic malignancies during childhood. Two-thirds of all liver tumors are hepatoblastomas. Benign liver tumors include vascular tumors, hamartomas, adenomas, and focal nodular hyperplasia. With advances in surgical technique, anesthesia, and chemotherapy, the 5-year survival of patients with hepatoblastoma has improved from 35% three decades ago to 75% at the present time [73]. However, the prognosis for patients with hepatocellular carcinoma remains poor.

Epidemiology

Hepatoblastoma and hepatocellular carcinomas occur more commonly in males and are more common in 0.5–3-year-old children, the median age at diagnosis being 18 months. Only 5% of new hepatoblastomas are diagnosed in children beyond 4 years of age. Other conditions associated with hepatoblastoma include Beckwith–Wiedemann syndrome, familial adenomatous polyposis, hemihypertrophy, and low birthweight. Hepatocellular carcinomas are diagnosed after 10 years of age and commonly occur in patients with underlying liver disease, such as cirrhosis, tyrosinemia, and other inherited metabolic disorders [74]. Genetic aberrations in several chromosomes have been identified that predispose patients to the development of malignant liver tumors.

Clinical presentation

Most children who have liver cancers present with a painless, palpable, abdominal mass. They may also have abdominal distension, anorexia, weight loss, and fatigue. Occasionally they present with abdominal pain, constipation, jaundice, or precocious puberty.

Diagnosis

Laboratory and imaging studies are key to the diagnosis of liver tumors. Laboratory studies include complete blood count, chemistry panel, liver function tests, coagulation profile, and serum α-fetoprotein (AFP) concentrations. AFP concentrations are the most sensitive laboratory test for hepatoblastoma and hepatocellular carcinomas, but this test is non-specific. On occasion, hepatoblastomas secrete β-human chorionic gonadotropin. Imaging studies, such as CT scan of the abdomen, ultrasonography, MRI, and magnetic resonance angiography, are also useful in diagnosing these tumors. The diagnosis is ultimately made, however, by liver biopsy.

Management

Treatment of hepatoblastoma has improved markedly during the past several decades. Primary resection of benign liver tumors and stage I hepatoblastoma is curative. Unresectable tumors are initially treated with vincristine, cisplatin, and fluorouracil before the tumors are resected. If the tumor remains unresectable despite chemotherapy and is not metastatic, orthotopic liver transplantation is considered. In recent years, international collaboration has resulted in a more precise staging and management system based on how many sectors of the liver are involved, and other features such as involvement of the IVC, hepatic, and portal veins. More

standardized approaches to intensive preoperative chemotherapy for high-risk tumors, and to extensive surgical resection, have increased survival to over 90% for patients with standard-risk hepatoblastoma, and 45–80% for patients with metastatic disease. Liver transplantation is now employed in as many as 27% of high-risk tumors in a recent series [75].

Preoperative assessment determines the extent of the tumor, whether it has metastasized, and if the patient has received chemotherapy. Careful attention should be paid to the patient's laboratory tests, liver function, blood count, coagulation status, and pulmonary, renal, and cardiac function, especially after chemotherapy. Echocardiography may be necessary after cardiotoxic chemotherapy. Patients should be typed and cross-matched for packed red blood cells and should have fresh frozen plasma and platelets available before and during surgery.

Anesthetic management of patients with liver tumors is challenging. Standard anesthesia induction agents are used. Tracheal intubation is facilitated with muscle relaxants, preferably *cis*-atracurium because its hepatic metabolism is minor. Standard monitors, plus intra-arterial and central venous pressure (CVP) monitoring, are usually used. Large-bore peripheral venous access is obtained, preferably in the upper extremities. In the event of major blood loss, perfusion, normothermia, and a normal pH should be aggressively maintained. It is occasionally necessary during surgery to quickly resuscitate patients who undergo acute, rapid hemorrhage. The main source of bleeding during liver resection is from the hepatic vein, which has no valves. High venous pressure increases bleeding. By keeping the CVP below 5 mmHg during the dissection phase, blood loss can be reduced. Vasopressors (e.g. norepinephrine or vasopressin) may be required to maintain arterial blood pressure during some phases of surgery. Whether the trachea is extubated in the operating room or the ICU depends on the extent of the liver resection, the amount of intraoperative blood loss, and the need for volume resuscitation. Postoperative pain is easily managed with patient- or nurse-controlled analgesia.

KEY POINTS: ABDOMINAL MASSES

- Neuroblastoma, Wilms tumor, and hepatomas are the most common intra-abdominal tumors in children
- Neuroblastomas account for about 7% of malignancies in patients younger than 15 years of age and 15% of all pediatric oncology deaths
- Diagnosis of neuroblastoma requires serological and urine examinations and both radiological and isotope studies
- Measuring 24 h urinary concentrations of vanillylmandelic acid, total metanephrine, and catecholamines makes the diagnosis of pheochromocytoma
- Preoperative preparation for pheochromocytoma surgery should begin with phenoxybenzamine-induced α-blockade prior to surgery
- Hepatoblastoma and hepatocellular carcinomas are the most frequent hepatic malignancies of childhood

Inguinal hernia

An inguinal hernia is a protrusion of intestine through an open processus vaginalis (Fig. 31.5). An incarcerated hernia is a hernia that is irreducible and does not slide back into the abdominal cavity. When bowel entrapment interferes with the vascular supply of the bowel, the hernia is said to be strangulated.

Epidemiology

Inguinal hernia repair is the most common elective procedure performed in pediatric patients. It occurs in 4.4% of all pediatric patients and is more common in males. Its incidence is 10–30% in premature infants versus 3–5% in full-term neonates [76,77]. Connective tissue disorders and cystic fibrosis also increase the incidence of inguinal hernia. Incarcerated hernias are more frequent in premature babies [78].

Clinical presentation and diagnosis

Inguinal hernias are diagnosed by physical examination when a bulge is felt at the internal or external inguinal ring. Most inguinal hernias are not painful, but large hernias may be. The bulge frequently disappears during sleep or rest. A Valsalva maneuver (e.g. crying) often provokes the bulge. The differential diagnosis of inguinal hernia includes hydrocele, retractable testis, lymphadenopathy, and a neoplastic process. Ultrasound helps diagnose a patent processus vaginalis. Patients with incarcerated hernias present with a tender, firm mass in the groin. These children are often inconsolable and may have anorexia. The "silk glove sign" (thickened peritoneum of the patent process vaginalis that can be felt during palpation of the cord) is suggestive of an inguinal hernia [79].

Management

Inguinal hernias do not heal spontaneously, but hydroceles often resolve during the first year of life. These hernias require surgical repair to reduce the risk of developing an incarcerated hernia. Incarcerated hernias can usually be manually reduced. Once reduced, the hernia should be repaired during

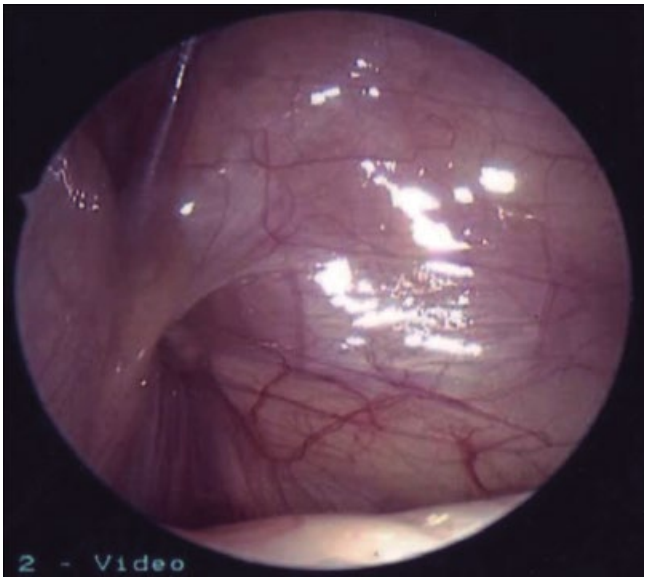

Figure 31.5 Laparoscopic view of a right inguinal hernia in a 2-month-old child.

the next 24–48 h to prevent recurrence of the incarceration [80]. If the hernia cannot be reduced, it may progress to strangulation, necrosis, and gangrene of the bowel. Strangulated hernias require immediate surgical correction. General anesthesia and muscle relaxation often make a non-reducible hernia reducible. Some patients with strangulated hernias have necrotic bowel and require bowel resection during herniorrhaphy. Table 31.1 details the characteristics of inguinal hernias. Children who are <6 months of age are at increased risk for developing strangulated or incarcerated hernias [81]. Consequently, their hernias are usually repaired soon after detection. Whether to operate on the contralateral side is debatable, but 28% of patients with a unilateral, clinically evident hernia early in life subsequently develop a symptomatic contralateral hernia [82]. Fifty percent of <2-year-old children have an open processus vaginalis, which should not be confused with an inguinal hernia. Laparoscopic visualization of the contralateral side is very helpful for determining if a second inguinal hernia exists on this side. This can be done even though the primary repair is done conventionally.

Premature babies often have bilateral inguinal hernias. Because of potential pulmonary complications and the fact that the surgical repair may be more difficult, there is controversy regarding when their hernias should be repaired. The reality is that most preterm neonates undergo hernia repair shortly before discharge home from the neonatal ICU for fear they will develop an incarcerated hernia.

Depending on co-morbidity and the surgical requirements, neuroaxial anesthesia or general tracheal, laryngeal mask, or facemask anesthesia is appropriate. Laryngeal mask airways (LMAs) should be used with caution in preterm infants. A no. 1 LMA increases the dead space by approximately 100% and may increase the $PaCO_2$ significantly. Unless the depth of anesthesia is adequate, laryngospasm may develop during surgical manipulation of the hernia sac. Despite these concerns, a new randomized controlled trial of LMA versus endotracheal tube in infants under 12 months of age demonstrated a much lower rate of perioperative respiratory adverse events, including laryngospasm and bronchospasm (18% versus 53%, n = 177 subjects, risk ratio 2.94, p <0.0001) [83]. Caudal blocks are often used as an adjunct to general anesthesia. In older patients, ileoinguinal or ileohypogastric nerve blocks can be helpful.

Postoperative apnea occurs in 20–30% of otherwise healthy former preterm infants who undergo inguinal hernia repair [84]. The risk for postoperative apnea decreases with increasing postconceptional age [85]. Spinal anesthesia is often used for these patients, although doing so does not decrease the incidence of apnea and bradycardia [86]. Ex-premature infants <60 weeks' post conception and full-term neonates <45 weeks postconception are usually admitted to hospital overnight for apnea monitoring. The recent GAS (*G*eneral *A*nesthesia compared to *S*pinal Anesthesia) Study had a primary aim of determining neurodevelopmental outcomes, but also assessed postanesthetic apnea. Early apnea at 0–30 min after surgery was less with spinal anesthesia (1% versus 3%, p = 0.04), but the overall rate at 0–12 h was similar at 3% with spinal and 4% with general anesthesia (p = 0.21). The strongest predictor of apnea was prematurity, with 96% of infants experiencing apnea being premature [87]. See Chapter 46 for further discussion of the GAS Study and anesthetic neurotoxicity.

Long-term outcome

In one study 28% of patients with a unilateral, clinically evident hernia had a symptomatic contralateral hernia later in life. The recurrence rate of an inguinal hernia repaired early in infancy is under 5% [88].

KEY POINTS: INGUINAL HERNIA

- Inguinal hernias are common in preterm infants
- It is important to determine whether the hernia is non-incarcerated, incarcerated, or strangulated
- Spinal anesthesia for premature infants does not reduce the incidence of postoperative apnea

Pyloric stenosis

Epidemiology

The incidence of idiopathic hypertrophic pyloric stenosis (IHPS) is 2–4 per 1000 livebirths, with a female to male preponderance of 1:3. Recently, the incidence of IHPS has decreased in some countries. Premature infants develop IHPS later than full-term infants [89].

Etiology

The mechanism for hypertrophy of the pyloric muscle is unknown, but the hypertrophy causes the gastroenteral obstruction (Fig. 31.6). The increased frequency of the condition in males and in first-born infants who have a positive family history for IHPS suggests that the lesion has a genetic predisposition. Feeding-related, environmental factors, duodenal feeding of premature infants, and erythromycin exposure have all been suggested as causes of IHPS. The pyloric muscle fibers are hypertrophic (not increased in number) and are markedly thickened and edematous. After a pyloromyotomy, the pyloric muscle becomes completely normal over time.

Clinical presentation and diagnosis

Between the 2nd and 12th (classically between the 3rd and 8th) weeks of life, most patients with IHPS present with

Table 31.1 Characteristics of inguinal hernias

	Simple	Incarcerated	Strangulated
Hernia sac	Herniates with Valsalva maneuver	Reducible	May or may not be reducible
Pain	No pain	Tender	Tender
Vascular supply	Intact	Intact	Compromised
Urgency	Elective	Within 24–72 h after reduction	Urgent

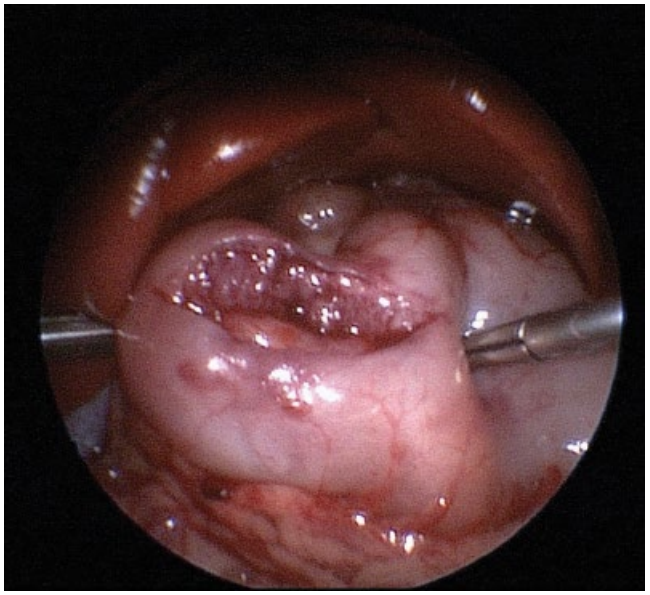

Figure 31.6 Pyloromyotomy. Note that the pyloric muscle has been partially transected and left open to heal. This increases the opening of the pylorus.

non-bilious, projectile vomiting. The differential diagnosis includes overfeeding, pylorospasm, gastroparesis, gastroesophageal reflux, and duodenal bands. Patients with pyloric stenosis are usually hungry and alert. When dehydration develops, they become lethargic.

The diagnosis of IPHS is usually confirmed by ultrasound. A barium swallow may be indicated if the ultrasound study is inconclusive. The hypertrophic pylorus can often be palpated through the abdominal wall. Careful observation of the child after feeding often reveals a characteristic peristaltic wave moving across the epigastrium. Historically, patients presented at an advanced stage of the disease. Now widespread use of ultrasound and much better understanding of the disease by pediatricians allow the diagnosis to be made earlier. Consequently, fewer patients have severe electrolyte disturbances and dehydration at presentation. If the diagnosis is made late, patients typically are dehydrated, hypochloremic, hypokalemic, and alkalotic at presentation. They may have lost weight and have gastritis with minor gastrointestinal bleeding. Initially these patients have an alkaline urine and loss of potassium and sodium as renal compensation for their vomiting. Later they secrete acidic urine, which further increases the metabolic alkalosis. This paradoxical aciduria occurs once potassium and sodium are depleted (Fig. 31.7).

Hypocalcemia often accompanies the hyponatremia. If this downward spiral is allowed to continue and additional fluid losses occur, prerenal azotemia, hypovolemic shock, and metabolic acidemia ensue.

Management

Idiopathic hypertrophic pyloric stenosis and concomitant hypovolemia represent a medical not a surgical emergency. The hypovolemia, acid–base abnormalities, and electrolyte abnormalities must be corrected prior to the induction of anesthesia. Surgery for IHPS is urgent but is not an emergency. Depending on the severity of these abnormalities, correction may require 12–48 h [90]. These patients should be made nil per os and their stomachs should be decompressed.

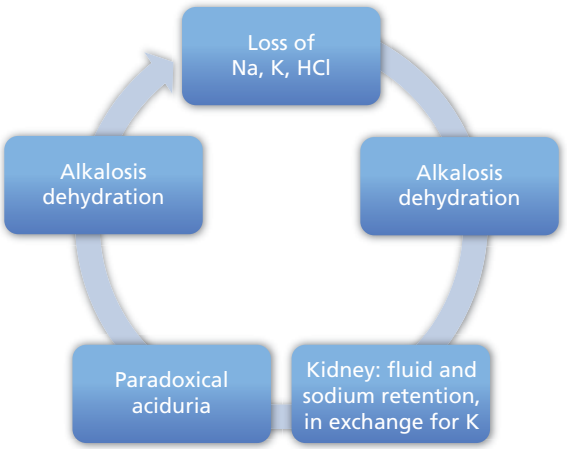

Figure 31.7 Pathophysiology of pyloric stenosis.

Intravenous fluid therapy usually includes normal saline (NS), dextrose 5% (D5) in 0.5 NS, or D5 in 0.25 NS at 1.5 times the maintenance fluid requirements. Care should be taken not to give excessive dilute solutions as they may cause seizures and death. Sufficient glucose should be provided to maintain normal blood glucose levels. Once satisfactory urine output is achieved, potassium can be added to the IV fluids. Homeostasis, as reflected by a serum chloride concentration >100 mEq/L and a serum bicarbonate concentration of <30 mEq/L, should be achieved before surgery commences. Urine chloride concentrations >20 mEq/L suggest adequate restoration of intravascular volume, since the kidney retains chloride during volume contraction. An underlying deficiency in glucuronyltransferase is responsible for jaundice in 2% of patients.

Before tracheal intubation, atropine is often given to prevent bradycardia, and the stomach is suctioned while tilting the patient in four different directions to empty the stomach as thoroughly as possible [91]. It is occasionally necessary to lavage the stomach to remove barium or milk curds. The high risk for aspiration of gastric contents warrants caution with airway management, but the prior practice of intubating the trachea whilst the patient is awake has decreased significantly in recent years because of the potential adverse effects of soft tissue injury, breath-holding, laryngospasm, aspiration, and the noxious and painful nature of the procedure.[90]. More commonly, a rapid sequence induction or modified rapid sequence induction of anesthesia with propofol and muscle paralysis with either succinylcholine or a non-depolarizing muscle relaxant is utilized. Intraoperatively, air is injected into the stomach through an orogastric catheter to verify the integrity of the duodenal mucosa. Preoperative cerebrospinal fluid alkalosis increases respiratory sensitivity to opioids. Consequently, these drugs are usually avoided because they can slow awakening from anesthesia and cause apnea. Acetaminophen per rectum or intravenously and infiltration of the wound with local anesthetics are often sufficient for postoperative pain management. Pyloromyotomy can be done open or laparoscopically. There are no clear advantages of one technique over the other, although recent meta-analyses demonstrate laparoscopy was associated with shorter time to full feeds and better cosmetic outcome, but also had a slightly higher rate of inadequate pyloromyotomy [92,93]. The hospital length of stay and postoperative complications are similar with

both techniques. Most patients have their trachea extubated at the conclusion of surgery. However, the presence of metabolic alkalosis increases their probability of postoperative apnea [94]. Other common complications of a pyloromyotomy include perforation of the duodenal mucosa (1–2%), wound infection, incisional hernia, incomplete myotomy, and bowel injury [95]. Oral feeds are usually instituted several hours after surgery. Some patients have persistent postoperative vomiting from gastroesophageal reflux or an incomplete myotomy.

Box 31.4 presents an evidence-based summary of perioperative management of pyloric stenosis [90].

KEY POINTS: PYLORIC STENOSIS

- Pyloric stenosis is a medical emergency, not a surgical emergency
- Allow time for adequate preoperative rehydration and correction of electrolytes
- Tracheal intubation is by rapid sequence induction or modified rapid sequence induction
- Opioids are avoided because they delay awakening from anesthesia and may increase apnea and the need for postoperative mechanical ventilation

Appendicitis

Epidemiology

Acute appendicitis is the most common abdominal lesion requiring surgical intervention. Four out of 1000 patients under 14 years of age will be diagnosed with appendicitis, and their lifetime risk for appendicitis is 7%. There is a male preponderance of appencititis (55–60%) [96]. No single test, examination, or symptom confirms the diagnosis in all cases. About 0.2–0.8% of patients with appendicitis die of complications of the disease. Preschool-aged children account for only about 5% of appendicitis, but the rate of appendiceal perforation in <4-year-old children is 80–100%, whereas it is 10–20% in children 10–17 years of age. The symptoms of appendicitis in younger children are often more diffuse [97], which makes the diagnosis more difficult to make. The atypical presentation increases the perforation rate in children [98].

Etiology and pathophysiology

Appendicitis is caused by luminal obstruction of the appendix by edema, inflammation, and overgrowth of fecal bacteria (Fig. 31.8). Lymphoid hyperplasia, a foreign body, or fecal

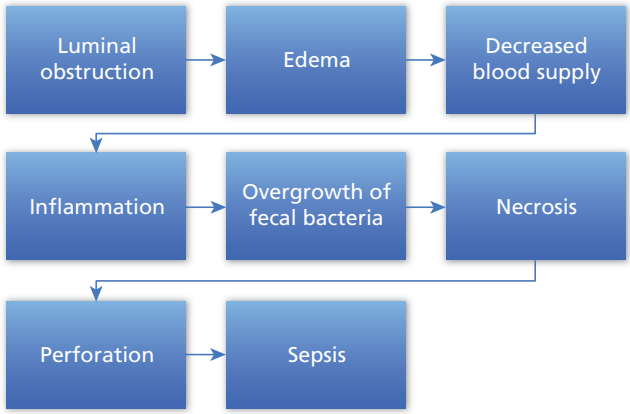

Figure 31.8 Pathophysiology of appendicitis.

Box 31.4: Summary of perioperative care for pyloric stenosis

Preoperative care

- Gastric fluid volumes are independent of a history of barium study, preoperative nasogastric suction, and fasting interval
- Preoperative decompression of the stomach by a nasogastric tube does not guarantee evacuation of gastric fluid
- Correction of electrolyte disturbances should target a serum chloride >100 mEq/L and serum HCO_3^- <30 mEq/L

Intraoperative care

- Aspiration of gastric contents by insertion of a large (e.g. 14 Fr), multiorifice orogastric catheter prior to the induction of anesthesia is warranted for avoiding aspiration of gastric fluid
- Atropine may be administered prior to endotracheal intubation in neonates to prevent reflex bradycardia during laryngoscopy
- Awake endotracheal intubation is not superior to rapid sequence intubation (RSI) or modified RSI
- Classic RSI including cricoid pressure is controversial and there is little to no evidence-based medicine supporting the role of that in preventing gastric aspiration
- Inhalation induction maybe safe in children undergoing pyloromytomy
- Succinylcholine continues to be employed because of its rapid onset and short duration of action
- A small dose of rocuronium (0.3–0.45 mg/kg) can achieve neuromuscular blockade and a shorter duration, but the onset of neuromuscular blockade may be delayed
- Desflurane has shorter recovery times (first movement, tracheal extubation, etc.) compared with sevoflurane or isoflurane
- Desflurane or sevoflurane is better in terms of the risk of postoperative apnea than isoflurane
- Nitrous oxide has the potential for the expansion of bowel gas. Its use should be limited especially during laparoscopic procedures
- Postoperative analgesia can generally be achieved with a combination of infiltration of the surgical site with a local anesthetic agent and the use of a non-opioid agent such as acetaminophen or a non-steroidal anti-inflammatory agent
- During laparoscopic procedures, the intra-abdominal pressure should be limited to ≤10 mmHg
- There is no strong evidence that shows that regional anesthesia is superior to general anesthesia for pyloromyotomy

Postoperative care

- The majority of patients can be managed with non-opioid analgesic agents and infiltration of the surgical site with a local anesthetic agent
- Regional anesthesia can be employed to provide postoperative analgesia
- Acetaminophen maybe a safer analgesic than ketorolac for postoperative pain control
- Preterm infants <44–60 weeks' postgestational age should receive appropriate monitoring for postoperative apnea
- The risk of postoperative apnea in preterm infants maybe increased by anemia (hemoglobin <10 g/dL)

matter causes the obstruction. If edema reduces the arterial blood supply, necrosis and perforation of the appendix may occur.

Clinical presentation and diagnosis

The diagnosis of appendicitis is often challenging because the position of the appendix within the abdomen varies. Only half of all patients have the classic symptoms of anorexia and periumbilical pain plus nausea, vomiting, and right lower quadrant pain. About one-third of patients present with atypical symptoms or are unable to describe their symptoms. In children, this leads to a false-negative appendectomy rate of 5–25%. Examinations by CT scan with contrast or ultrasound reduce the false-negative rate. The differential diagnoses include gastroenteritis, tubo-ovarian processes, mesenteric adenitis, cholecystitis, diverticulitis, pelvic inflammatory disease, ureterolithiasis, and more. Appendicitis rarely occurs in neonates, and when it does occur the symptoms are virtually indistinguishable from necrotizing enterocolitis [99].

Management

Fluid resuscitation and administration of intravenous broad-spectrum antibiotics that cover enteric organisms are required. Patients with a ruptured appendix require antibiotics until their clinical condition improves. The clinical goal is to perform an appendectomy before the appendix ruptures and to prevent peritonitis, sepsis, and abscess formation. Immediate surgery is not necessary if the appendix is unruptured and the patient has been appropriately treated with antibiotics [100]. This approach, combined with or without an interval appendectomy, is gaining popularity in acute, uncomplicated appendicitis in children. The presence of an appendicolith is a risk factor for failure of antibiotic treatment [101]. In one study 46% of non-operatively managed patients had an appendectomy in the first year after the initial appendicitis [102].

Most appendectomies are done laparoscopically because the incisions are smaller, there are fewer wound infections, and the incidence of ileus is lower. Initial experience with laparoscopic appendectomy suggested a higher incidence of intra-abdominal abscesses, but later studies have not confirmed this.

Anesthetic management

Anesthetic management of children undergoing appendectomy is usually straightforward and includes general endotracheal anesthesia. Rapid sequence induction of anesthesia is used to avoid aspiration of gastric contents. If patients are septic and have a ruptured appendix, aggressive fluid resuscitation is often required. Surgical manipulation of an infected abdomen may induce acute hemodynamic deterioration. Ketorolac plus opioids, along with infiltration of local anesthetic at the port sites, is usually sufficient for postoperative analgesia after endoscopic surgery [103]. Transversus abdominal plane block with ultrasound guidance has also been described as an effective pain management strategy, which may be associated with reduced opioid dosing, fasting time, antiemetic use, and duration of hospital stay [104]. Patient-controlled analgesia is seldom required if the appendix was not ruptured.

KEY POINTS: APPENDICITIS

- Rapid sequence induction of anesthesia is usually required to reduce the risk of aspiration of gastric contents
- Beware of contrast material given as part of the evaluation for appendicitis
- Patients with a ruptured appendix may require additional fluid resuscitation

SPECIFIC INERVENTIONAL AND SURGICAL PROCEDURES

Gastrointestinal/endoscopic retrograde cholangiopanceatography/endoscopy procedures

Sedation is adequate for most endoscopic procedures in adults, but children usually require general anesthesia. Since many of the procedures are done in non-operating room locations, it is important that operating room standards be applied when anesthetizing patients in these locations. This includes preoperative evaluation, monitoring, postoperative care, and having help readily available in case a problem arises. Anesthesiologists must understand the technical aspects of endoscopic procedures, some of which require multiple switching of endoscopes during the procedure or ultrasound examinations, banding varices, obtaining biopsies, and other interventions. Occasionally, the endoscope completely compresses the trachea and/or tracheal tube of an infant and obstructs the airway. Excessive insufflation of gas at high pressures and overdistension of the stomach and bowel may interfere with ventilation. Insufflation pressures should be kept at a minimum, usually 12 cmH_2O. At the end of the procedure, the stomach should be suctioned to remove as much gas and secretions as possible. Inserting a rectal tube may aid gas removal. Where multiple instruments are to be inserted through the esophagus or when contrast material or other fluids will be given into the esophagus or stomach during the procedure, it is advisable to intubate the trachea and secure the airway [105].

Esophago-gastro-duodenoscopy

Indications for esophago-gastro-duodenoscopies include gastroesophageal reflux and sclerotherapy for esophageal varices. Most anesthesiologists use inhalational induction of anesthesia if the patient has mild to moderate gastroesophageal reflux disease. It is usually safer and easier to secure the airway of younger children with an endotracheal tube, but some older children can be managed with intravenous anesthesia and a natural airway.

Insertion of the endoscope into the esophagus is the most stimulating part of the procedure and requires the deepest plane of anesthesia when procedures are done with a natural airway. Anteflexion of the neck makes insertion of the endoscope easier. The oropharynx can be anesthetized with topical local anesthetics, but doing so may leave the child without protective airway reflexes after the procedure and increase the likelihood of coughing spells and/or aspiration of fluids.

Most esophago-gastro-duodenoscopies take only a few minutes. If general anesthesia and tracheal intubation are used, it is helpful to avoid the use of muscle relaxants and to administer short-acting opioids, such as remifentanil, for the induction and maintenance of anesthesia. Tracheally

intubated patients are usually placed in the supine position for esophago-gastro-duodenoscopies. Patients with eosinophilic esophagitis must undergo repeated esophago-gastro-duodenoscopies. They frequently have multiple food allergies, including to soy and eggs, which contraindicate the use of propofol. They may also have asthma and atopic dermatitis so histamine-releasing drugs should be avoided [106].

Endoscopic retrograde cholangiopancreatography

Endoscopic retrograde cholangiopancreatography (ERCP) is used for patients with choledocholithiasis, for stent placement across malignant or benign strictures, and for tissue sampling [107]. Tracheal intubation is usually required when children undergo ERCP because the procedure can be long, patients are in the semi-prone position, and the use of multiple endoscopes may be required. These patients are often in acute distress from acute cholestasis and cholecystitis; they may also be dehydrated from prolonged anorexia, nausea, and vomiting. Injection of incremental doses of glucagon may be required during the procedure to increase bile duct motility.

Percutaneous endoscopic gastrostomy

A percutaneous endoscopic gastrostomy (PEG) allows placement of a gastrostomy tube without the need for a laparotomy. PEGs are usually indicated for prolonged nutritional support or decompression of the stomach, although they may not effectively do the latter. Surgical access to the stomach is identical to that used during an esophago-gastro-duodenoscopy; some surgeons verify placement of the gastrostomy by doing a mini-laparoscopy to rule out having produced a gastrocolic fistula. PEG placement in children has an increased risk of complications compared with laparoscopic gastrostomy tube placement, particularly perforation of intestines, infection, and mechanical complications such as excessive leakage [108].

The underlying disease (cerebral palsy, metabolic disease, congenital malformations) dictates the anesthetic management. Patients who already have a PEG in place should have their stomach decompressed prior to and during induction of inhalational anesthesia. Venting the stomach requires the use of a specific venting tube; the tubes used for feeding do not effectively allow air to escape from the stomach.

Colonoscopy

Colonoscopies are usually done in children who have inflammatory bowel disease or lower intestinal bleeding. Bowel preparation is required and may cause dehydration and electrolyte imbalances. In older children tracheal intubation is often not required for this procedure.

KEY POINTS: GASTROINTESTINAL/ERCP/ENDOSCOPY PROCEDURES

- Standards for monitoring and patient care in off-site areas should be the same as those used in the operating room
- Secure the airway with an endotracheal tube in smaller children when the esophagus is being instrumented
- Specific tubes (not feeding tubes) are required to vent gas through a PEG

Nissen fundoplication and gastrostomy

Gastroesophageal reflux is, to a certain extent, a physiological mechanism. The most common symptoms of this disorder in children are vomiting and regurgitation, pulmonary symptoms, dysphagia, abdominal pain, and hemorrhage [109]. In severe cases, life-threatening aspiration of gastric contents may have occurred.

Fundoplication is indicated for patients who have documented gastroesophageal reflux and who fail medical treatment, have recurrent aspiration of gastric contents, intermittent apnea, failure to thrive, and Barrett esophagitis. Infants who have had life-threatening events and gastroesophageal reflux frequently present for a fundoplication after other causes for these problems have been ruled out. In one case series, the life-threatening events resolved in most patients after surgery [110]. Neurologically impaired children who require a gastrostomy tube for feeding may also require fundoplication to prevent aspiration of gastric contents [111]. The former practice of performing a "prophylactic" Nissen fundoplication in neurologically impaired patients undergoing gastrostomy has largely been abandoned because of lack of any demonstrable difference in reflux symptomatology and complications [112]. In fact, many surgeons rarely perform this operation because of its lack of effectiveness and a significant failure rate of the procedure.

During a Nissen fundoplication, the fundus of the stomach is plicated 360° around the inferior esophagus to restore lower esophageal sphincter function. Once this is done, the patient cannot vomit. The anterior or Thal fundoplication, on the other hand, uses only a 270° wrap, which maintains the patient's ability to vomit. Intestinal obstruction is common after the open approach [113]. Inability to vomit can cause progressive intestinal distension, bowel ischemia, and death if the bowel obstruction is not quickly relieved. Typically, patients requiring a fundoplication have other underlying diseases, such as cerebral palsy, inborn errors of metabolism, trisomy 21, or other neurological impairments. The procedure is done either open or laparoscopically, and if needed, a gastrostomy is placed at same time. If a gastrostomy is placed without doing a fundoplication, the percutaneous approach is usually used.

Management

Symptoms of aspiration pneumonia or asthma may make it difficult to determine when to perform the procedure. One has to balance protecting the lungs from further aspirations with being able to improve the patient's pulmonary status. Rapid sequence induction of anesthesia is usually warranted. The trachea of most patients can be extubated at the end of the procedure, depending on their preoperative status.

Postoperative issues

The reoperation rate following Nissen fundoplication for recurrent gastroesophageal reflux is high (6–12%) [114].

KEY POINTS: NISSEN FUNDOPLICATION AND GASTROSTOMY

- The primary disease often dictates the anesthetic management
- There is a high risk for aspiration of gastric contents during the induction of anesthesia

- Patients may present with a suboptimal pulmonary status due to aspiration pneumonia
- Patients who require a gastrostomy frequently have a Nissen fundoplication to protect against aspiration of gastric contents

Laparoscopic surgery

Laparoscopic procedures are rapidly replacing many open pediatric surgical procedures (Box 31.5). Some advantages of the laparoscopic approach include minimizing the size of the incision and better visualization of the surgical area (Fig. 31.9). The pathophysiological changes associated with a pneumoperitoneum, the longer operating times, mechanical restrictions for the surgeon, and lack of haptic feedback and three-dimensional vision are the main drawbacks of laparoscopic surgery. A number of procedures are done laparoscopically without proof that the outcomes are better than those reported with open procedures.

Laparoscopic abdominal procedures require intraperitoneal access and insufflation of gas, often through the umbilicus.

Box 31.5: Common pediatric laparoscopic procedures

- Appendectomy
- Cholecystectomy
- Gastric banding
- Gastric bypass
- Colectomy
- Inguinal hernia repair
- Nephrectomy
- Pyloromyotomy
- Congenital diaphragmatic hernia
- Nissen fundoplication
- Orchidopexy
- Pyloplasty

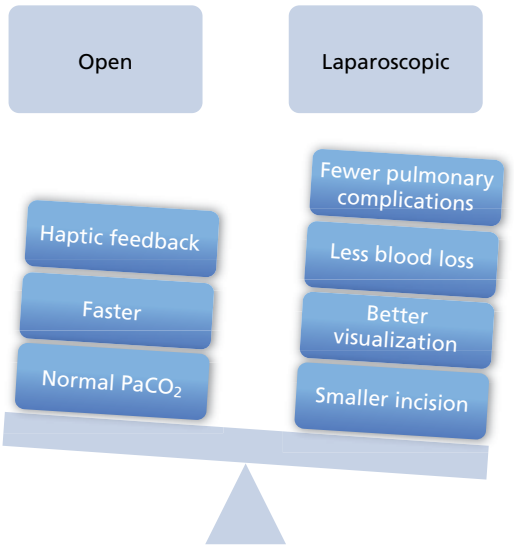

Figure 31.9 Advantages and disadvantages of open and laparoscopic procedures.

Usually, at least one additional incision is required for instrumentation, although single-port access through the umbilicus has been described for a variety of laparoscopic procedures, even in neonates and infants [115]. Various instruments are needed for ligation, stapling, suturing, and manipulation of viscera, but some are impractical for neonatal use because they are too large.

Pathophysiology

The effect of increased intra-abdominal pressure and absorption of the insufflated carbon dioxide are the two main pathophysiological changes associated with laparoscopic surgery.

Hemodynamic changes

Changes in cardiac output differ, depending on the patient's position during the procedure. Patients placed in the reverse Trendelenburg position, e.g. for laparoscopic cholecystectomy, often experience decreased arterial blood pressure, cardiac output, right atrial pressure, and wedge pressure. Pneumoperitoneum often raises the arterial, right atrial, and wedge pressures to their initial levels. Cardiac output also returns to baseline; systemic vascular resistance decreases mildly [116]. The reason why cardiac output normalizes is unclear, but it may be from reduced afterload or activation of the sympathetic nervous system by absorbed carbon dioxide. In the Trendelenburg position, cardiac output is unchanged or mildly increased from baseline during pneumoperitoneum. The increased intra-abdominal pressure and gravity synergistically reduce cardiac filling.

Changes in arterial blood pressure and pulmonary vascular resistance are independent of the patient's position during laparoscopy. Systemic vascular resistance (SVR) and arterial blood pressure increase. The combination of tachycardia and an elevated SVR raises myocardial oxygen consumption. Insufflation pressures below 10 cmH_2O have no significant effect on heart rate, arterial blood pressure, oxygen saturation, or base excess in children [117]. Absorbed carbon dioxide partially alleviates the effects of the increased intra-abdominal pressure. However, increased intra-abdominal pressure may also transiently reduce renal and splanchnic blood flow. Congestion and stasis of the lower extremities increase the risk for deep vein thrombosis. If there is a patent foramen ovale, the likelihood of paradoxical emboli and air embolism increases when the right atrial pressure rises. Peritoneal stretching may also produce vagally mediated hemodynamic changes.

Absorption of insufflated carbon dioxide

Carbon dioxide is absorbed from the abdominal cavity and causes respiratory acidosis and cardiac arrhythmias (in some patients). The rate of CO_2 absorption is higher when artificial cavities are created (e.g. nephrectomy) [118]. The rate of CO_2 absorption is very high when subcutaneous emphysema is present. Minute ventilation may need to increase as much as 400% to eliminate the insufflated CO_2 [119]. Occasionally, the increase in ventilation is insufficient to reduce the $PaCO_2$ to acceptable levels. When this occurs, the procedure must be halted and time allowed for return of the $PaCO_2$ to normal. It is rarely necessary to convert to an open procedure because of hypercarbia.

Pulmonary pathophysiology

The usual anesthesia-induced decrease in functional residual capacity and the mismatch of ventilation and perfusion are

aggravated by a further decrease in the functional residual capacity as the diaphragm is shifted more cephalad by the pneumoperitoneum. Due to the geometry of the infant's thorax (see Chapter 7), infants rely more on diaphragmatic excursion than on the intercostal muscles for ventilation. Positive end-expiratory pressure counteracts gas-induced pressure on the diaphragm and often improves ventilation and oxygenation. The tip of the tracheal tube can migrate towards the carina and enter a mainstem bronchus when a pneumoperitoneum is present [120].

Despite the negative intraoperative effects of the pneumoperitoneum, there are fewer postoperative pulmonary complications after laparoscopy than with conventional open procedures. On the other hand, the open approach for upper abdominal procedures decreases the vital capacity, forced expiratory volume in 1 s (FEV_1), and functional residual capacity. These decreases, plus the incisional pain, inhibit coughing and sighing. Laparoscopic cholecystectomy is less often associated with postoperative pneumonia [121,122].

Neuroendocrine effects

Surgical-induced inflammatory and immunosuppression responses are fewer with laparoscopic procedures. The concentrations of interleukin-1 and -6 and TNF-α are decreased compared with those found after open procedures. Dysfunction of mononuclear and polymorphonuclear cells, which are part of cell-mediated immunity, appears to be less deranged by laparoscopic procedures. The inflammatory effects are of concern with oncological procedures because tumor spread is a major concern.

Complications

Serious laparoscopy-related complications are rare. CO_2 is the gas used most often because it is more rapidly absorbed if it is inadvertently given intravascularly. Massive CO_2 embolism and venous air embolism produce the same sequelae [123]. Untreated pneumothoraces and pneumomediastina can be disastrous. Subcutaneous emphysema usually requires no treatment. CO_2-induced hypercarbia and acidosis occasionally cause cardiac dysrhythmias. Insertion of a trocar occasionally causes hemorrhage and injures internal organs, especially in thinner infants with more elastic abdominal walls [124]. Studies of three-dimensional laparoscopy (which allows the surgeon to have a three-dimensional view of the operative field) showed shorter operating times, but otherwise similar outcomes [125].

KEY POINTS: LAPAROSCOPIC SURGERY

- Intravenous access should be obtained above the diaphragm because a pneumoperitoneum can decrease blood flow through the inferior vena cava and delay drug and fluid administration
- Filling pressures are higher during a pneumoperitoneum because the increased intra-abdominal pressure is transmitted in the thorax. Effective transmural pressures are low to normal
- Changes in cardiac output are dependent on the patient's position
- Urine output decreases transiently
- Not all patients tolerate a pneumoperitoneum with high insufflation pressures

CASE STUDY

An 8-month-old, 10 kg child was brought to the emergency room with a history of loss of appetite, vomiting, irritability, and crying. His mother stated that he had diarrhea for the last 2 days and that his stools were initially watery but were now mucoid and blood tinged at the last diaper change. Only a minimal amount of urine had been noted during the last 8–12 h. The mother also stated that the child was no longer interactive and had become progressively lethargic during the last 2 days.

The emergency room physician saw the mother and child and obtained the following history. The boy was born at full term by normal vaginal delivery; there were no problems before or after birth. He went to the well baby nursery and was discharged home with the mother 24 h later. At home, the baby was feeding well and received his normal immunizations. He was well until 2 days before admission when he became increasingly irritable and had vomiting and diarrhea.

At admission he was found to be lethargic and had a sunken anterior fontanelle, sunken eyes, and dry oral mucous membranes. His heart rate was 160 beats/min, his arterial blood pressure was 80/40 mmHg, and his SaO_2 was 99% on room air. His abdomen was distended, and there was abdominal tenderness and guarding. An abdominal mass was palpated. A peripheral intravenous catheter was inserted and 5% dextrose with 0.45% normal saline was infused at 60 mL/h. Blood was sent for complete blood count and chemistry. Plain radiographs of the abdomen showed a paucity of bowel gas and air–fluid levels. The white cell count was 18,000 mm^3, the hematocrit 40%, and the platelet count 400,000 mm^3. The serum sodium was 138 mEq/L, serum potassium 4.5 mEq/L, serum chloride 100 mEq/L, serum bicarbonate 20 mmol/L, and the blood urea nitrogen and creatinine 20 and 0.5 mg/dL respectively. A surgery consult was obtained and a nasogastric tube was inserted. The surgeon entertained a differential diagnosis of bowel obstruction or intussusception and scheduled the child for an emergency exploratory laparotomy.

The anesthesiologist reviewed the patient's history with the mother and examined the child. The child was lethargic. Fluids were infusing through a peripheral intravenous line. After obtaining informed consent, the child was taken to the operating room. Rapid sequence induction of general anesthesia and tracheal intubation were planned. Standard monitors were placed, and suction was applied to the nasogastric tube. After preoxygenation, anesthesia was induced with

2 mg/kg of propofol and 1.2 mg/kg of rocuronium. Tracheal intubation was rapidly accomplished. A second peripheral intravenous line, an arterial line, and a Foley catheter were inserted. Anesthesia was maintained with sevoflurane and intravenous fentanyl. The patient was found to have an ileocolic intussusception, which was easily reduced; however, part of the bowel was ischemic and required resection. Intraoperatively, the patient required additional fluid resuscitation with a crystalloid solution. Blood loss was minimal and no blood transfusion was required.

At the end of the surgery, the trachea was extubated and the child was transferred to the intensive care unit. His postoperative pain was controlled with a continuous infusion of morphine and nurse-administered rescue boluses of the drug as needed.

This case illustrates the concepts that were explained in this chapter. Intussusception is a common cause of bowel obstruction in children less than 1 year of age, but the cause of intussusception is unknown in 90% of cases. Prompt diagnosis and treatment decrease the mortality and morbidity associated with intussusception. Preoperative assessment should include signs of dehydration, such as dry mucosal membranes, sunken fontanelles, sunken eyes, and minimal urine output, which together indicate significant dehydration. Fluid resuscitation should be initiated immediately to replete the intravascular volume. When the volume is repleted, surgery can proceed. Intraoperatively, the heart rate and arterial blood pressure may not truly reflect the patient's volume status. The urine output should exceed 0.5–1 mL/kg/h; urine output is a useful guide to circulating volume status. Careful fluid management is essential. The volume of fluid administered equals the sum of hourly maintenance fluid, pre-existing fluid deficits, plus an additional 6–10 mL/kg/h to compensate for the evaporative losses caused by the open abdominal wound.

Hourly fluid maintenance is calculated from the patient's bodyweight (see Chapter 9). For the first 10 kg, it is 4 mL/kg. For 10–20 kg it is 40 mL + 2 mL/kg for every kilogram over 10 kg. If the weight is >20 kg, the requirement is 60 mL + 1 mL/kg for every kilogram above 20 kg. Careful attention must be paid to blood loss. If significant blood loss is expected, the allowable blood loss should be calculated. Maximum allowable blood loss is:

$$\frac{\text{EBV} \times (\text{Starting hematocrit} - \text{Minimum acceptable hematocrit})}{\text{Starting hematocrit}}$$

Estimated blood volume (EBV) is 95 mL/kg for premature neonates, 85 mL/kg for term neonates, 70–75 mL/kg for infants and young children, and 65 mL/kg for older children and adults. The volume of packed red blood cells to be transfused can be determined by the following formula:

$$\frac{\text{EBV} \times (\text{Goal hematocrit} - \text{Current hematocrit})}{\text{Hematocrit of packed red blood cells}}$$

When blood products are used in neonates and infants, they must be filtered and irradiated to prevent emboli and graft-versus-host reactions. Normothermia is maintained by warming the operating room and the intravenous fluids, using warm irrigation fluids, and forced-air convention heating devices. Maintaining normothermia may be difficult during abdominal surgery because the bowels are exposed.

The postoperative decision to extubate the trachea depends on how awake the child is, whether he is breathing spontaneously after the reversal of muscle relaxants, and his core temperature. Intravenous fluids are continued until oral intake is re-established.

Introduction

Pediatric urological procedures are among the most common encountered by the pediatric anesthesiologist. A thorough understanding of the developmental pathogenesis and surgical procedures on the genitourinary system are important for the anesthesiologist to provide optimized care for these patients. This chapter reviews the embryological development of the common urogenital anomalies. Then the surgical approach, anesthetic considerations, and anesthetic management of these anomalies, including pain management, will be reviewed. In addition, robotic approaches to urological surgery will be explored.

Development of urological anomalies

Anomalies of the genitourinary system that require surgical procedures under anesthesia often arise from abnormal development *in utero*. A full description of the development of the genitourinary system is beyond the scope of this chapter. See Chapter 9 for further discussion of the development of the genitourinatry system. It is helpful to have a brief overview recalling that the urinary and genital systems are closely associated. Normal development is influenced by genetic, hormonal, and anatomical influences.

Both the urinary and genital systems develop from intermediate mesoderm at the level of the 7th through the 28th somite [1]. The nephrogenic mass (cord) arises from the dorsal side from a bulge into the coelom called the urogenital ridge, from which the urinary and genital structures are formed. The nephrogenic tissue from the 7–14th somite levels breaks up into four segments: the cervical, thoracic, lumbar, and sacral. The cervical nephrotomes eventually give rise to glomeruli. The excretory tubules arise from the thoracic, lumbar, and sacral segments. Subsequent development leads to the primitive pronephros. By the 4th week of gestation, the mesonephros is present as an intermediate step in renal development. By around week 10, the mesoneprhos has receded in females, while evolving into the vas deferens in males. The permanent kidney or metanephros begins to develop early in the 5th week and is functional by the 11th week of development. The metanephric blastema gives rise to nephrons including the Bowman capsule, proximal convoluted tubules, loops of Henle, and distal tubules. The ureters are an outgrowth of the primitive mesonephric duct forming the major and minor calices and collecting ducts. The terminal end of each ureter becomes part of the bladder wall. Each eventually develops a distinct separate entrance into the bladder with time. Normal development of the ureteric bud and the mesonephric blastema is closely dependent on each other. As the fetus grows, the kidneys migrate from the pelvis to the abdomen. Fetal urine production is critical to normal amniotic fluid circulation. Amniotic fluid is aspirated by the fetus, and absorbed into the fetal bloodstream and subsequently excreted into the amniotic sac. Failure to produce adequate amounts of urine can lead to oligohydramnios and associated anomalies. One significant anomaly associated with oligohydramnios is pulmonary hypoplasia.

Development of the external genitourinary system occurs in parallel to internal development. The cloaca (Latin for sewer) forms from the caudal end of the hindgut. The allantois and mesonephric ducts open into the cloaca. During weeks 4 to 7 of development, the cloaca subdivides into the posterior portion, which becomes the anorectal canal, and the anterior portion, which gives rise to the primitive urogenital sinus. The bladder is formed from the upper part of the primitive urogenital sinus. Initially, the bladder is continuous with the allantois; subsequent obliteration of the allantois lumen forms the urachus, which connects the apex of the bladder with the umbilicus. The urachus eventually becomes the median umbilical ligament.

Gregory's Pediatric Anesthesia, Sixth Edition. Edited by Dean B. Andropoulos and George A. Gregory.

The reproductive system makes its appearance during the 5th and 6th weeks of development. The fetus goes through an indifferent stage in which sex cannot be determined. Eventually, gonads (testes and ovaries) develop from a thickening of the urogenital ridge to form the gonadal ridge and primordial germ cells. Primary sex cords form and grow into the underlying mesenchyme. If the *SRY* gene is present (normal genetic male), differentiation will proceed along the path leading to testes. Absence of *SRY* gene expression (normal genetic female) will lead to development of ovaries. Development of external genitalia is determined by both genetic and hormonal factors. In the presence of normal testes, androgen production by the adrenal glands is required to stimulate the development of the mesonephric ducts and produce normal external male genitalia. In the absence of normal androgens, paramesophric ducts develop and the fetus will develop female external genitalia. External genital development first goes through the indifferent stage with the genital tubercle forming at the upper end of the cloacal membrane. In the male, this tubercle then elongates to form the phallus. Labioscrotal swellings and urogenital folds appear around this time. The cloacal membrane divides to form urogenital and anal openings around the 7th week.

In the male, the phallus elongates to form the penis, pulling the urogenital folds together. When the folds start to fuse, they enclose the urethra and the urethral opening moves progressively towards the end of the penis. The labioscrotal swellings fuse to form the scrotum. In the female, the phallus becomes the clitoris. The urogenital folds do not fuse, and become the labia minora. The labioscrotal folds fuse only at the ends to form the labia majora.

Anomalies of gonadal development can be divided into anomalies of sex chromosomes, true hermaphrodites, and anomalies of receptors. Conditions that represent anomalies of sex chromosomes include Turner syndrome (45,X), Klinefelter syndrome (47,XXY), and other syndromes with multiple X polyploidy. True hermaphrodites are extremely rare and have both true testes and ovaries. Anomalies of receptors result in testicular feminization syndrome (XY females). Congenital anomalies of the reproductive system in females include ovarian dysgenesis, rudimentary uterus, bifid uterus, septate uterus, and imperforate hymen. Congenital anomalies in males include testicular agenesis, undescended testes, and hypospadias.

KEY POINTS: DEVELOPMENT OF UROLOGICAL ABNORMALITIES

- Anomalies of the genitourinary system often arise from abnormal development *in utero* and often require surgical repair
- The genitourinary system is determined by both genetic and hormonal factors

Bladder exstrophy

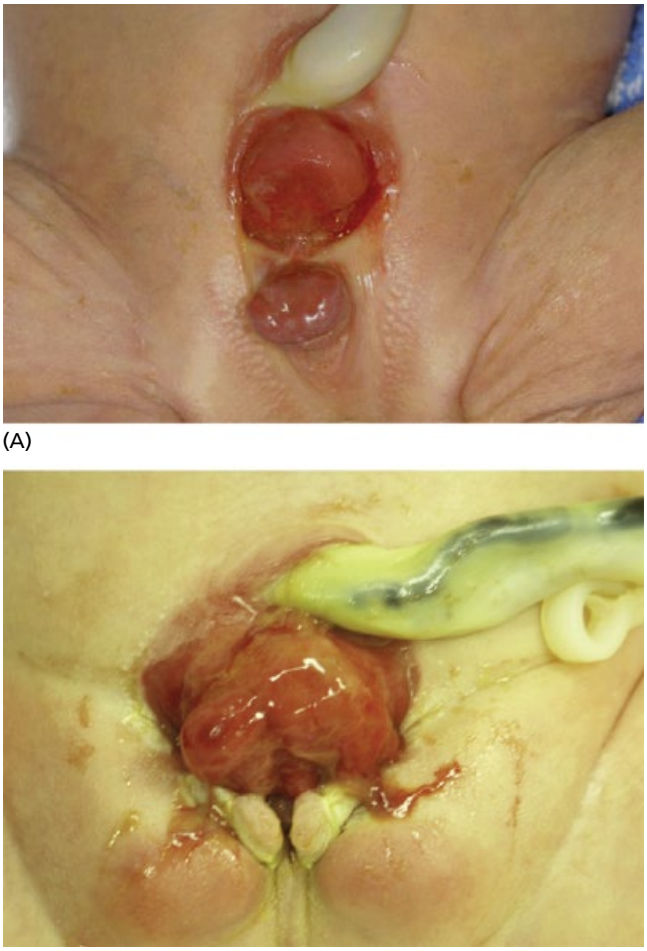
Bladder exstrophy remains one of the most challenging conditions managed by pediatric urologists. It can be likened to the challenges the cardiovascular surgeon faces with repair of the single ventricle. Although rare, this disorder imposes significant physical, functional, social, sexual, and psychological burdens on patients and families. For the healthcare system, the multiple, lengthy, and complex operative procedures for exstrophy consume resources disproportionate to the small number of affected individuals [2]. The rarity of this condition (2.5 in 100,000 livebirths in the United States) makes it imperative that communication between the anesthesiologist and urologist occurs well before the start of surgery. The correction choices and timing for surgery are continually being modified. While it was standard practice to perform surgery in the first several days of life, in some institutions surgeries are being delayed until the child is 4–6 weeks of age with no change in the success rate [3].

The goals of reconstructive surgery for bladder exstrophy are to achieve closure of the bladder, obtain urinary continence, preserve renal function, and produce satisfactory appearance and function of the external genitalia. Wound dehiscence, bladder prolapse, and multiple attempts at bladder closure have been identified as risk factors for lack of adequate bladder growth and inability to develop urine continence [4].

Classic bladder exstrophy can be conceptualized by visualizing one blade of a pair of scissors passing through the urethra into the bladder of a normal person; the other blade is used to cut the layers of the skin, abdominal wall, anterior wall of the bladder, urethra, and symphysis pubis, and the cut edges are unfolded laterally as if opening a book (Fig. 32.1) [5,6]. At birth, classic bladder exstrophy presents with an everted posterior bladder wall of varying size associated with separation of the symphysis pubis. This diastasis causes an outward rotation and eversion of the pubic rami at their junctions with the ischial and iliac bones [5,6]. Urine may be seen leaking from the inferior margin of the everted posterior bladder wall, but the ureteral orifices are not always obvious. The umbilicus is located on the immediate superior border of the bladder plate, and a small umbilical hernia or an omphalocele is ordinarily seen. The mucosa of the exposed bladder may look normal or thickened. In males, there is complete epispadias with dorsal chordee, and the overall penile length is approximately half of unaffected boys. The scrotum is typically separated from the penis and is wide and shallow. Undescended testes and inguinal hernias are common. Females also have epispadias, with separation of the two halves of the clitoris and wide separation of the labia. The anus is displaced anteriorly in both sexes, and there may be rectal prolapse [5–7].

In patients with classic exstrophy of the bladder, anomalous development in other systems is unusual. However, bladder exstrophy can be considered a spectrum of anatomical variants referred to as the exstrophy complex. These variants include bladder exstrophy with imperforate anus and cloacal exstrophy. With extreme cases of classic bladder exstrophy and cloacal exstrophy, omphaloceles are also encountered above the level of the exposed bladder. In cloacal exstrophy, some form of spinal dysraphism including tethered cord, myelomeningocele, or lipomyelomeningocele is present in nearly all patients, with recent reports ranging from 64% to 100% [8].

Two options have been described for surgical reconstruction: primary single-staged closure of the bladder or a planned staged repair [9–13]. Regardless of the strategy chosen, failure of the initial repair decreases the potential for the later



(A)

(B)

Figure 32.1 Features of classic bladder exstrophy (A, male; B, female): low umbilicus, exposed small bladder and bladder neck, pubis diastasis, rectus and pelvic floor divarication, anterior ectopia of the anus and/or vagina, and epispadias or bifid clitoris.

Figure 32.2 Modified Buck's traction. The child is positioned with weights maintaining the legs in an extended position parallel to the bed. *Source*: Reproduced from Kozlowski [14] with permission of Elsevier.

development of continence. Also, in each option, pelvic osteotomies are often used to allow approximation of the pubic symphysis. Modified Buck traction is often required after surgery for 4–8 weeks (Fig. 32.2) [14]. In a recently reported, large, single-center series, 67 infants with bladder exstrophy were treated; of 26 infants undergoing primary neonatal repair in the early years of the series, 21 were successful, and five had further operations for lack of healing or bladder dehiscence [6]. In the later years of the series, 41 had staged repair, with all achieving primary healing without would dehiscence. Because urinary tract infection (UTI) and renal scarring can result from the vesicoureteral reflux that is commonly present in these patients, this group now performs ureteral reimplantation at the time of the primary bladder closure, which has improved the rate of UTI.

Preoperative preparation involves an assessment of all organ systems to ensure that there are no associated anomalies of physiological significance. Preoperative complete blood count, and type and cross are recommended especially if pelvic osteotomies are necessary. Appropriate measures are taken to avoid trauma to the exposed bladder mucosa. Antibiotics are administered preoperatively and continued after surgery. The procedure involves a long operating time (5–7 h) and unpredictable bleeding and fluid shifts after intravenous induction of anesthesia and endotracheal intubation [15]. Therefore, two intravenous catheters should be placed in the upper extremities if possible, to avoid the sterile field. Central venous access may be necessary if peripheral venous access is difficult. An arterial line is also placed for both hemodynamic monitoring and measurement of blood gases, hemoglobin, coagulation studies, electrolytes, and glucose.

Preoperative placement of an epidural catheter is helpful for intraoperative and postoperative pain management (Fig. 32.3) [4]. The sacrococcygeal ligament is punctured, and an epidural catheter is threaded through the epidural insertion needle to reach a thoracic dermatome level of T10–12. The tunneling needle (a 17- or 18-gauge styletted Crawford or Tuohy needle) is inserted on the patient's side, near the posterior superior iliac crest. This is the final exit position and should be visible when the child is supine so that the site can be easily inspected in the postoperative period. The tunneling needle emerges at the epidural needle insertion. Note the epidural insertion needle is not removed and is left in place to protect the catheter. An 11 scalpel blade cuts the residual skin and subcutaneous tissue bridge between the two needles. The epidural insertion needle is removed leaving the catheter in place, depicted as a dashed line (Fig. 32.3D). The stylet from the tunneling needle is removed and the distal end of the epidural catheter is thread into the tunneling needle. The tunneling needle is then removed. The primary insertion site and the final catheter exit site are secured with Steri-strips and covered with transparent adhesive dressings. A loop is placed in the catheter to prevent accidental dislodgment [4].

At the time of surgery, the patient should have a wide surgical preparation, including the entire body anteriorly and posteriorly below the level of the nipples, so that turning the child for surgical orientation does not lead to wound contamination [5]. Timing of the removal of the endotracheal tube after surgery depends on the infant's age, the length and complexity of surgery, and the amount of fluid and blood the patient received during surgery.

In the postoperative period, it is imperative that the baby remain immobilized, sedated, and pain free to prevent movement that would cause distracting forces to compromise the repair. The tunneled epidural catheter is extremely useful in this situation. Epidural infusions through tunneled epidural catheters can provide safe analgesia for up to a month in

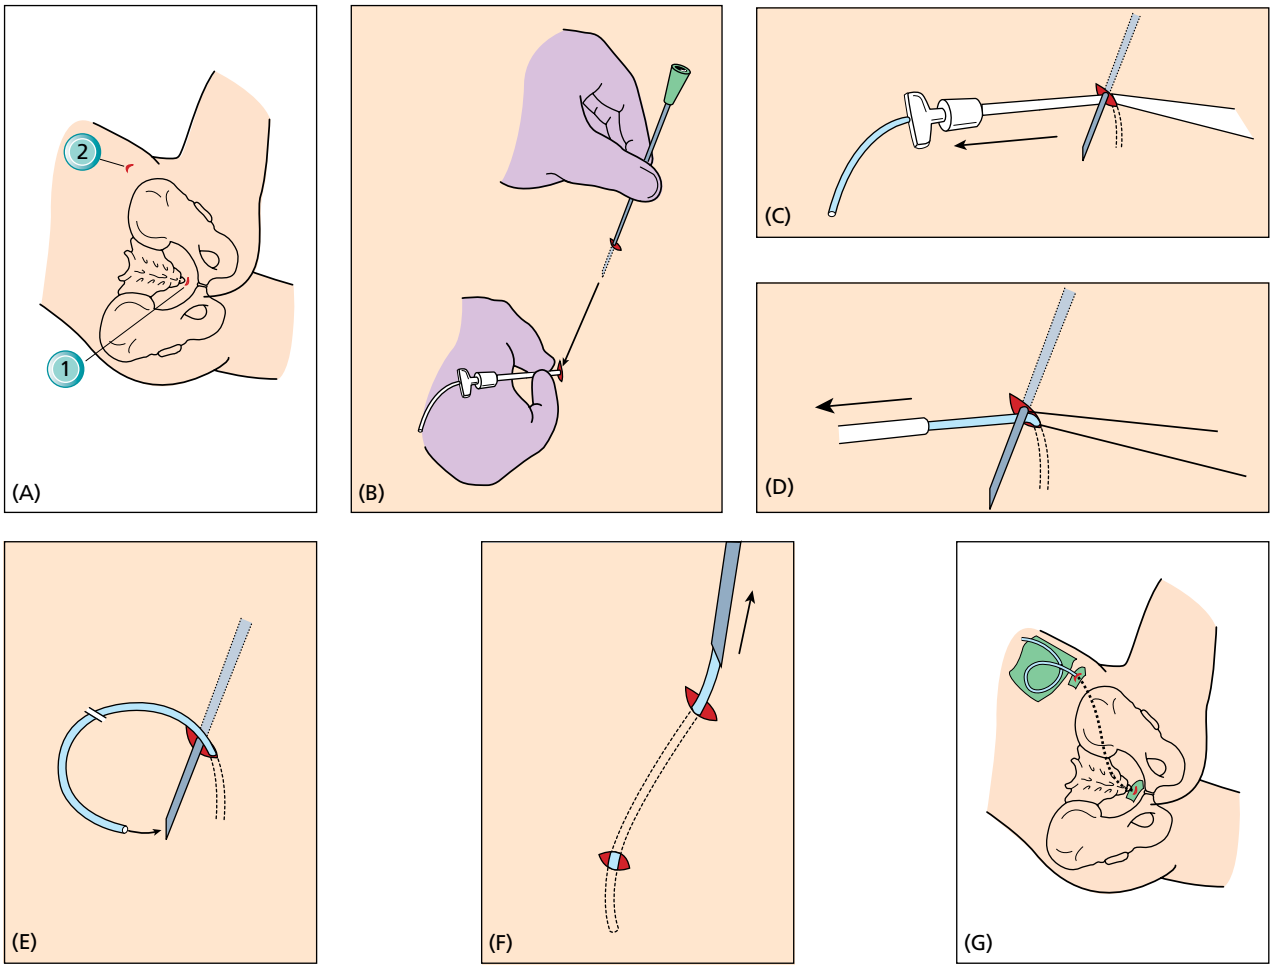


Figure 32.3 Placement of a tunneled caudal epidural catheter. (A) The sacorcoccygeal ligament is punctured at position 1, and then an epidural catheter (approximately 6–10 cm) is threaded through the epidural insertion needle to reach a thoracic dermatomal level of T10–12. (B) The tunneling needle (a 17 or 18 gauge styletted Crawford of Tuohy needle) is inserted on the patient's side, near the posterior superior iliac crest (positon 2 in A). This is the final exit position and should be visible when the child is supine so the the site can be easily inpected. (C) The tunneling needle emerges at the epidural needle insertion (position 1). Note the epidural insertion needle is not removed and is left in place to protect the catheter. An 11 scalpel blade cuts the resididual skin and subcutaneous tissue bridge between the two needles. (D) The epidural insertion needle is removed leaving the caatheter in place, depicted as a dashed line. (E) The stylette from the tunneling needle is removed and the distal end of the epidural cahtered is threaded into the tunneling needle (F). The tunneling needle is removed; the subcutaneous portion of the epidural catheter is depicted with a dashed line. (G) The primary insertion site and the final catheter exit site are secured with adhesive strips and covered with a transparent adhesive dressing. A loop is placed in the catheter to prevent accidental dislodgment. *Source*: Reproduced from Kost-Byerly et al [4] with permission of Elsevier.

neonates. Daily communication between pediatric urology and intensive care unit (ICU) staff, the pediatric pain service, and experienced nursing staff are the prerequisites to providing analgesia and sedation without undue complications for a neonatal population [4,14].

KEY POINTS: BLADDER EXSTROPHY

- Bladder exstrophy imposes significant physical, functional, social, sexual, and psychological burdens on patients and families and a significant burden on the healthcare system despite a small patient population
- Goals of reconstructive surgery are both functional and cosmetic
- Anesthetic considerations involve both postoperative pain control and intraoperative fluid shifts, blood loss, and long operating times

Posterior urethral valves

The most common cause of severe obstructive uropathy in children is posterior urethral valves (PUV). The urethral valves are tissue leaflets fanning distally from the prostatic urethra to the external urinary sphincter. A slit-like opening usually separates the leaflets. Valves are of unclear embryological origin and cause varying degrees of obstruction. The renal changes range from mild hydronephrosis to severe renal dysplasia; their severity probably depends on the severity of the obstruction and its time of onset during fetal development. As in other cases of obstruction or renal dysplasia, there may be oligohydramnios and pulmonary hypoplasia [16].

If the serum creatinine level remains normal or returns to normal after birth without intervention, treatment consists of transurethral ablation of the valve leaflets, which is performed endoscopically under general anesthesia. If the urethra is too small for transurethral ablation, temporary vesicostomy is preferred, in which the dome of the bladder is exteriorized on

the lower abdominal wall. When the child is older, the valves may be ablated and the vesicostomy closed [17].

There are several classifications of this disorder, based on the type and severity of obstruction. The spectrum of abnormalities may represent the different degrees of obstruction, the timing of obstruction, and other genotypic risk factors. Mild obstruction may have a delayed presentation until adolescence. It appears that a partial outlet obstruction can be overcome with bladder wall hypertrophy that generates high voiding pressures [16,17].

An infant with severe PUV may present in the neonatal nursery with anuria and a palpable bladder. The clinical sequelae from PUV result in persistent bilateral hydronephrosis, either from vesicoureteral reflux (VUR) or elevated bladder pressures [17]. When a newborn's condition is especially severe, with associated lung hypoplasia, serial percutaneous needle bladder drainage may be undertaken to decompress the bladder until the newborn is optimized to have surgical repair.

After the diagnosis is established, renal function and the anatomy of the upper urinary tract should be carefully evaluated. In the healthy neonate, a small polyethylene feeding tube (5 or 8 Fr) is inserted through the urethra into the bladder for several days. Passing the feeding tube may be difficult, because the tube tip may coil in the prostatic urethra causing urine to drain around the catheter rather than through it. A Foley (balloon) catheter should not be used, because the balloon may cause severe bladder spasm, which may produce severe ureteral obstruction [18].

Posterior urethral valves are now commonly diagnosed in the antenatal period. The ultrasound findings may include bilateral hydronephrosis, a distended thick-walled bladder, and oligohydramnios [17]. The incidence of PUV is one in 5000 livebirths. Of the 500 new cases of PUV each year, 150 will develop end-stage renal disease (ESRD) and require dialysis or transplantation in the first 18 years of life. Some institutions perform *in utero* interventions. Experimental and clinical evidence of the possible benefits of fetal intervention is lacking, and few affected fetuses are candidates. Prenatal diagnosis of PUV, particularly when discovered in the second trimester, is associated with a poorer prognosis than those detected after birth [18]. While antenatal intervention improves pulmonary function and the restoration of amniotic fluid volume, it does not guarantee an improvement in the renal insufficiency [16,17].

The appropriate treatment of PUV is determined by examining all contributing factors. These include the overall condition of the infant, renal function, hydration status, and lung maturity [17]. Prophylactic antibiotics are started at birth and the bladder may need decompression. Valve ablation may be undertaken if the creatinine falls to less than 1 mg/dL. When the renal function does not continue to improve, usually a vesicostomy is performed as the initial step to decompress the kidneys. Most boys have a good prognosis if they complete a normal gestation and undergo neonatal valve incision.

These patients may present in the neonatal period for PUV incision and also for circumcision which may decrease the rate of UTIs [17]. In the very small infant where the cystoscope will not pass through the urethra, a vesicostomy may be considered, with delayed valve incisions.

These infants may also have some degree of respiratory compromise, relating to the oliguria [18]. It is thought that the urinary obstruction and lack of urine production *in utero* limits the amount of fluid the fetus then aspirates, which helps to stent open the developing lungs. In turn, this leads to pulmonary hypoplasia and respiratory distress syndrome [19]. An appropriate volume of amniotic fluid, which is produced by the kidneys and then excreted as urine, is necessary for the complete and proper branching of the bronchial tree and alveoli. Physical findings can include poor fetal breathing movements, small chest cavity, ascites, limb deformities from compression, and Potter facies [16]. Potter facies develops *in utero* secondary to the effects of oligohydramnios from any cause. Features include micrognathia, hypertelorism, pulmonary hypoplasia, and spade-like hands [20]. Neonates with pulmonary hypoplasia may require perioperative mechanical ventilation. These patients may require high peak pressures, and permissive hypercapnia must be tolerated. The severe patient may even require an oscillating ventilator until the lungs mature further.

The preoperative evaluation of a neonate with PUV should include assessment of renal function including the extent of urinary retention and fluid overload. Appropriate laboratory testing should search for evidence of renal failure. Hyponatremia, azotemia, hypertension, and hyperkalemia must be identified and treated prior to anesthetizing the patient. Patients in renal failure must be treated with appropriate fluid management and judicious use of anesthetic agents affected by renal metabolism.

When PUV cause mild obstruction, the associated complications are also mild or non-existent. The length of surgical intervention is generally less than 1 h, and the anesthetic approach includes general anesthesia with endotracheal intubation or laryngeal mask airway (LMA) for airway management. Postoperative pain is minor for cystoscopy and valve ablation.

Long-term results after surgical repair for PUV vary. Late development of renal failure can present if the following risk factors are present: bilateral VUR, presentation in the first year of life, and diurnal incontinence at 5 years of age [21]. This may result in the need for renal transplantation. Other possible long-term outcomes that may be influenced by PUV repair are sexual function and fertility and urinary continence [21].

KEY POINTS: POSTERIOR URETHRAL VALVES

- The most common cause of severe obstructive uropathy in children is PUV and this may develop into significant renal failure
- Mild obstruction may not present until adolescence; when severe it presents in the first day of life with anuria, palpable bladder, and significant lung hypoplasia
- The appropriate treatment of PUV is determined by examining all contributing factors and may involve long-term antibiotics, decompression of the bladder, vesicostomy placement, and definitive surgical repair

Circumcision

Circumcision is the most commonly performed surgical procedure in the world. There are very few absolute indications for circumcision, especially in the neonate. The American Academy of Pediatrics does not recommend routine circumcision in otherwise healthy boys. In this age group, if hydronephrosis is present, then a circumcision may help decrease the likelihood of UTIs [17]. In older children, persistent phimosis and recurrent balanitis are indications for circumcision [17].

Newborn circumcisions are most often done at the bedside or as outpatients with a Plastibell device or Gomco clamp. These procedures are usually performed by the pediatrician or obstetrician while the infant is still in the newborn nursery. Circumcision in older children usually requires freehand sleeve resection performed under general anesthesia. Common surgical complications of circumcision include bleeding, infection, residual redundant skin, meatal stenosis, and skin bridges [22].

When infants and children require general anesthesia, anesthesia usually is induced via inhalational induction, a peripheral intravenous line is placed, and the airway is secured with an LMA or endotracheal tube. A penile nerve block placed prior to incision is effective in providing intraoperative analgesia and postoperative pain relief [23]. Although caudal epidural anesthesia can be used for analgesia, penile block is usually preferred because less local anesthetic is given and less time is spent performing that block [24]. Many urologists delay this typically elective procedure until the patient is 6 months of age to decrease anesthetic risks and eliminate the need for an overnight stay.

KEY POINTS: CIRCUMCISION

- In spite of circumcisions being one of the most commonly performed surgical procedure in the world, there are very few absolute indications for circumcision
- This is generally an elective procedure in an otherwise healthy population and is completed with a straightforward general anesthestic

Hypospadias

Hypospadias is the abnormal ventral opening of the urethral meatus, which results from incomplete development of the urethra. This defect may be located anywhere from the corona of the glans to the perineum [24]. Therefore, the extent of surgical dissection and the staging of the repair depend on the complexity of the lesion [25]. Hypospadias is often discovered during or after a routine neonatal circumcision. Signs of hypospadias include an abnormal prepuce, a persistent ventral curvature (also known as chordee), and a proximally displaced urethral orifice that is rarely obstructive, but often stenotic [17]. The meatus is located on the glans or distal shaft in 70–80% of cases and in the middle of the shaft 20–30% of the time [17]. Rarely, the meatus is located in the scrotum or more proximally in the perineum.

Hypospadias can be associated with inguinal hernias, cryptorchidism, and low birthweight. The incidence of hypospadias is higher in patients with affected siblings [26].

Early repair of this defect is important for aesthetic considerations and toilet training, and also for long-term psychosexual adjustment [25]. Skilled pediatric urologists perform this repair in healthy term babies as early as 3 months of age. Delaying the repair past 15 months may increase cognitive, emotional, behavioral, and psychosexual issues. In addition, younger infants may develop less scar tissue and have better wound healing than older children [17].

The goals of repair are straightening the ventral curvature and extending the urethra distally. Historically, these operations were done as staged procedures. Currently, the majority are done as one procedure, unless severe. Surgery may be staged if the penis has a curvature greater than 30°. A buccal graft may be needed for tubularization of the neourethra during the second stage, which occurs approximately 6 months later [17]. A recent review of several large series of proximal hypospadias repairs reported complications in 32–68% of patients, including fistulas, diverticulum, meatal stenosis, and glans dehiscience [27]. The complication rate was higher with single-stage repair for proximal hypospadias. Complication rates for distal hypospadias repairs are much lower, at 5–15%.

These patients are usually otherwise healthy. General anesthesia with an LMA and supplemental caudal anesthesia or a penile block is the most common approach. Postoperative urethral instrumentation must be avoided as catheterization of the newly formed urethra could cause disruption of the repair. These patients often have a urethral catheter left in place postoperatively, to allow passive urine drainage through the neourethra for approximately 1 week [17]. The penis is gently compressed with a Telfa® pad and bio-occlusive dressing following the procedure. Complications can include fistulas, meatal stenosis, urethral stricture, dehiscence, and recurrent curvature [17].

Recently, concerns have arisen about a possible increased rate of postoperative urethrocutaneous fistula development with caudal analgesia compared with penile nerve block. The postulated mechanism is increased blood flow leading to penile engorgement with tension on the suture lines, resulting in suboptimal healing and fistula formation. A prospective, randomized study of penile block versus caudal analgesia in 54 patients revealed a 27% increase in penile volume with caudal analgesia versus 2.5% with penile nerve block ($p < 0.001$); analgesia was improved and longer lasting with the penile nerve block [28]. Five cases of urethral fistula were observed; all were in caudal block patients. Subsequently, four retrospective studies describing 3300 patients have reported mixed results, with two indicating increased incidence of fistula with caudal analgesia [29,30], and two not finding a difference [31,32].

KEY POINTS: HYPOSPADIAS

- Hypospadias is the abnormal ventral opening of the urethral meatus and may be located anywhere from the corona of the glans to the perineum
- Hypospadias can be associated with inguinal hernias, cryptorchidism, and low birthweight, but is generally an isolated finding in an otherwise healthy patient
- Caudal analgesia is frequently utilized for hypospadias repair, but recent publications indicate that it may be associated with increased fistula formation

Cryptorchidism

Cryptorchidism (undescended testes, UDT) is the most common disorder of sexual differentiation and occurs in approximately 2% of male births [33]. The consequences of cryptorchidism include degeneration of the testes, impaired fertility, and increased risk for germ cell testicular tumors [18]. Despite the significance of this problem, the etiology of UDT in the majority of patients is unknown. It is unclear whether the pathological changes in the cryptorchid testis occur as a result of a primary defect or from secondary changes produced by the higher temperatures imposed on the undescended testis [18].

Two-thirds of patients present with a unilateral abnormality, and the other third present with bilateral abnormalities [17]. When the undescended testicle is unilateral, the right side is more often affected. The incidence ranges from 3.4% to 5.8% in full-term males. The usual timing for testicular descent into the scrotum is during the 7th month of gestation. Spontaneous descent may occur up until the first 6 months of life. A number of maternal risk factors have been implicated as a cause of undescended testicles. These include advanced maternal age, maternal obesity, breech presentation, low parity, preterm birth, low birthweight, and consumption of cola-containing drinks during pregnancy [17,34].

Cryptorchidism may occur as a single, isolated abnormality in an otherwise healthy patient or be associated with other congenital anomalies such as prune belly syndrome, posterior urethral valves, neural tube defects, gastroschisis, and microcephaly [35].

Treatment is focused on prevention of infertility, testicular malignancy, testicular torsion, and the psychological stigma associated with an empty scrotum. The rate of malignancy is approximately 1% in the cryptorchid patient. It is unknown whether this results from the abnormal position of the testis or an abnormality of the testis itself [17]. The rate of infertility is 38% in patients with bilateral cryptorchidism compared with 11% in unilateral cryptorchidism and 6% in normal males.

Treatment includes surgical exploration for the location of the testis. Sixty percent of the time, the testis is located in the inguinal canal or abdomen and 40% of the time, the testis is absent or comprised of fibrous tissue. The current method of treatment is orchiopexy, or relocation of the testis into the scrotum. If the location of the testis is not easily determined, the vas deferens and testicular vessels are used to help locate it [24]. Vessel length is the determining factor in deciding whether to undertake the procedure in one or two stages. Small, short spermatic vessels lead to the risk of a non-viable testis if placed into the scrotum without staging. In the first stage, the vessels are dissected and the testicle is brought as close to the scrotum as possible. The second stage 1 or 2 years later moves the testicle the remaining distance into the scrotum. The waiting period allows the blood supply to enlarge and form collateral circulation to supply the testicle.

Hormonal treatments intended to stimulate testicular descent include human chorionic gonadotropin, gonadotropin-releasing hormone, and luteinizing hormone-releasing hormone. These hormones stimulate the Leydig cells to produce androgens, but the mechanism for testicular descent is unknown [17]. Recent reviews report that hormonal treatments are not effective in stimulating and maintaining testicular descent, and that early surgery between the age of 3 and 12 months is the preferred approach [36]. Hormone therapy to improve fertility potential has been demonstrated to be effective.

Children who present for orchiopexy are usually otherwise healthy. These children require general anesthesia with either an endotracheal tube or LMA for airway management. Caudal epidural block is helpful to minimize postoperative pain. These procedures may be performed with conventional surgical incisions, or if abdominal position of the testes is suspected, laparoscopic surgery is often performed. If the anesthetic level is insufficient, laryngospasm may occur when the testis is manipulated. Otherwise, the postanesthetic course is generally unremarkable.

KEY POINTS: CRYPTORCHIDISM

- Cryptorchidism or undescended testes can result in degeneration of the testes, impaired fertility, and increased risk for germ cell testicular tumors
- Treatment may involve hormonal replacement or surgical exploration and repair
- Although presenting typically in an otherwise healthy patient, cryptorchidism may be associated with other congenital anomalies such as prune belly syndrome, posterior urethral valves, neural tube defects, gastroschisis, and microcephaly

Testicular torsion

Testicular torsion is a true surgical emergency. The diagnosis is usually made by history, physical examination, and diagnostic imaging studies. There are no definitive diagnostic imaging studies available, although color Doppler, isotope scans, and conventional ultrasound may be useful adjuncts [37]. Testicular torsion is best managed by early exploration, detorsion, and, when the testis is salvageable, fixation. When the testis is not salvageable, the surgeon will proceed with orchiectomy. In either scenario, a contralateral orchiopexy is usually performed [17].

Normally, the tunica vaginalis covers the anterior surface of the testis, epididymis, and spermatic cord, attaching with the gubernaculums and scrotal wall posteriorly, fixing the testis [17]. When these attachments are not secure, torsion may occur, leading to vascular compromise. There is a bimodal distribution in occurrence, with increased frequency during the neonatal period and puberty. During puberty, the rapidly increasing testicular mass increases the chances for rotation. In the neonatal period, the recently descended testis is very motile in the scrotum, increasing the risk of the spermatic cord to rotate en masse [17].

The patient's history should focus on the age of the patient, association with pain, and history of trauma. The onset and severity of pain may help differentiate torsion from epididymitis. The pain in torsion is acute in onset, severe, and ipsilateral [17]. The patient may also have symptoms of abdominal pain, thigh pain, and nausea and vomiting. The orientation and location of the testis in the scrotum must also be evaluated.

Testicular infarction may occur within a few hours of the torsion. After 8 h following the onset of pain, the testicular salvage rate declines precipitously [38]. In addition, studies in rats have confirmed that unilateral torsion can induce bilateral testicular damage and infertility [17]. This may result from reflex vasoconstriction, the formation of autoantibodies, or other chemically mediated mechanisms [17]. Therefore, surgery under general anesthesia with a rapid sequence induction and tracheal intubation should proceed as soon as possible. The goal is to begin surgery within 4–8 h of the time of testicular torsion whenever possible; unnecessary delays to obtain imaging studies when there is high clinical suspicion, or waiting to achieve nil per os status. are to be avoided [39].

KEY POINTS: TESTICULAR TORSION

- Testicular torsion is a true surgical emergency with no exact method for diagnosis. The methods used may include color Doppler or conventional ultrasound, along with a thorough history and physical exam
- There is a bimodal distribution in occurrence, with increased frequency during the neonatal period and puberty
- Surgical exploration and repair must occur within a few hours of symptom onset to have the best chance of testicular survival

Vesicoureteral reflux procedures

Vesicoureteral reflux is the retrograde flow of urine across the ureterovesical junction (UVJ). There is a high rate of familial recurrence, suggesting a genetic component. Risk factors for developing this condition include anatomical and functional abnormalities of the UVJ, high intravesical pressures, and impaired ureteral function [17]. If the VUR is severe, kidney dysfunction and hypertension may be present preoperatively, although the majority of presenting patients are healthy.

The unidirectional flow of urine through the normal ureter depends on both active and passive components. It appears that the tunneling path that the ureter travels through the submucosal layers of the bladder wall is inversely related to the rate of VUR. When the submucosal course is short, and therefore perpendicular to the bladder wall, the flap-valve mechanism normally in place to prevent reflux is absent. Additionally, the intravesical pressure must be lower than that in the ureter for there to be flow in the anterograde direction. Common clinical scenarios when VUR might occur are in patients with posterior valves, in patients with a neurogenic bladder, or when ureteral peristalsis is abnormal [17].

Long-term antibiotic prophylaxis is recommended in these children, especially up to the age of 8 years and in those with frequent recurrences [17]. This is continued until the reflux has resolved spontaneously or has been surgically corrected. This prophylaxis has been shown to decrease the amount of renal scarring and renal damage from repeated infections, helping to minimize the progression to chronic renal insufficiency and hypertension [17].

Management of VUR may be surgical or medical. The main goal is to prevent pyelonephrosis, which can lead to the complications mentioned. The treatment plan depends on gender, age, grade of reflux, concurrence of UTIs, renal function, and likelihood of resolution [17]. If the reflux is sterile, with no associated UTI, this reflux is not harmful to the kidneys and has no significant effect on kidney function and can probably be managed medically. Indications for surgical treatment include breakthrough UTIs despite prophylactic antibiotics, VUR associated with congenital anomalies at the UVJ, renal growth retardation, and the finding of worsening renal scarring. The endpoint of the surgical treatment is to restore the flap-valve mechanism, thereby preventing the VUR. The gold standard for this remains open surgical repair to establish an adequate submucosal tunnel for the ureter.

There are multiple techniques available for surgical repair, however the main component of each is freeing the ureter for mobilization, submucosal tunnel formation, transferring the ureter through the tunnel, and securing the ureter into the new position [17]. A minimally invasive technique for repair is also available. Using either an extravesical or intravesical approach, laparoscopic reimplantation can be undertaken. Endoscopic injection therapy, most frequently using polytetrafluroethylene or silicone, is then introduced submucosally at the 6 o'clock position of the UVJ [17]. By creating a mound at the opening of the UVJ, this narrows the ureteral orifice, thereby decreasing the amount of reflux allowed.

Anesthetic considerations for these cases include duration and blood loss, which can be significant during open repair. An epidural catheter or caudal epidural (catheter or single shot) may be placed to supplement anesthesia intra- and postoperatively. Postoperatively, these patients may have significant bladder spasm. This may be effectively treated in a variety of ways, including with belladonna and opium suppositories, oral or intravesiclular oxybutynin, ketorolac, or bupivacaine via epidural or in the bladder [22,23,40].

KEY POINTS: VESICOURETERAL REFLUX PROCEDURES

- Vesicoureteral reflux is the retrograde flow of urine across the ureterovesical junction and, if severe, can present concurrently with kidney dysfunction, hypertension, and long-term kidney infection
- Management of vesicoureteral reflux may be surgical or medical with the main goal being to prevent pyelonephrosis
- Multiple techniques, both minimally invasive and open surgical techniques, exist for treatment

Ureteropelvic junction obstruction

Ureteropelvic junction (UPJ) obstruction is the most common cause of obstructive uropathy in childhood and usually is caused by intrinsic stenosis. The typical appearance on ultrasonography is grade 3 or 4 hydronephrosis without a dilated ureter. UPJ obstruction most commonly presents on maternal ultrasonography revealing fetal hydronephrosis, as a palpable renal mass in a newborn or infant, as abdominal, flank, or

back pain, as a febrile UTI, or as hematuria after minimal trauma. Approximately 60% of cases occur on the left side, and the male to female ratio is 2:1. In 10% of cases UPJ obstruction is bilateral. In kidneys with UPJ obstruction, renal function may be significantly impaired from pressure atrophy, but approximately half of affected kidneys have relatively normal function [41].

Crossing vessels have been identified in 38–71% of patients with UPJ obstruction and in 19% of patients without UPJ obstruction [42]. Crossing vessels are believed to exacerbate rather than initiate the obstructive process [43]. If not recognized, crossing vessels can cause significant bleeding. These vessels are not excised as part of the repair, but the renal pelvis and ureter are rearranged by dismembered pyeloplasty [44].

The goal of surgery for UPJ obstruction is to preserve renal function by facilitating unobstructed drainage of urine. There are two common techniques: the more popular dismembered pyeloplasty and the flap technique. With the dismembered approach, there is complete severing of the ureter from the pelvis and then reanastamosis. With the flap approach, the renal pelvis is modified with the ureter intact.

The most common surgical approaches are the anterior subcostal, muscle-splitting approach and the dorsal lumbotomy approach. The anterior subcostal approach is performed in a modified supine position with the ipsilateral side at a 15–20° angle. The operating table is flexed at the level of the child's anterior superior iliac spine, and a "bump" placed under the patient. The lumbotomy approach is performed with the child in the prone position.

Pyeloplasty can also be performed by the laparoscopic approach with and without robotics. Potential benefits of the laparoscopic approach include shorter hospital admission, decreased postoperative pain, less superficial scarring, and earlier return to normal activity [45]. Because of the small incision used in the open procedure combined with the rapid convalescence of most children, controversy exists about which approach may be advantageous in this age group. The decision is likely left to surgeon preference and experience. Neither approach is responsible for prolonged extreme pain. The mean length of stay for an open procedure is 25 h [46].

In most children, the general risk of anesthesia is relatively low. These children are usually healthy, but it is always prudent to search for coexisting diseases. Renal failure is not usually an issue, especially with unilateral disease. Because of positioning, length of surgery, and when a laparoscopic approach is planned, tracheal intubation is usually the safest route for anesthesia. Liberal fluid therapy allows free flow of urine. Regional block with local anesthetic via the caudal route with or without opioids and clonidine provide excellent postoperative pain relief. Because the mean length of hospitalization is about 25 h, epidural catheter placement usually is not necessary [22]. Ben-Meir and others demonstrated that a regimen of opioids and non-steroidal anti-inflammatory drugs in children after open pyeloplasty has efficacy similar to that of epidural analgesia [46,47].

KEY POINTS: URETEROPELVIC JUNCTION OBSTRUCTION

- Ureteropelvic junction obstruction is the most common cause of obstructive uropathy in childhood and usually is caused by intrinsic stenosis; it can even be observed on maternal ultrasound
- The majority occur on the left side and more often in females than males
- The goal of surgery for UPJ obstruction is to preserve renal function by facilitating unobstructed drainage of urine and this can be done by a variety of techniques

Wilms tumor

Wilms tumor or nephroblastoma is the most common renal tumor of childhood and the seventh most common pediatric malignancy overall, accounting for about 5% of all childhood malignancies [48]. There are approximately 500 new cases of Wilms tumor each year. Most (75%) newly diagnosed patients are under 5 years of age, and usually aged between 2 and 3 years. Commonly, the tumor presents as a painless mass which is noticed by the parents as an abdominal bulge or a palpated mass. Some patients may exhibit signs and symptoms including malaise, fever, weight loss, and frank hypertension. Classic associations with Wilms tumor include crytorchidism or hypospadias, aniridia, and/or hemihypertrophy [49]. Table 32.1 lists the characteristics associated with

Table 32.1 Occurrence of characteristic congenital anomalies in Wilms tumor patients according to subgroups of the National Wilms Tumor Study

Subgroup	No. of patients evaluated	Percentage of patients in subgroups with			
		Aniridia	Cryptorchism/ hypospadias*	Hemihypertrophy	Beckwith–Wiedemann
Unilateral, unicentric	4165	1.3	5.0	2.6	0.5
Unilateral, multicentric	516	1.0	8.6	6.2	2.3
Bilateral at onset	315	1.3	16.8	8.6	1.6
Late bilateral	43	4.7	15.4	4.7	4.7
Familial Wilms tumor	61	1.6	5.1	3.3	0.0

different types of Wilms tumor. The tumor usually involves one kidney but may affect both kidneys in about 5% of cases. As the tumor grows it may spread by local invasion and in 12% may demonstrate hematogenous spread to the lungs and less commonly to the brain (0.5%) [50]. Children with tumors that are solitary, unilateral, and have a low-risk genotype have an excellent prognosis. Bilateral masses and those with higher risk tumors (by genotype) are associated with significant morbidity and mortality. Common morbidities include recurrence of tumor, complications secondary to chemotherapy or radiotherapy, and spread to other organs, particularly the lungs. Recent advances in molecular biology have improved understanding of factors that can affect the outcome of children with Wilms tumor. In particular, the loss of heterozygocity (LOH) of chromosome 1p and/or 16q is associated with anaplastic Wilms tumors, which have a worse prognosis than those without LOH. Older children also are more likely than younger ones to have LOH, and, therefore, a worse prognosis. Patients who exhibit LOH at both the 1p and 16q loci have a significant chance of relapse after therapy and, therefore, a worse prognosis. The epidemiological and genetic factors have been used to stratify the risk associated with Wilms tumor. These are summarized in Box 32.1. Current survival rates for Wilms tumor according to staging are presented in Table 32.2 [51].

Children with Wilms tumor may require anesthesia for a variety of conditions, including primary tumor resection, radiological imaging (magnetic resonance imaging), diagonostic bone marrow biopsy and lumbar puncture, placement of central lines (percutaneously inserted central catheters), or radiotherapy. Usually the child will present to the operating room for surgical resection and staging. The main responsibility of the surgeon is to remove the primary tumor completely, without spillage, and to accurately assess the extent to which the tumor has spread, with particular attention to adequately assessing lymph node involvement. There is a difference in approach to the timing of initial surgery between the guidelines of the Children's Oncology Group (COG) in the USA and

Box 32.1: Wilms tumor staging system

I. Tumor limited to kidney and completely excised. The surface of the capsule is intact. Tumor was not ruptured before or during removal. There is no residual tumor apparent beyond the margins of excision
II. Tumor extends beyond the kidney, but is completely excised. There is regional extension of the tumor, i.e. penetration through the outer surface of the renal capsule into perirenal soft tissues. Vessels outside the kidney substance are infiltrated or contain tumor thrombus. The tumor may have been biopsied or there has been local spillage of tumor contained to the flank. There is no residual tumor apparent at or beyond the margins of excision
III. Residual non-hematogenous tumor confined to the abdomen. Any one or more of the following occur:
    a. Lymph nodes on biopsy are found to be involved in the hilus, the periaortic chains or beyond
    b. There has been diffuse peritoneal contamination by tumor such as by spillage of tumor beyond the flank before or during surgery, or by tumor growth that has penetrated through the peritoneal surface
    c. Implants are found on the peritoneal surfaces
    d. The tumor extends beyond the surgical margins either microscopically or grossly
    e. The tumor is not completely resectable because of local infiltration into vital structures
IV. Hematogenous metastases. Deposits beyond stage III, i.e. lung, liver, bone, and brain
V. Bilateral renal involvement at diagnosis. An attempt should be made to stage each side according to the above criteria on the basis of extent of disease prior to biopsy

those of the International Society of Pediatric Oncology (SIOP) in Europe. The American practice is to perform primary resection and staging before administering chemotherapy. The SIOP recommends preoperative chemotherapy because the tumor then is easier to resect and may be associated with a decreased incidence of tumor spill and a lower mortality and morbidity rate [50].

Commonly, anesthesia for primary tumor resection is similar to that for any major open laparatomy or radical nephrectomy. Proper preoperative assessment is crucial. The anesthesiologist should be aware of the extent of the tumor and whether it is adherent to surrounding organs. The tumor may involve a good portion of the kidney as well as the inferior vena cava, mesenteric arteries, and a portion of the liver or right atrium. Patients with atrial involvement or atrial thrombus may need cardiopulmonary bypass support during the surgical procedure. Bilateral tumors or ones crossing the midline of the abdomen may affect the great vessels, adding potential risk of significant blood loss. In addition, the anesthesiologist should be aware of any associated anomalies and the nature of any preoperative chemotherapy or radiotherapy. Chemotherapeutic agents such as actinomycin, doxorubicin, and vincristine are used for preoperative and postoperative treatment. These drugs may be associated with myelosuppression, cardiotoxicity, pulmonary effects (pleural effusion, pneumonia, and interstitial pneumonitis), hepatotoxicity, and neurotoxicity in children [52]. The incidence varies and may depend both on dose and the patient's individual response to the agent [52–54].

The anesthetic plan depends on the preoperative condition of the patient and the surgical plan. These patients will require endotracheal intubation and general anesthesia with standard monitors. Two intravenous lines are useful, one to provide maintenance IV solutions and the second for rapid infusion of fluids or blood products. If there is intraatrial involvement or if thoracotomy or cardiopulmonary bypass is required, an arterial line is useful to closely monitor the patient's blood pressure and obtain blood specimens for testing. Central venous access, if not present preoperatively, may be desirable to monitor central pressures and provide longer term venous access. For the abdominal approach, patients are positioned supine and commonly the surgical approach is through a transverse abdominal transperitoneal incision. Epidural analgesia for intraoperative and postoperative pain management may be quite useful. The level of the catheter is determined by the site of the incision. The tip of the catheter is best located at the mid or low thoracic level in order to provide adequate analgesia. Despite proper planning and execution, up to 12% of cases may have a perioperative complication. Table 32.3 lists some of the possible surgical complications and reported incidence [55]. In addition to these, the anesthesiologist should be mindful of possible injury related to patient positioning and take proper precautions to minimize the risk. Patients may have significant postoperative pain and discomfort depending on the location of the incision and extent of the surgical dissection. Postoperative use of patient- or nurse-controlled epidural analgesia may result in more comfort and rapid return to activity by avoiding the common side-effects of intravenous opioid analgesia. Without surgical complications, patients usually recover from surgery within 3–5 days. Postoperative therapy is determined by the stage of the tumor and risk stratification.

Table 32.3 Incidence of surgical complications following surgery for Wilms tumor

Complication	*n*	%
Bowel obstruction	27	5.1
Extensive hemorrhage	10	1.9
Wound infection	10	1.9
Vascular injury	8	1.5
Splenic injury	6	1.1
Hypotension	3	0.6
Diaphragmatic tear	2	0.4
Liver injury	1	0.2
Chylous ascites	1	0.2
Incisional hernia	1	0.2
Pulmonary embolus	1	0.2
Respiratory failure	1	0.2
Pleural effusion	1	0.2
Pneumothorax	1	0.2
Urinary tract infection	1	0.2
Pancreatitis	1	0.2
Staph. sepsis	1	0.2

Seventy-six complications occurred in 68 of 534 children: 12.7% had at least one complication.

KEY POINTS: WILMS TUMOR

- As one of the most commonly diagnosed childhood tumors, the majority are noticed by the parents of children age 2–3 years with a significant abdominal bulge
- Morbidity is determined by laterality. Children with a solitary tumor have an excellent prognosis; those with bilateral masses have potential significant morbidity and mortality
- Genetic testing and molecular biology has become more important in the work-up of Wilms tumor and helps to determine potential chemotherapy treatments

Chronic renal failure and dialysis

Children in acute or chronic renal failure may require peritoneal dialysis or hemodialysis. The insertion of the appropriate catheter in non-critically ill patients is usually performed in the operating room under general anesthesia. The critically ill child may require a procedure in the operating room while undergoing continuous renal replacement therapy (CRRT) in the ICU. This section will describe the types of renal replacement available, the mechanism by which dialysis is performed, and finally a discussion of the types of dialysis catheters used for the pediatric patient. The perioperative care of children in renal failure requiring surgery will also be addressed.

Renal replacement therapy defines dialysis therapies. However, some authors now refer to dialysis as renal support therapy because only fluid removal and filtering wastes are performed by dialysis and not the endocrine functions [56]. Dialysis employs only two physiologies for solute and fluid

movement. Both methods require blood being exposed to a semi-permeable membrane against a dialysate solution of different concentration. Regardless of the modality employed, the goal of renal replacement therapy is to precisely control serum electrolytes, clear toxins, and provide fluid removal for the patient in renal failure.

Dialysis employs a diffusive clearance while hemofiltration employs convective clearance. Hemodialysis and peritoneal dialysis involve the diffusion of solutes across a concentration gradient from high to low concentration. Dialysate is passed across the semi-permeable membrane counter current to blood flow allowing equilibration of the plasma and dialysate solute concentrations. This process may remove or add solute to the plasma water space depending upon the composition of dialysate compared to the plasma. Water will also move along a gradient in effect "following" the solute (ultrafiltration). Diffusive clearance is effective for removal of the small solutes, including serum ions and urea, with subsequent fluid removal. In addition, other solutes such as antibiotics, narcotics, and other medications will cross the membrane. Diffusion gradients change dependent upon blood flow rates, dialysate flow rates, and starting concentration gradients. CRRT employing countercurrent dialysate for solute clearance is called continuous venovenous hemodialysis[57].

Hemofiltration uses a pressure gradient for fluid movement instead of solute concentration gradients. It is considered part of the CRRT modalities. A positive hydrostatic pressure drives water across the membrane from the blood side to the filter side and the solutes follow the water through the membrane. Due to the possibility of large shifts of volume during convective therapies, a filter replacement fluid is often utilized to replace fluid lost by convection. In patients undergoing CRRT, bicarbonate is lost in the ultrafiltrate. Therefore, the replacement fluid is usually an isotonic, buffered electrolyte solution. The buffer used in the replacement fluid may be acetate, citrate, lactate, or bicarbonate. The use of citrate is becoming more commonplace because it may be used as both a buffer and an anticoagulant to help prevent hemodiafilter clotting [58]. There are multiple names for the types of hemofiltration performed including slow extended hemofiltration, slow continuous ultrafiltration, continuous venovenous hemofiltration, and continuous venovenous hemodiafiltration [57].

Thresholds for the timing of dialysis in acute renal failure (ARF) are controversial and not well defined [56,59,60]. Indications for renal replacement therapy include: volume overload with evidence of hypertension and/or pulmonary edema refractory to diuretic therapy, persistent hyperkalemia, severe metabolic acidosis unresponsive to medical management, neurological symptoms (altered mental status, seizures), and the presence of progressive azotemia. The modulation of inflammatory mediators in ARF with sepsis or multiorgan system failure may be another indication [61]. An additional indication for dialysis is the inability to provide adequate nutritional intake because of the need for severe fluid restriction. In patients with ARF, dialysis support may be necessary for days or weeks [62].

In chronic renal failure, ESRD represents the state in which a patient's renal dysfunction has progressed to the point at which homeostasis and survival can no longer be sustained with native kidney function and maximal medical management. Relative indications for renal replacement therapy include weight loss, malnutrition, persistent nausea and vomiting, refractory metabolic disturbances, refractory hypertension, fluid overload, school performance failure, and chronic fatigue. Absolute indications include progressive uremic encephalopathy, bleeding diathesis related to uremia, pericarditis, pulmonary edema, and life-threatening hyperkalemia [56]. The ultimate goal for children with ESRD is successful kidney transplantation because it provides the most normal lifestyle and possibility for rehabilitation for the child and family.

Seventy-five percent of US children with ESRD require a period of dialysis before transplantation can be performed. It is recommended that plans for renal replacement therapy be initiated when a child reaches a glomerular filtration rate of between 29 and 50 mL/min/1.73 m^2 [62]. The optimal time to actually initiate dialysis, however, is based on a combination of the biochemical and clinical characteristics of the patient including refractory fluid overload, electrolyte imbalance, acidosis, growth failure, or uremic symptoms, including fatigue, nausea, and impaired school performance [56]. In general, most nephrologists attempt to initiate dialysis early enough to prevent the development of severe fluid and electrolyte abnormalities, malnutrition, and uremic symptoms. Pre-emptive transplantation before initiation of dialysis is increasingly observed [62]. Management of anesthesia for renal transplantation is discussed in Chapter 30.

The selection of dialysis modality must be individualized to fit the needs of each child. In the United States, two-thirds of children with ESRD are treated with peritoneal dialysis, whereas one-third are treated with hemodialysis. Age is a defining factor in dialysis modality selection: 88% of infants and children from birth to 5 years of age are treated with peritoneal dialysis, whereas 54% of children older than 12 years of age are treated with hemodialysis [63]. In ARF each modality has its indications, contraindications, and challenges (Table 32.4) [61].

Peritoneal dialysis involves the transport of solutes and water across the peritoneum. The blood in the peritoneal capillaries are exposed to the dialysis solution in the peritoneal cavity, which typically contains sodium, chloride, and lactate or bicarbonate along with glucose to make the solution hyperosmolar. During the course of a peritoneal dialysis dwell, three transport processes occur simultaneously: diffusion, ultrafiltration, and absorption. The amount of dialysis achieved and the extent of fluid removal depends on the volume of dialysis solution infused (called the dwell), how often this dialysis solution is exchanged, and the concentration of osmotic agent present [64].

Peritoneal dialysis requires less clinical expertise, fewer equipment resources, and decreased cost. It can be used in all pediatric patients including neonates and stable postoperative heart surgery patients. It can be performed in patients with a venticuloperitoneal shunt and also in patients with prone belly syndrome. Peritoneal dialysis provides gradual solute clearance and ultrafiltration, thus causing less hemodynamic instability. Slow solute clearance and ultrafiltration is an obvious disadvantage for patients with severe fluid overload or severe lactic acidosis requiring

Table 32.4 Comparison of the advantages and disadvantages of continuous renal replacement therapies (CRRT), peritoneal dialysis (PD), and intermittent hemodialysis (IHD)

Variable	CRRT	PD	IHD
Continuous therapy	Yes	Yes	No
Hemodynamic stability	Yes	Yes	No
Fluid balance achieved	Yes, pump controlled	Yes/no, variable	Yes, intermittent
Easy to perform	No	Yes	No
Metabolic control	Yes	Yes	Yes, intermittent
Optimal nutrition	Yes	No	No
Continuous toxin removal	Yes	No/yes, depends on the nature of the toxin – larger molecules not well cleared	No
Anticoagulation	Yes, requires continuous anticoagulation	No, anticoagulation not required	Yes/no, intermittent anticoagulation
Rapid poison removal	Yes/no, depending on patient size and dose	No	Yes
Stable intracranial pressure	Yes	Yes/no, less predictable than CRRT	Yes/no, less predictable than CRRT
ICU nursing support	Yes, high level of support	Yes/no, moderate level of support (if frequent, manual cycling can be labor intensive)	No, low level of support
Dialysis nursing support	Yes/no, institution dependent	Yes/no, institution dependent	Yes
Patient mobility	No	Yes, if IPD used	No
Cost	High	Low/moderate. Increases with increased dialysis fluid used	High/moderate
Vascular access required	Yes	No	Yes
Recent abdominal surgery	Yes	No	Yes
VP shunt	Yes	Yes/no, relative contraindication	Yes
Prune belly syndrome	Yes	Yes/no, relative contraindication	Yes
Ultrafiltration control	Yes	Yes/no, variable	Yes, intermittent
PD catheter leakage	No	Yes	No
Infection potential	Yes	Yes	Yes
Use in AKI-associated inborn errors of metabolism	Yes	No	Yes
Use in AKI-associated ingestions	Yes	No	Yes

AKI, acute kidney injury; ICU, intensive care unit; IPD, intermittent peritoneal dialyss; VP, ventriculoperitoneal.

precise fluid balance and controlled ultrafiltration that can only be attained with intermittent hemodialysis or continuous renal replacement therapy [59]. Peritoneal dialysis can worsen respiratory distress by limiting diaphragmatic movement. Diaphragm defects are a contraindication to peritoneal dialysis. Because peritoneal dialysis can result in the loss of immunoglobulins, peritonitis is a risk. Catheter malfunction is common resulting in leaks, hernias, and catheter obstruction.

Intermittent hemodialysis has the clear advantage of rapid ultrafiltration and solute removal when compared with peritoneal dialysis or CRRT. The hemodialysis circuit is comprised of the patient's blood compartment, access in the form of a surgically placed arteriovenous fistula or arteriovenous graft, or a venous catheter, and the polyethylene tubing through which the patient's blood travels to and from the dialyzer. The dialysate consists of highly purified water into which sodium, potassium, calcium, magnesium, chloride, bicarbonate, and dextrose have been introduced. The low molecular weight waste products that accumulate in uremic blood are absent from the dialysis solution. For this reason, when uremic blood is exposed to dialysis solution, the flux rate of these solutes from blood to dialysate is initially much greater than the backflux from dialysate to blood. During dialysis, concentration equilibrium is prevented, and the concentration gradient between blood and dialysate is maximized, by continuously refilling the dialysate compartment with fresh dialysis solution and by replacing dialyzed blood with undialyzed blood. Normally, the direction of dialysis solution flow is opposite to the direction of blood flow. The purpose of "countercurrent" flow is to maximize the concentration difference of waste products between blood and dialysate in all parts of the dialyzer [65].

Like peritoneal dialysis, intermittent hemodialysis can be performed outside the ICU. This modality is useful in children with toxic ingestions, tumor lysis syndrome, and inborn errors of metabolism [66,67]. Rapid solute and fluid removal afforded by intermittent hemodialysis can lead to disequilibrium syndrome. Careful dosing, dialysate solution selection, judicious use of mannitol, and monitoring are required to prevent the dangerous osmolar fluctuations leading to this complication [68,69].

CRRT refers to any continuous mode of extracorporeal solute or fluid removal. The common denominator to all forms of CRRT is an extracorporeal circuit connected to the patient via an arterial or venous access catheter. A variety of alternative CRRTs have been developed to address many of the problems associated with intermittent hemodialyisis and peritoneal dialyisis discussed above. CRRT provides better metabolic control of azotemia and fluid removal without compromising intravascular volume and facilitates fluid and electrolyte management and nutritional

support in critically ill patients. CRRT is an invaluable means of supporting critically ill children with a variety of illnesses, including ARF, drug intoxication, inborn errors of metabolism, liver failure, and multiorgan failure. However, the ideal method of applying the technique is unknown [70,71]. On the basis of the successful use of CRRT in patients with ARF, it is now occasionally used to facilitate fluid removal in patients without renal failure but for whom diuretic therapy alone has been unsuccessful or is contraindicated [70].

KEY POINTS: CHRONIC RENAL FAILURE AND DIALYSIS

- Placement of the hemodialysis catheter may occur urgently for acute renal failure or more electively for those with chronic renal failure
- Regardless of the modality employed, the goal of renal replacement therapy is to precisely control serum electrolytes, clear toxins, and provide fluid removal for the patient in renal failure
- The ultimate goal for children with ESRD is successful kidney transplantation because it provides the most normal lifestyle and possibility for rehabilitation for the child and family
- In the United States, two-thirds of children with ESRD are treated with peritoneal dialysis, whereas one-third are treated with hemodialysis. This is also dependent on age, with the vast majority of those under the age of 5 years being treated with peritoneal dialysis

Dialysis catheter placement in the operating room

For children who do not undergo pre-emptive renal transplantation or who initially present with ESRD, establishment of adequate dialysis access is of paramount importance because it is directly linked to the quality of life and health of the patient. With respect to hemodialysis, all attempts should be made to create a primary arteriovenous fistula. For patients without adequate veins, a polytetrafluoroethylene graft is required. A native fistula is clearly preferred because of superior patency rates, although this option does require the presence of suitable veins, which excludes infants and small children under 20 kg [65]. Vascular catheters are the predominant vascular access in children. In children with ESRD, renal transplant is the first line of therapy. As an arteriovenous graft is recommended for long-term dialysis, such grafts are inappropriate for children who will undergo renal transplantation within a year [73,74].

The National Kidney Foundation Kidney Disease Outcomes Quality Initiative guidelines recommend that the order of vascular access be sequential: the right internal jugular vein, right external jugular vein, left internal and external jugular veins, subclavian veins, femoral veins, or translumbar access to the inferior vena cava. This order is based on complication rates from lowest to highest [75]. Additionally, these catheters can lead to central venous stenosis and thrombosis, which can make future permanent upper extremity vascular access more difficult to achieve.

Peritoneal dialysis is performed after placement of a Tenckhoff catheter. A double-cuffed peritoneal dialysis (PD) catheter is inserted via an open or laparoscopic surgical procedure under general anesthesia. The loop of the catheter is placed in the pelvis. During the procedure it is important to ascertain that fluid can run freely through the catheter into the abdomen and drain freely as well.

The laparoscopic technique appears to afford no advantage for successful catheter function in the early postoperative period [76]. In addition, other factors that that do not influence catheter function include previous PD catheter placement, previous abdominal surgery, type of catheter, or location of catheter exit site. However, Arog et al showed that use of the laparoscopic technique was helpful in children with an *in situ* ventriculoperitoneal shunt [77].

The most common cause of catheter failure is occlusion: either from an internal fibrin plug or obstruction by omentum, bowel, or other structures. The single controllable factor that was associated with a decreased risk of occlusion was the performance of simultaneous omentectomy. Overall, children weighing less than 10 kg have a higher risk of PD catheter failure than children weighing more than 10 kg.

The annualized infection rate decreases with age. Tenckhoff straight and Tenckhoff curled catheters have similar times to first peritonitis infection. Overall, first time peritonitis infection took longer for catheters with two cuffs compared with one, for swan neck tunnels compared with straight tunnels, and for down exit sites compared with up and lateral exit sites [63,78].

Children who are scheduled for PD catheter insertion are usually in a stable condition with chronic renal failure and have a catheter for renal replacement therapy in anticipation for renal transplantation. Occasionally, a child in acute renal failure will require surgical insertion of a dialysis catheter, such as the patient with new-onset hemolytic uremic syndrome.

The preoperative evaluation includes a physical exam and review of the patient's metabolic status. The timing of the patient's most recent dialysis session, if any, is very important. Of particular importance are serum potassium concentration, fluid status, and dosing of drugs that undergo predominately renal clearance. The patient requiring a PD catheter or hemodialysis catheter will require standard ASA (American Society of Anethesiologists) monitoring but usually not invasive monitoring. Arterial catheters are normally avoided in these patients, as are blood pressure cuffs on the extremity of an existing arteriovenous fistula or graft. Of critical importance is a preoperative discussion with the patient's nephrologist or surgeon about vascular access sites to be avoided. It is critical to maintain long-term patency of major veins and arteries in these patients, who may undergo a number of vascular access procedures over a lifetime. It is also important, when anesthetizing a patient with an existing dialysis fistula, to monitor blood flow during the anesthetic, and maintain blood pressure and intravascular

volume status to ensure arteriovenous fistula or graft patency. Tracheal intubation is prudent since many children in acute and chronic renal failure have delayed gastric emptying and thus have a pulmonary aspiration risk. The need for rapid sequence induction or modified rapid sequence must be made on an individual patient basis. While succinylcholine may be used for rapid sequence induction if the serum potassium is at normal levels, rocuronium may be a better choice. Neuromuscular blockade with rocuronium is of similar duration or only slightly prolonged in patients with chronic renal failure as compared to patients with normal renal function [79]. Fentanyl and hydromorphone are not metabolized by the kidney and are reasonable choices for perioperative analgesia [80].

KEY POINTS: DIALYSIS CATHETER PLACEMENT IN THE OPERATING ROOM

- For children who do not undergo pre-emptive renal transplantation or who initially present with ESRD, establishment of adequate dialysis access is of paramount importance because it is directly linked to the quality of life and health of the patient
- A native fistula is clearly preferred because of superior patency rates, but cannot be obtained in infants and small children under 20 kg because of a lack of suitable vessel sizes. Vascular catheters are generally used in this population
- Important anesthetic considerations include the timing of the patient's most recent dialysis session, which can influence serum potassium concentration, fluid status, and dosing of drugs that undergo predominately renal clearance

Continuous renal replacement therapy in the operating room

Most patients receiving CRRT are critically ill, may be on mechanical ventilator support, and are often receiving a myriad of vasoactive agents. These patients are challenging because they may have underlying coagulopathies, yet CRRT requires anticoagulation for filter patency. If these children need surgical procedures, in most instances, CRRT treatment can be discontinued while in the operating room. However, in some procedures, for example liver transplantation, CRRT may be used during surgery to optimize fluid and electrolyte management [81].

Most anesthesiologists and operating room personnel are not familiar with CRRT or the equipment needed to provide the therapy. It is imperative that a meaningful discussion occurs among the intensivists, nephrologists, and surgeons involved in the procedure, in order to outline the operative care of the patient. At the Monroe Carell Jr Children's Hospital at Vanderbilt University Medical Center, a technician familiar with the CRRT device manages the apparatus in the operating room. Careful monitoring of arterial blood gases and electrolytes is essential to ensure normal acid–base balance [72].

KEY POINTS: CONTINUOUS RENAL REPLACEMENT THERAPY IN THE OPERATING ROOM

- Most patients receiving CRRT are critically ill, may be on mechanical ventilator support, and are often receiving a myriad of vasoactive agents. These patients are challenging because they may have underlying coagulopathies, yet CRRT requires anticoagulation for filter patency
- Most anesthesiologists are not intimately familiar with CRRT so it is imperative that a meaningful discussion occurs among the intensivists, nephrologists, anesthesiologists, and surgeons involved in the procedure, in order to outline the operative care of the patient

Priapism

Ischemic (veno-occlusive, low-flow) priapism is a non-sexual, persistent erection causing a compartmental syndrome that is a medical, and sometimes surgical, emergency in any episode lasting more than 4 h. Patients typically report associated pain. In children, the etiologies include sickle cell disease, oncological disease, and neuroleptic drugs. Unlike normal erections which involve engorgement of the corpora cavernosa and the corporus spongiosum, priapism only involves the engorgement of the corpora cavernosa.

Trazodone is a triazolopyridine derivative that holds considerable appeal for treatment of depressive illness and as an adjunct for chronic pain because it has little anticholinergic activity and few cardiovascular side-effects. However, trazodone possesses significant α-blocking activity. Trazodone-induced priapism resembles priapism due to sickle cell hemoglobinopathy [82].

In general, since ischemic priapism of more than 4 h in duration irrespective of etiology implies a compartment syndrome, decompression of the corpora cavernosa is recommended for counteracting and preventing ischemic injury. Definitive first-line treatment consists of evacuation of blood and irrigation of the corpora cavernosa along with intracavernous injection of an α-adrenergic sympathomimetic agent. A dorsal nerve block or local penile shaft block is generally performed prior to penile maneuvers. Priapism resolution employing aspiration with or without irrigation is approximately 30%.

Sympathomimetic agents can be expected to exert contractile effects on the cavernous tissue and thus facilitate detumescence. Among these, phenylephrine, as an α1-selective adrenergic agonist, is the preferred drug for this application since it minimizes the risk of cardiovascular side-effects compared with other sympathomimetic agents having β-adrenergic effects as well. Evacuation of stagnant intracorporal blood may be required for the medication to be most effective [83,84].

In patients with an underlying etiological disorder, intracavernous treatment of ischemic priapism should be provided concurrent with appropriate systemic treatment. This recommendation applies to priapism associated with sickle cell

disease as well as that associated with other hematological diseases, metastatic neoplasia, or other causes having standard treatments. Support for this recommendation is provided by literature review showing that ischemic priapism resolved in 37% or less of patients with sickle cell disease managed with systemic medical treatments, whereas much better resolution rates were achieved with therapies directed at the penis [82]. Thus, for priapism related to sickle cell disease, conventionally recommended medical therapies such as analgesia, hydration, oxygenation, alkalinization, and even transfusion may be performed, but these interventions should not lead to delays in intracavernous treatment if prolonged periods of ischemia have occurred [84].

The surgeon may proceed with surgical intervention once it is apparent that intracavernous treatment has failed [83]. A surgical shunt has the objective of facilitating blood drainage from the corpora cavernosa, bypassing the veno-occlusive mechanism of these structures [84]. Surgical correction involves connecting the engorged cavernosal tissue with the glans, corpus spongiosum, or dorsal or saphenous vein. This surgically created fistula will allow blood to drain from the corpora cavernosa until the pathological process has resolved. Ideally, the surgically created fistula will spontaneously close after the priapism-causing factors have resolved [85].

KEY POINTS: PRIAPISM

- Ischemic priapism is a non-sexual, persistent erection causing a compartmental syndrome that is a medical, and sometimes surgical, emergency in any episode lasting more than 4 h
- In children, the etiologies include sickle cell disease, oncological disease, and neuroleptic drugs
- Definitive first-line treatment consists of evacuation of blood and irrigation of the corpora cavernosa along with intracavernous injection of an α-adrenergic sympathomimetic agent. Surgical intervention is required if medical treatment fails

Robotic surgery

Laparoscopic and robot-assisted laparoscopic surgeries have gained increasing popularity for pediatric urological procedures. Compared with traditional open techniques, minimally invasive surgery offers the advantages of shorter hospitalization, decreased postoperative pain medication requirements, fewer postoperative respiratory complications, and smaller incisions with improved cosmetic outcome [86].

The first robotic procedure in a child was described by Meininger et al in 2001 for a robotic Nissen fundoplication [87]. Improvements offered by the robotic system over traditional laparoscopic surgery include enhanced dexterity, tremor filtration, motion scaling, and superior depth perception and magnification (Fig. 32.4) [88,89]. Disadvantages include inferior haptic feedback, a relatively limited selection of laparoscopic tools, and cost [88,90]. Many pediatric urological procedures have been successfully performed with a robot-assisted approach. These include pyeloplasty, ureteral reimplantation (intra- and extravesical), nephrectomy or partial nephrectomy, ureteroureterostomy, orchidopexy, bladder augmentation, and appendicovesicostomy [91]. The surgical outcomes for robot-assisted pyeloplasty are recognized as at least equivalent to the open or traditional laparoscopic approach while other procedures are still undergoing evaluation [92]. In 2013, a literature review of robotic surgery in children by Cundy et al found a conversion rate to a traditional laparoscopic or open approach of 2.5% [89]. Compared with gastrointestinal and thoracic surgery, genitourinary procedures demonstrated the lowest rate of conversion at 1.5% [89].

Co-morbidities leading to decreased tolerance of pneumoperitoneum and increased intra-abdominal pressure might make robotic surgery a less feasible option for some patients. Examples of such co-morbidities include bronchopulmonary illness with poor respiratory reserve, uncorrected congenital heart disease, and pulmonary hypertension. While small patient size can lead to challenging port placement and an increased risk of instrument collision, it is not a contraindication to robotic surgery [91,92]. Abdominal robotic procedures on a patient weighing 2.2 kg as well as on a 1-day-old neonate have been reported [93]. Prior abdominal surgery may complicate port placement; it is, however, not a contraindication to robotic surgery [91].

The anesthetic considerations in robotic surgery depend on the type of surgical procedure being performed. Some general considerations pertain to every case and focus on patient positioning requirements and the respiratory, cardiovascular, and neuroendocrine changes accompanying the creation of a pneumoperitoneum. The robot's reach is often a limiting factor, so the bed may need to be tilted to an extreme laterally. Some surgeries require a steep Trendelenburg or reverse Trendelenburg position for portions of the procedure. It is critical to pay close attention to securing and padding extremities to avoid inadvertent movement or pressure injury. The same is true for head positioning since the head may slide off the pillow if not secured and monitored (Fig. 32.5) [94]. Depending on the size and layout of the operating room, the anesthesia provider's access to the patient may be exceptionally limited. The operating room team should have a coordinated and practiced plan in place for optimum positioning of the robotic system (Figs 32.6 and 32.7) and to allow for quick disengagement of the robot and access to the patient in case of airway emergencies or the need to rapidly convert to an open procedure [95].

Effects of retro- or intraperitoneal CO_2 insufflation include hypercarbia and an increase in intra-abdominal pressure. Hypercarbia can increase systemic vascular resistance and mean arterial pressure [96,97]. If uncorrected, hypercarbia can result in acidosis, which in turn can decrease cardiac contractility, increase the risk of arrhythmias, and cause vasodilation [96]. CO_2 increases the release of catecholamines and vasopressin [97]. Children under the age of 4 years have an increased CO_2 absorption rate due to a high absorption surface to body weight ratio and a shorter distance between the absorbent membrane and capillaries [98]. CO_2 insufflation can lower core temperature and care must be taken to maintain normothermia.

Intra-abdominal pressures exceeding 15 mmHg can decrease venous return and lead to a decrease in cardiac output [86,98]. Recommended insufflation pressures are

8–10 mmHg for infants (0–2 years), 10–12 mmHg for children (2–10 years) and 15 mmHg for adolescents (>10 years) [99].

The peritoneal stretch during insufflation can cause transient bradycardia, which is poorly tolerated in neonates and infants given their rate-dependent cardiac output. Cephalad displacement of the diaphragm during insufflation can decrease functional residual capacity below closing volumes, causes atelectasis, and increases dead space [96]. Possible consequences include hypoxemia and right-to-left shunting [96,97]. Increased intra-abdominal pressure has also been shown to reduce the glomerular filtration pressure and may temporarily decrease urine output [96,100]. This makes urine output a poor indicator for volume status during robotic procedures. Tables 32.5 and 32.6 summarize the respiratory, cardiovascular, and renal effects of pneumoperitoneum [94].

Monitors for robot-assisted laparoscopic procedures in children include standard ASA monitors. The addition of a precordial stethoscope allows for early recognition of inadvertent mainstem intubation [95]. End-tidal CO_2 ($ETCO_2$) monitoring can be unreliable as an indicator for $PaCO_2$ in small infants and the setting of respiratory pathology or high intra-abdominal pressure requirements. Arterial line placement for blood gas sampling can be indicated for select patients or long procedures [97]. Induction of anesthesia can be intravenous or inhalational. Care must be taken to avoid gastric distension during mask ventilation. Both inhalational

and intravenous maintenance are good options. Some sources prefer total intravenous anesthesia to increase hemodynamic stability during pneumoperitoneum [87]. Peripheral intravenous access is preferably placed in an upper extremity given a possibly delayed effect of medications administered via lower extremity access in the setting of increased intra-abdominal pressure. Placement of a second peripheral IV access prior to procedure start is recommended [96,101].

Patients require intubation for most laparoscopic and nearly all robot-assisted laparoscopic procedures. Cuffed endotracheal tubes are preferred to ensure adequate controlled ventilation. Proper endotracheal tube position must be reconfirmed after patient positioning is completed and should be checked at the expected extremes of table positioning to rule out inadvertent endobronchial migration of the endotracheal tube tip during the case. Foam padding around the face can help prevent contact of the robot or a surgical assistant with the endotracheal tube [101]. Muscle relaxation minimizes the risk of patient movement and facilitates adequate

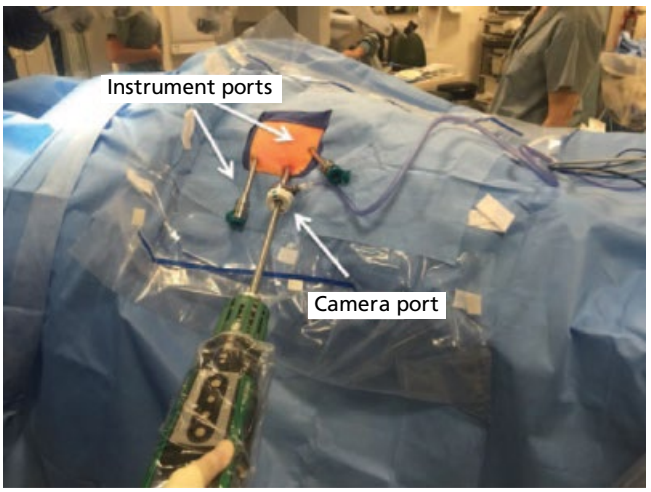

Figure 32.6 Intraoperative placement of the camera and instrument ports for pediatric robot-assisted urological surgery. Many surgeries can be accomplished with three ports but a fourth port may be necessary for more complex procedures. *Source*: Reproduced from Muñoz et al [94] with permission of Wolters Kluwer.

Table 32.5 Summary of the respiratory effects of pneumoperitoneum

Parameter	Change
Peak inspiration pressure	Increase
Chest wall mechanical resistance	Increase

CO_2 insufflation [88]. It also improves conditions for controlled ventilation to maintain normocapnia [88,97].

It is recommended to decompress the bladder before obtaining surgical access to minimize the risk of bladder injury and to improve visualization of pelvic structures during the procedure since the bladder is in a more abdominal position in infants [99]. A distended stomach can similarly obstruct the surgeon's view of the operative field. Placement of a nasogastric or orogastric tube after induction decreases the stomach [95,102]. Nitrous oxide is frequently avoided given the risk of bowel dilation and an increased risk of postoperative nausea and vomiting [96].

Many of the complications seen with robot-assisted laparoscopic surgery in children are associated with the establishment of the pneumoperitoneum. This begins with possible vascular or bowel injury during trocar placement. The open "Hasson" technique is generally preferred for initial trocar placement in the pediatric population [88,97]. The anesthesiologist must be prepared for occult bleeding after access is obtained. Maintenance of adequate insufflation during instrument change can be more challenging in children than adult patients due to their thinner abdominal wall [99]. Port site hernias have been reported but are a rare complication [88,92]. Subcutaneous tissue emphysema, pneumothorax, and pneumomediastinum can occur during insufflation. The anesthesia team must be vigilant for the event of a venous gas embolism (Table 32.7) which can present with hypotension, hypoxemia, or sudden decrease in $ETCO_2$ [94,96]. $ETCO_2$ monitoring has been suggested by many to be a sensitive and non-invasive means of detecting gas embolism [103–110]. Several sources state an abrupt rise in $ETCO_2$ will occur [104]. However, most of the literature suggests there will be a significant decrease in $ETCO_2$ with carbon dioxide embolism and compromised cardiac output [103–110]. Tissue injury can occur from retraction, puncture, and during instrument change, as well as from cautery devices [88,92]. The anesthesiologist also must be prepared for emergent opening of the abdomen to address acute vascular injury and hemorrhage (Table 32.8) [94].

In infants, a limited amount of gas is available to dissipate heat from cautery devices. Cautery settings and active cautery time should be reduced [111].

Hypercapnia increases cerebral blood flow [97]. Significant increases in intracranial pressure during laparoscopic procedures have been reported in patients with ventriculoperitoneal shunts [112]. Robot malfunction as a complication is rare, with a reported incidence of 0.38–0.5% [91,92].

Table 32.7 Detection and management of CO_2 embolism

Signs and symptoms	Treatment
Sudden rise in $ETCO_2$	Inform surgeon and call for help
Acute hypotension	Deflate the pneumoperitoneum
Hypoxemia	Hyperventilation with 100% O_2
Dysrhythmias	Left lateral decubitus position with Trendelenberg
Pulmonary edema	Full cardiopulmonary resuscitation
'Mill-wheel' murmur on auscultation	Placement of central venous catheter to aspirate CO_2
Cyanosis of head and neck	Cardiopulmonary bypass if unresponsive to above

$ETCO_2$, end-tidal carbon dioxide.

Two common pediatric urological procedures for which the robot-assisted laparoscopic approach has gained popularity are pyeloplasty and ureteral reimplantation. Technically challenging portions of both procedures, namely intracorporeal suturing during pyeloplasty and dissection and suturing of the bladder during reimplantation, benefit from the technical enhancements of robotic surgery over traditional laparoscopy [90,92].

The gold standard for pyeloplasty to treat ureteropelvic junction obstruction has traditionally been open dismembered pyeloplasty, with a success rate of 90–100% [92]. Transperitoneal and, less commonly, retroperitoneal robotic approaches have been described. In a multicenter observational study in 2015, Avery et al reported a 91% success rate for reduction or resolution of hydronephrosis and an 11% complication rate for the transperitoneal robot-assisted approach [111]. Robotic pyeloplasty has been associated with longer operating room time, but shorter length of stay and decreased total opioid requirement [113]. Children are generally placed on a clear liquid diet for 24 h prior to the surgery, and younger patients are given either a laxative or suppository [114]. The procedure typically includes retrograde or anterograde stent placement. Retrograde stent placement occurs during a cystoscopy at the beginning of the case [99]. Positioning for the robotic portion requires elevation of the affected side of 20–45°. The ipsilateral arm is extended [111]. Different options for port placement have been described. Triangular placement involves port insertion at the umbilicus, between the xiphoid and umbilicus, and in the ipsilateral lower quadrant. In smaller infants (<10 kg) an all midline placement (subxiphoid, umbilical, and suprapubic) approach is sometimes preferred [111]. Postoperative complications include ileus, evidence of bowel injury, urine leak, and persisting hydronephrosis [114].

Intra- or extravesical ureteral reimplantation is one of the treatment modalities for vesicoureteral reflux. The open approach has a reported success rate of 95–98% [115]. The

robotic intravesical approach is limited by challenges in maintaining pneumovesicum [90]. Patients with a bladder capacity of less than 130 mL are not considered good candidates [90,92,102]. In a small series, Marchini et al saw shorter urinary catheter drainage times, decreased bladder spasms, and shorter hospital stay in their robot-assisted intravesical ureteral reimplant patients compared with patients undergoing an open procedure [115].

Extravesical robotic ureteral reimplantation is more frequently performed than intravesical. Success rates are similar to open ureteral reimplantation [90]. The procedural steps are the same as for the open Lich–Gregoir technique [102]. Ports are placed at the umbilicus and in the midclavicular line bilaterally, approximately 1 cm below the level of the umbilicus. In small patients, the camera port may have to be placed above the umbilicus to avoid instrument collision [102]. The robot is positioned over the patient's feet [102]. Extravesical ureteral reimplantation can be associated with postoperative voiding dysfunction. Improved visualization with the robot may help avoid injury to the pelvic plexus [101]. In 2008, Casale et al reported robot-assisted extravesical ureteral reimplantation in 41 patients with a success rate of 97.6% and no occurrence of postoperative urinary retention [116].

KEY POINTS: ROBOTIC SURGERY

- Minimally invasive surgery is associated with less postoperative pain, shorter recovery, and better cosmesis
- Robotic surgery offers technical improvements over traditional laparoscopic surgery. However, space requirements, cost, and the lack of pediatric-specific equipment are limiting factors
- Good communication between the surgical team, anesthesia team, and operating nursing staff is essential
- Key anesthetic considerations are the management of the physiological changes associated with pneumoperitoneum, limitations in access to the patient, and proper patient positioning

CASE STUDY

An 18-month-old boy weighing 11 kg presents for robotic pyeloplasty for left ureteropelvic junction (UPJ) obstruction. He is an otherwise healthy product of a full-term birth without any complicatons. He has left hydronephrosis diagnosed on prenatal ultrasound, which has been followed with serial examinations and ultrasound; he has not had a urinary tract infection. Renal ultrasound a month before surgery demonstrated marked left intrarenal collecting system distension consistent with UPJ obstruction. He is taking no medications and has no drug allergies. Baseline vital signs and physical examination are normal.

The pediatric anesthesiologist explained the anesthetic plan to the parents, which included general endotracheal anesthesia, local anesthetic infiltration of the port sites by the surgeon, and parenteral analgesia. The low risk of acute anesthetic complications was discussed. Because the procedure was anticipated to last longer than 3 h, the anesthesiologist discussed the 2016 US Food and Drug Administration (FDA) warning about prolonged anesthesia in patients less than 3 years of age, and the theoretical risk of longer term neurodevelopmental problems. The surgery could not be deferred until a later date, and the parents had received a preanesthetic educational brochure that included the FDA warning information, and the surgeon had also discussed this with them during the office visit to schedule the surgery. They did not have any further questions and agreed to proceed, signing the anesthesia consent form.

After an oral midazolam premedication, an inhalation induction with sevoflurane was performed, after attaching standard ASA monitors. Two 22 g peripheral IVs were inserted and after muscle relaxation with rocuronium a 4.0 mm cuffed endotracheal tube was placed. After a dose of cefazolin was administered, a cystoscopy was performed in the supine position, confirming normal bladder and ureterovescicular junction anatomy. A left retrograde ureterogram confirmed UPJ obstruction. An orogastric tube to decompress the stomach, and Foley catheter to decompress the bladder, were placed. The patient was then postioned supine, and his left side was elevated on a gel roll such that he was at a 45° angle to the table. A right-sided axillary roll was then placed. He was carefully padded at all pressure points, including a gel pad under his head, and then he was secured to the table with silk tape across the chest, hips, and legs. The operating room bed was then airplaned 45° to the right side and to the left side to ensure that his position was stable and that he would not fall off the table. Endotracheal tube security and ventilator tube connections were checked carefully before draping, because access to the patient's head would be limited by the surgical robot. Final bed position was tilted left 45° to allow the surgical robot access to the field.

After sterile prep and draping, an infraumbilical port was placed and CO_2 pneumoperitoneum was achieved. The robotic camera scope was then placed in the infraumbilical port, and two additional robotic ports were placed, one in the midline just below the xyphoid process, and one in the left lower quadrant. An accessory laparoscopic port was placed in the right upper quadrant. The surgical robot was then docked into position for the surgery. A dismembered left pyeloplasty was performed, and a stent placed from the renal pelvis into the bladder. After inspection for intra-abdominal injury, the robotic instruments were removed and the robot undocked, and the port sites were closed. Estimated blood loss was 5 mL.

The anesthetic course was uncomplicated, with sevoflurane end-tidal concentration between 2.6% and 3.3% for anesthesia maintenance, and dense neuromuscular blockade was maintained with rocuronium to ensure motionless

operating conditions. No nitrous oxide was used to avoid bowel distension; and air–oxygen at a total flow of 2 L/min, with FiO_2 of 0.4–0.5, was utilized. Ventilation was with pressure control mode, and during CO_2 pneumoperitoneum peak inspiratory pressures were 24–25 cmH_2O, with tidal volumes of 65–75 mL (6–7 mL/kg) with end-tidal CO_2 values of 52–57 mmHg. Hemodynamic status was stable during the case, with a heart rate 120–130 bpm and systolic blood pressure of 75–90 mmHg. Ketorolac 0.5 mg/kg and morphine 0.2 mg/kg were administered at the beginning of the case, and the port sites infiltrated with 0.25% bupivacaine by the surgeon at the end of the case. A total of 450 mL of lactated Ringer solution was administered and the patient had 80 mL of urine output. At the end of the case the neuromuscular blockade was reversed, and the trachea was extubated with the patient awake. The total anesthetic time was 3 h 32 min.

The patient was transferred to the postanesthesia care unit (PACU) where he received two additional doses of 0.5 mg morphine for analgesia. After a 1 h PACU stay he was transferred to the surgical ward for overnight admission. Analgesia was with one dose of morphine, and then oral hydrocodone-acetaminophen and ibuprofen. He resumed a normal diet by the morning after surgery and was discharged home later that day with instructions to use acetaminophen and ibuprofen first for pain, and only use the hydrocodone-acetaminophen for significant pain.

This case illustrates the anesthetic considerations for robotic surgery: a long anesthetic period in a young child that may necessitate discussion of potential anesthetic neurotoxicity, very careful positioning and padding to ensure security of the patient with extremes of operating room bed position, a cuffed endotracheal tube to maintain ventilation during pneumoperitoneum, maintenance of neuromuscular blockade, vigilance for hemodynamic changes from CO_2 insufflation or bleeding, and the general lack of severe pain, and rapid recovery and discharge home after a hospital stay of less than 24 h. Although surgical duration may be longer with the robotic technique, in experienced hands the difference is minimal compared with conventional laparoscopic techniques.

CHAPTER 33
Anesthesia for Orthopedic Surgery

Cathy R. Lammers, Cecile Wyckaert, and Julianna Clark-Wronski
Pediatric Anesthesiology, UC Davis Children's Hospital, University of California, Davis, CA, USA

Introduction

Orthopedic surgery procedures are among the most common anesthetics that many pediatric anesthesiologists perform, and include a wide variety of surgeries, and patients. This includes many patients with significant neuromuscular diseases and multiple co-morbidities, healthy children with fractures, fractures from non-accidental trauma, and very healthy teenaged athletes with sports injuries. This chapter presents the major neuromuscular and genetic diseases that result in patients presenting for orthopedic surgery. It also covers orthopedic surgeries in otherwise healthy children such as fractures and septic joints. Non-accidental trauma as a cause of fractures is also discussed. Anesthesia for spinal surgery is presented in Chapter 29.

Clubfoot

Clubfeet or congenital talipes equinovarus are classified as being positional or rigid. Rigid abnormalities are either flexible or resistant. The incidence of clubfoot is 1/1000 livebirths in the United States but may be higher in certain ethnicities (e.g. Polynesian islanders). Males are twice as affected as females. There is bilateral involvement in 30–50% of cases. Parents of a child with clubfoot have a 10% chance of having another child with clubfoot [1]. The etiology is often unknown. Most infants have no identifiable genetic syndrome or extrinsic cause. Extrinsic causes include oligohydramnios, congenital concentric rings, and teratogenic agents. Pathophysiological theories include arrest of fetal development, defective cartilage production, changes in innervation leading to paresis, increased fibrous tissue in muscles and ligaments, abnormal tendon insertion, and possible prenatal polio-like condition; the latter is based on changes in the motor neuron of the anterior horn in the spinal cord [2].

On physical examination, the foot is supinated in the varus position and adducted (Fig. 33.1). Dorsiflexion is limited. The navicular, cuboid, and anterior aspects of the calcaneus are displaced medially [3]. There are contractures of the medial plantar soft tissues. The heel is small and empty. The medial malleolus is difficult to palpate and is often in contact with the navicular bone. The tibia is often internally rotated. The leg muscles are frequently atrophied, especially the peroneal muscle group. Although the number of muscle fibers is normal, they are smaller in size. The calf is often small and remains small even after successful correction of the lesion [4].

The goal of therapy is to correct the deformity early and maintain alignment of the foot until growth ceases [5]. The Pirani scoring system is used to identify the severity of the clubfoot and is based on the curvature of the lateral border, medial crease, uncovering of the lateral head of the talus, posterior crease, emptiness of the heel, and degree of dorsiflexion [6]. Non-operative treatment (splinting and casting) begins 2–3 days after birth with forefoot adduction, followed by forefoot supination, and then correction of the equinus [7]. Gentle manipulation of the foot is needed to avoid producing a rocker-bottom foot. If splinting and casting are unsuccessful, surgery is indicated, usually at 6 months of age when the anatomy is more identifiable. In children younger than 5 years of age, soft tissue procedures are indicated. In children older than 5 years, bony reshaping or osteotomy of the calcaneum may be needed. Lateral wedge tarsectomy or triple fusion is required in children older than 10 years [8]. Complications of surgical correction are wound breakdown, infection, avascular necrosis, stiffness, and residual deformity.

Gregory's Pediatric Anesthesia, Sixth Edition. Edited by Dean B. Andropoulos and George A. Gregory.

Figure 33.1 Clubfoot. (A) Anterior view of a baby with clubfoot. (B) Posterior view of the same child.

Preoperatively, one looks for co-morbid conditions (e.g. arthrogryposis, myelomeningocele) that include cardiovascular, respiratory, hematological, and neurological problems that have their own anesthetic implications. Although both general and regional anesthesia may be performed for clubfoot surgery, peripheral nerve blocks like posterior sciatic and femoral nerve blocks are generally avoided because the surgeons must examine the patient for postoperative neurological changes and for possible compartment syndrome with casting. While spinal and epidural anesthesia have been used for clubfoot surgery, there was no significant decrease in postoperative opiate use [9]. Tourniquets must be used cautiously in patients who have fragile bones. Postoperatively, pain is minimal and amenable to standard doses of opiates and acetaminophen.

KEY POINTS: CLUBFOOT

- A relatively common disorder that requires early treatment
- Initial treatment is splinting or casting at 2–3 days of age
- Failed correction with casting requires surgery
- Femoral and sciatic nerve blocks are avoided because surgeons must examine patients postoperatively

Hip dysplasias/dislocations

Hip dysplasia refers to a hip that can be dislocated from or relocated into the acetabulum. Hip dislocation describes a non-reducible hip that is associated with shortening, decreased abduction, and asymmetry of skinfolds. The normal hip joint consists of a femoral head and the acetabulum which develop from the same primitive mesenchymal cells. In the 11th week of fetal life, the hip joint is fully formed and may begin to dislocate if predisposed to do so [10]. Subluxation of the hip occurs in 1% of newborn infants. Patients with dysplasia or dislocation of the hip do not have the normal tight fit between the femoral head and the acetabulum. The majority of abnormalities in developmental hip dysplasia or dislocation are on the acetabular side. Acetabular shape is determined by 8 years of age in most children. Growth of the acetabulum is affected by abnormal acetabular cartilage, which is influenced by several factors, including the presence of a spherical femoral head, interstitial growth within the acetabular head, appositional growth under the perichondrium, and growth of adjacent bones (ileum, ischium, pubis). The dysplastic hip has a ridge (the limbus) in the superior, posterior, and inferior aspects of the acetabulum that is made of cellular hyaline cartilage. The limbus is a hypertrophied labrum [11].

Increased risk for abnormalities of the hips is indicated by female gender, first born, breech delivery, oligohydramnios, a positive family history for hip dysplasia, persistent hip asymmetry, torticollis, and lower limb deformity. All newborns are now screened for hip dyslplasia and dislocation with the Ortlani and Bartlow signs [12]. The *Ortlani sign* is positive when the hip is abducted, the trochanter is elevated, and the femoral head glides back into the acetabulum with a characteristic click. The *Barlow sign* is positive when the femoral head exits the acetabulum with the hip flexed and adducted. Ultrasonography helps to confirm the diagnosis and identify more subtle forms of dysplasia or dislocation. This should be performed in suspected cases at 4–6 weeks of age. If the diagnosis is missed at birth, there are four possible outcomes. The hip may become normal, subluxate or develop partial contact, completely dislocate, or remain located in the hip with dysplastic features. Physical findings of late diagnosis include shortened limb, asymmetry of gluteal, thigh, or labial skinfolds, and limited hip abduction. Patients with bilateral involvement have a waddling gait and hyperlordosis.

The Pavlik harness is the treatment of choice for infants and neonates with developmental hip dysplasia or dislocation. This device consists of a chest strap, shoulder straps, and anterior and posterior stirrup straps that maintain the hips in flexion and abduction while restricting extension and adduction (Fig. 33.2) [13].

Contraindications to the Pavlik harness include major muscle imbalance (e.g. myelomeningocele), major stiffness (e.g. arthrogryposis), ligamentous laxity (e.g. Ehlers–Danlos), patients older than 10 months of age, and lack of family support and care. The harness is worn until there are no positive findings on clinical, ultrasonographic, or radiographic

(A) (B)

Figure 33.2 Pavlik harness: (A) posterior and (B) anterior aspects.

examinations. If the hip remains unstable with use of a Pavlik harness, a hip abduction brace is recommended. Complications of the harness include inferior dislocation, femoral nerve palsy, and avascular necrosis of the hip from excessive hip flexion [14].

An abduction orthotic is an alternative for infants who are more than 9 months of age. This maintains abduction while allowing the child to walk. Skin traction is recommended for older infants who have a dislocated hip and have failed to improve with a Pavlik harness or for children more than 9 months old. Skin traction is followed by adductor tenotomy, closed reduction of the abnormality, and spica cast application [15]. Children more than 2 years old are treated with primary femoral shortening, open reduction of the hip, capsulorrhaphy (suture of capsule tear in order to prevent dislocation), and pelvic osteotomy [16,17]. The decision to perform open reduction of the hip is made in the operating room after arthrography and failed closed hip reduction [18].

Preoperatively, it is important to identify co-morbid conditions or underlying bone pathology that may affect the overall anesthetic. Baseline laboratory studies, such as complete blood count, chemistry, and coagulation studies, are not necessary for healthy children but will help identify abnormalities if co-morbidity exists. Intraoperative anesthesia technique includes general anesthesia with the possible addition of regional anesthesia during correction of hip pathology, if no contraindications exist. Spinal or epidural anesthesia may help with postoperative pain control in inpatients. If an epidural catheter is placed, care must be taken to cut a hole posteriorly in the spica cast so that the catheter can be removed from the patient. While the child is being placed in a spica cast under anesthesia, care must be taken during cast application to ensure that the arms are supported and head and neck are in alignment to prevent injury to major nerves. Postoperatively, oral pain medication can include acetaminophen, opioids, and short-term non-steroidal anti-inflammatory drugs (NSAIDs).

KEY POINTS: HIP DYSPLASIA

- Diagnosed at birth (ideal): Pavlik harness, serial ultrasounds, no surgery
- Older than 10 months: hip abduction brace, closed hip reduction with spica; if surgery then skin traction, adductor tenotomy, closed reduction of abnormality, spica cast
- Older than 2 years: primary femoral shortening, open reduction of the hip, capsulorrhaphy, pelvic osteotomy
- Surgical decisions in the operating room should be made with arthrography if closed hip reduction has failed
- Anesthesia: consider intrathecal or epidural for osteotomy postop pain

Spica cast

Spica casts create stability and immobilize femoral fractures or hip abnormalities (Fig. 33.3).

Contraindications to these devices include unacceptable shortening or angulation of the lower extremities, open fractures, thoracic or intra-abdominal trauma, and large or obese children [19]. Anesthesia is usually required to apply a spica cast. Fluoroscopy is used to determine optimal position, i.e. the affected limb or hip is placed in mild abduction. Too much abduction results in lateral bowing of the femur due to pull of the adductors. The degree of hip flexion, hip adduction, and external rotation depends on the location of the femoral fracture or hip abnormality [20]. A folded towel is placed on the anterior thorax and abdomen and padding and casting material are placed over the towel. When the towel is removed (after the cast is applied) this creates space between the cast and the thorax/abdomen, allowing for free breathing. Two layers of stockinette are placed to ensure that the cast padding can be pulled over the edges of the cast. Gore-Tex™ soft wrap

(A) (B)

Figure 33.3 (A) Spica cast table and (B) with a child on the table.

is often applied prior to applying a thick felt belt across the chest, sacrum, posterior superior iliac spine, and anterior superior iliac spine. The casting material is often placed over the non-affected side for stability. A wooden stick is placed between both legs and covered in cast material. This reinforces the cast and prevents breakdown of the cast at the hip joint. In small children, spica casts are applied while the child is on a portable, elevated, narrow table that provides very little head support.

The goals of anesthesia during cast placement include hemodynamic stability, appropriate amnesia and analgesia, and safe positioning of the patient. The choice of anesthetic technique is dictated by the patient's health status and by any coexisting disease. With elevation of the patient off the operating room table, vigilance is required to assure that the upper extremities and neck are in alignment with the long axis of the body to prevent nerve injury and paralysis.

Blount disease

Blount disease is a growth disorder of the medial aspect of the tibia in children. It causes the legs to bow outwards below the knees [21]. Normal infants have a small amount of physiological bowing that usually resolves by 2 years of age. In Blount disease the legs remain bowed, and the inner surface of the legs bulge outward just below the knee. A metaphyseal–diaphyseal angle greater than 11° is more indicative of Blount disease [21]. The toes also begin to point inwards as internal tibial rotation and asymmetrical leg shortening develop. Most patients are healthy, without congenital abnormalities, and may not experience much pain. If pain is present, it is usually related to the knee joints.

Blount disease usually affects children younger than 4 years old, in which case it is called infantile tibia vara. Adolescent tibia vara occurs after 4 years of age. Blount disease is more common in Africa, the West Indies, and Finland. Sixty to 70% of cases are bilateral and symmetrical [22]. Risk factors for Blount disease include female sex, African-American race, obesity, early age at walking, and a positive family history for this problem. The cause of Blount disease is unknown but may be related to a combination of genetic, environmental, and mechanical factors [23]. The medial aspect of the growth plate fails to develop properly, while the lateral aspect grows normally. This results in deviated growth of the tibia. If untreated, the disease results in the onset of osteoarthritis in the third decade of life. In the USA, the estimated prevalence of infantile Blount disease is less than 1% and adolescent disease is 2.5%. The disease is non-existent in non-ambulatory people. Adolescent tibia varus differs from Blount disease in that patients with varus complain more about knee pain, have unilateral involvement in 80% of cases, have shortened leg length, and may be obese [24–26].

Under 2 years of age, observation of the patient and follow-up with an orthopedic surgeon are recommended to distinguish physiological bowing from abnormal bowing. If bowing persists during ages 2–4 years, orthotic braces from the top of the thigh to the tips of the toes are recommended [27]. In children with severe bowing or who are more than 4 years of age, osteotomies of the tibia and occasionally the fibula are most commonly performed to correct the misalignment [28]. Other operative treatments include removing the epiphysis to stop abnormal growth or an osteotomy followed by external fixation [29,30]. If treated early, patients develop fully functioning lower limbs and have no limitations of movement. Complications of treatment include loss of alignment of lower extremities, vascular impairment, pathological fractures, and wound infection.

Preoperatively, the anesthetic implications of existing comorbidities must be considered. Concurrent obesity may lead to airway difficulties, respiratory problems, obstructive sleep apnea, increased risk of aspiration, and difficulty inserting an intravenous catheter. Intraoperatively, both general and regional anesthesia can be utilized if they are not contraindicated. Fat or venous air embolism must always be suspected if acute decompensation in the patient's condition occurs during surgery. Presenting symptoms of fat embolism under general anesthesia may include hypoxemia, petechial rash, and hypotension. Presenting symptoms of venous air embolism under general anesthesia may include decreased end-tidal carbon dioxide and hypotension. Surgical blood loss is usually minimal. Postoperatively, it is important to perform a neurovascular examination to make sure that no important

vascular or neural structures were damaged during corrective repair. Pain control can be managed with intravenous patient-controlled analgesia or regional blocks. Obesity with or without the diagnosis of obstructive sleep apnea puts the patient at increased risk of respiratory depression with opiates. NSAIDs such as ketorolac and ibuprofen in addition to acetaminophen can be administered around the clock to minimize the cumulative dose of opiates.

KEY POINTS: BLOUNT DISEASE

- Associated with obesity/obstructive sleep apnea with increased risk of respiratory depression with opiates
- Fat or venous air embolism risk

Slipped capital femoral epiphysis

Slipped capital femoral epiphysis (SCFE) consists of a defect of the proximal femoral growth plate, which causes instability of the femoral head. The femoral head is displaced posteriorly and inferiorly from the femoral neck. SCFE presents with hip, medial thigh, and knee pain. The range of motion of the hip is limited and causes a limp. The incidence of SCFE is 10.8/100,000 children. Higher rates of prevalence exist in males, African-Americans, Hispanics, and people who live in the west and north-east of the United States [31]. The average age of occurrence of SCFE is between 10 and 16 years. Twenty percent of patients have bilateral involvement. High-risk patients include those with obesity, hypothyroidism, low concentrations of growth hormone, pituitary tumors, craniopharyngioma, Down syndrome, renal osteodystrophy, and adiposogenital syndrome [32–34]. The left hip is affected more commonly than the right. Familial involvement is present in 5–7% of patients with SCFE. In patients younger than 10 years of age, SCFE is associated with metabolic endocrine disorders. Unstable SCFE produces a non-ambulatory patient and has a higher risk of avascular necrosis [35]. On physical examination, internal rotation of the affected leg is very painful.

Emergency treatment is necessary. If surgical correction is performed within 24 h of onset, the risk of avascular necrosis decreases. Immediate internal fixation with a screw is the treatment of choice [36]. Repair of SCFE permits early stabilization of slippage, prevention of further slippage, increased physeal closure, and improvement of symptoms [37]. The fixation may require revision if the child outgrows the screw. Prophylactic fixation of unaffected hips should only occur if patients have endocrine or metabolic conditions and are outside the usual age group of 10–16 years [38,39]. Osteotomy of the proximal femur may be required to reposition the femoral head and improve functional range of motion. Bone graft epiphysiodesis and internal fixation can be performed but may result in avascular necrosis, chondrolysis, poor initial fixation, prolonged operative time, increased intraoperative blood loss, and loss of epiphyseal position [40].

Preoperatively, a thorough history and physical examination elucidate significant co-morbidities that may affect anesthetic technique. Given that obesity has a high association with SCFE, one must evaluate and prepare for an obstructed airway, restrictive lung disease, and a difficult airway. Some obese patients also have type 2 diabetes. In rare cases hypothyroidism and renal osteodystrophy may also be present. Preoperative studies should include baseline hematocrit, serum electrolytes, and a type and screen for blood.

Intraoperatively, the patient may be placed supine or in lateral position. During positioning of the patient, care must be taken to avoid nerve compression or injury, especially in obese patients. The Chick fracture table (Fig. 33.4) or the Hana fracture table (Fig. 33.5) are often used and require careful padding and securing of the patient to the table. Access to the airway during surgery can be limited. Tracheal intubation is usually done prior to transfer to the fracture table both for patient comfort and better access to the head of the bed.

The choice of anesthetic technique is influenced by the patient's baseline health status and co-morbidities. General anesthesia, in conjunction with regional anesthesia if an open procedure is being done, may be performed if there are no contraindications to regional anesthesia. A one-time caudal injection of local anesthetic can be helpful; inserting caudal catheters is usually unnecessary. If the repair is achieved with pinning, pain control is generally good without regional block. If the patient is obese or has a difficult airway, a modified rapid-sequence induction may be considered. Third space fluid losses are usually 3–6 mL/kg/h. Blood loss is typically minimal. Postoperative pain is usually controlled with opioids and acetaminophen. Short-term NSAIDs may also be helpful and have not been shown to significantly affect epiphyseal growth.

KEY POINTS: SLIPPED CAPITAL FEMORAL EPIPHYSIS

- Obesity association: increased risk of respiratory depression with opiates and occurrence of obstructive sleep apnea
- Fracture table limits patient access
- Emergent case to decrease risk of avascular necrosis
- Internal fixation with a screw (pinning) is most common approach; open repair for complex SCFE

Hand surgery

Many different types of disorders that require hand surgery exist in childhood (Box 33.1). These include, but are not limited to, extra fingers (polydactyly), webbed fingers (syndactyly), missing fingers (symbrachydactyly – hand or arm deficiency), abnormal thumbs, stiff joints, and nerve and skeletal injuries [41,42]. The abnormalities range from mild to severe in their presentations. Given the complexity and variation of each deformity, only a few of them will be described in detail in this text. Although most hand malformations cause little functional deficit, surgery is usually performed within the first 2 years of life to improve growth and reduce scarring, and to reduce psychological trauma. Early surgery also improves adaptation to the use of the newly formed part [43].

Syndactyly surgery is performed after a child is 2 years old and growth of the hand has slowed [44]. Syndactyly is twice as common in boys as in girls and occurs in 1/2000 livebirths. It commonly affects the long and ring fingers [45]. Skin grafts may be required to close the defects caused by separation of the digits. About half of treated children return for surgery during adolescence for further cosmesis once the hand reaches full size [46]. Symbrachydactyly is a condition in which a child is born with small or missing fingers, a short forearm, or a missing hand. It is the most common form of hand or arm deficiency [47]. The cause is unknown and is not attributed to genetic inheritance. It is usually unilateral; muscular abnormalities may be present on the ipsilateral side. Although surgery is often not required, it can help to deepen the webs between the fingers and to stabilize the fingers when bone grafts are used. Thumb polydactyly has varying forms, ranging from a broad fingernail to complete double thumbs [48]. Reconstructive surgery sometimes combines parts of the two different thumbs to create one functional thumb. Surgery is usually delayed until the thumb is large enough to allow the surgeon to reconstruct the nerves, ligaments, and bone.

Trigger thumb occurs when a nodule on the tendon causes the thumb to jump or lock into a bent position with movement. This condition develops after birth and is present at 1 year in 3.3/1000 livebirths. Hand surgeons must evaluate and treat this condition promptly to prevent contracture, but 30% of these lesions resolve spontaneously. Treatment involves surgery to enlarge the tendon sheath and to allow the tendon to move more smoothly. This is performed usually between the ages of 1 and 3 years.

Radial club hand is a deficiency of the radius in the forearm. It occurs 1/30,000–1/100,000 livebirths and includes an absent or incomplete radius, absent or incomplete thumb, deviation of wrist toward the radial side, and some degree of neuromuscular deficiency. The cause of radial club hand is unknown, but it has been suggested that irradiation or environmental and nutritional factors may be involved. Radial club hand may be associated with other genetic syndromes such as VACTER (vertebral, anal, cardiac, tracheoesophageal, and renal anomalies), Holt–Oram syndrome (heart and hand syndrome), thrombocytopenia with absent radius syndrome, and Fanconi anemia [49]. Therefore a thorough investigation of other possible organ abnormalities must be undertaken. Treatment of radial club hand starts with splinting, casting, and non-surgical manipulation of the hand. If needed, surgery is typically performed between 6 months and 1 year of age. The procedure is called centralization/radialization of carpus on ulnar epiphysis, which relocates the hand over the

- Symbrachydactyly
- Syndactyly

ulna [50]. The affected limb is usually shorter than the contralateral limb after this repair. If too severe, a procedure can be done between 6 and 8 years of age to lengthen the extremity. If the thumb is absent or underdeveloped, the hand surgeon can also make the index finger into a thumb ("pollicization") to allow grasping.

Preoperative evaluation consists of gathering information about other possible co-morbidities and evaluating the child's maturity and social environment. All may affect the type of anesthesia chosen. For example, it must be determined if children with congenital hand deformities have associated heart, lung, kidney, or airway problems that must be addressed. If there are vascular malformations of the hand, one must be suspicious that there are other vascular malformations (e.g. oropharyngeal) and that the child may have a high output state and heart failure. In trauma, full stomach aspiration risks need to be addressed. The child's maturity will also dictate whether a procedure should be performed with sedation or local anesthesia, with or without general anesthesia. If the surgery is elective or semi-urgent, laboratory tests are performed if anemia or coagulopathy is suspected. If other co-morbidities exist, an electrocardiogram and chest x-ray should be considered if indicated. A baseline neurovascular examination should be performed to evaluate sensation and perfusion to the affected hand. The findings of the examination should be documented in the anesthetic record.

Intraoperatively, combined regional and general anesthesia has been shown to improve postoperative recovery and decrease the need for postoperative analgesics. Most children who undergo surgery require general anesthesia. Small cases, such as distal fingertip amputation, can be performed with local anesthesia and sedation if the child is cooperative. More extensive cases are amenable to using a combined regional and general anesthetic if there are no contraindications. Contraindications to peripheral blocks include hand infection, generalized sepsis, coagulopathy, predisposition to compartment syndrome, parental/child dissent, or the surgeon's need to perform an immediate postoperative examination of the extremity [51].

The nerve supply to the hand includes three major branches of the brachial plexus (Table 33.1). The median nerve originates from the lateral and medial cords of the brachial plexus (C5–T1). It innervates the muscles involved in pinching and grasping (i.e. flexor carpi radialis, palmaris longus, flexor digitorum superficialis, flexor pollicis longus, flexor digitorum profundus, and pronator quadratus). It provides sensation to the lateral aspect of the palm, including the thenar eminence and the distal ends of the first three and a half fingers dorsally. The ulnar nerve originates from the medial cord of the brachial plexus (C8–T1). Motor branches innervate the flexor carpi ulnaris, flexor digitorum profundus, and the hypothenar muscles. This nerve provides sensation to the medial dorsal aspect of the hand and to the last one and a half fingers. The radial nerve originates from the posterior cord of the brachial plexus (C6–8) and innervates the wrist extensors and provides sensation to the lateral dorsal aspect of the hand and proximal portion of the first three and a half fingers (Fig. 33.6) [131].

Regional anesthetic techniques appropriate for hand surgery include Bier block (intravenous local anesthetic), axillary block (Fig. 33.7), infraclavicular block, wrist block, elbow block, and digital block (Table 33.2) [51]. Of these, the infraclavicular block is best suited to catheter placement because the area is generally cleaner, and it is easier to secure the catheter. Regional anesthesia is relatively contraindicated in children less than 1 year old due to systemic local anesthetic toxicity. It may also be contraindicated in children susceptible to tourniquet injury (e.g. osteogenesis imperfecta). Most hand surgery requires use of a tourniquet, which is associated with hyper/hypotension and respiratory and lactic acidosis from repeated inflation and deflation of the tourniquet. If not properly applied, tourniquets can lead to paralysis, sensory loss, excessive edema, skin problems, and muscle damage. Chapter 20 presents a detailed discussion of regional anesthetic approaches to the brachial plexus including ultrasound-guided techniques.

Postoperatively, it is important to determine if there are new or worse neurovascular deficits. Pain can be controlled with residual regional anesthetic, intravenous patient-controlled analgesia, and oral medication.

Supracondylar femur fractures

A supracondylar fracture represents 12% of femoral fractures in children and is the most common femur fracture in infants less than 1 year old, often due to non-accidental trauma (child

Figure 33.7 This patient with thumb polydactyly is undergoing an axillary nerve block.

Table 33.2 Regional anesthetic techniques appropriate for hand surgery

Block	Technique details
Bier block (intravenous local anesthetic)	Limited use in pediatric patients due to volume of local anesthetic needed to achieve surgical anesthesia Provides little postoperative analgesia
Axillary block	Effective block due to the proximity of axillary artery to median, ulnar & radial nerves Musculocutaneous nerve spared Not amenable to catheter placement
Infraclavicular nerve block	Brachial plexus block at the level of all three cords Stable location for catheter placement
Forearm blocks	Include radial, ulnar and median nerve blocks Anesthetize proximal palmar and dorsal cutaneous nerves of the hand Spare flexors/extensors of the arm at the elbow

abuse) [54]. Although the incidence is slightly less, it is still very common at ages 1–4 years. The American Academy of Orthopedic Surgeons recommends screening children younger than 36 months of age with femoral shaft fracture for non-accidental traume. In adolescents, motor vehicle accidents (cars, bicycles) are the leading cause of femoral shaft fractures. Other causes of femoral shaft fracture include falling hard on the playground and in contact sports. Fractures are described by location, shape of fractured ends, and number of fractured parts [55].

Non-surgical treatment of some femoral fractures includes closed reduction, a Pavlik harness, or spica casting (see earlier) [56]. Pathological bone is often treated with closed methods, due to abnormal bone fragility. Closed reductions are often done under sedation, but the child may require general anesthesia if they are uncooperative or the defect is extreme. Pavlik harnesses are soft restraints that go around the patient's shoulders and body and hold the hips in a flexed position. Spica casts typically begin at or below the nipple line of the chest and extend to slightly beyond the fracture or defect [57]. They hold the broken bone in alignment while it heals. The broken bones should not overlap by more than 2 cm when in the cast. Increased growth of the damaged femur will overcome the initial shortening caused by the overlap [58]. If casting causes greater than 3 cm shortening or misalignment of the bones, traction may help to align the bones properly. Children who are older, large, or obese and have multiple trauma, head injury, and/or soft tissue damage usually require operative fixation of the bones.

Recently, there has been a trend towards more surgical stabilization than in previous years, due to earlier mobilization, faster rehabilitation, and less time spent in hospital [59]. Flexible intramedullary nails are used in 6–10-year-old children [60]. If the bone is broken into many pieces (comminuted), other options include a plate with screws to bridge the fracture, an external fixator, or prolonged traction with a temporary pin in the femur [61]. Once skeletal maturity is achieved (about 11 years of age), there is less risk of vascular compromise to the growth plate. Treatment options at this point include flexible or rigid locked intramedullary nails. Rigid locked intramedullary nails allow walking immediately. Most children with femoral shaft fractures will heal, regain normal function, and have legs of equal length. The intramedullary nails may need to be removed after healing if skin or tissue irritation occurs [62]. If there is significant leg length discrepancy, angulation or rotation of the leg, or if infection or non-union persist, further surgical intervention will be required [63].

Preoperatively, it is important to note the mechanism of injury, as this may provide clues to other associated injuries (e.g. neck or skull injury). Conditions associated with bone fragility require care in positioning the patient, care in the use of non-invasive versus invasive blood pressure monitoring, and care in the use of a tourniquet. In addition to thorough airway, respiratory, and cardiovascular examinations, it is important to perform and document a neurovascular examination that will provide the baseline for evaluating postoperative changes. A preoperative hematocrit and a type and cross-match of blood should be obtained because hemorrhage can occur into the thigh with femur fractures.

Intraoperatively, either general or regional anesthesia may be used to provide anesthesia. Spinal anesthesia works well in older, cooperative children if there are concerns for a full stomach or a difficult airway. Peripheral nerve blocks plus general anesthesia work well, but a thorough discussion with the surgeon should take place beforehand, as there is a high risk of compartment syndrome (which can be masked by a nerve block) and coagulopathy. Adequate intravenous access must be present for infusing fluid and blood products. Depending on the location of the fracture and the size of the patient, a tourniquet may be used to limit the amount of blood loss. The anesthesiologist must be prepared for the hemodynamic changes that are sometimes associated with using a tourniquet. Fat and venous air embolism from bone manipulation may also cause adverse hemodynamic effects. Postoperatively, patients are typically placed into casts to stabilize the fracture site. Opioids and acetaminophen are usually adequate for pain control.

KEY POINTS: SUPRACONDYLAR FEMUR FRACTURE

- Preoperative hemoglobin, blood type, and cross-match packed red blood cells
- Tourniquet to limit blood loss
- Preoperative neurovascular exam; may limit regional anesthesia options
- Fat/venous air embolism risk

Septic arthritis

Septic arthritis usually occurs in the first 3 years of life or during teenage years (gonococcal infections). Septic arthritis is a true clinical emergency because it can have serious implications for future joint mobility and organ dysfunction [64]. Pain with passive motion is the most common finding on physical examination. Prior to the introduction of antibiotics, septic arthritis was often severely incapacitating and/or fatal [65]. *Haemophilus influenzae* type b (Hib) was previously the most common causative organism associated with septic arthritis but since the institution of Hib vaccination in the 1970s, *Staphylococcus aureus* is now the foremost culprit [66,67]. Other less common pathogens include *Streptococcus* species, *Pseudomonas aeruginosa*, pneumococci, *Neisseria meningitidis*, *Escherichia coli*, *Klebsiella* species, and Enterobacter. Newborns can acquire *Neisseria gonorrhoeae* from an infected birth canal. *Kingella kingae*, a fastidious aerobic gram-negative micro-organism, has rapidly become a formidable pathogen that is difficult to grow in culture but must be suspected and treated, if septic arthritis is present, in children aged 3 years and younger [68].

Septic arthritis may develop after a penetrating wound or from trauma, surgery, or adjacent cellulitis. However, the most common cause is hematogenous spread from transient bacteremia. Usually in healthy individuals, the bacteremia is quickly eliminated by intrinsic immune defense mechanisms. In immunocompromised and extremely young patients (neonates), the defense mechanisms are too overwhelmed or immature to eliminate the infection. Developing pediatric bone has vascular loops that provide nutrients to the metaphyseal side of the growth plate. The blood supply to this area is relatively slow, and the growth plate is not well covered by the reticuloendothelial system. This leaves the area vulnerable to infection. From 0 to 18 months of age, an abscess in the metaphyseal area may spread into the epiphysis through blood vessels that cross the cartilaginous physis and enter the joint. Those blood vessels disappear after 18 months of age. An abscess in the metaphyseal area will only cause septic arthritis in the areas where the joint capsule is attached to the metaphyses, such as the hip, shoulder, ankle, and elbow joints [65].

Once in the joint, the pathogens and the counteracting leukocytes release proteolytic enzymes that degrade the articular cartilage. Damage can occur in as little as 8 h. The synovial membrane becomes edematous and hypertrophied and produces increased amounts of exudative fluid and pus. Increased pressure within the joint can interrupt the blood supply to the epiphysis. This causes bone destruction, loss of adjacent growth plate, dislocated joints, and injury to the capsule ligament. Rupture of the synovium can lead to extracapsular infections, such as myositis, soft tissue abscesses, and bacteremia.

Presenting symptoms that should make one suspicious of septic arthritis include fever, malaise, erythema, swelling, and tenderness of the joint. Pain with passive motion of the joint is the most common finding. As in the hip, the child will hold flexion, abduction, and external rotation to diminish pain and increase intracapsular volume. Refusal to move the affected joint is called pseudoparalysis, which can be mistaken for a neurological problem. Differential diagnosis of septic arthritis includes, but is not limited to, juvenile rheumatoid arthritis (more gradual onset), Legg–Calvé–Perthes disease (avascular necrosis of the proximal femoral head), Lyme disease, mycobacterial or fungal infections, abscess of the psoas muscle (presents with bladder irritability or a femoral nerve neuropraxia [69]), or transient synovitis from a self-limiting viral infection, mostly involving the hip [70]. A high index of suspicion must be present for neonates and immunocompromised patients, as they can have multiple sites affected without fever and without an elevated white blood cell count [71].

Septic arthritis is a true surgical and/or procedural emergency. Aspiration of the joint in the emergency room, interventional radiology suite, or operating room must be accomplished quickly to insure prompt diagnosis and appropriate therapy. Typically these cases are completed within several hours of being scheduled. Frequently it is necessary to keep the child anesthetized while a gram stain and initial pathological evaluation of the aspirated fluid are performed. Treatment includes appropriate antibiotic therapy and drainage of the affected joint to prevent degradation of joint and bone. Open drainage of the joint is more effective than percutaneous aspiration and is indicated if the hip, shoulder, and peripheral joints fail to respond to percutaneous aspiration. Open drainage is also indicated for patients with systemic illness, *Staphylococcus aureus*, and gram-negative bacteria that produce cartilage-destroying enzymes. Patients with pus in fascial layers have a high mortality rate, as these pockets of infection can lead to venous thrombosis.

Preoperative assessment includes assessment for comorbidities. Patients can be quite ill with multiple manifestations of sepsis. Hematogenous spread of bacteria can cause lung involvement that manifests as pleural effusion, pneumatoceles (lung abscesses), pneumothorax, wheezing, inflammation, and edema-induced stridor. If respiratory symptoms present, a chest x-ray may help to identify the problem. Cardiac involvement includes pericardial effusion, myocarditis, endocarditis, and pericarditis, which can all limit cardiac function. An echocardiogram is recommended for patients with congenital defects, unresolved fever, or prolonged bacteremia without a known source. Renal function may be affected through hematogenous spread of infection, decreased intravascular volume, or medication-induced injury. Baseline laboratory studies and a coagulation profile are helpful as they can be adversely affected by infection. Chronically ill anemic patients may require blood transfusions. Platelets and coagulation factors may be decreased. Disseminated intravascular coagulation is a major complication of dispersed infection so blood products should be available prior to surgery and administered if needed. Adequate venous access must be available for giving volume support, blood products, and inotropes if necessary.

Shoulder or neck septic arthritis may cause cervical ligamentous laxity that can cause C1–2 subluxation during tracheal

intubation. Intravascular volume must be repleted prior to induction of anesthesia to avoid hypotension. Chronic illness-induced decreased concentrations of intrinsic catecholamines may also cause acute decompensation of vital signs with induction of anesthesia. Intraoperative manipulation of the infected joint during surgery may release pathogens and their toxins into the bloodstream and produce acute hemodynamic changes. General anesthesia is typically required for these types of surgeries because regional anesthesia may obscure a possible compartment syndrome or lead to a new infectious point of entry/spread or a hematoma if coagulation abnormalities exist. Although positive pressure ventilation may predispose to pneumothorax and decreased venous return, it is still preferred over spontaneous ventilation, which may be associated with breath holding, laryngospasm, and bronchospasm.

Intraoperatively, the choice of anesthetic drugs can vary. Ketamine should be avoided for induction of anesthesia if catecholamine stores are depleted or are suspected to be depleted, as this can cause hypotension after induction of anesthesia. Succinylcholine should also be avoided if renal dysfunction and chronic illness exist because hyperkalemia can lead to significant injury and/or death.

Postoperatively most patients improve quickly after drainage and removal of infectious material. Fluid, blood products, and inotropes should be continued if needed. Pain is controlled with opioids and acetaminophen. NSAIDs are avoided when renal dysfunction or abnormal coagulation status is present. Although chronic NSAID use has been suggested to inhibit osteogenesis, new evidence indicates that perioperative use of these drugs for 48 h use may not significantly affect osteoblasts and bone formation. This should be addressed with the surgeon on a case-by-case basis.

KEY POINTS: SEPTIC ARTHRITIS

- Emergent drainage or surgery to preserve the joint
- Aspiration of joint for diagnosis
- Often remain anesthetized while awaiting gram stain
- If gram stain is positive usually use open incision and drainage
- Possible sepsis and hemodynamic instability
- Neonates and immunocompromised are the most susceptible

Osteogenesis imperfecta

Osteogenesis imperfecta (OI), also called brittle bone disease, blue sclera syndrome, fragile bone disease, and Lobstein disease, is a relatively common skeletal dysplasia. It has long been documented in human history and was found in a partially mummified infant's skeleton from Egypt. Oral historians believe that a Viking chieftain named Ivan the Boneless (865 AD) may also have had the disease (Fig. 33.8).

Osteogenesis imperfecta is most commonly identified by three characteristics: blue sclerae, bone fragility, and hearing loss. Less common symptoms include triangular facies, macrocephaly, defective dentition, barrel chest, scoliosis, joint laxity, growth retardation, constipation, and sweating. Type 1 collagen is an important component of bone, ligament, dentin, and sclera. In OI, there is a decrease in either quality or quantity of type 1 collagen. Most cases of OI are autosomal dominant mutations of the genes encoding type 1 collagen [72]. Quantitative defects typically cause mild clinical disease, while qualitative defects cause severe clinical disease.

Figure 33.8 Child with osteogenesis imperfecta. Note abnormal chest and extremities.

Osteogenesis imperfecta (types I–IV) occurs in 1/20,000 births. There is no predilection for OI by race, gender, or age. More severe forms present at a younger age [73]. Types I and IV have milder clinical presentations, while types II and III are more severe (Table 33.3).

Recently, bisphosphonates have been used to increase bone mass and strength. Intravenous pamidronate, a synthetic analog of pyrophosphate, inhibits osteoclast-mediated bone resorption on the endosteal surface of bone by binding to hydroxyapatite. This allows unopposed osteoblastic new bone formation on the periosteal surface and increases cortical bone thickness. Bisphosphonates decrease the number of fractures by increasing bone mineral density [74]. This decreases bone pain and increases height. Physiotherapy, in conjunction with bisphosphonate therapy, promotes gross motor development and maximizes function. Adverse effects of bisphosphonate therapy include acute febrile reaction, leukopenia, a transient increase in bone pain, mild hypocalcemia, and scleritis. Other medical therapies under investigation include growth hormone, a recombinant human form of parathyroid hormone, bone marrow transplantation, and gene therapy.

Orthopedic goals for osteogenesis imperfecta include improving strength and preventing fractures. The aim of surgical intervention is to improve function [75]. Release of lower limb contractures improves mobility. Bony deformities and fractures are treated with intramedullary stabilization with or without corrective osteotomies [76]. Rods, pins, and wires are preferable to nails, plates, and screws as the former are less frequently associated with bone fractures. Complications of rods include breakage, rotational deformities, and migration.

Table 33.3 Osteogenesis imperfecta

	Clinical features	Bone fragility	Presentation
Type I	Blue sclera Normal birthweight Moderate bone deformity	Variable degree of bone fragility Fracture onset when child begins to walk Fractures may diminish with puberty	Mildest form Up to 20% have scoliosis May have dentinogenesis imperfecta
Type II	Blue sclera Dwarfism Bowed limbs at birth	Multiple fractures at birth	Most severe form Usually fatal during perinatal period (either at birth or shortly after)
Type III	Blue sclera (become white in adulthood) Short stature Bowed limbs Wheelchair bound May have mild pectus carinatum	Severe bone fragility Bone fractures at birth Progressively deforming	Severe presentation Dentinogenesis imperfecta Chest and rib cage involvement spared
Type IV	White sclera	Mild to moderate bone fragility	Milder severity Kyphoscoliosis common

Table 33.4 Preoperative considerations in osteogenesis imperfecta

Organ system	Clincial features	Consideration
Airway: potential for difficult airway	Short neck Macrocephaly Macroglossia Fragile dentition Decreased neck mobility	Consider x-ray of craniovertebral junction if symptoms of upper cervical cord compression are present (odontoid complex)
Pulmonary	Chest wall deformities may result in restrictive lung disease	Consider chest x-ray and pulmonary function tests
Cardiovascular	Rare, usually related to aortic root dilation causing aortic insufficiency	Echocardiogram indicated if murmur present, suspicion/known aortic insufficiency
Hematological: increased risk for bleeding diathesis	Abnormal collagen on platelet–endothelial cell interaction Increased capillary fragility Defective platelet aggregation Defective contraction of small blood vessels	Normal prothrombin time Normal partial thromboplastin time Platelet count may be normal Abnormal platelet function

With the use of bisphosphonates, non-extendable rods are being used more often than extendable rods [77]. Posterior spinal arthrodesis is preferable to ineffective bracing for scoliosis. Arthrodesis is done in mild OI patients with greater than 45° curvature or in severe OI with greater than 35° curvature.

Preoperatively, it is important to identify the type of OI and the severity of clinical symptoms. Often the patient has required previous medical care. Lung function may be restricted due to chest wall deformities. A chest x-ray and pulmonary function tests, although not required, may help predict postoperative respiratory failure. Airway examination includes neck mobility, dentition, and mouth opening, as there may be a high likelihood of difficult tracheal intubation due to a short neck, macrocephaly, macroglossia, and fragile dentition. Ventral brainstem compression by an invaginating clivus–odontoid complex may further make tracheal intubation difficult. Therefore, evaluation of the patient for symptoms of upper cervical cord compression and x-rays of the craniovertebral junction may help prevent injury. Cardiovascular abnormalities, although not significantly increased in comparison to healthy individuals, are usually related (when present) to aortic insufficiency caused by aortic root dilation. If a murmur is present or suspicion of aortic insufficiency is high, echocardiography is indicated. Patients with OI have an increased risk for bleeding diathesis [78]. The abnormal collagen on platelet–endothelial cell interaction results in increased capillary fragility, defective contraction of small blood vessels, and defective platelet aggregation. Typical coagulation studies (prothrombin time (PT) and partial thromboplastin time (PTT)) will be normal but platelet function will be abnormal. Patients at risk should avoid NSAIDs for at least 7 days preoperatively (Table 33.4).

Intraoperatively, care must be taken to position and pad the patient so no further fractures occur. Non-invasive blood pressure monitoring may cause fractures [79] so less frequent monitoring or invasive arterial blood pressure monitoring is preferred. Tourniquets may produce fractures and should be placed on top of a soft material, such as Kerlix™ or Coban™. Facemasks may damage fragile mandibles and maxillae. Laryngeal mask airways have been used successfully in lieu of facemasks to prevent facial fractures. Tooth guards are used when patients have fragile dentition. The increased incidence of difficult tracheal intubation warrants having a wide variety of airway equipment immediately available, including multiple sizes of tracheal tubes, multiple laryngoscope blades, gum elastic bougies, laryngeal mask airways, video laryngoscopy, and fiberoptic laryngoscopes. See Chapter 16 for additional discussion of management of the difficult airway.

Hyperthermia and lactic acidosis have occurred in patients with OI, possibly from an increased metabolic rate or associated hyperthyroidism. Hyperthermia is more often associated with the administration of anticholinergic drugs and with inhaled anesthetics. A cooling blanket should be used to treat

hyperthermia. Succinylcholine is avoided due to the theoretical risk of fasciculation-induced fractures.

Postoperatively, patients may also have febrile responses from the increased metabolic rate or hyperthyroidism. Because these patients suffer from chronic pain, they should be treated with their baseline opioid plus adjuvant pain medications, as needed. The patient's respiratory status should be carefully evaluated postoperatively to detect obstruction that is caused by residual anesthesia or by decreased hypercapneic-hypoxic respiratory drive from restrictive lung disease. Caution must be exercised during transfer from one bed to another to prevent additional fractures occurring.

KEY POINTS: OSTEOGENESIS IMPERFECTA

- Difficult airway potential
- Restrictive lung disease
- Careful padding and positioning
- Blood pressure cuff and tourniquets can fracture bones
- Increased metabolic rate/hyperthyroidism
- Hyperthermia and lactic acidosis reported

Arthrogryposis

Arthrogryposis is a clinical finding that can be separated into two groups: arthrogryposis multiplex congenital (AMC) and distal arthrogryposis syndromes (DAS). AMC is more severe and tends to involve multiple joints and to have other coexisting syndromes and diseases. It is present in 1/3000 livebirths and is more common in isolated populations such as in Finland and the Bedouin community in Israel [80]. Males and females are affected equally. Thirty percent of cases have a genetic abnormality [81].

The major cause of arthrogryposis is fetal akinesia (decreased fetal movement *in utero*) [82]. The etiologies of arthrogryposis are many, often unknown, and include neurogenic, muscular, connective tissue abnormalities, mechanical limitations, or maternal factors such as infection, drugs, trauma, and other illnesses. Malformations of the central and peripheral nervous systems are the most common cause of arthrogryposis [83]. Decreased fetal movement can also cause polyhydramnios, pulmonary hypoplasia, micrognathia, ocular hypertelorism, and short umbilical cord. Lack of fetal movement results in the development of extra connective tissue around the joints, which limits joint movement and fixes it in a contracted state [84]. Half of patients with associated central nervous system abnormalities die within the first year. Infants born to mothers with myotonic dystrophy, myasthenia gravis, or multiple sclerosis are at high risk for developing resistant contractures. Exposure of mothers to hyperthermia, such as hot tubs or prolonged hot baths, can cause abnormal nerve growth and decreased fetal movement.

Patients with arthrogryposis have cylindrical extremities, decreased subcutaneous tissue, and absent skin creases. Defects are symmetrical and are more severe distally in the hands and feet. Joint dislocation may occur in the hips and knees [85]. Sensation is present but deep tendon reflexes may be decreased or absent. Limb malformations include deletion anomalies, radioulnar synostosis, syndactyly, and short digits. Deformities associated with fetal akinesia include intrauterine growth retardation, pulmonary hypoplasia, short gut syndrome, scoliosis, genital deformities, and hernias (both inguinal and umbilical). Congenital cardiac anomalies and cardiomyopathy may be present. The genitourinary system may have structural abnormalities. Musculoskeletal abnormalities include decreased muscle mass, soft muscle texture, fibrous bands, and abnormal tendon attachments. The skin is often soft, doughy, and thick with webs and dimples over affected joints.

Goals of orthopedic treatment for arthrogryposis are lower limb alignment, stability for ambulation, and upper limb function for self-care [86]. Early gentle manipulation of the contractures after birth helps passive and active range of motion [87]. Physical therapy is indicated for most forms of arthrogryposis but recurrence of the contractures can be high following stretching, necessitating surgery. Soft tissue surgery should be undertaken early and osteotomies performed when growth plates have fused. The most common deformity in the foot is a rigid talipes equinovarus deformity. The goal is to make the foot plantigrade and braceable. Casting often fails early on and typically the patient has to undergo an extensive medial and lateral release of ankle tendons with postoperative bracing. Recurrence of talipes equinovarus is common and other procedures, such as lateral column shortening (distal calcaneal resection), may be required. In an older child in whom the bone is skeletally mature, a triple arthrodesis (fusion of talocalcaneal, talonavicular, and calcaneocuboid joints) is performed. In the knees, flexion deformities are more common than fixed knee deformities and are more resistant to treatment. Moderate contractures of between 20° and 60° require soft tissue release with posterior capsulotomies. Severe contractures of greater than 60° may require femoral shortening in addition to soft tissue release. Older children with severe deformity may require a knee disarticulation. Extension deformities, if unresponsive to physical therapy, will need quadricepsplasty if the child is younger than 6 months of age.

Hip deformities should be addressed after foot and knee deformities have been corrected [88]. Intervention to improve the hip should take place before 1 year of age to make ambulation easier. Hip flexion greater than 35° requires soft tissue release. Bilateral hip dislocations that exceed 35° and the presence of a flexion contracture should be treated with soft tissue release but no reduction [89]. Unilateral hip dislocation requires reduction to avoid the development of scoliosis and pelvic deformity. Upper extremity surgery should be done when the patient is older than 5–6 years. With elbow contractures, the goal is to make possible arm flexion for feeding and extension for hygiene needs. Extension is corrected with either a capsulotomy or capsulotomy plus triceps or pectoralis major transfer. Wrist deformities are usually flexed with ulnar deviation [90]. A severe deformity requires proximal row carpectomy with or without fusion. For severe finger deformities, soft tissue releases and proximal interphalangeal fusions are done. In scoliotic spines, curvatures greater than 35° are treated with spinal fusion.

Preoperatively, any co-morbid conditions that would affect an anesthetic must be identified (Table 33.5). Intraoperatively, care with positioning and tourniquet use is needed, as these children have osseous hypoplasia and are prone to fractures.

Table 33.5 Anesthesia implications in arthrogryposis (consider etiology – neurogenic versus muscular)

Organ system	Clinical features	Consideration
Airway	Limited jaw motion Micrognathia Craniofacial anomaly Laryngeal/tracheal cleft Airway stenosis High arched palate	Difficult airway preparation
Vertebral instability	Hypoplastic cervical vertebrae C1/C2 Decreased muscle mass	Videoscope, fiberoptic bronchoscope, or direct laryngoscopy with midline neutral stabilization Minimize neck extension/flexion
Pulmonary	Scoliosis /restrictive lung disease Hypoplastic diaphragm	Consider chest x-ray and pulmonary function tests
Cardiovascular	Cardiomyopathy Congenital anomalies	Echocardiogram
Neuromuscular junction upregulation	Decreased muscle mass	Increased sensitivity non-depolarizing muscle relaxants Hyperkalemia with succinylcholine
Hyperthermia (10% incidence)	Hypermetabolic Typically unrelated to malignant hyperthermia (MH) unless underlying etiology is susceptible to MH (e.g. King–Denborough, central core disease)	Cooling blankets Avoid triggers if MH
Genitourinary anomaly	Structure and function	Basic metabolic panel Decreased metabolism and excretion of anesthetic drugs
Contractures Decreased subcutaneous tissue "Doughy" skin Gastrointestinal reflux	Difficult IV access Difficult regional block access	Careful positioning Foam padding

Intraoperative hyperthermia is usually caused by hypermetabolism, not malignant hyperthermia (MH), unless there is an underlying predisposing neuromuscular disorder like King–Denborough [91]. Hyperthermia occurs regardless of the type of anesthetic used. A cooling blanket should always be available. There are controversial, anecdotal case reports of MH in patients with arthrogryposis. The majority of temperature increases are not MH and respond to cooling blankets. Due to the extensive list of etiologies for arthrogryposis that are often undiagnosed, one should remain vigilant for hyperthermic events that do not respond to cooling and consider other diagnostic criteria for MH and proceed with treatment. Challenging the traditional belief that arthrogryposis patients have an increased incidence of hyperthermia, a recent retrospective review of 369 arthrogryposis anesthetics (264 AMC, 105 DAS) reported a similar incidence of hyperthermia in the AMC (10%) and DAS (11%) groups. However, the AMC anesthetics were also compared with matched controls without arthrogryposis (n = 222) and showed no increased incidence of hyperthermia compared with AMC cases [92].

Choice of anesthetic agent depends on co-morbid conditions. Ventilation may be affected by scoliosis-induced restrictive lung disease. Pneumothorax, during either spontaneous or mechanical ventilation, may be the result of pulmonary hypoplasia. Postoperatively, there is an increased risk of aspiration when the cause of arthrogryposis is neurogenic or muscular. Therefore, full return of baseline neuromuscular function and ability to protect the airway is required before emergence from anesthesia and tracheal extubation. Patients will be in casts postoperatively for approximately 6 weeks. Preoperative pain medication should be continued into the postoperative period and enough pain medication given to treat surgical pain. This helps prevent opiate withdrawal and a wind-up phenomenon.

Cerebral palsy

Cerebral palsy (CP) describes the movement and posture disorder that is the result of a motor deficit caused by brain injury *in utero*, at birth, or postnatally. It is present in approximately 2/1000 births [93]. The clinical features of CP are classified by the number of extremities with motor deficits (mono-, di-, tri-, or quadri-). Involvement of one side of the body is hemiparesis. Spastic quadriparesis is the most common form of CP, requiring multiple surgeries. The causes of CP are many, but the exact etiology is often difficult to define in any given infant. The functional limitations from paresis include hypotonia or hypertonia and occasionally extrapyramidal symptoms. Function can frequently be improved by multiple surgical procedures that address the extremities. Surgeries to straighten the spine help maintain posture and lung volumes. Anesthesia is often required to inject medications for treatment of spasticity and contractures (e.g. botulinum toxin-A or baclofen) [94].

Preoperative assessment and medical optimization should occur ahead of the surgery, since the majority of surgeries are elective (Box 33.2). Anesthetic challenges include appropriate communication with children who can have either normal cognitive abilities or severe developmental delay. A particularly challenging group of CP patients are cognitively intact, non-verbal patients. Patients with hypotonic CP often have the most severe developmental delay. Preoperative discussions with the family should include estimation of the child's developmental level and the best means of communicating

Box 33.2: Typical procedures in cerebral palsy

- Heel cord lengthening
- Contracture releases
- Tendon lengthen/transfer
- Botulinum injection
- Nissen fundoplication
- Gastrostomy tube
- Scoliosis repair

with them. Ideally a pain scale is identified that will be used postoperatively so the child and family can become familiar with its use.

Patients with CP may also have epilepsy. Their scheduled antiepileptic drugs are administered, despite preoperative fasting, and should be given either orally or converted to IV doses in the preoperative area if missed. A history of recent seizure patterns and frequency is obtained. Many of the antiseizure medications increase activity of cytochrome P450 degradation pathways. Drugs utilizing these pathways for elimination include non-depolarizing neuromuscular relaxants; train-of-four monitoring and more frequent dosing are desirable to achieve the desired effects due to the fact that the duration of action of the non-depolarizing agent may be shortened [95].

Pulmonary pathology includes the usual incidence of childhood diseases (e.g. reactive airway disease), and they may be exacerbated by anatomically scoliosis-induced restricted airways. Feeding dyscoordination increases the risk of aspiration and recurrent respiratory infections. Gastroesophageal reflux is common, difficult to control medically, and often requires fundoplication. Respiratory muscle strength may also be compromised. Poor oropharyngeal function often causes excessive drooling. This is controlled with antisialogogues or salivary gland surgery. Premedication with glycopyrrolate facilitates tracheal intubation and decreases pooling of secretions intraoperatively.

Patients with severe CP may be chronically underhydrated, since most of them are tube fed and empirically hydrated. Preoperative rehydration may be required. Complete blood count and coagulation studies are indicated for potentially bloody procedures because the incidence of prolonged PT/PTT in this patient group is increased.

Scoliosis surgery is discussed in Chapter 29. Other orthopedic procedures often required include extremity surgeries to address contractures and gait abnormalities. Historically, these procedures have been done serially as the child grows and movement is evaluated. Some centers are now undertaking elaborate gait and movement studies preoperatively to plan and perform a single operation that addresses multiple extremities simultaneously. The advantage of doing this is that the child can be mobilized more quickly and there is one recovery process instead of several. An important component of this approach is close coordination with a pediatric acute pain service to optimize pain management postoperatively, often with regional analgesia.

Clubfoot and hip dislocations are common acquired deformities in CP and often require surgery. They are described in detail earlier in this chapter. Heel cord lengthening, adductor myotomy, and hamstring lengthening are the most common surgeries needed. For clubfoot, the foot is rotated inward, the back of the heel is moved up, and the forefoot deviates medially. During the newborn period the heel cord is cut under local anesthesia and the lower extremity is serially casted. For surgical correction of clubfoot, general anesthesia, with or without caudal block, is usually used. Acquired clubfoot is the result of the paralysis associated with CP.

Contracture releases are performed to facilitate patient comfort, positioning, and mobility. Ober fasciotomy is done for flexion at the hip that is abducted and externally rotated (frog leg in appearance). Incision is anterolateral and just distal to the iliac crest. The fascial attachments are loosened to obtain neutral extension. The iliotibial band may be tight, causing flexion of the knee. In the Yount procedure, a distal midlateral longitudinal incision is made above the knee, and a segment of the iliotibial band and lateral intermuscular septum is removed and not repaired. Tendon lengthening/transfer is done to release contractures. Tendon transfers are done to change the direction of muscle force to compensate for paralysis or paresis of muscle groups.

Intraoperative considerations for CP include maintaining body temperature since these patients tend to be hypothermic (Table 33.6). Using warm blankets and forced-air warming devices in the preoperative area facilitates venous cannulation. Non-depolarizing neuromuscular relaxants are less potent in patients with CP, with or without the presence of chronic anticonvulsants. Contractures present positioning problems and make vessel cannulation difficult.

The use of succinylcholine is controversial and best avoided in CP patients. There are anecdotal reports of succinylcholine-induced cardiac arrest in CP patients [96]. Moreover, Theroux et al reported increased sensitivity of CP patients to succinylcholine due to CP patients having a lower effective dose (ED50) [97]. The relative immobility of CP patients may also upregulate their acetylcholine receptors [98]. However, Dierdorf did report normal plasma potassium concentrations before and after succinylcholine administration in CP patients as well as normal controls [96]. Muscle biopsies demonstrate variable neuromuscular junctions in CP patients undergoing spinal fusion, with about 30% of them having abnormal apposition of the acetylcholine receptor compared to normal control patients undergoing spinal fusion [99]. When the risk for aspiration is increased, sufficient rocuronium can be used to safely allow a modified rapid-sequence induction of anesthesia and tracheal intubation considering the potential risk of hyperkalemia.

Postoperative concerns include resumption of all preoperative medications, with close attention paid to the dosing of antiseizure medication and to spasticity regimens. Serum drug levels may be indicated if medications were discontinued for a prolonged period. Postoperative spasms can be painful and may require acute and chronic pharmacological therapy. Current oral regimens include diazepam, baclofen, tizanidine, and dantrolene. Intrathecal pumps are used to deliver baclofen for chronic spasticity. Baclofen overdosing or underdosing can be life threatening, particularly with abrupt withdrawal of the drug. Regional anesthesia supplementation decreases spasms in some instances.

Table 33.6 Perioperative considerations in cerebral palsy

Organ system	Clinical feature	Consideration
Muscular	Spasticity	Baclofen, botulinum injections, diazepam Source of pain postop
Pulmonary	Scoliosis/restrictive lung disease Aspiration pneumonia Reactive airway disease Inadequate cough	Consider chest x-ray and pulmonary function tests Consider ICU postop At risk for respiratory depression with opiates
Neuromuscular junction acetylcholine upregulation	Decreased muscle mass Relative immobility	NDMR: TOF monitor and increased redosing if seizure meds affect P450 degradation Succinylcholine is controversial: may be at risk for increased plasma K^+ concentrations
Contractures	Difficult IV access Difficult regional block access	Careful positioning
Neurological	Seizures	Insure a.m. meds oral or IV were given
Aspiration risk	± GERD	Consider rapid-sequence induction with NDMR
Oropharyngeal dyscoordination	Copious secretions	Consider glycopyrrolate
IV fluids	Chronic dehydration	Continue G-tube clear liquids per fasting protocol
Hematological	± Prolonged PT/PTT	CBC and coags for case with increased EBL

CBC, complete blood count; EBL, estimated blood loss; G-tube; gastrostomy tube; GERD, gastroesophageal reflux disease; ICU, intensive care unit; IV, intravascular; NDMR, non-depolarizing muscle relaxants; PT, prothrombin time; PTT partial thromboplastin tie; TOF, train-or-four.

KEY POINTS: CEREBRAL PALSY

- May have chronic aspiration of secretions
- Less sensitive to non-depolarizing muscle relaxants
- Avoid depolarizing muscle relaxants as they may elevate K^+
- Gastrostomy-fed patients may be dehydrated due to limited administration of fluid

Neuromuscular diseases

Perhaps one of the most common dilemmas in pediatric anesthesia is the anesthetic choice for a patient with neuromuscular disease, including those with hypotonia of unknown etiology [100–102]. The potential for anesthetic complications, based on choice of anesthetic technique, is present, and yet the recommendations are still varied and controversial. Each technique carries its own risk profile. Furthermore, regardless of anesthetic technique, these patients have a higher incidence of cardiomyopathy and arrhythmias from disease effects on the heart muscle. Respiratory function can also be compromised, due to both decreased respiratory muscle strength and to restrictive function associated with advanced spine and rib cage deformity induced by the diseases.

Neuromuscular diseases can be divided into muscular dystrophy (progressive and congenital), developmental myopathy, and metabolic myopathy.

Progressive muscular dystrophies (Duchenne and Becker)

Progressive muscular dystrophies include the dystrophinopathies (absent or deficient dystrophin such as Duchenne muscular dystrophy (DMD) and Becker muscular dystrophy), limb–girdle muscular dystrophies, fascio-scapulo-humeral muscular dystrophy, and oculopharyngeal muscular dystrophy. Most expert opinions now agree that there is not an increased risk of malignant hyperthermia, but life-threatening rhabdomyolysis can occur. Frail muscle membranes break down with exposure to halogenated volatile agents. Thus, in clinical practice many anesthesiologists still choose to deliver a trigger-free anesthetic (i.e. avoidance of succinylcholine and volatile anesthetics). The risk of rhabdomyolysis is highest in young children with more muscle mass. As the child ages and the disease progresses, muscle mass decreases and is replaced with fibrosis. An elevated creatine kinase (CK) is common in this group of patients.

Duchenne muscular dystrophy is the most common and severe muscle disease presenting in childhood and is caused by a complete absence of dystrophin protein in muscle. Disease severity progressively worsens over time. Typical presentation occurs in a toddler or early school-age boy with delayed walking or global motor delay. The incidence is approximately 30 per 100,000 births [103]. Patients have progressive lower extremity weakness, pseudohypertrophy of the calves, and markedly elevated CK levels. A waddling gait and proximal muscle weakness are hallmark signs. The Gower sign is common and describes the process of using the arms to rise from the floor. Approximately one-third will develop cardiomyopathy and/or arrhythmias by 14–18 years of age. However, cardiac disease does not necessarily correspond to the severity of skeletal muscle disease.

Early intervention and surveillance of cardiac status is warranted with electrocardiogram and echocardiogram. Cardiac magnetic resonance imaging can also be used to assess both function and arrhythmia potential and may be more sensitive than echocardiogram. At about age 10 years, empirical afterload reduction with an angiotensin-converting enzyme (ACE) inhibitor is generally started regardless of cardiac function status. Once systolic or diastolic dysfunction is diagnosed, patients are assessed every 6 months. Additionally, aldactone or eplerenone may be added for cardiac remodeling effects. In severe dysfunction, carvedilol or digoxin may be needed. Holter monitors are indicated for moderate to severe dysfunction. Patients with severe dysfunction and dilation may also be on aspirin therapy. Close coordination of preanesthesia

planning with the cardiology team is essential to optimize the patient's cardiac function prior to anesthesia. Some teams elect to admit patients with moderate to severe dysfunction preoperatively to begin milrinone. Corticosteroid regimens are also sometimes prescribed for muscular dystrophy patients, and despite their beneficial effects on disease progression, side-effects must be evaluated preoperatively. Deflazacort is a heterocyclic glucocorticoid prodrug of the oxazoline steroid class. In a randomized controlled trial of deflazacort, prednisone, and placebo in 196 boys aged 5–15 years with DMD, deflazocort and prednisone were equally efficacious in increasing muscle strength but deflazocort was associated with less weight gain [104].

Historically, patients typically died in early-adulthood (mid-20s) due to cardiac disease and heart failure. In the past two decades, life expectancy has increased by enhanced multidisciplinary clinical management and the use of corticosteroids (prednisone, prednisolone, deflazacort) with some patients now surviving into their 30s (Box 33.3) [105–115].

Becker muscular dystrophy is similar to DMD in its clinical presentation but presents in the adolescent years and progresses more slowly, due to a partial loss of dystrophin. It is less common, with an incidence of 3–6 per 100,000 births. Cardiomyopathy generally presents about age 30 with most patients surviving to 30–60 years of age.

Anesthetic risks for progressive muscular dystrophy, in addition to succinylcholine-induced hyperkalemia and rhabdomyolysis, are related to the degree of cardiac and respiratory compromise. Preoperative preparation includes an annual cardiac assessment for cardiomyopathy and/or arrhythmias and pulmonary function tests. Cardiac condition should be medically optimized prior to anesthesia and surgery. Postoperative planning should include longer observation times after surgery and the possible need for ventilatory assistance in an intensive care setting.

KEY POINTS: DUCHENE AND BECKER MUSCULAR DYSTROPHY

- Late onset of walking
- Baseline CK is elevated
- DMD is primarily found in males
- Consider use of a trigger-free anesthetic
- Close coordination with cardiologists and pulmonologists is important
- Close postoperative observation is needed

Box 33.3: Corticosteroid regimens and muscular dystrophy

- Corticosteroids improve and prolong ambulation in both Duchenne and Becker muscular dystrophies
- Corticosteroids reduce the incidence and severity of scoliosis
- Corticosteroids increase the incidence of pathologic fractures
- Duchenne muscular dystrophy patients are more prone to fat embolism syndrome
- Corticosteroids suppress the hypothalamus–pituitary–adrenal axis (HPA)
- Deflazacort was approved for use in the USA in February 2017

Congenital muscular dystrophies

These are characterized by early infancy presentation and slow progression and are sometimes associated with central nervous system anomalies. The incidence is only about four per 100,000 births; thus much less is known and/or written about preferred anesthesia techniques for patients with congenital muscular dystrophy. CK levels are usually elevated. There is a case report of an undiagnosed hypermetabolic response with volatile agent use and a report of rhabdomyolysis.

Congenital myopathies (central core disease and core-rod myopathies)

These infants primarily have contractures with decreased muscle strength; diagnosis is based on the histology of a muscle biopsy. The CK level is normal or only mildly increased, and the disease progresses slowly. Patients with central core disease and core-rod myopathy are at high risk for MH. Other congenital myopathy patients have milder MH or no association with MH. However, given the difficulty for the anesthesiologist to track down and interpret specific genetic testing, a trigger-free anesthetic is prudent in the known or suspected congenital myopathy patient.

Myotonias

There are several variants, both autosomal dominant and recessive, and they are divided into dystrophic and non-dystrophic forms. Myotonia congenita is a non-dystrophic form. The primary symptom for all myotonia patients is impaired muscle relaxation following sudden contraction.

Myotonic dystrophies are chronic, slowly progressing muscular dystrophies characterized by myotonia, posterior iridescent cataracts, cardiac conduction defects, and endocrine derangements [116–118]. They are best known for their skeletal muscle manifestations (distal skeletal muscle atrophy) and are the most common form of muscular dystrophy to present in adulthood with an estimated prevalence of one in 8000. Clinical presentation is highly variable with type I being more severe than type II. Cardiac involvement is always present and is a common cause of mortality after respiratory failure (Table 33.7). Treatment is primarily symptomatic.

Myotonic dystrophy patients are exquisitely sensitive to hypnotic/sedative medications as well as opioids, there may be prolonged emergence, and the drugs should be carefully titrated to effect [117]. Propofol-associated pain on injection may cause myotonia. Reported use of etomidate and ketamine is limited. Anticholinesterase drugs have been reported to cause sustained contraction, and adverse response after administration is poorly predictable. Therefore if neuromuscular blockade is necessary, the use of short-acting non-depolarizing muscle relaxants is preferred. The dose should be adjusted based on the severity of the muscle wasting. Succinylcholine is avoided as it may result in total body sustained contraction and/or masseter muscle rigidity. Halogenated agents have been used safely in these patients, but there are also some case reports of hypermetabolic reactions. Neuraxial techniques have been successfully utilized in myotonic dystrophy patients and offer both intraoperative

Table 33.7 Features of myotonic dystrophy type I (Steinert's disease)

	Features
Age at onset	
Congenital	Profound hypotonia at birth
	Delayed motor and speech development
	Hypotonia usually improves
	Most patients are eventually able to ambulate
Childhood	Onset between 1 and 10 years of age
	Uneventful neonatal period, mild hypotonia may be present
	Facial and neck muscle weakness
	Early motor development may be delayed or normal
Adult	Onset of symptoms between 10 and 40 years
	"Classic" form of myotonic dystrophy
Non-skeletal muscle manifestations	
Pulmonary	Hypoxemia and altered response to CO_2
	Respiratory muscle weakness
	Centrally mediated dysregulation of control of breathing
	Sleep apnea
	High risk for anesthesia-related pulmonary complications
Cardiac	Conduction abnormalities
	Dilated cardiomyopathy
	Little correlation between severity of cardiac involvement and peripheral muscle disease
	Annual EKG is advisable
	Symptomatic patients may benefit from echocardiogram, Holter monitoring, electrophysiology studies
Endocrine	Insulin resistance, glucose intolerance
	Dysthyroidism (usually hypothyroidism)
	Hypogonadism
Gastrointestinal	Dysphagia and delayed gastric emptying
	Pseudo-obstruction
	Increased incidence of prolonged ileus

and postoperative analgesia. Use of intrathecal additives to local anesthetic medications need to be weighed against the increased risk of respiratory/sedative adverse effects.

KEY POINTS: MYOTONIC DYSTROPHY TYPE I

- There is respiratory weakness and central apnea
- Avoid succinylcholine and neostigmine
- Volatile agents and propofol have been used
- There is no MH association (hypermetabolic reaction is reported)
- Volatile agents may cause prolonged sedation/weakness
- Aspiration risk – consider rapid-sequence induction
- Shivering, pain from propofol, etc. can elicit dystonia
- Cardiac conduction delays/arrhythmias – consider pacer pads
- Post-anesthesia intensive care unit is warranted

King–Denborough syndrome

This rare autosomal dominant disease has a high association with MH, so succinylcholine and halogenated agents are avoided. The muscle disease is non-specific and mild. These patients are characterized by short stature, pectus carinatum, kyphosis, cleft palate, low-set ears, ptosis, down-slanting palpebral fissures, and delayed motor development.

Metabolic myopathy (mitochondrial and carnitine disorders)

Mitochondrial diseases interact either with the energy supply to the muscle (adenosine triphosphate synthesis) or with ion channels involved in the process of contraction and relaxation. These patients develop progressive dysfunction in organs with high-energy requirements such as brain and muscle. All anesthetic agents interfere with mitochondrial function so there is no ideal anesthetic for these patients [119–122]. However, many anesthetics have been conducted safely with all anesthetic agents. There is increasing evidence that propofol infusion syndrome results from mitochondrial dysfunction and thus propofol should be avoided or used cautiously [120] in patients with mitochondrial disease. These patients do not have a clear genetic or clinical association with MH, although there are two case reports of possible MH [121,122]. One suggested anesthetic technique is to use ketamine and a low-dose volatile agent and avoid using propofol. Dexmedetomidine can also be added as another adjuvant agent when titrated carefully with prolonged postoperative observation. Ketamine, midazolam, and dexmedetomidine used together for muscle biopsies can be titrated to a depth sufficient to allow muscle biopsy without the use of a volatile agent. Spinal, caudal, or epidural anesthesia can also be employed.

Carnitine deficiency or any problem with its transport makes patients dependent on glucose for energy needs. The most common of these rare disorders is carnitine-palmitoyl transferase II deficiency that also has been associated with rhabdomyolysis following stress, exercise, or anesthesia. There is one case report of MH.

Other forms of metabolic myopathy include potassium-related periodic paralysis, glycogenoses, and lipid myopathies.

Undiagnosed hypotonia

Clinical experience and a recent retrospective study suggest that a cerebral cause for hypotonia is far more frequent than a peripheral neuromuscular cause in a neonate or infant with undiagnosed hypotonia who is presenting for muscle biopsy [100–102,123]. Since many infants/small children who present for muscle biopsy are not diagnosed, the best anesthetic choice is difficult to determine [124,125]. Taking a careful family history and reviewing genetic or neurological consultations, as well as laboratory results, are critical. An elevated CK may represent the presence of an undiagnosed progressive muscular dystrophy, such as DMD or Becker muscular dystrophy. A recent review article recommends that all children with motor delay who are not walking at 18 months of age should undergo neurological evaluation and/or genetic evaluation prior to elective general anesthesia or sedation [125]. An elevated serum lactate concentration may be indicative of metabolic myopathies such as mitochondrial diseases. Discussion with the infant or child's pediatrician or neurologist, in addition to obtaining CK and lactate levels, may help elucidate a more exact clinical suspicion or diagnosis to help guide anesthetic planning for diagnostic examinations and elective surgeries.

Anesthetic complications associated with neuromuscular diseases

Succinylcholine-induced hyperkalemic cardiac arrest following succinylcholine administration to patients who have neuromuscular disease still occurs despite the US Food and Drug Administration black box warning initiated in 1992 (Box 33.4). The hyperkalemic response is proportional to the upregulation of the nicotinic acetylcholine receptors (nAChRs). Pretreatment with a non-depolarizing neuromuscular relaxant does not prevent succinylcholine-induced hyperkalemia. Thus succinylcholine is avoided for any patient with a known condition associated with upregulation of these receptors and patients who have weakness and/or hypotonia without a diagnosis.

Acute rhabdomyolysis occurs due to the breakdown of the muscle surface membrane and causes the release of myoglobin, potassium, and CK. This can be life threatening and difficult to differentiate from malignant hyperthermia.

Hypermetabolic response with unexplained fever can mimic MH but is distinguished by the absence of acidosis and the presence of a normal CK. This condition has been described during anesthesia in both primary neuromuscular conditions and orthopedic syndromes such as osteogenesis imperfecta and arthrogryposis.

Malignant hyperthermia (see Chapter 45) has been associated with most neuromuscular diseases but most experts now classify only central core disease and King–Denborough as being high risk for MH.

Juvenile rheumatoid arthritis

Juvenile rheumatoid arthritis (JRA) (also known as Still disease) is diagnosed approximately three times per 100,000 children under the age of 15 years, and approximately 70% of these patients are female [126]. In addition to the usual childhood surgeries, JRA patients require general anesthesia for surgery on multiple affected joints as well as diagnostic examinations. Intra-articular corticosteroid injection in very young children may also require general anesthesia.

The usual age for presentation of JRA is 2–4 years of age. It is a systemic condition that is characterized by fever, rash, joint redness, leukocytosis, and increased erythrocyte sedimentation rate. It affects collagen and the connective tissues of joints and organs. About 36% of JRA patients have cardiac involvement, with pericarditis being the most common cardiovascular presentation. Severe disease may also include splenomegaly, lymphadenitis, and polyarthritis. JRA is an autoimmune disease that causes deposition of autoantibodies (antinuclear antibodies and rheumatoid factor) in the affected joints. Reactive lysosomal enzymes are released and ultimately damage the joints.

Preoperative preparation includes careful assessment of the airway with regard to neck and jaw mobility because temporomandibular ankylosis, mandibular hypoplasia, and cricoarytenoid arthritis can be present. Fiberoptic intubation of the trachea may be indicated. JRA patients may have atlantoaxial or low cervical subluxation, so extension of the neck should be limited or avoided. Anemia is also common. Children may be on multiple medical therapies, including steroids, NSAIDs, and methotrexate.

Postoperative analgesia can be challenging due to the preexisting chronic pain. Continuous regional anesthesia has been used to provide acute pain relief for larger surgeries, such as hip arthroplasty.

Box 33.4: Neuromuscular and orthopedic diseases associated with anesthetic complications

Succinylcholine-induced hyperkalemic cardiac arrest (upregulation of nAChR)
- Muscular dystrophy
- Acute burn patients
- Denervation
- Muscle atrophy

Rhabdomyolysis
- Duchenne and Becker muscular dystrophies
- Dystrophinopathies (absent or deficient)

Hypermetabolic response with unexplained fever but no acidosis or increase in CK
- Duchenne muscular dystrophy
- Osteogenesis imperfecta
- Arthrogryposis

Malignant hyperthermia
- Central core disease (and core-rod myopathies)
- King–Denborough

Genetic syndromes and orthopedic surgery

There are many syndromes with accompanying orthopedic problems. Table 33.8 contains a listing of these syndromes. The reader is referred to Chapter 43 for a discussion of the anesthetic approach to patients with these conditions.

Fractures in healthy children: supracondylar humerus fracture

Among the most common fractures requiring surgical intervention are the supracondylar humerus fractures, which account for 3% of all pediatric fractures, and most commonly involve a fall onto an outstretched hand with the elbow in extension (97–99% of cases) [127]. These fractures are classified as Gartland type I through IV, depending on the degree of displacement; with type I non-displaced fractures treated nonoperatively with casting (Fig. 33.9A). Type II fractures have slight displacement and may be treated operatively, while types III and IV are always treated operatively. Closed reduction with internal fixation with K wires is the standard treatment, and general anesthesia is required. Because these patients will frequently be considered to have full stomachs, appropriate precautions to protect the airway must be taken, and endotracheal intubation with rapid sequence, or modified rapid-sequence induction of anesthesia is often indicated. Although these fractures are often treated as emergencies, if there is no neurovascular compromise, studies have reported no outcome differences with up to 24 h of delay between fracture and surgery. Analgesia may be provided with opioids or NSAIDs. In a retrospective study of 221 pediatric fractures repaired operatively, ketorolac use was not associated with risk of non-union or delayed union, infection, or bleeding [128].

Table 33.8 Orthopedic syndromes with potential anesthetic implications

Syndrome	Potential anesthetic implications
Achondroplasia	Chronic respiratory infection, hydrocephalus, long narrow mouth with high arched palate, limited head extension, prominent mandible and forehead, constrictive thoracic cage, cyanotic and apneic episodes, dwarfism
Apert	Facial, limb, and cardiac anomalies, hydrocephalus, choanal atresia, craniosynostosis
Arnold–Chiari	Vocal cord paralysis, stridor, respiratory distress, apnea, abnormal swallowing, recurrent aspiration pneumonia, possible increased intracranial pressure, unstable blood pressure, weakness → paralysis
Cri du chat	Microcephaly, micrognathia, facial asymmetry, high vaulted palate, cleft lip/palate, feeding and swallowing difficulties with chronic aspiration, congenital heart defects, seizures, severe retardation
Crouzon	Facial and ocular anomalies, upper airway obstruction, choanal atresia, seizures, craniosynostosis, mental retardation
Cornelia de Lange	Facial and cardiac anomalies, micrognathia, seizures, choanal atresia, contractures, hypertonia
Ehlers–Danlos	Joint laxity, fragile blood vessels, cardiac valvular prolapse, glaucoma
Ellis van Creveld	Facial and cardiac anomalies, small thorax
Freeman–Sheldon	"Whistling facies" with microstomia, increased muscle tone, vertebral anomalies, myotonia
Goldenhar	Laryngeal, ocular, cardiac, and renal anomalies, cervical spine fusion, hemifacial micrognathia, glaucoma, encephalocele
Holt–Oram	Cardiac, vertebral, and upper limb and shoulder girdle anomalies, hypoplasia of distal blood vessels
Hurler	Facial anomalies, macroglossia, chronic respiratory infections, growth and mental deficiencies, joint stiffness, cardiac failure, hydrocephalus
Lesch–Nyhan	Self-mutilation, airway distortion 2° to scarification, mental retardation, spasticity, choreoathetosis, seizures, contractures, hypertension, aspiration pneumonia
Marfan	Joint laxity, vertebral and ocular anomalies, mitral valve prolapse, dilation or dissection of ascending aorta with aortic valve insufficiency
Möbius	Microstomia, micrognathia, limb and brain anomalies, cranial nerve palsies
Morquio	Odontoid hypoplasia, vertebral anomalies, growth deficiency, aortic value insufficiency, joint contractures
Neurofibromatosis	Brain, vertebral, dermal, and cardiac anomalies, subcutaneous tumor with tendency to malignancy, mental deficiency, kyphoscoliosis
Noonan	Facial, vertebral, and cardiac anomalies, micrognathia, mental deficiency, pectus evacatium
Radial aplasia-thrombocytopenia (Tar)	Facial, vertebral, cardiac, and renal anomalies, micrognathia, severe thrombocytopenia, anemia, intracranial hemorrhage
Robin (Pierre–Robin)	Severe micrognathia, cleft palate, laryngeal anomalies, mandibular growth improves with age during infancy
Treacher Collins	Severe micrognathia (not improving during infancy), facial, auricular, and cardiac anomalies, choanal atresia, microstomia, airway hypoplasia
Trisomy 21 (Down)	Odontoid hypoplasia, macroglossia, cardiac defects, joint laxity, mild mental deficiency
Turner (XO)	Micrognathia, short neck, growth retardation, cardiac anomalies
VATER association	Vertebral, cardiac, renal, and limb anomalies, tracheoesophageal fistula, esophageal atresia, congenital scoliosis, imperforate anus

Supraclavicular nerve block with ultrasound guidance can be utilized after induction of general anesthesia to provide intra- and postoperative analgesia. Before performing regional anesthesia for a supracondylar humerus fracture (or other long bone fractures), a complete neurovascular examination of the upper extremity must be done, including sensation, movement of hand and fingers, assessment of radial and ulnar pulses, and perfusion to the hand (color, capillary refill). A discussion with the surgeon should also ensue. The proximity of the brachial, radial, and ulnar arteries, and ulnar, median, and radial nerves, clearly indicate the risk of injury to these structures (Fig. 33.9B). Any sign of neurovascular compromise is a contraindication to regional anesthesia. Open supracondylar fractures are uncommon, but vascular and nerve injuries are present in 12–20% of open fractures. Neurovascular compromise is less common with closed fractures. If neurovascular compromise is diagnosed or suspected, emergent reduction is indicated; in most cases the vascular compromise will improve within a few minutes – if it does not an open exploration with vascular repair is indicated. Compartment syndrome is a rare but serious complication, occurring in 1–3 per 1000 fractures. Increasing pain and anxiety, along with limb pallor, paralysis, and pulselessness, are the signs of compartment syndrome, and emergent fasciotomy is indicated. It is because of concern for compartment syndrome that some orthopedic surgeons do not agree to regional anesthesia, for fear of masking the pain that heralds this complication. See Chapter 20 for detailed discussion of supraclavicular nerve blocks.

Sports medicine procedures in teenaged athletes

The significant increase in youth sports participation for both girls and boys has given rise to the development of adolescent sports medicine, and orthopedic surgery for sports injuries in children and adolescents has increased dramatically. For example, anterior cruciate ligament (ACL) surgery in patients <20 years of age increased threefold in the USA from 1990 to 2009 [129].

A complete discussion of surgery for sports injuries is beyond the scope of this text, but because ACL surgery is the most common sports surgery in adolescents, information about this injury and the procedure for the pediatric anesthesiologist is important. Historically, non-operative treatment of skeletally immature patients was common, delaying repair until skeletal maturity. This approach may lead to meniscal and articular cartilage damage, and other problems including dropping out of sports, so early operative repair is now the standard approach. Different techniques are used before

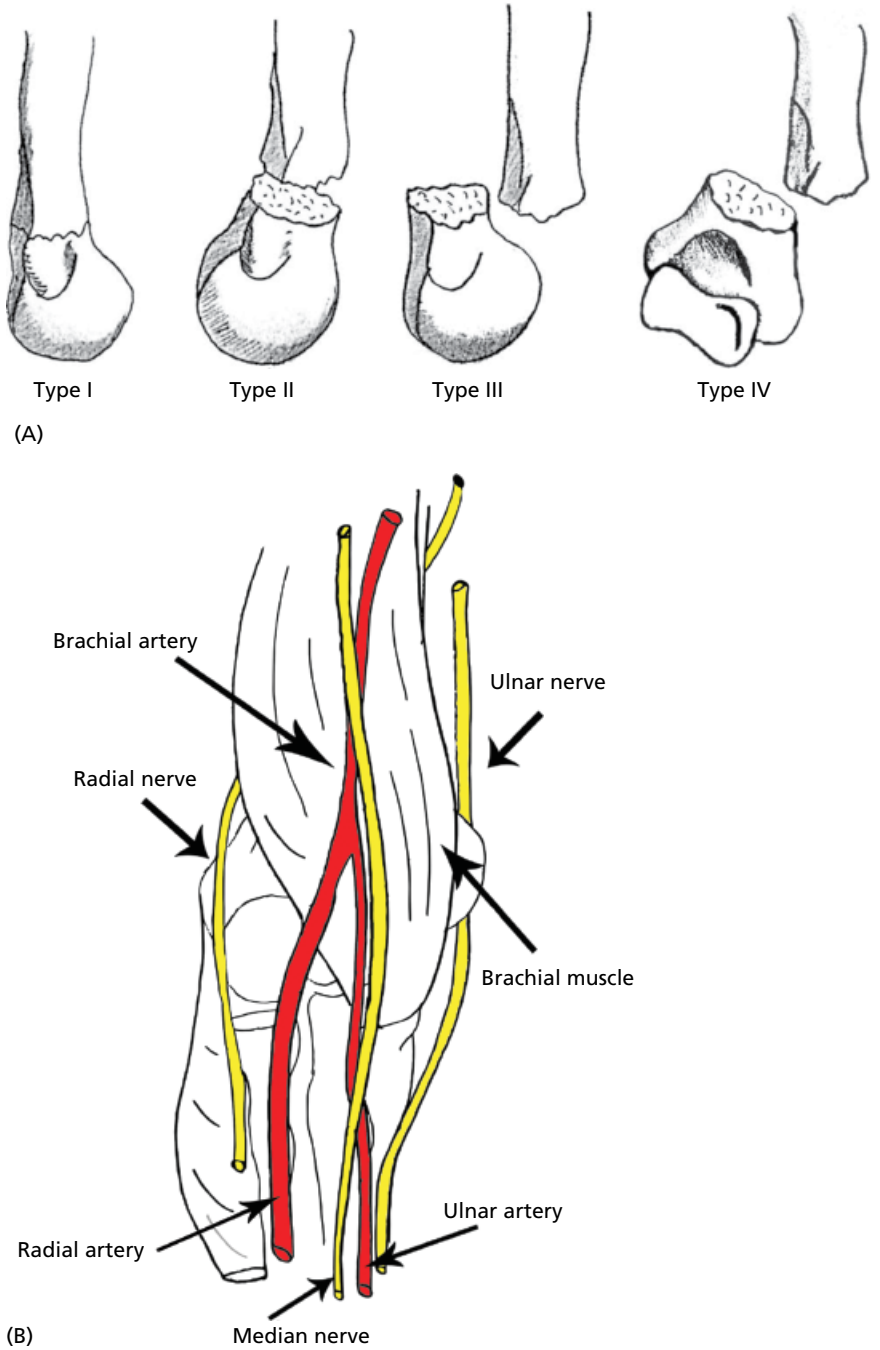

Figure 33.9 (A) Gartland classification of supracondylar humerus fractures. (B) Anatomical relationships of neurovascular bundles and supracondylar region. The brachial artery descends superficially by the anteromedial aspect of the brachial muscle, providing deep collateral arteries that run down the anterior aspect of the humerus. The median nerve descends with the brachial artery, the radial nerve runs down the lateral aspect of the humerus between brachialis and brachioradialis, and the ulnar nerve runs down the posteromedial aspect through the cubital tunnel of the medial epicondyle. *Source*: Reproduced from Zorrilla et al [127] with permission of Springer Nature.

skeletal maturity, at about 12–13 years in girls and 14 years in boys. Epidemiological studies have revealed that the overall incidence of ACL tears is greater in boys, while girls have a 2–8 times greater ACL injury rate per athletic exposure than boys.

There are a number of approaches to ACL repair, but most are arthroscopic for adolescents. Anesthesia technique may be general anesthesia or sedation combined with regional anesthesia. Local anesthetic instillation in the joint space by the surgeon can also be employed. Femoral or femoral–sciatic nerve blocks can be utilized for intra- and postoperative analgesia, and a femoral nerve catheter can be placed and local anesthetics infused via a disposable infusion pump in the patient's home after ambulatory surgery. Concern over reports of femoral nerve block leading to increased quadriceps weakness, and potentially delaying functional recovery, have limited the use of this technique in some institutions [130]. A conversation with the surgeon is clearly important before employing these techniques. A thorough presentation of nerve blocks of the lower extremity is given in Chapter 20.

CASE STUDY

A 4-year-old boy is scheduled for muscle biopsy. He has a history of walking at 20 months and is noted to walk on his toes. His parents observe that he uses his upper extremities to pull himself from the floor. He plays at the same exercise tolerance as peers but parents report that he falls down frequently. Parents are not aware of any family history of muscular dystrophy. He had an uneventful volatile anesthetic at 18 months of age for a spine MRI to evaluate his late onset of walking. The spine MRI was normal. With regard to family history of anesthesia complications, an uncle died during anesthesia for tonsillectomy as a child. He has no cardiac or respiratory problems.

On physical exam he is developmentally appropriate and has a completely normal physical exam except that his calves are hypertrophic.

Preoperative preparation includes a high suspicion for Duchenne's muscular dystrophy given his male sex, toe walking, and presence of the Gower sign (using the hands and arms to walk up one's own body to stand from a squatting position due to proximal lower extremity weakness). Furthermore, his family's anesthesia history is suspicious for hyperkalemic cardiac arrest in a male relative.

At this young age cardiac and respiratory systems are frequently unaffected; although in some cases cardiac symptoms can occur early. A cardiology consultation should be obtained preoperatively for patients with known DMD regardless of whether the patient has documented cardiac dysfunction. ACE inhibitors to treat these patients medically, even before the onset of cardiac failure, is now recommended. Thus, cardiologist involvement at an early stage of overall care is ideal. Since this child is young, asymptomatic, and does not have a DMD diagnosis confirmed, most anesthesiologists would proceed without an echocardiogram for this minor operative procedure. If DMD is diagnosed then all subsequent anesthetics should be preceded by cardiology consultation to address cardiac medications to optimize cardiac function, ECG, echocardiogram, and Holter examination if indicated. Cardiac MRI is also used extensively to evaluate both function and arrhythmia risk. If cardiac function is known to be reduced, this consultation and echocardiogram should occur close to the planned anesthetic (within 3–6 months, depending on severity). Baseline tachycardia, irrespective of cardiac function, can be present, and it is helpful to document this preoperatively. Hypotension is often present when cardiac manifestations are advanced. In the absence of respiratory symptoms a pulmonary consult would not be indicated in this case but would be a routine part of the preanesthesia evaluation for a symptomatic muscular dystrophy patient to both optimize pulmonary function preoperatively and plan for postoperative care.

Laboratory studies should be done prior to anesthetic, including a basic metabolic panel, CK (CK and potassium may be elevated in the presence of progressive muscular diseases such as muscular dystrophy), and lactate level (elevated in metabolic myopathies) since the diagnosis is unknown in this child.

Due to the high suspicion of DMD diagnosis, the anesthesiologist proceeded with a trigger-free anesthetic to avoid the risk of rhabdomyolysis and cardiac arrest. However, these patients are not at risk for malignant hyperthermia (MH). A prior exposure to MH triggers without problems does not predict the outcome with future anesthetics. Therefore, an IV catheter was placed after sedation with oral midazolam and nitrous oxide. The surgery was scheduled as a first start both to decrease exposure to volatile anesthetic and to allow adequate observation time prior to anticipated discharge home. Manufacturer recommendations vary with regard to how best to prepare the anesthesia machine for a trigger-free anesthetic. Most recommend changing the CO_2 absorbent and flushing with high fresh gas flows. Activated charcoal filters (Vapor-Clean™, Dynathetics, Salt Lake City, UT, USA) are now available for use in patients at risk for MH or rhabdomyolysis. The filters are attached to the inspiratory and expiratory limbs of the circuit to filter anesthetic gases. A total intravenous anesthetic was maintained with propofol, low-dose opioid, and nitrous oxide. Post-biopsy analgesia was provided with local anesthetic infiltration, acetaminophen, and ketorolac.

The patient was observed for 2 h postoperatively and discharged home without the need for additional opioid in the postanesthesia care unit. His muscle biopsy was consistent with DMD.

CHAPTER 34
Otolaryngological and Dental Surgery

Olutoyin A. Olutoye, Arvind Chandrakantan, and Mehernoor Watcha
Department of Pediatric Anesthesiology, Perioperative, and Pain Medicine, Texas Children's Hospital; and Department of Anesthesiology, Baylor College of Medicine, Houston, TX, USA

Introduction

More than a million children undergo surgery every year, a third of these are performed for problems in the ear, nose, or throat (ENT) areas. In this chapter, we discuss the perioperative anesthetic considerations and management of the most common conditions requiring surgical intervention in the head and neck region. These include the following:

- Myringotomy and pressure equalization tube insertion for treatment of chronic otitis media
- Middle ear surgery
- Tonsillectomy and adenoidectomy for relief of obstructive sleep apnea or for the management of recurrent pharyngitis
- Airway surgery for evaluation of subglottic stenosis and resection of laryngeal papillomas
- Removal of foreign bodies in the airway and esophagus.

Many children scheduled to undergo head and neck surgery present with nasal discharge that may represent either allergic rhinitis or an upper respiratory tract infection (URI). Children with a URI are at increased risk for developing perioperative respiratory adverse events (PRAEs), such as episodes of breath holding, laryngospasm, bronchospasm, oxygen desaturation, and occasionally stridor [1–3]. This may be because children who have a URI also have abnormalities of the peripheral lower airways and airway hyper-reactivity. Decreased functional residual and diffusion capacity and increased closing volumes and airway resistance have been noted during a URI [4–8]. This may also explain why apneic, anesthetized children with a URI more rapidly decrease their oxygen saturation to 95% [9]. Delayed respiratory complications may occur up to 18 h postoperatively in some children [10]. Therefore, it is important to differentiate between allergic rhinitis and URIs, especially since over 90% children undergoing ENT surgery do so on an outpatient basis [11]. Tait et al described a point system to help differentiate between allergic rhinitis and actual URIs; others have noted that parental reports are just as accurate [12,13].

Approach to the child with an upper respiratory tract infection

The anesthesiologist is faced with a dilemma when deciding whether or not to anesthetize a child who has a URI. Should they anesthetize the child or should they postpone the surgery? The anesthesiologist must balance the risk for laryngospasm, bronchospasm, oxygen desaturation, and postintubation croup with the fact that these risks may not be significantly reduced without waiting 4–6 weeks or longer. By that time the child will probably have another URI [14,15]. Emergent procedures should be performed, even in the presence of significant medical problems. However, elective procedures should be undertaken cautiously in the presence of a URI. Most anesthesiologists would postpone elective surgery in a child who presents with purulent secretions and fever, but the problem is that there is no consensus on how long to postpone the procedure. The increased airway reactivity can last 4–6 weeks. Empey et al [16] demonstrated a 200% increase in airway resistance after adults who had a URI inhaled histamine. The controls had only a 30% increase. The increase persisted for as long as 6 weeks after the URI ended. Nandwani et al [17] studied the sensitivity of upper airway reflexs of non-smoking adult patients with URIs by having them inhale ammonia vapor. Airway reactivity was 2–2.5 times higher than normal in those with a URI, but had returned to baseline 2 weeks after termination of their URI.

Gregory's Pediatric Anesthesia, Sixth Edition. Edited by Dean B. Andropoulos and George A. Gregory.

Many children have at least 6–10 URIs per year, making it difficult to schedule the procedure during a period when airway reactivity is normal. Furthermore, waiting 6 weeks has not reliably been shown to decrease the incidence of respiratory complications with general anesthesia [14]. There are, however, good data to show the incidence of PRAEs is higher if URI symptoms are present or if the URI occurred less than 2 weeks before the procedure [15]. The incidence of PRAEs is higher in young children with a URI and in the presence of copious airway secretions and/or nasal congestion. Other risk factors include asthma, cystic fibrosis, bronchopulmonary dysplasia, exposure to second hand (passive) tobacco smoke, and surgery involving the airway [18,19]. These factors must be taken into consideration when deciding whether to proceed with an anesthetic or delay the procedure.

The choice of anesthetic agents and airway devices used may also influence the incidence of PRAEs. Increased rates of PRAEs are seen with inhalation induction, maintenance of anesthesia with desflurane, and airway management by trainees [15]. Children with an URI who present for minor surgery, where instrumentation of the airway is not required, are not at increased risk of complications following general anesthesia [12,20]. Both laryngeal mask airway and a tracheal tube increase PRAEs in children with a recent URI [1,21,22]. Laryngospasm is twice as common in children undergoing airway surgery if they have symptoms of a URI [23]. Tracheal intubation elicits a potent airway reflex which further decreases the changes in functional residual capacity that occurs following induction of general anesthesia [24]. A recent study by Ghareai et al [25] shows that this effect can be attenuated with intravenous lidocaine but not with topical lidocaine. The intense physical and pharmacological stimulation of the airway associated with tracheal intubation causes significant airway hyper-reactivity in patients with asthma. Administration of albutamol preinduction of anesthesia has been recommended for asthmatic children who have had a recent URI [26]. However, even patients without underlying bronchospastic disease may develop a temporary increase in airway reactivity when they have a viral infection and this increases the likelihood of laryngospasm and bronchospasm.

Laryngospasm is the most frequently reported respiratory complication associated with URIs, particularly in younger children undergoing airway surgery and in those cared for by less experienced anesthesiologists [23]. This threatening event is characterized by the midline apposition of either the true vocal cords or both the true and false vocal cords, which involuntarily close the glottis and make it difficult or impossible to breathe [27]. The primary muscles involved in laryngospasm are the lateral cricoarytenoid, the thyroartenoid muscles (adductors of the glottis), and the cricothyroid muscles, which are tensors of the vocal cords.

Laryngospasm occurs most commonly during airway manipulation (e.g. intubation or extubation of the trachea), foreign material in the larynx (e.g. secretions), or with light anesthesia in a non-intubated patient. Clinical signs of laryngospasm and partial airway obstruction start with an irregular breathing pattern or noisy airway sounds that vary in intensity and tone but usually resemble a high-pitched squeak. When this occurs, it can be managed by jaw thrust and/or application of steady positive airway pressure for 30–45 seconds. If the airway obstruction is not resolved with these measures, it may be necessary to increase the depth of anesthesia with propofol or intravenous lidocaine [28–31]. It may also be necessary to administer a rapidly acting muscle relaxant, e.g. succinylcholine, to break the laryngospasm. The lungs should be ventilated with 100% oxygen. Laryngospasm and its treatment is also discussed in Chapter 17.

Acute postobstructive pulmonary edema may occur after relief of laryngospasm-induced total airway obstruction [32,33]. Attempts by the patient to breathe against a closed glottis generate negative intrapleural pressures of approximately 30–60 cmH_2O. This, together with the immediate decrease in airway pressure that occurs with relief of the laryngospasm, induces pulmonary edema [34]. The increased negative intrapleural pressure increases venous return (i.e. increased preload) and injures the microvasculature. The combination of the increased preload and the increased vascular permeability permits fluid to move out of the vasculature and causes both interstitial and pulmonary edema. The negative intrathoracic pressure also increases left ventricular transmural pressure (i.e. afterload) [35], which affects cardiac performance. Mechanical stress at the alveolar–capillary membrane is thought to be responsible for both pulmonary edema and for frank alveolar hemorrhage. While pulmonary hemorrhage may be the result of breathing against an acute airway obstruction [36], other etiologies of pulmonary hemorrhage should be ruled out [37]. Laryngospasm-induced pulmonary edema is most effectively managed by prompt tracheal intubation and application of continuous positive airway pressure (CPAP) or positive end-expiratory pressure (PEEP) during positive-pressure ventilation. Diuretics, morphine, and sedatives may also aid in treatment of the edema. If the patient has no underlying cardiorespiratory problems, the pulmonary edema resolves quickly, allowing the trachea to be extubated within several hours.

Bronchospasm is a potentially life-threatening intraoperative event that occurs more frequently in children with a URI, whether or not they have a prior history of asthma. This increased airway reactivity is thought to represent immunological and inflammatory mediator release in response to the viral infection. Epithelial damage from viral infections may also cause airway receptor sensitization and abnormal neural responses to tachykinins, such as substance P. The contractile effects of both substance P and capsaicin were enhanced in bronchial ring segments taken from guinea pigs infected with the parainfluenza 3 virus. Pretreatment with histamine-1 and -2 (H_1, H_2), muscarinic, serotonergic, and α-adrenergic blockers did not obliterate the effect of substance P [38]. This noncholinergic bronchospasm may explain why pretreatment with albuterol failed to decrease the incidence of bronchospasm in children with URI [39]. Due to its increased vagal reactivity, acetylcholine-related bronchospasm can be inhibited by atropine [40]. Atropine blocks the smooth muscle effect of acetylcholine and decreases the release of acetylcholine from vagus nerve endings [41]. A better strategy would be to use a more selective drug to block the muscarinic M3 receptor (stimulation of which causes bronchoconstriction) but not the M2 receptor (which inhibits acetylcholine release at nerve terminals).

Viruses can produce other substances that result in airway hyper-reactivity during URI. Parainfluenza and influenza viruses contain an enzyme, neuraminidase, which cleaves

sialic acid residues from M2 muscarinic receptor agonist binding sites. Inhibition of the M2 inhibitory site increases acetylcholine release. Studies in guinea pigs have demonstrated alteration of high-affinity agonist binding (carbachol) in lung membrane preparations in response to either neuraminidase or parainfluenza virus. In addition, a neuraminidase-blocking agent inhibited viral-induced changes [42].

The use of a laryngeal mask airway (LMA) rather than a tracheal tube for children with a recent or active URI may cause less tracheal stimulation and fewer respiratory complications [22]. While some studies have shown that LMAs can be safely used in children with an active URI undergoing elective surgery, other studies have shown an association between LMA use and respiratory complications, especially in children who have an active URI or have had a URI within the past 2 weeks [43,44]. A more recent randomized controlled trial compared PRAEs after tracheal intubation with the use of an LMA in anesthetized infants. The study was terminated early because those treated with an LMA had fewer complications [45].

The choice of anesthetic can also influence the incidence of PRAEs in children with URI. While the lower blood : gas partition coefficient of desflurane (0.45) allows for rapid emergence from anesthesia, it is associated with a higher incidences of laryngospasm, breath holding, and coughing following either tracheal extubation or removal of the LMA [46,47]. The incidence of laryngospasm may be decreased during deep anesthesia, but it is not completely abolished. A recent observational study by Erb and colleagues [48] revealed that laryngospasm still occurred in children despite a high concentration of sevoflurane (4.7% ED_{95} intubation). Careful vigilance by the anesthesia provider for, and rapid management of, laryngospasm cannot be overemphasized.

In summary, children with URIs are predisposed to developing adverse respiratory events in the perioperative period. Although "URIs" are considered a single disease process, often with a common set of presenting symptoms, there may be enormous variability in the pathophysiological effects and clinical manifestation of a particular virus, depending on the stage of the illness (e.g. initial symptoms, height of symptoms, recovery phase). There are algorithms to aid in the decision of whether to proceed with an anesthetic or not, and an evidence-based management plan has also been described [49]. This includes preinduction of inhaled albutamol; use of α2-receptor agonists (clonidine or dexmedetomidine) if premedication is required; induction of anesthesia with IV agents such as propofol; maintenance of anesthesia with inhaled anesthetics such as sevoflurane (avoid desflurane); and use of the least invasive airway device consistent with the surgical procedure (preferably face mask over LMA, and LMA over tracheal intubation). The anesthesiologist should consider administering IV lidocaine or propofol before manipulating the airway and should remove the device with the child deeply anesthetized. If possible, an experienced pediatric anesthesiologist should manage the child's care [15]. Anesthesiologists must be prepared to aggressively treat bronchospasm, and to deliver supplemental oxygen to patients during transport from the operating room to the recovery room and during the recovery period. Breathing patterns and oxygen saturation should be carefully monitored in the postanesthetic care unit (PACU) to ensure adequate ventilation and oxygenation before discharging the patient home or to the ward.

KEY POINTS: ANESTHESIA IN THE CHILD WITH UPPER RESPIRATORY INFECTION

- Children with a recent URI are more prone to develop laryngospasm or bronchospasm
- The decision on whether to proceed with the surgery depends on medical need alone
- Use the least stimulating airway device possible and only during deep anesthesia
- Fewer complications occur in patients with recent URIs when anesthesia care is provided by an experienced anesthesiologist

Anesthesia for specific surgical procedures

Surgery of the head and neck involves sharing of the workspace and airway by the surgeon and anesthesiologist, making close communication between them imperative. A preoperative meeting of the operating room team is useful to determine how best to establish optimal operative conditions. The discussion should include the steps involved in the procedure, patient positioning, the need for intraoperative movement of the tracheal tube, the potential effect of neuromuscular blockade on nerve integrity monitoring, and a need for precautions to avoid airway fires.

Ear surgery

Myringotomy and insertion of pressure equalization (ventilation) tympanostomy tubes (grommets)

Otitis media is an inflammatory process of the middle ear that often accompanies viral or bacterial upper respiratory tract infections and is a common occurrence in pediatric patients. An otitis media-induced collection of thick, glue-like fluid in the middle ear may cause conductive hearing loss if left untreated. Failure of antibiotic therapy to resolve the symptoms of otitis media warrants surgical drainage of this middle ear fluid. A simple myringotomy opens the tympanic membrane and allows the accumulated fluid to drain, but this drainage path eventually heals, and the symptoms recur. Placement of a ventilating tube in the ear drum stents open the membrane and allows drainage of fluid for 6–12 months after which the tubes are often extruded spontaneously.

A myringotomy and/or placement of ventilating tubes can be usually be completed in 5–10 min and usually only requires inhalation anesthesia via a facemask. The procedure may be more surgically challenging in children with some syndromes (e.g. Down, Apert) who have narrow ear canals. For these longer procedures, it is often better to use a laryngeal mask airway (LMA) for maintenance of anesthesia. This is associated with fewer hypoxemic episodes and provides better peroperative working conditions for the surgeons [50]. Abnormalities in the cartilages and muscles surrounding the eustachian tubes frequently cause children with cleft palates to develop otitis media; procedures in these children may also last longer than routine myringotomy tube insertions, but mask ventilation usually suffices for their intraoperative airway management.

Anesthetic management for children requiring placement of myringotomy tubes usually is accomplished with brief inhalation of potent inhalation agents (commonly sevoflurane) and nitrous oxide in oxygen. Maintenance of airway patency and adequate ventilation are essential, so an oral airway is often placed to alleviate/avoid airway obstruction. Assisted ventilation may be required if the depth of anesthesia exceeds the apneic threshold. Most practitioners do not establish vascular access in healthy patients undergoing this short procedure but reserve that for children with significant underlying medical conditions. Nevertheless, an intravenous fluid set-up should be readily available in the operating room and it is important to locate a good vein for catheter insertion before induction of anesthesia. This avoids wasting time searching for venous access if a problem occurs.

A variety of management strategies exist for treatment of the mild postoperative pain associated with the placement of myringotomy tubes. Preoperative oral acetaminophen (15–20 mg/kg) or intraoperative acetaminophen suppositories (40–45 mg/kg) are often used. Intraoperative administration of ketorolac, intranasal butorphanol, or fentanyl (2 μg/kg) have been shown to reduce the need for rescue analgesics [51–53]. Since this patient population is at high risk for emergence agitation following sevoflurane anesthesia, it may be appropriate to administer intranasal fentanyl to reduce the agitation near the end of anesthesia [54]. Intramuscular morphine 0.1 mg/kg reduces postoperative pain scores and rates of emergence delirium to the same degree as IV or intranasal fentanyl [55]. A study in this patient population compared dexmedetomidine with acetaminophen and intranasal fentanyl on demand. The study was terminated early due to prolonged recovery room stays by the dexmedetomidine group [56]. In another study, patients receiving intraoperative blocks of the auricular branch of the vagus nerve had similar postoperative pain scores as patients receiving intranasal fentanyl, but those with blocks had less postoperative emesis [57].

KEY POINTS: MYRINGOTOMY TUBES

- Myringotomy tubes provide temporary (6–12 months) drainage for middle ear effusions
- Inhalation anesthesia with a facemask, and no IV catheter, is the most common approach
- Analgesia can be provided via the intranasal (fentanyl, dexmedetomidine), intramuscular (ketorolac, morphine), or rectal (acetaminophen) routes

Middle ear and mastoid surgery

Most myringotomy tubes are eventually spontaneously extruded, but some require surgical removal. While tube removal is frequently performed in the clinic, small children may require general anesthesia due to their inability to cooperate. Surgically created myringotomy openings usually heals spontaneously, but not always. When they fail to do so, they usually require the placement of a paper patch or a fat graft over the opening under anesthesia. Anesthetic management for placement of a fat graft differs slightly from anesthesia for a routine myringotomy. Nitrous oxide administration should be discontinued or limited to 50% prior to placing the tympanic membrane graft to prevent pressure-related graft displacement. Nitrous oxide diffuses into air-filled middle ear spaces faster than nitrogen moves out because nitrous oxide is 34 times more soluble in blood than nitrogen. Normal passive venting of the eustachian tube occurs at 20–30 cmH_2O pressure; nitrous oxide administration produces pressures that exceeds this level. When this occurs, the patient may complain of pain, and the graft may be displaced [58].

Repeated middle ear infections can cause mastoiditis and produce large perforations in the tympanic membrane that are difficult to repair via the auditory canal. When this occurs, additional surgery may be required via posterior auricular exposure. The skin over the outer surface of the eardrum can also grow through the perforation and into the middle ear, forming a destructive and expanding growth called a cholesteatoma. Cholesteatomas require surgical repair, occasionally in stages.

Anesthetic management for middle ear surgery typically includes inhalational agents and opioid administration. Tracheal intubation is facilitated by intravenous propofol, with or without laryngotracheal application of lidocaine. Following tracheal intubation, the operating table is usually turned 90° or 180° away from the anesthesia machine with the patient's head positioned on a soft head rest below the height of the operating table. The surgeon may request extreme lateral rotation of the operating room table to improve their view of the ear. The anesthesiologist and surgeon must ensure that nerves, muscles, and bony structures are properly padded to avoid injury during positioning. They must also prevent accidental dislodgment of the tracheal tube during positioning. The use of extra-long anesthesia circuits is required if the patient's head is positioned some distance from the anesthetic machine. Surgical drape placement should allow easy access to the patient and the tracheal tube. Careful head positioning is particularly important in children with Down syndrome and achondroplasia, as 15–31% of these children are prone to atlantoaxial (C1–2) subluxation [59,60]. The facial nerve is in close proximity to the surgical field during middle ear and mastoid surgery. Monitoring nerve integrity during surgery requires avoidance of neuromuscular blockade or demonstration of return of neuromuscular response to at least 70% of baseline by the time surgery begins.

The operative site is visualized through a microscope. Bleeding during middle ear surgery is usually minimal, partly because the surgeon injects epinephrine around the tympanic vessels to produce vasoconstriction. Close attention should be paid to the amount of epinephrine injected to avoid excessive absorption of epinephrine, arrhythmias, and wide variations in blood pressure. Relative hypotension (mean arterial pressure ≤25% below baseline) is sometimes used to decrease intraoperative bleeding.

Nitrous oxide administration during these cases may increase the volume of gas in the air-filled cavities of the middle ear and sinuses. When the nitrous oxide is subsequently discontinued, it is rapidly absorbed, causing negative pressure in the middle ear and displacement of tympanic patches. Disarticulation of the stapes bone of the middle ear can occur. When it does, hearing is impaired for up to 6 weeks postoperatively. Nitrous oxide also increases the incidence of postoperative nausea and vomiting in children undergoing middle ear surgery. Nitrous oxide reabsorption can produce sufficient

negative pressure to cause traction on the round window during recovery from anesthesia. This causes the relatively compliant walls of the eustachian tubes to collapse and prevents re-equilibration of the middle ear with atmospheric pressure [61]. Older children (more than 8 years of age) have less compliant eustachian tubes and do not suffer the effects of negative middle ear pressure or the postoperative nausea and vomiting. Children between 3 and 8 years of age seem to be affected the most [62]. Prophylactic administration of antiemetics, like dexamethasone and ondansetron, have been recommended for these patients [63]. Pre-emptive blockade of the great auricular nerve caused no greater decrease in postoperative analgesic requirements than placing the block 1 h before the end of tympanomastoid surgery [64]. It did, however, decrease postoperative opioid requirements and postoperative nausea and vomiting by approximately 66% [65].

A smooth emergence from anesthesia without coughing is preferred after middle ear surgery. Toward the end of surgery, the child is allowed to breathe spontaneously while gradually titrating opioids as tolerated to reduce postoperative pain. Administration of intravenous lidocaine 1–1.5 mg/kg in children older than 1 year of age and gentle suctioning of the oropharynx minimizes or prevents coughing following tracheal extubation.

Cochlear implant surgery

Early insertion of cochlear implants is rapidly gaining acceptance as a method for rehabilitating profoundly hearing-impaired children because it permits better development of auditory, speech, and language skills and more successful integration with normal-hearing peers. Children as young as 6 months of age have had successful cochlear implants. Placement of cochlear implants requires meticulous soft tissue dissection, hemostasis, and bone drilling; bleeding from the bone marrow can be very difficult to control. The implant stimulates the auditory nerve to enable hearing. Limits of implant stimulation are set intraoperatively with evoked stapedius reflex thresholds (ESRTs) and with evoked compound action potentials. The latter are not affected by anesthetics, but volatile anesthetics are known to abolish the stapedius reflex in more than 50% of children [66]. Anesthetics also cause a dose-dependent increase in the ESRT. This results in ESRT levels that overestimate a child's comfort level, which may lead to postoperative difficulty adjusting to the implant. Therefore, use of volatile anesthetics during this phase of the surgery is discouraged. Propofol has no effect on ESRT. Other anesthetic considerations are similar to those for middle ear surgery and appropriate communication with the surgeon ensures the successful outcome of these procedures.

KEY POINTS: MIDDLE EAR AND MASTOID SURGERY

- Care must be taken to prevent tracheal tube dislodgment during mastoid surgery
- Nitrous oxide may increase intraotic pressure and dislodge fat grafts
- Muscle paralysis should be avoided in facial surgery to prevent inadvertent damage to the facial nerve

Nasal and pharyngeal surgery

Adenoidectomy and tonsillectomy

Adenoidectomy is performed alone or in conjunction with tonsillectomy and/or myringotomy and the insertion of myringotomy tubes. The indications for adenoidectomy alone include chronic otitis media with adenoid hyperplasia-induced middle ear effusion, chronic sinusitis, and chronic or recurrent purulent adenoiditis. Severe adenoid hyperplasia results in nasopharyngeal obstruction, obligate mouth breathing, failure to thrive, and speech disorders. Long-standing nasal adenoid hyperplasia-induced obstruction may result in narrowing of the upper airway and dental abnormalities ("adenoidal facies").

Tonsillectomy, with or without adenoidectomy, is one of the most common ambulatory pediatric surgery procedures performed in the United States [67]. Two common indications for this are: (1) recurrent or chronic tonsillitis refractory to medical therapy, and (2) obstructive adenotonsillar hyperplasia and obstructive sleep apnea (OSA). Children who undergo tonsillectomy for recurrent tonsillitis are usually older and have fewer perioperative problems than those with chronic airway obstruction from hypertrophic tonsils. The latter group may present with failure to thrive, dysphagia, speech abnormalities, halitosis, cervical pharyngitis, and persistent pharyngitis. Severe airway obstruction can result in carbon dioxide retention, vasoconstriction of the pulmonary vasculature, right ventricular hypertrophy, and cardiac failure (cor pulmonale). Children less than 3 years of age presenting for adenotonsillectomy require special attention, as they have the highest perioperative respiratory morbidity [68,69].

Preoperative assessment

Habitual snoring, without alterations in gas exchange, is very common in children and may not result in sleep disruption or morbid consequences. In contrast, children with OSA have a "disorder of breathing during sleep characterized by prolonged partial upper airway obstruction and/or intermittent complete obstruction which disrupts normal breathing and normal sleep patterns during sleep" [70]. Sleep disordered breathing and OSA are interchangeable terms. The features of OSA differ in children and adults. In children, the peak incidence of OSA occurs between 2 and 6 years of age, with an equal male/female distribution, and an excellent response to adenotonsillectomy in most children. With the increased incidence of childhood obesity, the clinical patterns of adult and pediatric OSA are begining to resemble each other [71]. Obstructive sleep apnea occurs during rapid eye movement (REM) sleep and is characterized by snoring and continuous partial upper airway obstruction during sleep. This results in paradoxical respiratory efforts, ineffective ventilation, hypercarbia, and hypoxemia [72].

Snoring, breath holding or apneic spells, failure to thrive, and repeated respiratory infections are all suggestive of OSA and indicate the need for overnight sleep polysomnography. Prior to the ubiquitous availability of mobile recording devices, definitive diagnosis of OSA was made by polysomnography; currently, not all patients undergo polysomnography preoperatively, because parents are able to provide a video or audio recording of witnessed snoring and apneic episodes on their smart phones. Respiratory events that are documented during polysomnography are outlined in Table 34.1.

Table 34.1 Respiratory events that may occur during polysomnography

Event	Definition
Central apnea	Pause in airflow with absent respiratory effort, scored when >20 s or two missed breaths and >3% decrease in oxygen saturation
Obstructive apnea	>90% reduction in airflow despite continuing respiratory effort, scored when event lasts at least two missed breaths in children
Obstructive hypopnea	>50% reduction in airflow despite continuing respiratory effort, scored when event lasts at least two missed breaths in children and >3% decrease in oxygen saturation or arousal
Mixed apnea	≥90% reduction in airflow, lasting at least two missed breaths, and containing absent respiratory effort initially (central apneic pause), followed by resumption of respiratory effort without resumption of airflow (obstructive apnea)
Obstructive hypoventilation	End-tidal CO_2 > 50 mmHg for >25% of total sleep time with paradoxical respirations, snoring, and no baseline lung disease

Source: Reproduced from Schwengel et al [225] with permission of Wolters Kluwer.

The number of hypopnea-obstructive episodes occurring during a sleep study are usually combined to give an apnea-hypopnea index (AHI), which is defined as the number of discrete obstructive events that occur per hour. Many sleep laboratories report an AHI or a respiratory disturbance index that includes the total number of respiratory events, including the number of central apnea events per hour. However, central apnea is a normal occurrence in children and is not associated with impaired respiration. True documentation of OSA in children should be based only on obstructive episodes associated with respiratory impairment [73,74]. OSA is considered to be severe if the AHI is ≥10 per hour and if the oxygen saturation nadir is ≤80%. The severity of OSA is usually based on the patient's overall clinical picture, including the frequency and severity of oxygen desaturation during the apneic episodes, duration of elevated carbon dioxide, and the number of obstructive events per hour [75–78].

Children with severe OSA are occasionally admitted to hospital preoperatively for optimization of their condition prior to undergoing adenotonsillectomy. Optimization may include oxygen administration and non-invasive nasal CPAP to stents the airway open, prevent airway collapse, and increase functional residual capacity. Bilevel positive airway pressure ventilation may also be instituted. This form of ventilation has been shown to improve pulmonary hypertension, decrease the postoperative complication rate, and may be beneficial in some pediatric patients [79,80].

KEY POINTS: ADENOIDECTOMY AND TONSILLECTOMY

- Tonsillectomy and adenoidectomy are very common surgeries performed in outpatient facilities
- The incidence of OSA is high and may be associated with CO_2 retention, hypoxemia, and pulmonary hypertension
- Parents can record their child's breathing preoperatively on their smartphone for viewing by the anesthesiologist preoperatively

Special situations in children undergoing adenotonsillectomy

A variety of special challenges may be encountered in children who present for adenotonsillectomy. These include patients with craniofacial disorders, Down syndrome, sickle cell disease, and those with known bleeding disorders. Risks of general anesthesia in these patient populations are discussed in Chapters 12 and 43. The anesthesiologist should be prepared for potential difficulty in maintaining airway patency, intubating the trachea, and maintaining ventilation, particularly in patients with craniofacial disorders. For example, patients with mucopolysaccharidosis I (Hurler syndrome) and II (Hunter syndrome) have diffuse infiltration of the upper airway and larynx with abnormal mucopolysaccharides, which predisposes them to upper airway obstruction and difficult tracheal intubation. Patients with Hurler syndrome may also have abnormal heart valves and coronary arteries at an early age. Patients with Hunter syndrome can have severe kyphoscoliosis, which may affect positioning for tracheal intubation.

Patients with trisomy 21 (Down syndrome) have midface hypoplasia that is characterized by narrow oral and nasal passages and glossoptosis. In addition, these children have hypopharngeal hypotonia that leads to hypopharyngeal collapse during induction of anesthesia. Mask ventilation may be difficult, and insertion of an oral and/or nasal airway may be necessary. Some of these patients develop hypertrophy of their lingual tonsils, which are not easily appreciated on oral examination because they are located posterior to the tongue (Fig. 34.1) [81]. Lingual tonsil hypertrophy can be responsible

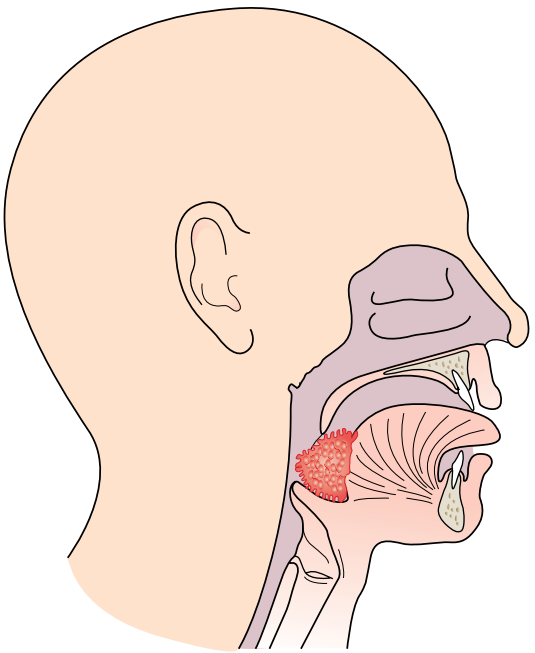

Figure 34.1 Hypertrophied lingual tonsil, which is difficult to appreciate on oral examination. *Source*: Reproduced from Olutoye et al [85] with permission of Wolters Kluwer.

for the persistence of OSA following adenotonsillectomy [82]. While the presence of hypertrophied lingual tonsils is not readily appreciated on oral examination, anesthesiologists must be aware that they are a cause of a "cannot ventilate-cannot intubate" clinical scenario [83–85].

Patients with sickle cell disease and recurrent tonsillitis are predisposed to developing sepsis. Hypoxemia in patients with OSA and sickle cell disease may have a sickling crisis. Therefore, frequent episodes of tonsillitis (>6 episodes per year) or adenoid hypertrophy resulting in upper airway obstruction are treated very aggressively in this subset of patients. Patients with sickle cell disease undergo special perioperative evaluation and management, depending on the preference of the hematologist. The main goals of these regimens is to prevent perioperative hypoxemia, maintain adequate hydration to decrease blood viscosity and subsequent concentration of sickled cells, to increase the concentration of hemoglobin to 10 g/dL via simple blood transfusion, and to decrease the concentration of hemoglobin S by blood transfusion. There are differences in opinion regarding the trigger hemoglobin value for preoperative blood transfusion in sickle cell disease patients undergoing minor surgical procedures. However, most centers have firm policies for the management of sickle cell patients undergoing routine surgery, including temperature maintenance, hydration, oxygen therapy, and pain management. The evidence that these measures are useful has not been well established [86–91]. Due to chronic pain, patients with sickle cell disease require adequate postoperative analgesic therapy [92]. Treatment of this pain may pose a challenge because even moderate doses of opioids can cause shallow breathing and hypoxemia, especially if the patient also has OSA. This makes the management of pain for these children more difficult than it is for the average patient. Preoperative consultation with the hematology service and pain service are essential before these children undergo surgery (see Chapters 12 and 37).

KEY POINTS: ADENOTONSILLETOMY IN CHILDREN WITH GENETIC SYNDROMES

- Maintenance of the airway and tracheal intubation may be difficult for patients with some syndromes
- Hypoxemia during adenotonsillectomy may result in a sickle cell crisis
- Patients with sickle cell disease must have their pain treated effectively
- Perioperative consultation with the hematology service is imperative prior to providing anesthesia for a patient with sickle cell disease

Coagulation status

Adenotonsillectomy differs from other operations in that a large, raw surface (tonsillar bed) is left open and the unopposed edges do not provide hemostasis at the end of surgery. It is, therefore, very important to obtain any history suggestive of bleeding tendencies and to discontinue medications that interfere with coagulation, such as aspirin, nonsteroidal anti-inflammatory drugs (NSAIDs), and valproic acid, prior to surgery. However, discontinuing these medications perioperatively may cause problems managing the patient's underlying disorder. For example, discontinuing aspirin in a child with a Blalock–Tausig shunt increases the risks of clot development within the shunt. Preoperative consultation with the patient's cardiologist should be obtained to balance the risks of bleeding with the risks of a blocked shunt.

Preoperative consultation with a hematologist is indicated for children with a personal history or family history of bleeding disorders. While routine coagulation studies may not be necessary in all subjects undergoing adenotonsillectomy, they are certainly required for a history suggestive of a bleeding disorder in either the patient or the family. Appropriate laboratory tests include prothrombin time to test the extrinsic and common coagulation pathway, activated partial thromboplastin time to test the intrinsic and common pathway, and a bleeding time and studies of platelet function. Children with known inherited coagulation disorders are sometimes scheduled to undergo adenotonsillectomy. These disorders include von Willebrand disease, a hereditary disorder characterized by a deficiency of von Willebrand factor and prolonged bleeding time, and hemophilia A or B, hereditary disorders characterized by deficiency of clotting factors VIII and IX, respectively. Consultation with the hematology service to determine the dose and time for the administration of specific factors to correct the coagulation defect is indicated prior to surgery (see Chapter 12).

Intraoperative management

Adenotonsillectomy is usually completed in 15–30 min by a variety of methods, including guillotine and snare, cold and hot dissection, ultrasound coblation, and electrocautery. Many combinations of inhaled and intravenous agents have been used to provide satisfactory anesthesia for these procedures. However, it usually involves induction of anesthesia via a facemask, establishing vascular access, tracheal intubation with a preformed Ring–Adair–Elwyn (RAE) tube, and maintenance of anesthesia with volatile anesthetics. Use of an oral RAE tube allows the surgeon to easily position the self-retaining mouth gag. In addition, the shape of the tube allows the anesthesia circuit to be connected away from the surgical site (Fig. 34.2). However, some surgeons prefer to work around a regular/straight oral tracheal tube. The LMA is routinely used for adenotonsillectomy in some centers. Some anesthesiologists recommend routine use of a cuffed tracheal tube to reduce the leak of anesthetic gases and oxygen into the pharynx, which reduces the risk of airway fires. Adenotonsillectomy is a high-risk procedure for airway fires because there is an ignition source (electrocautery) in close proximity to an oxidizer-enriched environment (>21% oxygen and nitrous oxide in the pharynx), and combustible tissue, the triad necessary for an operating room fire [93]. An FiO_2 of 0.30 or less should be employed during the period of electrocautery use for adenotonsillectomy. Cuffed tracheal tubes limit the number of repeated laryngoscopy attempts, allow for use of low-flow anesthesia, and decrease the amount of detectable anesthetic gas in the operating room [94]. There is no existing randomized controlled trial that has studied the safety of LMAs versus cuffed tracheal tubes for securing the airway for this procedure.

Figure 34.2 Child positioned for tonsillectomy and/or adenoidectomy. The tracheal tube is secured along the mandible away from the operative field. It is imperative to ensure that the tracheal tube is not kinked or occluded by the retractor.

At the end of surgery, the trachea can be extubated with the patient awake or during deep anesthesia, provided they are breathing comfortably without episodes of breath holding or apnea. Studies have shown that there is no difference in the incidence of oxygen desaturation, breath holding, laryngospasm, or the need for an emergency rescue airway in children extubated awake or in deep anesthesia after adenotonsillectomy [95,96]. The experience of the anesthesiologist is also a factor in reducing PRAEs [15].

The goal of the adenotonsillectomy anesthetic is to have a comfortable child without episodes of respiratory obstruction in the postoperative period. This is usually achieved by intraoperative administration of opioids. However, children with OSA may be more sensitive to the effect of opioids and reduced doses may be required to prevent postoperative respiratory depression [97]. In patients with severe OSA, small doses of opioids are titrated to effect in the PACU once the patient is awake. Acetaminophen is administered intraoperatively to provide postoperative analgesia for tonsillectomy. However, enteral administration of acetaminophen alone does not provide adequate analgesia due to delayed drug absorption and attainment of subtherapeutic plasma drug concentrations [98]. Intraoperative use of IV acetaminophen and opioids together was associated with the need for fewer rescue medications, decreased side-effects, and decreased recovery times and costs compared with single IV opioid therapy alone post tonsillectomy [99]. This was because less opioid was required.

Intraoperative infiltration of the tonsillar bed with local anesthetic is utilized by some surgeons to decrease postoperative morbidity in this population [100–102]. Different surgical techniques have also been used to determine which technique causes the least postoperative pain [103–106].

The α2-agonist dexmedetomidine was shown to reduce postoperative opioid consumption in adults undergoing major inpatient surgery [107]. This drug provides mild analgesia without respiratory depression and has increased the time to the first rescue opioid analgesic in the PACU when given in doses of 1 or 0.75 μg/kg in adenotonsillectomy patients during surgery [108]. Dexmedetomidine 0.1 μg/kg produced less respiratory depression, but provided less effective analgesia than morphine 0.1 mg/kg in children with OSA who underwent adenotonsillectomy [109].

In the United States, acetaminophen combined with codeine was formerly commonly administered for analgesia following tonsillectomy ± adenoidectomy. Codeine is converted to morphine by the highly polymorphic *CYP2D6* gene. Consequently, there are patients who are poor metabolizers (low activity variants), extensive metabolizers (high or normal activity variants), or ultra-rapid metabolizers (multiple gene copy variants). Poor metabolizers cannot convert codeine to morphine efficiently. Consequently, these patients experience no pain relief from codeine. Ultra-rapid metabolizers metabolize codeine too efficiently and can develop morphine intoxication, respiratory depression, and perioperative death. This resulted in the US Food and Drug Administration (FDA) issuing a black box warning (absolute contraindication) against the use of codeine in children in 2012 [110,111]. The decrease in narcotic use led to an increase in the use of NSAIDs, such as ibuprofen, post tonsillectomy. Prior to the FDA black box warning, the concern about the effects of NSAIDs on hemostasis had limited their use perioperatively [112]. A Cochrane systematic review of studies examining risk of bleeding with NSAIDs in post-tonsillectomy children provided inconclusive evidence one way or the other. Results of the most recent review have also failed to conclusively exclude excessive postoperative bleeding when these drugs are utilized in patients undergoing a adenotonsillectomy [113,114]. Studies have shown that the incidence of bleeding is not increased when ibuprofen with acetaminophen is administered postoperatively to treat the pain of adenotonsillectomy [115,116]. Due to these findings, and the FDA black box warning on codeine, the present practice in the United States is for some surgeons to discharge patients home post tonsillectomy and/or adenoidectomy with ibuprofen alternating with acetaminophen.

Intraoperative dexamethasone has also been used to reduce postoperative pain, edema, and to prevent nausea and vomiting after adenotonsillectomy. The minimum dose required to reduce opioid consumption was 0.5 mg/kg, however parents reported improved pain scores with 1 mg/kg of dexamethasone [117]. This report was criticized for the reported increased bleeding, the high incidence of primary hemorrhage, and the rate of need for reoperation on the day of surgery [118]. Follow-up studies and Cochrane systematic reviews have not supported an increased incidence of bleeding following use of dexamethasone during adenotonsillectomy [119]. Dexamethasone is also useful as an antiemetic. Its administration intraoperatively, in conjunction with an antiserotonin drug, such as ondansetron, is the recommended antiemetic prophylaxis for this procedure [63].

Complications

Postoperative or secondary hemorrhage and respiratory impairment are the most frequently observed complications following adenotonsillectomy. The incidences of these complications greatly depend on age of the patient and associated medical conditions. Postoperative hemorrhage is more common in children older than 10 years of age [120], while respiratory complications (supraglottic obstruction, breath holding, and need for airway rescue maneuvers) are more common in children younger than 3 years of age [75,121,122].

In many institutions, children less than 3 years of age are observed overnight in the hospital following adenotonsillectomy, particularly if they have co-morbid conditions (e.g. Down syndrome, developmental delay, OSA).

Other rare complications following adenotonsillectomy include uvular edema, uvula amputation, velopharyngeal insufficiency, and nasopharyngeal stenosis. Throat pain, otalgia, and poor oral intake are common following discharge home.

Post-tonsillectomy hemorrhage

Primary post-tonsillectomy hemorrhage is a common complication that often requires surgical re-exploration, usually within the first hour after surgery. Secondary hemorrhage presents within 2 weeks after the initial surgery, when the eschar on the surgical site is dislodged and raw mucosal surfaces are exposed. Secondary hemorrhage occurs in 0.5–2% of all tonsillectomies. Mild post-tonsillectomy bleeding can be managed conservatively, but 41% of patients with minor bleeding subsequently develop major bleeding within 24 h and require surgical exploration and cauterization of the bleeding surface.

Post-tonsillectomy hemorrhage occurs more commonly in older children. Children with bleeding tonsils usually swallow the blood before they show evidence of frank hematemesis. Therefore, they have a full stomach and must be treated accordingly during the induction of anesthesia. In rare cases, they may have significant anemia from blood loss. If there has been significant bleeding, a preoperative hemoglobin level should be obtained. If necessary, blood should be transfused. The degree of dehydration observed on clinical examination helps determine the amount of volume replacement required. Since they have a sore throat, they may not have been drinking. A severely dehydrated child has dry mucus membranes, sunken orbits, and decreased skin turgor; tachycardia and hypotension may also be present. Urine output is often decreased or absent. If the amount of bleeding and dehydration is significant, it may be difficult to obtain intravenous access. Insertion of an intraosseous needle may be required. If possible, large-bore intravenous needles should be placed because large volumes of crystalloid, with or without colloid, may be required.

Preparation for the induction of anesthesia includes having two suction catheters available, preferably of the firm Yankauer type, and medication for a rapid-sequence induction of anesthesia. Preoxygenation should be followed by rapid-sequence induction of anesthesia. The surgeon should be holding one suction and the other should be within easy reach of the anesthesiologist to quickly suction vomited blood if necessary. In situations of severe bleeding, the vocal cords may not be visible. If this occurs, an assistant should gently press on the anterior chest wall, and the anesthesiologist should aim the tip of the tracheal tube at the site where bubbles are seen during compression. Careful laryngoscopy is required because it may scrape the tonsillar bed and precipitate further bleeding. Cuffed tracheal tubes are recommended because of the full stomach. Prompt identification of the bleeding sites usually occurs during surgery. Cauterization of the tonsillectomy bed lasts only about 20 min. If signs of shock are present, blood may be transfused intraoperatively or in the recovery room. The stomach should be emptied of blood and secretions as best it can before removing the tracheal tube.

KEY POINTS: ADENOTONSILLECTOMY INTRA- AND POSTOPERATIVE MANAGEMENT

- Adenotonsillectomy is a high-risk procedure for airway fires and FiO_2 should be ≤30% during surgery
- Because they have chronic hyper-reactivity of their airways, patients are prone to laryngospasm and/or bronchospasm during tracheal tube insertion
- Postoperative respiratory complications are common in younger children while postoperative bleeding is more common in older children
- Acute postoperative bleeding from the surgical site occurs within 2 h of terminating surgery, while secondary bleeding occurs 1–2 weeks later

Endoscopic sinus surgery

Chronic sinusitis is characterized by inflammation of the sinuses and occlusion of the sinus ostia. The latter prevents the normal drainage of fluid from the sinuses into the nose. In some patients, adenoidectomy relieves the symptoms, although endoscopic sinus surgery is the mainstay for surgical treatment of chronic sinusitis that is refractory to antibiotic therapy and adenoidectomy. Direct telescopic visualization of the nasal mucus membranes allows relief of the obstruction by sharp, biting instruments or a microdebrider. This improves ventilation of the sinuses while leaving the mucous membranes intact. Children with cystic fibrosis often present for this surgery, due to impaired mucociliary function and chronic infection. The anesthesiologist should ensure that the pulmonary function of patients with cystic fibrosis has been optimized prior to surgery.

Bleeding during sinus surgery often makes visualization of the surgical field difficult. To reduce bleeding, the nasal cavity is packed with pledgets soaked in a vasoconstricting solution, usually oxymetazoline 0.025–0.05%, phenylephrine 0.25–1%, cocaine 4–10%, or lidocaine 2% with epinephrine 1:100,000 or 1:200,000. The anesthesiologist must be aware of the type and dose of vasoconstrictive agent used and ensure that the maximum allowable concentration/amount of the drug is not exceeded. Rapid absorption of these drugs from raw mucosal surfaces leads to tachycardia or bradycardia and/or hypertensive episodes in some patients [123,124]. This is especially true if intraoperative anticholinergic drugs have been administered. The intraoperative hypertension is usually transient and resolves spontaneously without aggressive treatment. The recommended maximum dose of phenylephrine in children is 20 μg/kg. Cocaine use during surgery has resulted in myocardial infarction in otherwise healthy individuals [125]. Cocaine may also block the nasociliary ganglion and cause transient postoperative anisocoria [126].

Intraoperative management for endoscopic sinus surgery requires tracheal intubation with an oral RAE tube, which is securely fixed to the mandible; this allows easy surgical access to the maxilla and sinuses. The use of cuffed tracheal tubes prevents fogging of the endoscopic equipment by excessive gas leakage from around the tube. Throat packs are almost always utilized during this surgery to prevent escape of anesthetic gases and oxygen into the surgical

environment. The surgeon and anesthesiologist must confirm the throat pack has been removed *prior* to extubation of the trachea, as a retained pack may cause airway obstruction, emergence agitation, or even death if not recognized. Intraoperative administration of intravenous corticosteroids has been used to prevent postoperative airway swelling. At the end of surgery, the surgeon often leaves stenting material in the sinuses. This may cause patient discomfort or a perception of difficult breathing during emergence from anesthesia. Therefore, the anesthetic technique should provide adequate analgesia and quick emergence from anesthesia.

A second endoscopic procedure is usually required approximately 6 weeks after the initial surgery to remove the packs (if non-absorbable packs were used) and to examine the surgical site. This second-look procedure is usually quick and the LMA is usually sufficient for airway maintenance.

Endoscopy of the larynx, trachea and bronchial tree

The major challenge during endoscopy of the respiratory tract is for the anesthesiologist to maintain adequate alveolar ventilation and oxygenation, and to provide a quiet surgical field while having a clear view of a patient who has some degree of upper or lower airway compromise. They must do this while sharing the airway with the endoscopist. Preoperative communication between the surgeons, nurses, and anesthesiologist is essential so that all members of the team are aware of the aims, steps in the procedure, equipment required, and any special precautions or requirements, e.g. need for spontaneous respiration, method of lung ventilation during the procedure, and potential fire hazards.

Lesions commonly diagnosed endoscopically include laryngomalacia or tracheomalacia, vascular anomalies that are causing tracheobronchial compression, congenital or acquired subglottic stenosis, vocal cord palsies, abnormal growths in the airway (e.g. papillomas, hemangiomas, cysts, granulomas), and foreign bodies [127,128]. Therapeutic bronchoscopy is performed to extract foreign bodies from the airway or to aspirate thick, tenacious mucus plugs from bronchi [129].

Preoperative evaluation of the airway requires a careful history of the extent of airway obstruction during sleeping, crying, or feeding. It also requires knowledge of the extent of accompanying respiratory distress (use of accessory muscles of respiration, tachypnea) and which positions or maneuvers aggravate or alleviate the symptoms. The anesthesiologist should examine any available chest radiographs, head and neck computed tomography scans, magnetic resonance imaging scans, pulmonary function tests, and arterial blood gas determinations to obtain a complete understanding of the patient's clinical situation [130,131].

Flexible fiberoptic and direct laryngoscopy and bronchoscopy

With the miniaturization of flexible endoscopic equipment, appropriately sized flexible bronchoscopes can be used to directly examine the airway of children of any age [132]. These bronchoscopes are available in sizes ranging from 2.2 to 6.3 mm outer diameter (internal channel 1.2–3.2 mm) and have been increasingly used in the smallest and sickest of children. As with any procedure, flexible airway endoscopy is performed when it is the easiest, safest, and most effective method to obtain the diagnostic information required [133]. It is often performed at the bedside of patients in the intensive care unit (ICU). In rare situations, this procedure is accomplished in infants or older children with only topical anesthesia and minimal sedation. More commonly, general anesthesia is required. Preoperative sedatives and opiates must be administered with caution to those who have airway compromise, and then only with appropriate monitoring and by persons who are skilled in advanced airway management. Some experts recommend an antisialogue to minimize secretions [134–136].

For procedures occurring in the operating room, sedation/anesthesia can be provided with midazolam, propofol, or with inhaled anesthetics, usually sevoflurane (which is less irritating to the airway than desflurane). One hundred percent oxygen is also administered. Dexmedetomidine can be used, but with caution, as the hemodynamic imbalances can be wide ranging, particularly if bolus doses of the drug are administered. The larynx and trachea may also be anesthetized by spraying local anesthetics (2–4% lidocaine 3–5 mg/kg (total dose)) on the vocal cords with an atomizer. This reduces the inhalation agent requirement and allows for maintenance of spontaneous ventilation. Spontaneous ventilation allows the surgeon to observe movement of the vocal cords with breathing. Dexmedetomidine also provides jaw relaxation and satisfactory conditions for airway endoscopy [137]. Propofol infusions 150–200 μg/kg/min plus an inhalation agent also provide adequate conditions for laryngoscopy. Others have used propofol plus remifentanil for this procedure.

A flexible bronchoscope can be inserted into the airway by one of six methods: transnasal, transoral, or via a facemask, LMA, tracheal tube, or a tracheostomy. Some devices have channels that permit easy insertion of the bronchoscope through them and are available for each route. Flexible bronchoscopy is usually performed to evaluate airway dynamics and anatomy, particularly of the upper airway. A transnasal or transoral approach provides the best views of the upper airway; an LMA or tracheal tube cannot do this.

Laryngomalacia is a common indication for using a flexible bronchoscope to assess the airway. It is used to make the diagnoses and to determine if the application of CPAP improves the airway dynamics of the affected child. This information may have a direct impact on long-term management.

Other indications for flexible bronchoscopy include cystic fibrosis, ventilator-associated pneumonia, pulmonary aspiration, bronchoalveolar lavage, and when needed (e.g. Langerhans cell histiocytosis, pulmonary alveolar microlithiasis and pulmonary alveolar proteinosis). Transbronchial biopsies can also be performed via the flexible endoscope to evaluate nodules, infiltrative disorders (e.g. after lung transplantation), infections, airway lesions, and tumors.

The American Thoracic Society has published technical standards for equipment, personnel, and competencies required to perform flexible airway endoscopy in children [133]. They have also provided extensive guidelines for the inspection, maintenance, storage, cleaning, and manual or automated reprocessing of flexible bronchoscopes for

infection control and prevention of cross-infections from patient to patient [133].

Spontaneous ventilation may be maintained throughout the whole procedure, provided the patient can effectively breathe spontaneously while anesthetized. At times, movement of the airway with breathing will interfere with accomplishing the procedure (e.g. laser therapy). If oxygen desaturation occurs during the procedure, the procedure should be stopped long enough to administer positive pressure ventilation and restore the oxygen saturation to normal. When a rigid bronchoscope is used, positive pressure ventilation can be provided throughout the procedure. Jet ventilation has been used in older children, but the potential for airway trauma has caused jet ventilation to be abandoned in younger children [134]. The goal at the end of the bronchoscopic procedure is to have the patient breathe spontaneously through their natural airway. Therefore, muscle relaxants (if used) must be utilized judiciously, and adequate reversal of neuromuscular blockade must be demonstrated before the child is awakened.

Rigid bronchoscopy

Rigid bronchoscopy may be preferred when the area of interest is the posterior larynx and cervical trachea or if the procedure requires the insertion of multiple instruments. Segmental stenosis of large airways can often be managed by bronchoscopic dilation and placement of stents. Because of the potential for trauma-related complications, these procedures must only be performed by experienced personnel in carefully selected cases.

Rigid pediatric ventilating bronchoscopes are equipped with an optical telescope and a fiberoptic light source. The optical telescope, when used with the Storz pediatric bronchoscope, provides superior resolution, magnification, and a wide-angle view [129]. Miniaturized grasping or biopsy forceps can be inserted through the channel of the instrument. An advantage of this system is that it is closed, which permits use of anesthetic gases and positive pressure ventilation while the viewing telescope is in place [129,136]. Another advantage is that it can be used to retrieve foreign bodies, which requires removal of the magnifying telescope. A sidearm port makes it possible to attach the ventilating bronchoscope to any anesthetic system to maintain anesthesia, oxygenation, and to assist or control manual ventilation (Fig. 34.3).

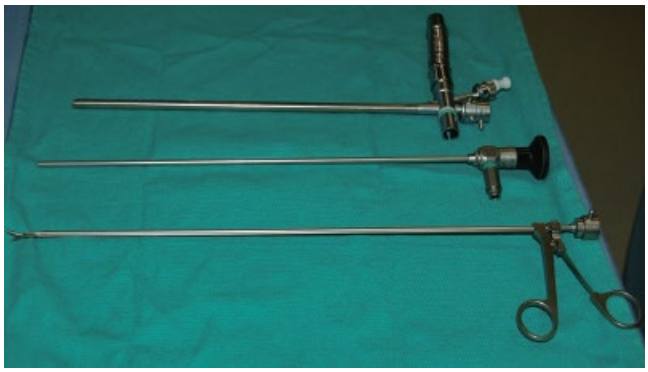

Figure 34.3 Ventilating bronchoscope, optical telescope, and foreign body forceps.

The optical telescope occupies nearly the entire internal lumen of smaller bronchoscopes, which reduces the area for gas flow, markedly increases airflow resistance, and retards passive expiration. This can potentially cause hyperinflation of the lung and hypoventilation [138]. A persistent increase in intrathoracic pressure increases the risk for barotrauma and impairment of cardiac output [138]. Maintaining adequate expiratory time is essential for complete expiration. A 2.8 mm telescope in a 3.5 mm bronchoscope permits adequate exhalation and prevents hyperinflation of the lungs, even during positive pressure ventilation [136]. When smaller bronchoscopes are used, the endoscopist can intermittently remove the telescope and occlude the orifice of the scope manually, thereby allowing the anesthesiologist to deliver brief periods of unobstructed positive pressure ventilation [138]. For bronchoscopic examinations of longer duration, intermittent determinations of $PaCO_2$ will confirm the adequacy or inadequacy of ventilation. When evaluating the airways of small infants with a 2.5 mm bronchoscope, the surgeons must remove the telescope more frequently to allow adequate ventilation and passive exhalation.

Any rapid deterioration in the patient's hemodynamic status during bronchoscopy should make one highly suspicious of a tension pneumothorax [139]. Clinical findings of a pneumothorax alone justify thoracostomy before obtaining a chest radiograph. Vocal cord movement is often evaluated by laryngoscopy while the patient awakens from anesthesia. Care must be taken during this time to avoid causing laryngospasm; many practitioners utilize topical lidocaine for this purpose.

There are competing views of the first choice of instruments (flexible or rigid bronchoscopy) for viewing the airway, depending on the indication for endoscopy. However, rigid bronchoscopy is still the first choice in children with asphyxiating foreign body aspiration (see later in this chapter) [140].

KEY POINTS: DIRECT LARYNGOSCOPY AND BRONCHOSCOPY

- Flexible fiberoptic bronchoscopy can be accomplished via facemask, LMA, endotracheal tube, or tracheostomy, or through direct nasal or oral routes
- Rigid bronchoscopy is useful for the removal of foreign bodies from the airway
- Most rigid scopes permit ventilation of the patient's lungs during the examination
- Smaller rigid scopes are more likely to cause hyperinflation of the lung and a pneumothorax
- Hyperinflation of the lung may cause hypotension and decreased cardiac output

Stridor

Stridor is noisy breathing caused by turbulent gas flow through the narrowed lumen of an airway and can occur during either inspiration or expiration. Inspiratory stridor is the result of anomalies that narrow the airway above the thoracic inlet (e.g. cysts or masses, laryngomalacia, vocal cord paralysis, hemangiomas, laryngoceles, papillomas, adenotonsillar

hypertrophy, midfacial hypoplasia, croup). Expiratory stridor is most commonly associated with airway obstruction below the thoracic inlet (e.g. cysts, hemangiomas, vascular rings, foreign bodies, bronchomalacia) [35,128]. Biphasic stridor is common and characteristic of midtracheal abnormalities caused by tracheomalacia, tracheal stenosis, or tumors. Diagnostic laryngoscopy/bronchoscopy and a variety of imaging procedures are often required to determine the etiology of stridor. These procedures usually require deep sedation or general anesthesia in young children. The anesthesiologist must understand the physiology and clinical implications of stridor.

Inspiration through a partially obstructed extrathoracic airway reduces the intraluminal airway pressure below atmospheric pressure. Because the intratracheal pressure is lower than atmospheric pressure, the extratracheal lumen narrows, increasing stridor. During expiration, the extrathoracic intraluminal pressure is positive with respect to atmospheric pressure, which dilates the lumen and decreases stridor. On the other hand, a partially obstructed intrathoracic airway dilates during inspiration due to the increased extraluminal negative pressure. During expiration, the reverse occurs, and the expiratory noise (wheezing) worsens [35,128].

A careful medical history defines the severity and duration of symptoms, age, and acuteness of onset of the symptoms, and any history of previous tracheal intubation or anesthesia. A stridulous newborn, for example, is likely to have a congenital anomaly of the airway as the etiology for stridor. A 3-year-old with sudden onset of severe stridor is more likely to have a foreign body or an infectious etiology as the cause for stridor. The stridor of a child in the PACU or ICU, whose stridor develops after tracheal extubation, is likely to have airway edema. The severity and rapidity of the progression of symptoms guides the diagnostic and treatment plan.

Approximately 45–60% of stridor is due to laryngomalacia in young infants (excluding postextubation stridor) [128,141]. Symptoms of this process are generally present from birth and must be differentiated from other congenital causes of stridor. Babies with laryngomalacia seldom have feeding difficulties. But children with glottic or oropharyngeal lesions or those with a tracheoesophageal fistula commonly have both stridor and difficulty feeding. The noise usually worsens when babies with stridor are agitated or positioned supine. The symptoms of some of these babies improve when they are placed in the prone position. Although many the infants with laryngomalacia do well and their clinical status improves with increasing age, the stridor of some children persists for 4–5 years [141].

While the incidence of upper or lower respiratory tract infections is not increased in infants and children who have laryngomalacia, their upper airway obstruction often worsens in the presence of a URI [141]. A child with laryngomalacia and URI who presents for anything but emergency surgery should be very carefully evaluated and delaying the surgery should be considered, especially if general anesthesia and tracheal intubation are required. If surgery is emergent, the anesthesiologist should maintain an audible air leak around the tracheal tube when a positive pressure of 20–25 cmH_2O is generated. A tracheal tube 0.5–1.5 mm smaller than usual may be required. These patients should be monitored postoperatively in a pediatric ICU, where prompt airway and ventilatory support are immediately available if needed.

Although uncommon, an infant with neurological abnormalities may present with stridor. Laryngeal nerve paralysis due to birth trauma, or cardiac malformations that affect the left recurrent laryngeal nerve, or postoperative complications of patent ductus arteriosus surgery may cause stridor. Frequently, the etiology of the nerve injury is unclear. Unilateral vocal cord paralysis is often the result of a peripheral nerve lesion. Infants with unilateral cord paralysis often have stridor or hoarseness and feeding difficulties. Those with bilateral vocal cord paralysis often have central nervous system problems (e.g. hydrocephalus, Arnold–Chiari malformation, Dandy Walker cyst, encephalocele, posterior fossa hematomas, or due to child abuse) [142–146]. While some authorities relate the stridor of neurological disease and vocal cord paralysis to stretching of the vagus nerve over the jugular foramen, it is often unclear what the actual cause is and why it persists after the increased intracranial pressure is normalized. Sometimes children with bilateral vocal cord paralysis and serious respiratory obstruction, or recurrent aspiration pneumonia, require a tracheostomy. As children grow, their stridor often improves.

Anesthetic considerations for children with stridor are similar, regardless of the etiology of the obstruction. Maintaining CPAP during spontaneous ventilation via a facemask often reverses the upper airway pressure gradient and decreases or eliminates the obstruction. Before the start of anesthesia, it is vital to have a wide range of tracheal tubes available for intubation, as some airway lesions, such as cricoid ring stenosis, webs, cysts, hemangiomas, epiglottitis, and croup, necessitate the use of a smaller than normal tube. Lesions such as vocal cord paralysis may cause stridor without narrowing the airway. The tracheal tube used should have a gas leak at approximately 20–25 cmH_2O airway positive pressure to prevent further tracheal injury.

Postextubation stridor is a significant problem in children after prolonged mechanical ventilation because they often have laryngeal/tracheal edema, airway narrowing, and stridor. Stridor is also common after airway surgery.

The use of high-pressure cuffed tracheal tubes in children in the past was sometimes associated with postextubation stridor. Newer low-pressure cuff tracheal tubes have not been associated with an increased incidence of stridor. Use of the newer tubes has also decreased the number of attempts for tracheal intubation with the appropriate size tube [147]. Reducing the number of attempts is important because the subglottic mucosa of children is vascular, loose areolar tissue which can fill with edema fluid with repeated trauma. In children less than 5 years old, the narrowest portion of the upper airway is the cricoid cartilage. A tight-fitting tracheal tube, burns, or other trauma causes inflammation and narrowing of the internal diameter of the cricoid ring area. This is made worse by the fact that the tracheal cartilages confine the edema to the tracheal mucosa making this area prone to edema, especially following long-term tracheal intubation.

Inhaled racemic epinephrine, heliox, and occasionally steroids are utilized to treat stridor. Racemic epinephrine (0.5 mL of 2.25% solution in 2.5 mL of normal saline) can be administered at 5 min intervals by nebulization to decrease airway edema if the heart rate remains below 200 beats/min. Oxygen saturation should be monitored during treatment. If multiple treatments are required, an arterial blood gas should be

obtained to ensure that ventilation is adequate. This is important, particularly if the child has increased work of breathing.

Heliox (usually 70% helium and 30% oxygen) facilitates ventilation in patients with stridor. The decreased density of heliox allows more laminar flow in obstructed airways and decreases the work of breathing. To avoid hypoxia, however, heliox should not be used in children whose FiO_2 requirements exceed 0.3.

Steroids are also used to manage stridor. When using them, the potential effect of these drugs on delayed wound healing should be balanced against the possible beneficial effects of steroids on the airway. When a patient cannot be weaned from mechanical ventilation for no obvious reasons, a 48 h trial of steroid therapy is warranted. This may decrease airway edema and allow successful tracheal extubation. Dexamethasone 0.25–0.5 mg/kg every 6 h is a common regimen.

KEY POINTS: STRIDOR

- Stridor has multiple causes that must be differentiated from one another
- With extrathoracic lesions, stridor is most prominent during inspiration
- With intrathoracic lesions, stridor is most prominent during expiration
- Mask CPAP may improve stridulous breathing

Supraglottitis

Acute supraglottitis (previously known as epiglottitis) is a life-threatening infection characterized by severe supraglottic edema and a risk for upper airway obstruction (Fig. 34.4). Children with this problem usually have rhinorrhea, cough, a severe sore throat, and fever. As the symptoms progress, the child constantly drools and often prefers to lean forward (tripod position) to improve their pattern of breathing. Prior to the routine immunization of children with the *Haemophilus influenza* type b (Hib) polysaccharide vaccine, many of the invasive cases of acute supraglottitis in 2–6-year-old children were the result of infection with this organism. Because of vaccination, the incidence of infection with Hib has diminished [148,149] and has been replaced by infections with group A *Streptococcus* [150], *Neiseria meningitides*, and *Candida albicans* [151,152]. The onset of supraglottitis is fulminant. The differential diagnosis of this disease includes laryngotracheobronchitis (croup) and tracheitis (Table 34.2).

Patients with suspected supraglottitis are at risk for sudden and complete airway obstruction. These patients should be managed by a multidisciplinary team from the time they present to an emergency room or clinic. The hospital or clinic should have a coordinated approach to supraglottitis that is well established. The members of this team should be immediately available. When the diagnosis of supraglottitis is made or strongly suspected, the primary goal is to quickly secure the airway. Tracheal intubation has been shown to be a safe and efficacious alternative to tracheostomy and is the preferred method for providing an airway for these patients. The following approach is consistent with those of other centers [153].

A pediatrician, an anesthesiologist skilled in pediatric airway problems, and a surgeon skilled in placing a tracheostomy in an infant or child are notified when or shortly after the child arrives in the emergency room. A thorough, rapid cardiopulmonary history and assessment is made. Examination of the airway is limited to noting respiratory rate, observing the pattern of breathing, and assessing the child's work of breathing and level of respiratory distress. At most, the heart and lungs are examined. Any maneuver likely to cause or increase agitation in the child should be reserved for the operating room; this includes manipulation or examination of the mouth and oropharynx, intravenous catheter placement, venipuncture, or arterial blood gas sampling. The child should remain sitting on a parent's (or other familiar caretaker's) lap and breath supplemental oxygen. Oxygen saturation should be monitored while the child is being closely observed by the medical team.

If the child does not have significant respiratory distress, obtaining a single lateral radiograph of the neck to confirm the diagnosis may be considered. If this is done, the child must receive supplemental oxygen while sitting up on a stretcher during transport to the radiography suite. Someone who can emergently intubate the trachea if necessary must accompany the child. If the child is in significant respiratory distress or the diagnosis is made clinically, the child should be promptly transported to the operating room while sitting up.

Table 34.2 Features of supraglottitis, laryngotracheobronchitis, and tracheitis

	Supraglottitis	Laryngotracheobronchitis	Tracheitis
Age	2–6 years	2 months to 3 years	2–6 years
Onset	Fulminant	Gradual	Gradual
Etiology	Bacterial	Viral	Bacterial
Presentation			
Voice	Muffled	Bark	Bark
Secretions	Drooling	Drooling	None
Fever	>38.5°C	37–38°C	>38.5°C
Distress	Anxious, sitting up	Normal	Toxic appearing, sitting up

Oxygen should be administered and oxygen saturation monitored during transport. Radiological confirmation of the lesion is unnecessary and potentially dangerous in this urgent situation. Those who accompany the child during transport to the operating room must be skilled in pediatric airway management and cardiopulmonary resuscitation.

A tracheostomy tray should be open and the surgeon present when the patient arrives in the operating room. A smooth induction of anesthesia with the child sitting on the caretaker's lap and breathing sevoflurane in 100% oxygen allows for minimal airway irritation [154]. Halothane is still a viable option for the induction of anesthesia if sevoflurane is not readily available. The appropriateness of the presence of a parent or other caregiver during the induction of anesthesia must be assessed for each patient.

With the onset of anesthesia, the patient is placed in the supine or more commonly in the semi sitting position, while the jaw thrust is used and CPAP is applied via facemask to overcome upper airway obstruction. Intravenous catheter placement commences once the level of anesthesia is sufficiently deep to avoid precipitating laryngospasm with the needle insertion. Tracheal intubation is often accomplished with a tube that is 0.5–1.5 mm smaller in outer diameter than is appropriate for the patient's age and size. When everything is stable, some anesthesiologists will change the orotracheal tube to a nasotracheal tube because the child will remain intubated for several days, and a nasotracheal tube may be more secure and better tolerated by the patient.

Blood and laryngeal cultures are obtained during anesthesia, and appropriate antibiotics are administered intravenously. The selection and dose of antibiotic varies depending on the predominant organisms in the geographic area and in the patient (e.g. immunocompromised, HIV infection). If during upper airway examination, the diagnosis of supraglottitis is ruled out, and a diagnosis of tracheitis is made, the choice of antibiotic administered before cultures and sensitivities are available may differ from those chosen to treat supraglottitis. Consulting with a pediatric infectious disease specialist is appropriate and helpful. The morbidity from 24–48 h of tracheal intubation is minimal with excellent nursing care. Consequently, most otolaryngologists prefer to use a tracheal tube rather than a tracheostomy during this time. Once a gas leak (indicating resolution of the airway edema) has developed around the tube, the patient may return to the operating room for endoscopic examination of the airway.

KEY POINTS: SUPRAGLOTTITIS

- Supraglottitis is a life-threatening infection caused by several different organisms
- Successful care requires a skilled team of pediatricians, surgeons, nurses, and anesthesiologists
- Tracheal intubation should occur in the operating room emergently
- Induction of anesthesia should take place with the child sitting in a parent's lap while the child breaths sevoflurane in 100% oxygen
- Tracheal intubation often requires a tube that is 0.5–1.5 mm smaller than normal for a child of that size and age

Airway foreign bodies

Foreign body aspiration

Aspiration of foreign bodies, including food, toy parts, batteries, coins, pin caps, etc. (Fig. 34.5), is a major source of morbidity and mortality in children below the age of 5 years, with a peak incidence occurring between 1 and 2 years [155–159]. Depending on the nature and location of the aspirated object,

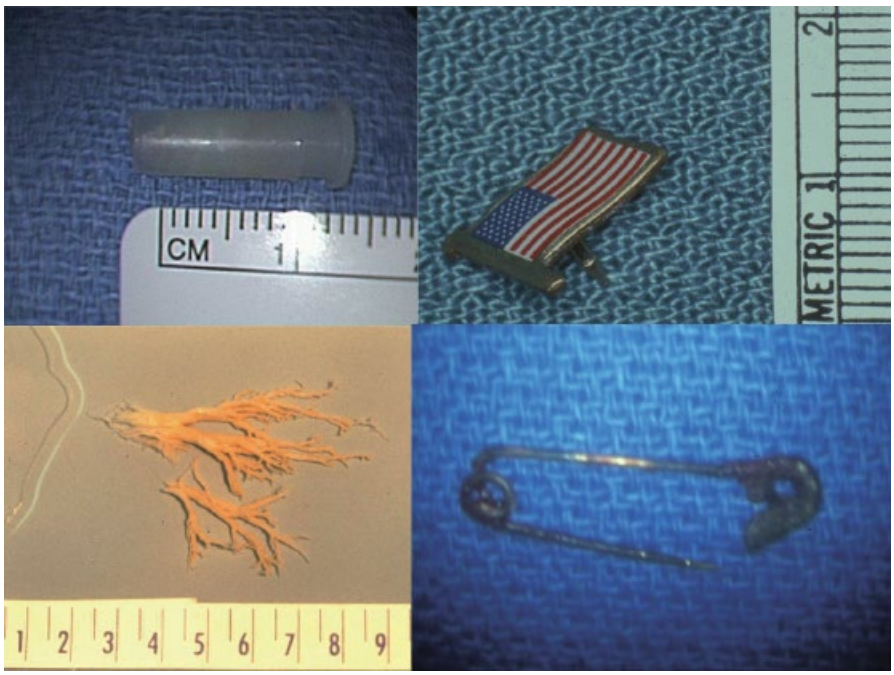

Figure 34.5 A variety of foreign bodies retrieved from the airway; clockwise from top left: plastic tube, toy flag, safety pin, and bubble gum. *Source*: Courtesy of Ellen Friedman MD.

removal can be lifesaving [160]. A detailed preoperative discussion with the anesthesia, surgery, and nursing teams allows for proper coordination and a smooth procedure.

A thorough patient history often helps establish the diagnosis of foreign body aspiration. Some parents report witnessing a choking episode, which they did not consider significant at the time because it was short lived. This often results in delayed presentation and diagnosis of the problem. The presenting symptoms of foreign body aspiration vary depending on the location, size, and duration of the aspirated object. Acutely, a child may present with hoarseness, stridor, dyspnea, and unilateral decreased air entry or wheezing [161–164]. There is often acute airway distress, especially if the object is lodged at or near the glottic inlet [160]. However, normal auscultation or physical examination does not eliminate the possibility of an aspirated foreign body because 14–45% of patients with abnormal bronchoscopic findings, including foreign bodies, have normal physical examinations preoperatively [165–167]. Objects located in the larynx or trachea are associated with as high as 45% mortality [168]. According to one study, the diagnosis of laryngotracheal foreign body aspiration was only made within 24 h of aspiration in slightly more than one-half of the patients. The diagnosis was made in the remaining patients following failure of medical management for croup or reactive airway disease, usually within 1 week of aspiration. Late diagnosed children either did not respond to medical therapy or their condition deteriorated despite appropriate medical therapy [163,169]. Partial obstruction by smaller objects may go unrecognized for weeks [168] and then present with recurrent or chronic pneumonias or bronchiectasis [170]. Some episodes of choking are not witnessed, but physicians should have a high index of suspicion for foreign body aspiration when a toddler/child presents with respiratory distress without a prior history of infection or trauma. Chronic abnormalities on chest radiography should also raise suspicion for pneumonia due to aspiration of a foreign object.

Radiopaque objects, such as coins, are easily appreciated on chest x-ray; some plastic toys now contain radiopaque markers that also makes them visible on chest x-ray. Unfortunately, the most frequently aspirated items, foodstuffs, are radiolucent and not likely to be detected by radiography. In such instances, lateral decubitus views confirm the presence of lower airway obstruction by an aspirated object. Four major patterns of airway obstruction have been described (Fig. 34.6) [171,172]:

1. *Bypass valve obstruction* involves both phases of respiration, and the chest x-ray is usually normal. Aeration is seen beyond the point of obstruction, although it is somewhat diminished.
2. *Check valve obstruction* is characterized by normal inhalation of air and impedance of exhalation, which results in hyperinflation of the ipsilateral affected lung. To appreciate this effect, inspiratory and expiratory radiographic films are required. Because expiratory films may be difficult to obtain in children, lateral decubitus films are obtained. When a foreign body has been aspirated, the mediastinum shifts toward the normal side. This is readily apparent if the gas volume between the two lungs is significantly different. When a normal child is in the left lateral decubitus position, the mediastinum and heart shift to the left; when they are on their right side, there is a shift to the right on the radiograph. A foreign body that obstructs the right main bronchus causes inflation and aeration of the ipsilateral (right) lung on a right lateral decubitus film.
3. *Ball valve obstruction* is characterized by a lesion that intermittently partially obstructs the affected bronchus. In this instance, a chest radiograph demonstrates a mediastinal shift toward the involved side due to decreased air entry, early atelectasis, and lung collapse.
4. *Stop valve obstruction* denotes a complete bronchial obstruction with impedance to air flow during both inspiration and expiration. Consolidation of the involved bronchopulmonary segment is present.

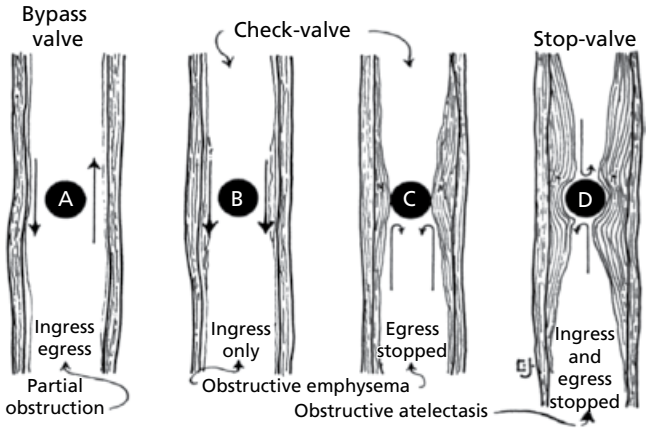

Figure 34.6 Patterns of foreign body induced airway obstruction. (A) Bypass valve. (B, C) Check valve. (D) Stop valve. *Source*: Courtesy of Ellen Friedman MD.

The urgency to proceed with anesthesia and bronchoscopic removal of a foreign body is dictated by the severity of respiratory distress and the location and nature of the aspirated material. Foreign bodies can move from one part of the airway to another and cause sudden complete airway occlusion. Ideally, the foreign body should be removed very shortly after aspiration to minimize the occurrence of pneumonia or other complications. When possible, removal of the object should occur as an urgent, not emergent, procedure in a well-prepared patient [161,173,174]. Bronchoscopic removal of a foreign object is successful 95–98% of the time, but a small number of patients may need repeated bronchoscopies because the foreign body either was not found or was incompletely removed [161,174]. In extremely rare cases, thoracotomy may be required to remove the object [174,175].

A variety of methods have been successfully utilized to anesthetize children for bronchoscopy and retrieval of a foreign body [176,177]. The anesthetic technique chosen depends on a number of factors, namely the condition of the patient, suspected location of the foreign body, and the personal preference of the anesthesiologist or surgeon. Having venous access before proceeding with surgery allows for administration of an anticholinergic agent to dry secretions, to prevent a vagal response with insertion of the bronchoscope, and to attenuate cholinergic-mediated bronchoconstriction during airway manipulation. It also allows for steroid administration to decrease airway swelling. The administration of preoperative sedatives may be controversial, as sedation can exacerbate upper airway obstruction. Parenteral presence is often as effective or more effective than drugs for calming the child.

Inhalation induction allows the anesthesiologist to avoid using positive pressure ventilation, which may dislodge the foreign body and move it. However, spontaneous ventilation does not protect against aspiration of gastric contents if the child has a "full stomach". Few anesthesiologists would advocate a rapid-sequence induction of anesthesia in infants with respiratory distress and no absolute knowledge of the current location of the foreign body. Routine fasting guidelines should apply if the patient's ventilatory status is stable.

Once anesthesia is induced, the head of the table is rotated 90° away from the anesthesiologist, and the airway is managed from the side of the table by the anesthesiologist or the head of the bed by the surgeon. The gums (in an edentulous infant) or teeth are protected from injury by moist gauze or a plastic guard. A laryngoscope is inserted into the vallecula to expose the epiglottis, arytenoids, and vocal folds, which are then inspected for mucosal abrasions or the presence of a foreign body. Next, a rigid bronchoscope is inserted to visualize the distal airway. Once the ventilating bronchoscope is in the subglottic area, the anesthesia circuit is connected to the scope to allow delivery of oxygen and positive pressure ventilation (if necessary).

For anesthesia maintenance, most anesthesiologists follow a "middle course" and allow the child to breathe oxygen and a potent inhalation anesthetic until the chest can be adequately expanded with gentle positive pressure. At that point, a decision is made about whether muscle relaxation is required. If the decision is made that muscle relaxation is unnecessary, the level of anesthesia is kept sufficiently deep to permit bronchoscopy without the patient coughing. Supplementation of anesthesia with topical anesthetic further attenuates the airway reflexes. Regardless of the method of ventilation used, the child's airway will be exposed to the atmosphere multiple times during the procedure when the surgeon removes the bronchoscope or optical eye piece. For this reason, total intravenous anesthesia may be preferred to decrease pollution from inhalational agents and to provide an uninterrupted source of anesthesia for the patient.

Ideally, spontaneous ventilation should be preserved, at least until the nature and location of the foreign body has been identified, especially if the object could not be localized radiographically. Even if the position of the foreign body was detected radiographically, its position may have changed.

Administration of nitrous oxide during this procedure is contraindicated because its use reduces the inspired oxygen concentration. Also, if there is significant gas trapping, nitrous oxide could increase the trapped gas volume and the pressure in the affected lung. On occasion, a tracheal foreign body will completely obstruct the airway; it can often be intentionally pushed distally into a mainstem bronchus. This often improves ventilation and relieves the immediate crisis. The object can then be removed under more controlled circumstances.

Occasionally, the size of the foreign body exceeds the internal diameter of the bronchoscope. When this occurs, the foreign body, forceps, and bronchoscope are withdrawn together through immobile vocal cords [173]. Administering a small dose of a short-acting non-depolarizing muscle relaxant may make it easier to do this. If the foreign body is lost during attempted removal, the pharynx should be immediately inspected. If the object is not found, the bronchoscope should be reintroduced and the larynx or trachea re-examined. If tracheal obstruction occurs and the object cannot be immediately removed, it may be necessary to push the object back to its original location to allow ventilation of the lungs. If possible, the foreign body should be returned to the affected and not to the unaffected lung because placing it in the unaffected lung could result in unreliable ventilation of both lungs. Following removal of the foreign body, the endoscopist must re-examine the airway for additional or fragmented foreign bodies and to remove secretions distal to the obstruction. It may be necessary to reinsert the bronchoscope several times before all of the foreign body and secretions are successfully removed. Doing so may cause mucosal edema and respiratory distress post bronchoscopy. Administration of steroids, humidified oxygen, nebulized racemic epinephrine and, rarely, tracheal reintubation may be required for 1 or 2 days until the edema subsides [178]. Initial doses of 0.5–1.5 mg/kg of dexamethasone (and smaller doses for 2–3 days) are often used. Racemic epinephrine (2.25%) can be administered in a 1:6 to 1:10 dilution via a nebulizer and clear plastic facemask for periods of 10 min while monitoring the electrocardiogram. This treatment is repeated every 2 h as necessary [178]. Some patients treated with racemic epinephrine develop "rebound" edema and have worse airway obstruction. Therefore, those who respond to racemic epinephrine should be monitored carefully for at least 3–4 h after each dose of the drug to detect this problem.

Aspirated vegetable matter (e.g. peanuts) are occasionally fragmented during their removal and pose a significant challenge for the bronchoscopist. Larger aspirated material may acutely occlude both mainstem bronchi, and require a thoracotomy to retrieve the material. A Fogarty no. 3 embolectomy balloon catheter may also help dislodge an impacted foreign body [129,173].

Although prompt removal of a foreign body through an open rigid bronchoscope is the mainstay of treatment for tracheal foreign body removal, diagnostic flexible bronchoscopy also may have a role [179–181]. When foreign body aspiration is not clearly evident by history, physical examinations, and radiography, some surgeons perform diagnostic flexible bronchoscopy under local anesthesia and sedation instead of rigid bronchoscopy because this is less traumatic for the patient and their airway [180]. If a foreign body is subsequently identified, the patient then undergoes rigid bronchoscopy. Flexible bronchoscopy is not usually recommended for children with respiratory distress. The decision to utilize fiberoptic bronchoscopy for diagnostic evaluation of a foreign body depends on the skills and services available at each medical center. The risks of possibly having to undergo two procedures (flexible and rigid bronchoscopy) should also be carefully considered.

KEY POINTS: FOREIGN BODY ASPIRATION

- Foreign body removal is an emergency if the child has repiratory distress
- Spontaneous ventilation should be preserved until the nature and location of the foreign body has been identified, particularly if the foreign body was not localized radiographically
- Rigid bronchoscopes allow administration of inhaled anesthetic if assisted ventilation is required

- Foreign bodies are usually best removed through a rigid bronchoscope
- Organic materials occasionally fragment during their removal
- Post bronchoscopy, edema can occur with repeated insertions of the bronchoscope and may require treatment with steroids, racemic epinephrine, or even tracheal intubation and mechanical ventilation

Esophageal foreign body aspiration

Over 100,000 children are seen annually in emergency departments after ingesting coins, buttons, beads, marbles, button batteries, can pull-tops, toys and their parts, glass, straight pins, screws, nails, and eraser heads. Ingestion of safety pins is less common today, presumably due to the advent of disposable diapers. A particularly dangerous situation occurs when button batteries get lodged and erode through the esophagus. Patients with esophageal foreign body ingestion often present with dysphagia, vomiting, abdominal pain, cough, localization or foreign body sensation, and refusal to take solids and liquids. Esophageal foreign bodies usually lodge at one of the three sites of narrowing – at the cricopharyngeal muscle (C6), at the cardioesophageal level (T4), and at the gastroesophageal junction. Lateral and anteroposterior x-rays of the chest are useful for determining if the radiopaque foreign body (e.g. a coin) is lodged in the esophagus and not the trachea [182]. Coins in the trachea are usually aligned in the sagittal plane, while those in the esophagus are aligned in the coronal plane. If the foreign body has not passed the gastroesophageal junction, it should be removed endoscopcally, often with a flexible endoscope.

Tracheal intubation and airway protection should precede extraction of a foreign body from the esophagus, as inadvertent release of an esophageal foreign body into an unprotected larynx during retrieval may be disasterous [169]. Foreign bodies can be removed endoscopically from the upper gastrointestinal inlet in More than 98% of cases [181]. An immediate "second look" should occur after removal of the foreign body to rule out trauma during the retrieval process or the presence of another foreign body or a congenital defect (e.g. pouch, esophageal stenosis). Foreign bodies that have passed through the gastric outlet into the small and large intestines usually pass through the gastrointestinal tract spontaneously; surgical intervention is rarely needed [183]. Retained esophageal foreign bodies can be treacherous because they can cause a bronchoesophageal fistula, aortoesophageal fistula, mediastinitis, esophageal diverticulum, and lobar atelectasis. In rare cases, the foreign body must be removed via thoracotomy [184].

KEY POINTS: ESOPHAGEAL FOREIGN BODY ASPIRATION

- Esophageal foreign body aspiration is common in young children
- Aspiration of button batteries may be lethal if not removed early
- Foreign bodies that pass into the small bowel are usually eliminated without the need for surgery

Laser microlaryngeal surgery

The most common indication for laser microlaryngeal surgery in children is recurrent laryngeal papillomas or juvenile laryngeal papillomatosis. Papillomatosis is a chronic, debilitating, and frequently life-threatening condition. These laryngeal tumors occur as a result of a human papillomavirus (HPV) infection acquired from the mother during pregnancy. These tumors are typically located on the vocal cords, epiglottis, and in the larynx or trachea (Fig. 34.7). They are usually symptomatic and cause aphonia, hoarseness, stridor, or respiratory distress. When a large amount of tumor is chronically present, the patient may have symptoms of right ventricular hypertrophy or cor pulmonale. Surgical excision and ablation of these lesions, the current mode of management, is accomplished with a carbon dioxide laser via an operating microscope [185]. CO_2 lasers have a fully reflective mirror at one end and a semi-reflective mirror at the other. When the material inside the resonating chamber is stimulated by an external source of energy, it emits a beam of monochromatic light that travels large distances. Light waves of the CO_2 laser are absorbed by all biological tissues and rapidly vaporize intracellular water. The resultant heat denatures protein. The laser light wave is easily focused to target tissue, including the capillaries, and vaporizes them without affecting the surrounding tissues. This provides excellent hemostasis and minimal postoperative edema and scarring. CO_2 lasers are used to treat papillomas of the nose, oral cavity, or larynx and to treat subglottic stenosis, subglottic hemangiomas, glottic webs, choanal atresia, postintubation granulomas, vocal cord nodules, and lymphangiomas, all with excellent results [186,187]. This laser has the advantage that its use allows rapid healing and preserves the quality of voice [187,188].

In a recent survey of pediatric otolaryngologists, the laryngeal microdebrider has supplanted CO_2 laser for removal of laryngeal papillomas by about 50% of practitioners [189]. A microdebrider uses suction and a rotating cold blade to more precisely excise the papillomas. It has a slightly angulated tip that suctions mobile papilloma tissue into the cutting blade and leaves firmer underlying native tissue intact. A prospective comparison of the microdebrider and the CO_2 laser revealed that the microdebrider and laser cause equivalent postoperative pain, but the microdebrider is associatesd with

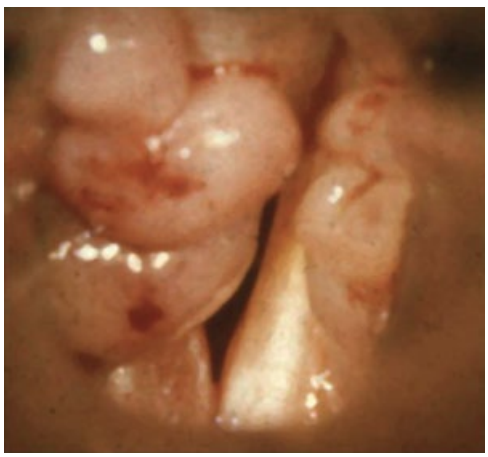

Figure 34.7 Papillomas on the vocal cord. *Source*: Courtesy of Deidre Larrier MD.

greater improvements in voice quality, shorter procedure times, and overall lower cost [190]. Microdebrider use has reduced the need for laser treatment of these lesions [189].

Adjuvant medical therapy for laryngeal papillomas is also on the rise. Cidofovir and interferon have proven to be beneficial in some children. Cidofovir is, however, reserved for patients requiring four or more surgical treatments per year because it has carcinogenic potential, and because there are not good supportive data for its use [191]. There are some reports of HPV vaccine resulting in a reduction or resolution of laryngeal papillomatosis in children [192]. The recommendation in 2006 that girls in the USA should receive HPV vaccine may reduce the future incidence of laryngeal papillomatosis in children [193].

Use of either the CO_2 laser or the laryngeal microdebrider requires suspension laryngoscopy, hyperextension of the neck, and a motionless surgical field (i.e. relaxed vocal cords) to prevent injury to the surrounding healthy tissue. Prompt recovery of consciousness and protective airway reflexes are necessary at the conclusion of surgery.

KEY POINTS: LASER MICROLARYNGEAL SURGERY

- The virus causing airway polyps can be transmitted from mother to fetus
- Lasers and microdebridors are commonly used to treat airway polyps
- Patients must be still during the procedure to avoid injury to normal tissue
- Children with papillomatosis often require multiple surgical procedures and may be quite fearful. Administration of preoperative medications to allay their anxiety may worsen the degree of airway obstruction

Anesthesia for laser microlaryngeal surgery

Children with recurrent laryngeal papillomas often present for treatment of recurrent tumors. The only effective way to keep their airway "tumor free" is by repeated endoscopic and laser excision of the papillomas until puberty, when the tumors tend to regress [194]. Perioperative anxiety is, therefore, fairly common in affected children due to the need for repeated surgeries. The judicious use of sedatives and, most importantly, a reassuring preoperative visit by the anesthesiologist, helps allay their fears. A child with significant airway obstruction should only receive preoperative sedation while being monitored and then only when oxygen, positive pressure ventilation, suction, and an anesthesiologist or surgeon skilled in advanced airway intervention is immediately available. Pedunculated papillomas can cause ball-valve obstruction of the airway in certain positions, which a good history will elucidate. It is usually prudent to avoid administering muscle relaxants and to maintain spontaneous ventilation until the surgeon has examined the airway and determined the location and extent of the lesions. Induction of anesthesia is similar to that for any child with anticipated severe airway obstruction: a slow inhalation induction with sevoflurane in 100% oxygen and avoidance of agitation and worsening the airway obstruction. It is often helpful to maintain 5–10 cm of PEEP in the anesthetic system to distend the hypopharynx, improve the airway, and facilitate mask ventilation. Muscle relaxants are administered when necessary, but only after demonstrating an ability to ventilate the child's lungs with positive pressure.

Laser surgery can be performed with spontaneous ventilation or with apnea. Jet ventilation and laser-safe tracheal tubes were mainstays of this type of surgery but have fallen out of favor. Only 10% of otolaryngologists now use laser-safe tracheal tubes to secure the airway [189]. This is in part due to the fact that laser-safe tubes do not completely prevent an airway fire if there is an inadvertent laser strike against the tracheal tube, even when lower oxygen concentrations are being used [195].

Spontaneous ventilation without tracheal intubation allows the surgeon to work without interruption. Otherwise, they must intermittently remove and place the tracheal tube to allow positive pressure ventilation. A deep anesthetic plane can be achieved with total intravenous anesthesia using propofol 200–300 μg/kg/min plus intermittent opioid administration morphine 0.5 mg/kg, fentanyl 2–3 μg/kg, or remifentanil infusion 0.1–0.25 μg/kg/min. Aerosolized lidocaine reduces airway irritability. Intravenous dexamethasone administration reduces postoperative swelling. Periods of hypoxemia can be treated with intermittent mask ventilation or by the surgeon reintubating the trachea to allow brief periods of manual ventilation. Jet ventilation with intermittent apnea provides ventilation and a quiet surgical field, but concerns that jet ventilation might force papillomas into the tracheobronchial tree and might cause barotrauma, plus the inability to monitor expired carbon dioxide tensions, has decreased its use for airway surgery.

If spontaneous ventilation was maintained via a natural airway during surgery, a tracheal tube can be inserted and secured until the child is completely awake. Alternatively, the inhalation agents can be discontinued and the patient transported to the recovery room breathing blow-by oxygen until completely recovered from anesthesia. Patients occasionally develop postoperative stridor, which can usually be managed with racemic epinephrine.

KEY POINTS: INTRAOPERATIVE MANAGEMENT OF MICROLARYNGEAL SURGERY

- Children with papillomatosis require multiple procedures to remove the lesions
- In some children with complete airway obstruction, CPAP is required during the induction of anesthesia to maintain a patent airway
- Surgery may be performed either during spontaneous breathing or during periods of apnea
- Jet ventilation is seldom used any more for fear of forcing tumor into the distal airways

Safety precautions during laser surgery

The major risks of laser therapy are fires and injury to operating room personnel by overshoot of the laser beam or reflection of the beam off of a polished instrument. Red rubber tracheal tubes wrapped with metallic tape will deflect the beam and prevent a fire. However, it is not possible to tape the part of the tube located beyond the vocal cords, making that portion of the tube vulnerable to the beam and to vaporization. Some tracheal tubes (non-latex) are manufactured specifically for laser surgery. However, they are more expensive and have larger outer diameters than regular polyvinyl chloride tubes, especially in the smaller sizes. As a result, they are not useful for small children or for those with an airway markedly narrowed by papillomas.

Laser radiation increases the temperature of the material it strikes, which can cause a fire. Therefore, flammable material (e.g. surgical drapes) must be kept out of the laser beam path. Use of surgical drapes should be kept to a minimum during laser surgery for this reason. Burning surgical drapes not only burn the patient, they also produce a significant amount of smoke that poses a hazard to both the patient and the operating room staff [196]. As a preventive measure, the face, neck, and shoulder surfaces of the patient should be covered with wet towels to absorb stray laser energy and prevent fires.

The CO_2 laser beam does not penetrate the cornea, but operating room personnel should wear glasses (regular eyewear will suffice) or protective goggles and place moist gauze pads over the eyes of patients as a precaution when using this type of laser. The primary uses of argon and neodymium:yttrium-aluminum garnet (Nd:YAG) lasers are for ophthalmological surgery and for excision of endobronchial lesions and treatment of gastrointestinal bleeding. The beam from Nd:YAG lasers can penetrate the cornea and damage the retina. It can also penetrate glass, which necessitates covering glass windows in the operating room with appropriate material. Special protective eyewear is mandatory when using these lasers.

As stated, the shaft of a tracheal tube can be covered with protective material to reduce the chance of a fire. Tracheal tube cuffs should be filled with saline rather than air. Placement of saline-soaked pledgets above the tracheal tube cuff during laser surgery offers some protection. Care must be taken to remove the pledgets before removing the tracheal tube to prevent aspiration of the pledget and obstruction of the airway.

The mixture of gases used during airway surgery affects the combustion risk. The use of more than 30% oxygen or of nitrous oxide sustains combustion, and their effects are additive [198]. Helium impedes combustion; and the differences between nitrogen and helium are not clinically significant [197].

The different methods available for airway management during laser surgery attempt to prevent airway fires, but this is not always possible. If, despite all precautions, a fire occurs, the flow of oxygen should be discontinued immediately and the tracheal tube disconnected from the gas source and removed. Tracheal tubes do not readily burn in air, which is why it is best to use air as the carrier gas whenever possible [188]. The anesthesiologist must check that the entire tube has been removed. A chest radiograph should be obtained and bronchoscopy performed to determine the extent of lung and tracheal burn injury, smoke inhalation, and possible retention of a foreign body. Complications are treated, based on the severity of the injury. Treatment may include steroids, humidification of inspired gases, tracheostomy, and assisted ventilation. Tracheal stenosis may occur later [188].

KEY POINTS: LASER MICROSUGERY FIRE PREVENTION AND TREATMENT

- Airway fires can occur during laser treatment of airway papillomas
- The inspired gas used during laser surgery should be as close to room air as possible to prevent ignition of the tracheal tube if there is a laser strike
- The use of oxygen and nitrous oxide together poses a greater risk of airway fire

Subglottic stenosis and tracheal reconstructive surgery

Endoscopic assessment of the airway is the gold standard for diagnosis of subglottic stenosis, which is defined as any narrowing of the airway from just below the vocal folds to the lower border of the cricoid cartilage. The narrowing may be either congenital or acquired. Some congenital subglottic stenosis is associated with chromosome 22q11 deletion, Down syndrome, and CHARGE syndrome (*C*, coloboma, *H*, heart defect, *A*, atresia of choanae, *R*, retarded growth and development, *G*, genital hypoplasia, *E*, ear anomalies/deafness) [199,200]. Neonatal congenital subglottic stenosis presents with biphasic stridor, chest wall retractions, and a barking cough that is somewhat similar to the cough of laryngotracheobronchitis. Airway inflammation associated with a URI often worsens these symptoms. Persistent croup that is refractory to treatment should raise a high index of suspicion for subglottic stenosis. Fortunately, congenital subglottic stenosis frequently resolves as children mature. Acquired subglottic stenosis, on the other hand, persists until definitive therapy occurs. Acquired subglottic stenosis is commonly the result of prolonged tracheal intubation but may also be the due to blunt or penetrating injury of the larynx. In these instances, symptoms such as progressive hoarseness, dyspnea, stridor, or feeding difficulties can occur 2–4 weeks following injury. Children with subglottic stenosis/injury are prone to frequent URIs. The exact location of the injury is usually identified by careful endoscopic evaluation of the airway [201].

The Myer–Cotton grading system classifies subglottic stenosis. It is based on the degree of stenosis: grade 1: <50% lumen obstruction; grade 2: 51–70% lumen obstruction; grade 3: 71–99% luminal obstruction; and grade 4: complete luminal obstruction [202]. The degree of stenosis is determined by inserting various size tracheal tubes and determining the largest tube that can be easily inserted while still being able to maintain a gas leak below 20 cmH_2O with positive pressure. Grades 1 and 2 can be managed endoscopically, but grades 3 and 4 require open surgery.

About 50% of patients with congenital subglottic stenosis require a tracheostomy. An even higher percentage of those with severe acquired subglottic stenosis require tracheostomy (see Chapter 16) [203]. With time many children "outgrow" the need for ventilatory support. Tracheostomy significantly

changes the quality of the child's life. Although a tracheostomy is often life saving, it can be associated with significant morbidity and mortality. The risk of death from complications of tracheostomy is 1–2% per year [204].

Periodic endoscopic airway evaluations are performed to assess whether there has been interim resolution of the stenosis. This procedure is performed during deep general anesthesia using suspension laryngoscopy. The child breathes spontaneously throughout the procedure. By redetermining the size of tracheal tube that can most easily be inserted and still allow an audible gas leak, physicians can determine if there is less narrowing and if it might be possible to remove the tracheostomy. If attempted decannulation fails or if the airway obstruction exceeds 50% of the normal lumen size, further intervention is required. This can include endoscopic balloon dilation or CO_2 laser endoscopic scar excision, with or without mitomycin application to prevent reapposition of the raw submucosal edges [205]. Children with firm mature scars, cartilaginous narrowing, and structural defects in the airway exoskeleton are likely to fail balloon dilation of the airway and require open reconstructive procedures, such as splitting the anterior cricoid cartilage or laryngeal reconstruction.

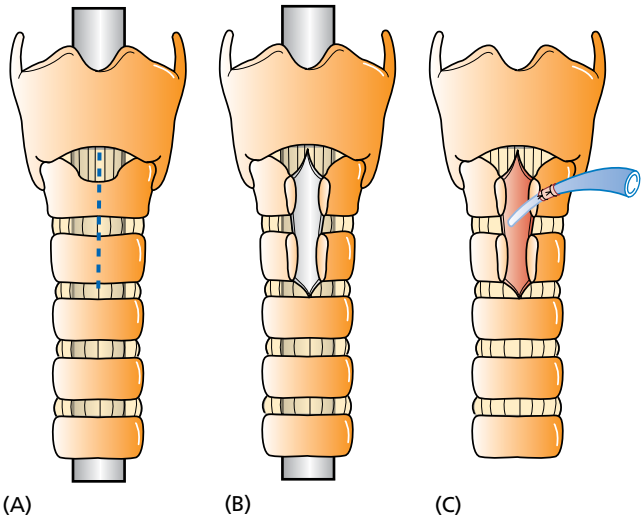

Figure 34.8 Cricoid split procedure. (A) A midline vertical cartilaginous incision is made 2 mm from the thyroid notch inferiorly through the second tracheal ring. (B) The largest possible tracheal tube is inserted. (C) Stay sutures are placed through the cricoid ring, and the skin incision is closed. *Source*: Reproduced from Zalza and Cotton [206] with permission of Elsevier.

KEY POINTS: SUBGLOTTIC STENOSIS

- Children with subglottic stenosis are prone to frequent respiratory tract infections
- Balloon dilation of the stenotic area improves symptoms in some patients
- Tracheostomy is necessary in some patients until they "outgrow their stenosis" or have definitive surgery to correct the lesion

Anterior cricoid split procedure

The goal of the cricoid split procedure is to decompress the subglottic space by opening the cricoid ring, the only complete cartilaginous ring of the airway. Cricoid spit surgery is performed over the largest nasotracheal tube possible. A midline vertical cartilaginous incision is made 2 mm from the thyroid notch inferiorly through the second tracheal ring, and a tracheal tube inserted (Fig. 34.8) [206]. Stay sutures are placed through the cricoid ring, as for tracheostomy, and the skin incision is closed. It may be necessary to leave the tracheal tube in place for up to 2 weeks to temporarily stent the incision open to allow fibrous ingrowth in the cricoid ring and to prevent airway obliteration by granulation tissue. This also allows time for the mucosal swelling to subside and for the split cricoid to heal. Tracheal extubation is then attempted after treatment with steroids.

Laryngeal reconstruction

Laryngeal reconstruction is performed when the subglottic stenosis is refractory to endoscopic balloon dilation or when the stenosis is severe (grade 3 or 4). This surgery is successful about 90% of the time when anterior costal cartilage or thyroid ala cartilage are used for the reconstruction [207]. A shoulder roll is placed and the head is hyperextended. Induction and maintenance of anesthesia can be accomplished with inhalation or intravenous anesthesia or both. During surgery, the tracheostomy is replaced with a tracheal tube inserted through the tracheostomy stoma and anchored in place with sutures. It may be necessary to shorten the oral RAE tube to prevent endobronchial intubation in some patients. Laryngeal reconstruction or laryngotracheoplasty is performed through a horizontal skin incision with midline dissection from the cartilage of the thyroid notch superiorly to the third or fourth tracheal rings inferiorly (Fig. 34.9) [203]. A vertical median anterior incision is made into the stenotic lumen. Posterior subglottic or posterior commissure stenosis may require a midline posterior cartilaginous incision to increase the diameter of the posterior lumen. Sculpted segments of harvested costal cartilage are then sutured into the midline incision to increase the airway lumen. A solid stent, when necessary, provides support during the postoperative period. This stent is sometimes wired to the tracheostomy tube. After allowing an appropriate period for healing of the grafts, the stent may be removed and the intraluminal granulation tissue excised. Alternatively, if a solid stent is not required, towards the end of surgery the oral RAE tube is replaced by a nasotracheal RAE tube. Further operative procedures may be required to remove granulation tissue and to allow the epithelium to cover the grafts and operative sites. Tracheal extubation occur when the airway lumen is deemed adequate; often prolonged intubation of up to 2 weeks is required after laryngeal reconstruction.

Both total intravenous and inhalation anesthesia have been used successfully for this surgery. The anesthesiologists are challenged during this procedure to provide a quiet surgical field while sharing the airway with the surgeon. The most important requirement for perioperative management is constant effective communication between the surgeon and anesthesiologist, particularly at times when the airway is removed to allow surgical access and stent placement. Knowledge of the critical points and the required precautions during this surgery are paramount. These include: (1) tracheal incision and the risk of coughing, damage to the tracheal tube cuff, or extravasation of air into the mediastinum; (2) risk of pneumothorax or pneumopericardium;

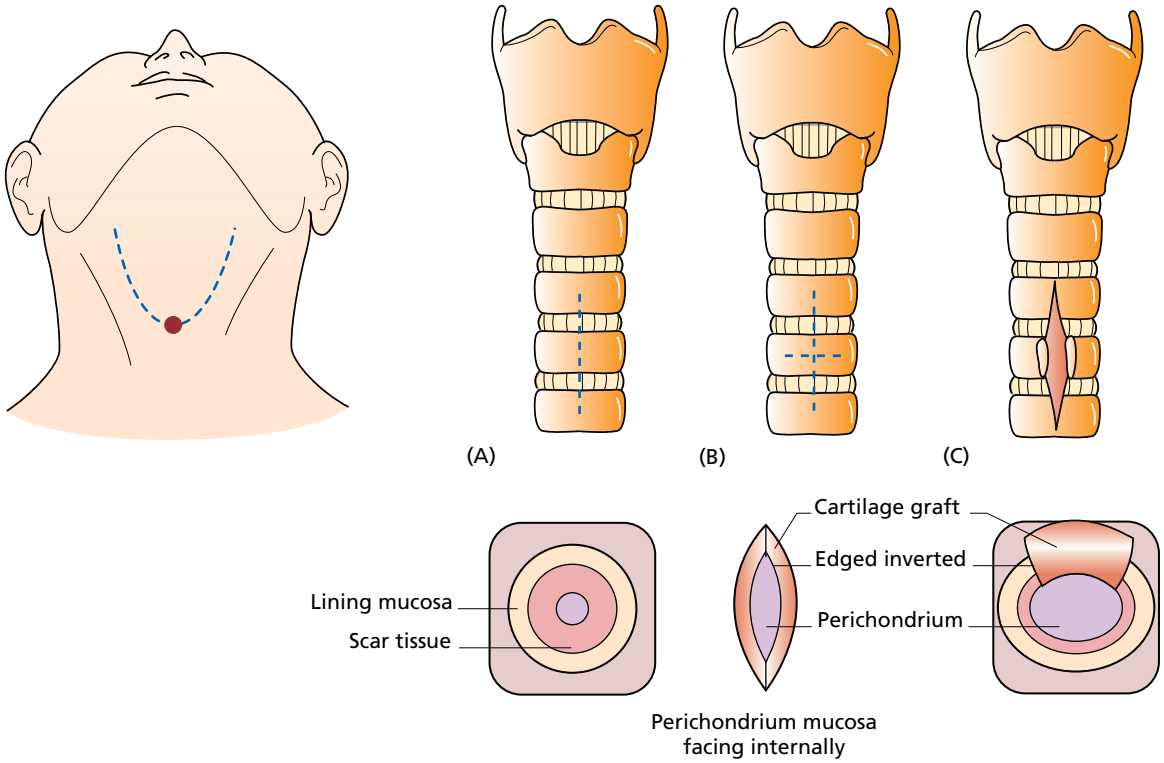

Figure 34.9 Laryngotracheoplasty. (A) A horizontal skin incision is made incorporating the superior aspect of the stoma. A vertical incision is made in the thyroid cartilage from a point immediately below the anterior commissure through the upper tracheal rings with care to remain in the midline. (B) The intraluminal scar and lining mucosa are incised along the length of the stenotic segment. (C) The costal cartilage graft is then shaped into an ellipse and placed in position with the lining perichondrium facing internally. *Source*: Reproduced from Cotton and Myers [203] with permission of Elsevier.

(3) replacement of an oral tracheal tube with a nasotracheal tube and possible loss of the airway; (4) hemorrhage from injury to thymic, innominate, or thyroid vessels; (5) mainstem bronchus intubation with the initial intubation through the tracheostomy site; (6) occlusion of the tracheal tube with blood or mucus or tracheal tube kinking and impaired ventilation due to high resistance; and (7) replacement of an oral or nasotracheal tube with possible trauma to the surgical site [208]. Precautions must be taken throughout the procedure to avoid surgical fires.

Adequate postoperative sedation and relaxation are mandatory to avoid excessive coughing and movement of the tracheal tube. Both can interfere with healing.

KEY POINTS: CRICOID SPLIT AND LARYNGOTRACHEAL RECONSTRUCTION

- An anterior cricoid split is performed to open a narrowed subglottic space and is followed by postoperative tracheal intubation for at least a couple of weeks
- Laryngotracheal reconstruction is performed for severe subglottic stenosis or stenosis that is refractory to balloon dilation
- Vigilance is required throughout the surgery because the surgeon may have to remove the tracheal tube for short periods of time to accomplish the surgery
- Knowledge of the critical points of the surgery is mandatory for safe, effective accomplishment of this surgery
- Prolonged tracheal intubation is often required

Dental procedures

Pediatric dental procedures are routinely performed in a dentist's office with local anesthesia, with or without sedation. Children with behavioral disturbances, such as severe autism or developmental delay, children with multiple medical problems, and those requiring extensive dental restoration often require general anesthesia to facilitate their surgery. General anesthesia allows the dentist to complete dental restoration in a timely fashion without administering excessive amounts of local anesthetic or approaching the maximum limits of sedation with which they are comfortable in their dental office.

Sedation versus anesthesia

Pediatric dental sedation is occasionally complicated by serious morbidity and mortality. Most serious adverse events are respiratory [209]and are the result of opioid administration as part of the sedative regimen [210,211] or as a result of the administration of higher than usual doses of local anesthetics, sedatives, or analgesics, in particular. These adverse events are also more common when monitoring is inadequate or the personnel is insufficiently skilled [212]. The increased prevalence of childhood obesity also poses a challenge for pediatric dentists. If the sedative doses are based on the patient's total body weight, oversedation and airway obstruction may occur. If they are based on lean body mass, the patient may be undersedated with a shorter duration of the sedative effects [213]. An increase in adverse events with sedation [214,215] and the increased mortality associated with office-based procedures [216] strengthens the case for improved monitoring

during sedation for outpatient procedures in general [217]. A revised recommendation by the Committee on Drugs, Section on Anesthesiology of the American Academy of Pediatrics, [218] states that:

1. Appropriate documentation, including informed consent prior to procedure, must be obtained.
2. The patient must undergo a documented presedation medical evaluation to rule out underlying medical and surgical conditions that may place the child at increased risk from sedative medications. This should also include a focused airway examination for large tonsils or airway abnormalities that may increase the potential for airway obstruction.
3. There should be an appropriate interval of fasting before sedation.
4. A balance must be sought between the depth of sedation and risk for children who are unable to fast because of the urgent nature of the procedure.
5. There should be a clear understanding of the pharmacokinetic and pharmacodynamic drug effects and drug interactions of the medications being used for sedation.
6. Appropriate sedative medications and reversal agents should be available.
7. Sedative and anxiolytic medications should only be administered by or in the presence of individuals skilled in airway management and cardiopulmonary resuscitation and the use of emergency checklists is recommended.
8. Age- and size-appropriate equipment for airway management and venous access should be checked beforehand and be immediately available.
9. Appropriate physiologic monitoring should be employed during and after the procedure.
10. Sufficient number of staff to both perform the procedure and monitor the patient afterwards should be available for deeply sedated patients; that individual should have no other responsibilities and should record vital signs at least every 5 minutes.
11. Specific discharge criteria to responsible party accompanying patient is required.

Unfortunately, there is no exact definition of conscious sedation in outpatient settings. Customarily it is defined as a state of sedation that "permits appropriate response by the patient to physical stimulation or verbal command, e.g. 'open your eyes'." This implies that the patient retains their ability to interact with the medical care team. Purely reflexive activity, such as the gag reflex, simple withdrawal from pain, or making inarticulate noises are not appropriate responses for the purpose of this definition. A sedated child who displays only reflex activity of this sort is in a state of deep sedation, not conscious sedation. The Committee on Drugs states that the term "conscious sedation" should be replaced with "moderate sedation" [219].

Considerations for dental surgery

Existing co-morbidities must be considered when planning anesthetic management for this group of children. Many of them have underlying cardiac anomalies and require systemic bacterial endocarditis prophylaxis (see Chapter 27). The facial and airway structures of some patients make direct laryngoscopy challenging and may require special intubation equipment. Patients with developmental delay or serious behavioral disturbances can pose difficulties because they have poor motor control and involuntary movements, spasticity, and aggressive behavior (screaming, biting, kicking), particularly when they are frightened by a strange environment. This behavior may make it difficult to place and secure an intravenous catheter or to perform inhalational induction of anesthesia. Intramuscular ketamine 3–5 mg/kg mixed with atropine 10–20 μg/kg and midazolam 0.1 mg/kg is useful for inducing anesthesia in noncooperative patients [220,221]. Sedation or a "catatonic state" are induced by this combination of drugs, which allows easy movement of the patient, obtaining intravenous access, inducing general anesthesia, tracheal intubation, and maintenance of anesthesia with the technique of choice. If the patient has a seizure disorders, they should take their anticonvulsant medications on the day of surgery. Ketamine does not increase the incidence of seizures in patients with seizure disorders.

Dental anesthesia

Extensive dental restoration is best managed with nasotracheal rather than orotracheal intubation. The tube is secured around the patient's head with a fabric tube holder. In some patients, however, nasotracheal intubation is not practical, including patients with previous cleft palate repair or epidermolysis bullosa. In these patients, an oral RAE tube is placed. When it is, constant vigilance is required to prevent accidental dislodgment of the tube. Oral tubes are secured to one side of the mouth initially and moved to the other side when required to facilitate the procedure.

Prior to nasotracheal intubation, oxymetazoline drops are applied to both nares to induce mucosal vasoconstriction and decrease bleeding during insertion of the tracheal tube. Graduated sizes of well-lubricated nasopharyngeal airways are commonly used to dilate the nares in preparation for nasotracheal intubation. Placing the tube in warm water for a few minutes decreases its stiffness, which decreases the incidence of epistaxis following nasotracheal intubation. Cuffed tracheal tubes should be used when possible. Limiting the number of attempts at nasotracheal intubation reduces the incidence of epistaxis. Epistaxis complicates nasotracheal intubation because it makes visualization of the larynx more difficult.

Following inhalation induction of anesthesia and 2–3 mg/kg of intravenous propofol, a tracheal tube can be inserted under direct vision without difficulty. Once the vocal cords are visualized, a RAE tube can be inserted through the nares and passed through the vocal cords, with or without the use of Magill forceps. Nasal RAE tubes are commonly used for dental surgery because they allow the use of a rubber dam when required [222]. The preformed, fixed bend in the tube helps stabilize the tube, decreases the likelihood of kinking, reduces the likelihood of injury to the nares, and allows a low profile for maximum surgical convenience. The problem with tubes with a preformed bend is that they have a fixed distance from the bend to the distal end of the tube. For most children this places the tip of the tube in the midtrachea. In others, the tube is too long and causes bronchial intubation. For some, the tube is too short, which places the tip of the tube barely

below the vocal cords. The bend also makes tracheal suctioning difficult. It is important to remember that flexing the head on the chest moves the tip of the tube deeper into the trachea and that extension of the head moves it towards the vocal cords.

A gauze throat pack is usually inserted before initiating surgery to prevent aspiration of blood or extracted teeth. Confirmation of the removal of the pack must occur at the end of surgery because retention of a pack after tracheal extubation can be disastrous. Either spontaneous or mechanical ventilation is acceptable.

The postoperative period is often characterized by emergence delirium, with or without postoperative nausea and vomiting. Occurrence of these events should be managed accordingly.

KEY POINTS: DENTAL SEDATION AND ANESTHESIA

- When dental anesthesia is provided in a dentist's office, suction, oxygen, monitoring equipment, sedative medications as well as the drugs and equipment needed for resuscitation must be available
- Vasoconstrictive drugs should be placed in the nose before insertion of a tracheal tube to minimize bleeding
- Many children undergoing dental surgery have co-morbid diseases that must be fully understood before undertaking sedation and anesthesia, especially in non-hospital settings
- Gauze throat packs must be removed prior to tracheal extubation to prevent airway obstruction

CASE STUDY

A 13-year-old obese male who resides in a home for children with special needs was admitted for outpatient dental restoration for severe dental caries. His history includes severe developmental delay and occasional violent behavior. Other pertinent medical history includes obstructive sleep apnea, for which his pediatrician has prescribed a CPAP machine. The caregiver accompanying the patient states the patient has not been compliant with using his CPAP machine.

Preoperative considerations

The patient is considered to have moderate to severe OSA (Table 34.3). This information was important in planning his anesthetic. One question was whether he should receive intraoperative opioids. The immediate challenge, however, was how to separate this child from his caretaker and take the child to the operating room. He was unlikely go willingly with only the anesthesia care provider. It was decided that a staff member of the resident home, with whom he has a special rapport, would accompany him to the operating room and remain with him during the induction of anesthesia. This is usually the preferred approach.

An alternative method of managing his separation anxiety would be the administration of IM ketamine (4 mg/kg), midazolam (0.1 mg/kg), and glycopyrrolate (0.01 mg/kg). The latter two medications are given to counteract any ketamine-induced hallucinations and to prevent excessive airway secretions. While it is possible that midazolam 0.5–1 mg/kg could be given orally, it was thought that this patient's history of combative behavior would make it difficult to get him to swallow oral medication. Some practitioners would reduce the PO dose of midazolam to 0.25 mg/kg due to the patient's history of OSA. The administration of IM ketamine IM would be a good option.

Table 34.3 Severity ranking system of obstructive sleep apnea (OSA) based on polysomnography*

	Apnea-hypopnea index	Oxygen saturation nadir
Normal	0–1	>92%
Mild OSA	2–4	
Moderate OSA	5–9	
Severe OSA	>10	<80%

* Peak end-tidal CO_2 ($ETCO_2$) and duration of time spent with $ETCO_2$ >50 mmHG should be considered when assessing severity of OSA.

Intraoperative considerations

Because of the patient's obesity and sleep apnea, tracheal intubation was the best option for assuring an effective airway. This also provided the dentist with good operative conditions, especially because a nasotracheal tracheal tube was utilized. Following inhalation induction of anesthesia, a short-acting muscle relaxant was administered intravenously. Muscle paralysis was provided because the surgeon planned to do extensive dental work, and muscle paralysis would improve operating conditions for the dentist. Nasotracheal intubation was accomplished with a sedative-hypnotic agent alone. Desflurane was used for maintenance of anesthesia because its low blood gas solubility would not lead to significant absorption of the agent into fat. This would shorten the time to awakening from anesthesia, which was preferred in this child. Despite the fact that desflurane is associated with airway irritability, it was felt to be the best choice for this patient. Because no dental extractions were planned, intraoperative opioids were not administered. If teeth had been extracted, intraoperative opioids could be carefully titrated once the patient resumed spontaneous ventilation to maintain a spontaneous respiratory rate of 16–20 breaths/min. For this patient with significant OSA, it was decided to administer opioids after tracheal extubation, when the patient was awake. Small amounts of dexmedetomidine 0.25 μg/kg could also have been administered intraoperatively to reduce the possibility of having him awaken in a pain-induced agitated state. Additional analgesics were administered following tracheal extubation as needed.

Intraoperatively, the heart rate gradually decreased from 110 to 60 beats/min. Despite the decrease in heart rate, the patient remained normotensive. Some practitioners would have administered IV glycopyrrolate at the beginning of the dental restoration procedures for both heart rate control and control of oral secretions. This was not done in this case. Aliquots of IV glycopyrrolate 5–10 μg/kg would have been administered if hypotension had developed. It must be remembered that giving IV glycopyrolate for dexmedetomidine-induced bradycardia may produce an exaggerated hypertensive response [223]. At the conclusion of surgery, the patient's neuromuscular blockade was fully reversed, and his trachea was extubated when he was fully awake.

Postoperative considerations

This patient was placed in a semi-upright, lateral (non-supine) position throughout recovery to decrease the incidence of airway obstruction, to improve breathing, and to allow drainage of blood or oral secretions.

Despite awake tracheal extubation, it was not possible to wean him from oxygen. His oxygen saturations intermittently decreased to 85–88% for approximately 10 s. An oral airway (which he tolerated) and shoulder roll were placed to prevent flexion of the head and obstruction of the airway, but this only partially resolved the problem. Mask CPAP was applied, which decreased his bradycardia and hypoxemic episodes and improved his breathing. Fortunately, he was receptive to using this device. Over about 6 h, he was able to maintain his oxygen saturation in a normal range, and CPAP was applied when he slept.

While most dental restoration procedures are performed on an outpatient basis, because of this patient's co-morbidities, he remained in the hospital overnight in a stepdown unit. Part of that decision was based on the fact that it was unclear if suitable care (availability of a nurse on site and the degree of supervision/care needed) could be provided in the residential home. Fortunately, one of the staff from the residential home was able to remain in the hospital with the patient overnight, which was calming for the patient.

Since the patient was admitted to the hospital, a prolonged PACU stay was unnecessary, but would have occurred if he were going "home" after surgery – as the American Society of Anesthesiology suggests for patients who have OSA [224,225]. The recovery of patients with OSA also depends on the amount of opioids they have received. To reduce potential problems, NSAIDs or NSAIDs combined with smaller doses of opioids, e.g. acetaminophen/hydrocodone, are considered when additional drugs are required in the recovery room or on the floor. Often the presence of a familiar caregiver in the recovery room and hospital prevents or decreases postanesthetic agitation and the need for sedation and opoids.

There is no consensus regarding postoperative disposition of patients with OSA within the hospital after surgery, i.e. the intensive care unit versus a stepdown unit. There is agreement, however, that these patients should be observed in a monitored postoperative setting with pulse oximetry monitoring [222].

Twenty-four hours after surgery, the patient was fully awake and had returned to his preoperative state. He was discharged back to his care facility.

Introduction

Pediatric ophthalmological surgeries are among the more common procedures in pediatric anesthesia practice. The patients range from healthy outpatients undergoing relatively simple procedures such as strabismus correction, to more complicated patients with syndromes requiring cataract removal, to premature infants requiring laser photocoagulation for retinopathy of prematurity. This chapter starts with a review of extraocular conditions, including nasolacrimal duct obstruction and strabismus. Then intraocular conditions will be discussed, including glaucoma, open globe injuries, cataracts, retinoblastoma, and retinopathy of prematurity. Finally, a case study of a retinoblastoma patient will be presented which synthesizes many of the concepts in the chapter into a real-life scenario.

Anesthetic effects of commonly used ophthalmic drugs

Several medical problems are associated with congenital and acquired eye anomalies and pathology. The anesthesiologist must have a good understanding of the associated medical entities as well as the different anesthetic drugs and procedures that profoundly affect ocular physiology. A basic understanding of intraocular pressure and its control, along with the pharmacology of drugs used by the ophthalmologist, and the potential for drug interactions with anesthetic agents is necessary to provide adequate anesthetic care for pediatric patients during eye surgery (Table 35.1).

Extraocular conditions

Nasolacrimal duct obstruction

Up to 6% of healthy neonates have congenital nasolacrimal duct obstruction, presenting with epiphora or continuous tearing. In the absence of infection, a conservative approach is appropriate for a few months to see if the tear duct opens with time. However, if nasolacrimal duct stenosis persists, a series of procedures with increasing invasiveness are performed. Initial intervention involves probing and irrigation of the nasolacrimal duct. Nasolacrimal duct probing can be performed in an office setting or in an operating room with a general anesthetic depending on the age of the patient as well as surgeon preference. In the later scenario, a standard mask induction and maintenance of anesthesia with inhalational agents can provide satisfactory operative conditions. Some anesthesiologists place a laryngeal mask airway (LMA) to secure the airway. If simple probing and irrigation does not resolve the condition, the child may require balloon dilation and/or silicone tube placement, either following the initial probing or on a subsequent operating room visit.

In a very small percentage of patients the obstruction may persist and could result in infections of the tear sac. This would require a more invasive and longer procedure such as dacryocystorhinostomy which involves creation of a communication between the lacrimal sac and the nasal cavity. The anesthetic management for this procedure should include securing the airway with an endotracheal tube, as access to the airway will be limited during the operation. Analgesic drugs should also be administered. All procedures described are performed on an outpatient basis unless the child has other concomitant medical conditions that warrant postoperative observation.

Strabismus

Strabismus correction is one of the most common surgical procedures in ophthalmology. It is characterized by a misalignment of the visual axes and may be congenital or acquired. It occurs in 2–7% of children. The congenital form may occur as a result of abnormal innervation while the acquired form may occur following traumatic nerve palsies.

Gregory's Pediatric Anesthesia, Sixth Edition. Edited by Dean B. Andropoulos and George A. Gregory.

Table 35.1 Anesthetic effects of commonly used ophthalmological drugs

Drug	Dose (mg/drop)	Ophthalmological effect	Anesthetic implication
Atropine (1%)	0.5	Mydriasis, cycloplegia	Tachycardia, flushing
Cocaine (1%)	0.5	Vasoconstriction	Hypertension, dysrhythmia, hyperthermia
Cyclopentolate (0.5%)	0.25	Mydriasis, cycloplegia	Convulsions (not common)
Cyclopentolate (1%)	0.5		
Echothiophate (0.25%)	0.1	Antiglaucoma	Anticholinesterase (long acting)
Epinephrine (0.25%)	0.1	Antiglaucoma	Hypertension, dysrhythmias
Phenylephrine (2.5%)	1.2	Mydriasis, vasoconstriction, decongestion	Hypertension
Scopolamine (0.25%)	0.1	Mydriasis, cycloplegia	Central nervous system excitement
Timolol (0.25%)	0.1	Antiglaucoma	β-blockade, non-selective
Timolol (0.5%)	0.25		
Tropicamide (0.5%)	0.25	Mydriasis, cycloplegia	Tachycardia
Tropicamide (1%)	0.5		

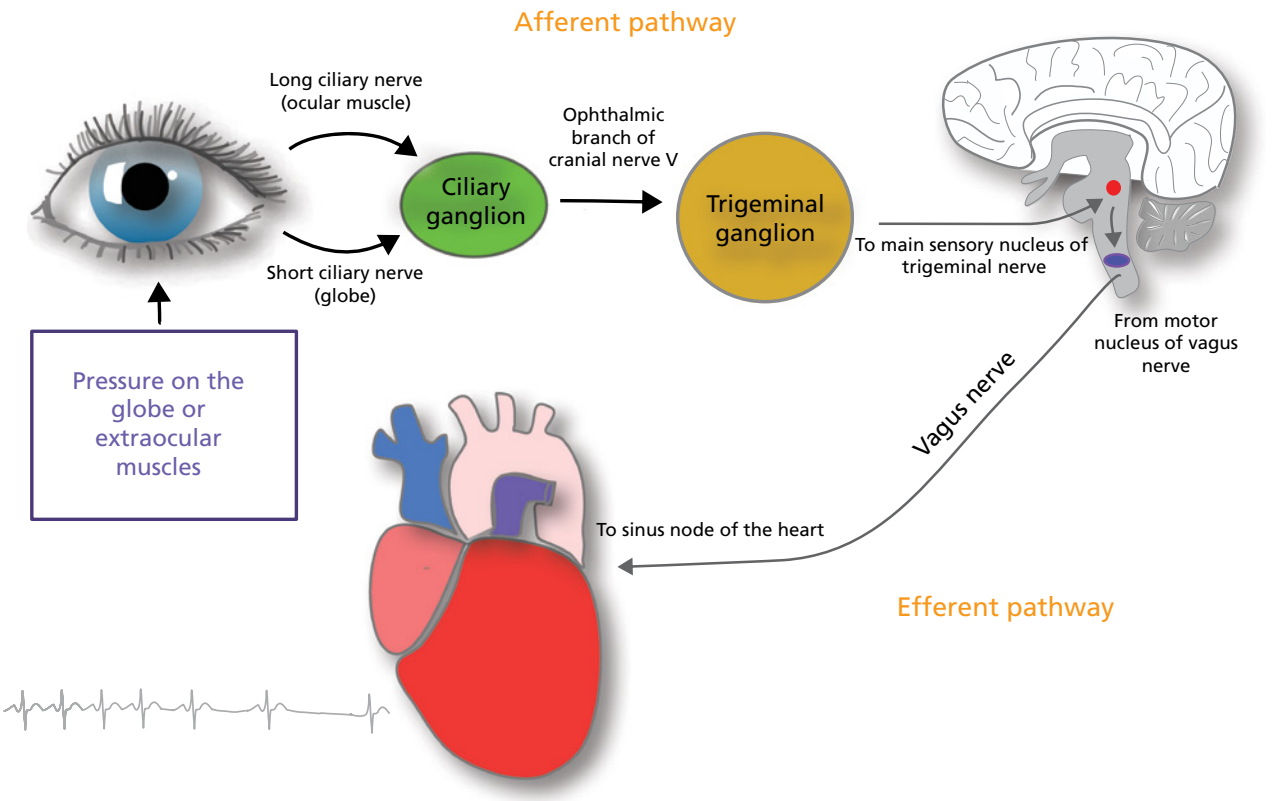

Figure 35.1 Oculocardiac reflex pathway. *Source*: Diagram by Mark Mazziotti MD.

Strabismus may present in healthy children but can also occur in association with congenital syndromes and neurological disorders. The outcome of the surgical correction for this surgery is excellent when performed early in life. The primary considerations for anesthesiologists caring for children having strabismus surgery include the cardiovascular effects of the required preoperative eye drops, the oculocardiac reflex, and postoperative nausea and vomiting.

Ophthalmic drugs

Phenylephrine drops may be placed in the eye(s) prior to strabismus repair in order to facilitate mydriasis and hemostasis. However, absorption of ophthalmic phenylephrine can cause profound systemic vasoconstriction and hypertension. A recommendation to prevent systemic hypertension following phenylephrine eye drops (2.5%) is the instillation of one drop in each eye [1,2]. Other agents (0.5% cyclopentolate, 0.5% tropicamide) may be used to induce mydriasis without causing hypertension.

Oculocardiac reflex

Traction on the extraocular muscles, which inevitably occurs during strabismus surgery, produces vagal stimulation via the trigeminal-vagal reflex, also referred to as the oculocardiac reflex (Fig. 35.1). The afferent pathway of this reflex involves the ophthalmic division of the trigeminal nerve, while the efferent pathway involves the vagus nerve. The oculocardiac reflex may be triggered during any surgery in which there is traction on the extraocular muscles or eyelid. Some studies suggest that the oculocardiac reflex occurs more frequently when the medial rectus is stimulated, however other studies report no difference in the potential to trigger the

reflex between the different extraocular muscles [3,4]. A gentle surgical technique can prevent the oculocardiac reflex. If the reflex does occur, alerting the surgeons and the subsequent alleviation of traction on the rectus muscles or pressure on the eye usually dissipates symptoms. Other situations that may trigger this reflex include placement of a retrobulbar block, enucleation, and maxillofacial or endoscopic sinus surgeries. Pressure on the eye or empty globe may also elicit this reflex. The oculocardiac reflex can result in a variety of dysrhythmias including sinus or junctional bradycardia, atrioventricular block, bigeminy, multifocal premature ventricular contractions, ventricular tachycardia, or sinoatrial arrest [5].

These changes in rhythm may decrease as surgery progresses, as the reflex may fatigue, or it may diminish with continued intermittent traction. Medical therapy (i.e. administration of anticholinergic agents) may be necessary. Prophylactic administration of glycopyrrolate or atropine may help decrease the frequency, intensity, and duration of this reflex. However, this practice remains controversial as dysrhythmias have been associated with the administration of anticholinergic agents and the reflex may still occur regardless of pretreatment [6]. A retrobulbar block may trigger the oculocardiac reflex if moderate pressure is applied to the eye but when the block takes effect, it can prevent the oculocardiac reflex by blocking the afferent limb of the reflex.

The LMA provides an effective alternative to endotracheal intubation in otherwise healthy children undergoing elective strabismus surgery [7]. In the absence of gastroesophageal reflux, the LMA provides an excellent airway for patients who can sustain spontaneous ventilation for the duration of eye muscle surgery. Hypercarbia may exacerbate the oculocardiac reflex [8], therefore in order to treat or prevent hypercarbia during anesthesia with a LMA, the anesthesiologist may consider mechanical ventilation with positive inspiratory pressures not exceeding 20–25 mmHg or pressure support ventilation.

Postoperative nausea and vomiting

Nausea and vomiting occurs in 50–80% of patients in the postoperative period following strabismus surgery and may delay discharge from the hospital. A recent review revealed postoperative nausea and vomiting (PONV) as the reason for 50% of unplanned overnight hospital admissions following strabismus surgery [9].

The exact mechanism of the observed increased predisposition to nausea and vomiting following strabismus surgery is not known but may be related to altered visual perception and a different afferent input postoperatively or it may be secondary to an oculoemetic reflex, which is analogous to the oculocardiac reflex. It is worthy of note, however, that prevention of the oculocardiac reflex during strabismus surgery by prophylactic treatment with anticholinergic agents (atropine or glycopyrrolate) has not been found to reduce the incidence of nausea and/or vomiting [10]. A large number of studies have examined the management of postoperative nausea and vomiting in general. Prophylactic treatment using more than one drug is clearly indicated according to the consensus statement of the Society for Ambulatory Anestheia [11]. However, no single agent, combination of agents, or anesthetic technique has completely eliminated this problem.

Despite persistence of this problem, propofol has contributed to the decline in the incidence of PONV [12] and studies have shown that it offers some protective effect against PONV following strabismus surgery [13–16]. Droperidol and metoclopramide, both antidopaminergic drugs, reduce nausea and vomiting by their action on dopaminergic sites [17,18]. Droperidol is, however, now rarely used in the United States due to the Food and Drug Administration (FDA) black box warning (strong contraindication) against its use. This warning cites serious cardiac arrhythmias due to prolongation of the QTc interval and recommends 12 lead electrocardiogram (ECG) monitoring 1 h before surgery and 2–3 h postoperatively if droperidol is administered to a patient [19,20]. Droperidol had been favored in the past as an antiemetic as it was cheaper than its counterpart serotonin antagonist agents. However, its use was also associated with occasional prolonged periods of sedation. Metoclopramide has also been used for many years to treat PONV. When compared with ondansetron, a serotonin antagonist also utilized in the management of PONV, metoclopramide decreased nausea and vomiting to a much lesser degree than ondansetron in patients following strabismus surgery [21,22].

Strategies to decrease PONV in strabismus patients currently revolve around serotonin antagonists. Dexamethasone is often used in conjunction with this class of drugs. When administered at a dose of 50 μg/kg, dexamethasone was found to be just as effective as higher doses of 250 μg/kg [23]. Nitrous oxide and the use of opioids have been implicated in the development of PONV. Therefore, avoidance of nitrous oxide as a maintenance agent and administration of non-steroidal agents such as ketorolac will help decrease the incidence of PONV following strabismus surgery. High-risk patients such as those undergoing strabismus correction surgery have been found to benefit from combination antiemetic therapy [24–26].

Malignant hyperthermia considerations

In the past patients with strabismus were thought to be susceptible to malignant hyperthermia as most patients with malignant hyperthermia had associated musculoskeletal disorders including strabismus and ptosis. A subsequent review of 2500 patients tested for malignant hyperthermia susceptibility did not show any association with strabismus surgery. Malignant hyperthermia is no longer considered to be a risk for children with strabismus and these children are now routinely anesthetized with inhalational anesthetics without an observed increase in the incidence of malignant hyperthermia [27,28]. Masseter muscle spasm has also been associated with strabismus surgery, particularly in patients who received halothane and succinylcholine [5], although another study contradicted this finding [29]. The increase in jaw tension that may be observed initially following succinylcholine administration, together with an inability to displace the mandible from the maxilla to facilitate insertion of an oral airway, is now thought to represent a normal clinical state following succinylcholine administration [27,28]. Succinylcholine has a black box warning from the US FDA against its use for elective airway management in children and so this problem should not be clinically relevant for contemporary anesthetic practice.

In summary, it does not appear there is an association between strabismus and malignant hyperthermia [30]; however, if masseter muscle spasm is suspected in a patient,

particularly a young or preadolescent child, it is important to recognize that the patient may be susceptible to developing malignant hyperthermia [27,31,32]. The importance of a detailed anesthetic family history also cannot be overemphasized.

KEY POINTS: EXTRAOCULAR CONDITIONS

- Nasolacrimal duct obstruction surgery can involve simple probing, balloon dilation with or without tube placement, or dacryocystorhinostomy; airway management techniques range from facemask, to LMA, to endotracheal intubation
- Strabismus surgery drug interactions such as hypertension from absorption of 2.5% phenylephrine instilled in the eye can be prevented by limiting the dose to one drop in each eye
- The oculocardiac reflex is produced by traction on the extraocular muscles or pressure on the globe, and is mediated by the ophthalmic division of the trigeminal nerve (afferent) and the vagus nerve (efferent). It can be prevented by gentle surgical technique and pretreatment with an anticholinergic agent, and fatigues with repeated stimulation
- Postoperative nausea and vomiting is very common after strabismus correction; multimodal antiemetic therapy with ondansetron, dexamethasone, and avoidance of nitrous oxide and opioids, are effective

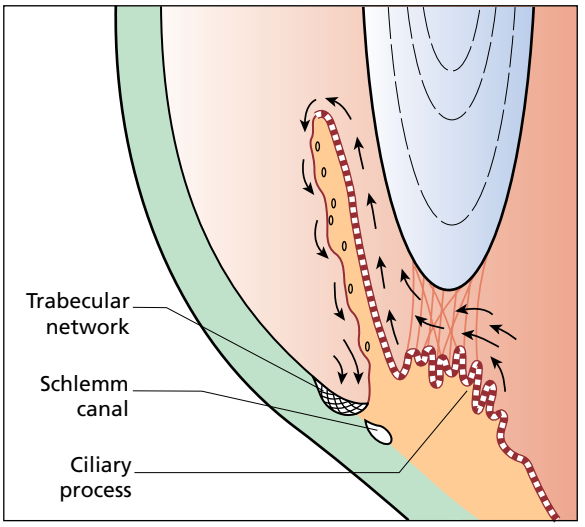

Figure 35.2 Magnified view of ciliary body showing aqueous humor production and flow pattern.

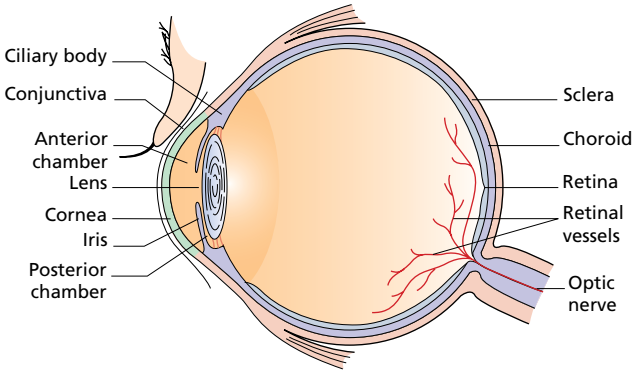

Figure 35.3 Anatomy of the anterior chamber of the eye.

Intraocular conditions

Prior to an in-depth discussion of the intraocular conditions, it is imperative to understand the production and regulation of aqueous humor in the eye as well as intraocular pressure and how it may be impacted by different anesthetics.

Control of intraocular pressure

Aqueous humor is present in both the anterior and posterior chambers of the eye. The majority of the aqueous humor is produced in the posterior chamber by active secretion, filtration, and diffusion from the blood supply to the ciliary body (Fig. 35.2). Aqueous humor passes from the posterior chamber, through the ciliary body behind the iris to the front of the lens, then through the pupil into the anterior chamber (Fig. 35.3). The most lateral portion of the anterior chamber, called the angle, contains a meshwork of tissue that filters the aqueous humor before it reaches the canal of Schlemm and eventually drains into the episcleral veins. This fluid contains no blood cells and only 1% of the concentration of protein found in plasma. Thus, the aqueous humor is clear and allows transmission of light to the retina [33].

Normal intraocular pressure (IOP) is maintained between 10 and 21 mmHg by a balance between the production and drainage of aqueous humor, choroidal blood volume, extraocular muscle pressure, and vitreous humor volume [34]. Sudden increases in IOP may result in acute glaucoma. If this occurs in the presence of an open globe, prolapse of the iris or lens and/or hemorrhage from blood vessels may occur. Therefore, it is imperative that the anesthesiologist maintains normal IOP during eye surgery. Laryngoscopy and intubation of the trachea, coughing, vomiting, or straining during induction or emergence from anesthesia can all dramatically increase IOP to values as high as 40 mmHg [35]. Although the effect of laryngoscopy is transient and of no serious consequence in the patient with normal intraocular physiology, this increase in pressure may be very significant for patients with glaucoma or other eye pathology. Administration of intravenous lidocaine prior to intubation has been found to prevent an increase in IOP [36–38]. IOP changes with LMA insertion are less than those following tracheal intubation [39].

Coughing causes venous hypertension which increases the intraocular blood volume and has a dramatic effect on IOP. Several metabolic or acid–base derangements may occur during general anesthesia and can also impact IOP. Hypoxia and hypercarbia cause retinal venodilation and an increase in IOP [40]. Both mild hypo- or hypercarbia produce clinically insignificant effects [41]. Hypothermia decreases IOP by decreasing the rate of aqueous humor production. Arterial pressure changes have little effect on IOP [34].

Effect of anesthetics on intraocular pressure

In general, sedative–hypnotic agents, inhalational agents, and opioids tend to decrease IOP with the exception of ketamine [34,42]. Earlier reports on the use of ketamine and IOP measured by Schiotz tonometry, which measures corneal compressibility, indicated that ketamine resulted in an elevation of IOP [43]. Currently, IOP is routinely measured with applanation tonometry, a method believed to more accurately measure IOP. While ketamine does not lower IOP, the IOP measured following ketamine administration may be more reflective of the awake measurement rather than an elevated value. The use of ketamine may actually be preferable to other agents when an accurate measurement of IOP is necessary, as is the case of children with suspected glaucoma in whom accurate measurements of the IOP can only be obtained under anesthesia [44,45]. Nystagmus and blepharospasm associated with ketamine administration may preclude its use in children with an open globe injury.

Non-depolarizing muscle relaxants decrease pressure on the globe and may decrease intraocular pressure [34]. Succinylcholine, a depolarizing muscle relaxant, increases IOP by inducing tonic extraocular muscle contracture, choroidal vascular dilation, and relaxation of orbital smooth muscle. In normal eyes, an increase in IOP of about 7 mmHg has been observed following succinylcholine use [46]. This modest increase is transient and of little consequence in a patient with normal IOP. However, if a patient has a high baseline IOP, the increase in IOP induced by succinylcholine administration may be greater and any rise may be significant in that setting. In the case of an open globe, an increase in pressure could result in the loss of vitreous humor. Despite reports to the contrary, no one method has been shown to prevent the intraocular hypertension observed with the administration of intravenous succinylcholine [47–49]. While some reports state there are no adverse events following the use of succinylcholine for anesthesia in a child with an open globe injury [50], caution should be exercised using this drug in the presence of such an injury. High-dose rocuronium provides a viable option for modified rapid-sequence induction without the concern of associated elevation of IOP in this subset of children who present for emergency surgery. In addition, the availability of sugammadex for the reversal of dense neuromuscular blockade after a short procedure should render succinylcholine use even less necessary in this scenario [51].

KEY POINTS: INTRAOCULAR PRESSURE

- Intraocular pressure is dramatically increased by laryngoscopy and intubation, coughing, vomiting, or straining; all should be minimized in patients with elevated IOP
- Sedative–hypnotic agents, inhalational agents, and opioids all decrease IOP, except ketamine, which maintains baseline IOP
- Non-depolarizing muscle relaxants decrease IOP; succinylcholine increases IOP and should be avoided in patients with elevated IOP or an open globe

Glaucoma

If outflow of aqueous humor is obstructed for any reason, IOP increases and can lead to glaucoma. Primary congenital glaucoma includes neonatal and infantile glaucoma, which presents at birth or within the first 2 years of life, respectively. Juvenile glaucoma presents in late childhood without corneal enlargement (buphthalmos), and often in children of families with a strong history of open-angle glaucoma. Secondary glaucoma develops in association with an underlying ocular or systemic condition (e.g. Sturge–Weber syndrome, neurofibromatosis, mesodermal dysgenesis) [52].

Successful surgical treatment of primary congenital glaucoma requires early recognition of the problem. Confirming the diagnosis in infants who present with a history of excessive tearing, photophobia, irritability, and buphthalmos usually requires measuring the IOP during an exam under general anesthesia. The eye examination and pressure measurement can be followed by surgery if the diagnosis is confirmed. The initial surgical procedures for pediatric glaucoma include goniotomy or trabeculotomy to create a route for the exit of aqueous humor via the Schlemm canal. If unsuccessful, other surgical options include trabeculectomy, placement of a glaucoma drainage device, or cyclodestructive therapy to destroy the ciliary body and decrease aqueous humor production [53].

Anesthetic considerations for patients during glaucoma surgery include awareness and management of associated medical problems as indicated; especially if glaucoma exists as part of a syndrome, as well as use of appropriate medications and methods/drugs to prevent further increase in IOP (see section “Control of intraocular pressure”).

Open globe injuries in a patient with a “full stomach”

Traumatic eye injuries are common in children. Surgical exploration of the eye wound, removal of any existing foreign material, and closure of the laceration within several hours of the injury offer the best chance of salvaging the eye following traumatic injury. After penetrating trauma, the pressure inside the eye is atmospheric. External pressure on the eye or an increase in internal pressure can prolapse the lens, iris, or vitreous and markedly reduce the chance of recovery of vision. The goal preoperatively and during the induction of anesthesia is to prevent coughing, crying, and vomiting because these activities increase intraocular venous blood volume. Increased intraocular venous blood volume and IOP may cause extrusion of the ocular contents.

Preventing an increase in IOP is important, but difficult to accomplish. Preoperatively, the child should remain flat and quiet, and the eyes should be patched to minimize eye movements (this can be scary and confusing to young children). Sedating the child before patching the eyes is essential if the child is too young to cooperate and cannot understand a careful, gentle explanation of the procedure. Giving a young child midazolam (0.5–0.75 mg/kg PO) or diazepam (0.2 mg/kg PO) will provide adequate sedation. Intranasal midazolam may cause crying and agitation and should therefore be avoided in the setting of an open globe injury. The α2-agonist, dexmedetomidine, is an effective premedication when administered intranasally and it has an advantage over intranasal midazolam as it is not associated with pain when administered via

this route [54–57]. Administration of dexmedetomidine has also been found to attenuate the increase in IOP associated with succinylcholine administration [58].

In a calm, sedated child, application of EMLA (eutectic mixture of local anesthetics) cream may provide adequate topical anesthesia to allow for insertion of an intravenous catheter. The EMLA cream should be applied to several sites where veins are visible (or likely to be present) and covered with a clear occlusive dressing. Forty-five to 60 min later, the skin should be anesthetized to allow painless insertion of an IV catheter. Once vascular access has been achieved, subsequent doses of sedatives can be titrated to effect, and a rapid-sequence induction of anesthesia can be easily accomplished. The anesthesiologist should assume that all children who present with a penetrating eye injury have a full stomach. After trauma, gastric emptying time is quite erratic and unpredictable such that delaying surgery for 6–8 h does not reliably decrease the risk of aspirating gastric contents.

In the presence of an open eye injury, the anesthesiologist must preoxygenate the patient, being careful not to exert pressure on the injured eye with the mask. Preoxygenation is followed by injection of a sedative–hypnotic anesthetic agent and a muscle relaxant into an injection port of a rapidly flowing IV catheter. Options to minimize the effects of laryngoscopy and intubation on IOP include: intravenous administration of lidocaine (2 mg/kg), fentanyl (2–3 μg/kg), or morphine sulfate (0.05–0.1 mg/kg) prior to the administration of either propofol (2 mg/kg) or thiopental (4–6 mg/kg). Administration of the sedative–hypnotic agent should be followed immediately by a dose of succinylcholine (2 mg/kg) or high-dose rocuronium (1–1.2 mg/kg) to facilitate rapid-sequence induction. High-dose rocuronium offers advantages over succinylcholine because rocuronium provides rapid onset of neuromuscular blockade without impacting IOP. Tracheal intubation should only be attempted after the muscle relaxant has taken effect. This will prevent coughing during laryngoscopy and the detrimental effect on IOP.

Cricoid pressure, which is traditionally applied during induction of anesthesia to occlude the esophagus and prevent passive regurgitation of stomach contents into the lungs, should be maintained until the airway is secured. In situations where intubation is not achieved on first attempt and/or there is accompanying desaturation, the application of cricoid pressure may also decrease the likelihood of stomach dilation if gentle manual positive pressure ventilation is required prior to endotracheal intubation. While utilization of cricoid pressure may be under some debate, it remains the traditional approach to securing the airway in a patient with a potential full stomach [59].

Securing intravenous access for the induction of anesthesia may be challenging in a child. For the normal, chubby toddler who has no visible veins, the risk of crying, struggling, and raising IOP while venous access is being secured, may pose a greater risk than aspiration during induction of anesthesia with inhaled anesthetics and cricoid pressure.

Cataracts

Cataracts in children may be congenital or acquired. Congenital cataracts are of two types: idiopathic and those associated with syndromes. Several syndromes (e.g. Stickler, Hallermann–Streiff, Laurence–Moon–Biedl, Lowe, cerebrotendinous xanthomatosis, and Marfan) are associated with a high incidence of cataracts (see Chapter 43 for further discussion of these syndromes). Metabolic disease states such as galactosemia, and chromosomal abnormalities, such as trisomy 21, are also associated with the presence of cataracts. Cataracts may also be associated with systemic disease, steroid induced, or acquired as a complication of radiotherapy.

Cataract surgery in otherwise healthy children or in those with minimal associated medical co-morbidities, is performed as an outpatient procedure. While this surgical procedure is routinely performed under general anesthesia with supplemental opioid analgesia in children, one study has shown that general anesthesia supplemented with a regional block (sub-Tenon block) resulted in less postoperative pain and fewer requirements for postoperative rescue medication [60]. As with other surgical procedures, associated co-morbidities or medical conditions must be taken into account when administering anesthesia for cataract surgery. A deep plane of anesthesia is required during surgery for all patients to minimize the chance of coughing or straining and loss of vitreous humor or other intraocular contents once an incision has been made on the globe. If a patient's cardiovascular system cannot tolerate a deep plane of anesthesia, neuromuscular-blocking agents should be administered to supplement general anesthesia. Succinylcholine should not be administered after the globe is incised, because the ensuing contraction of the extraocular muscles which may occur for up to 15–20 min can potentially increase IOP sufficiently to extrude the ocular contents through the surgical incision.

Ideally, the patient who has had cataract surgery should not cry excessively or struggle postoperatively. Extubation of the trachea or LMA removal while the patient is still deeply anesthetized will help achieve this goal.

KEY POINTS: GLAUCOMA, OPEN GLOBE INJURIES, AND CATARACTS

- Glaucoma involves the obstruction of outflow of aqueous humor; an eye exam under anesthesia may reveal increased IOP and may be followed by goniotomy or trabeculotomy as surgical interventions
- Avoiding increases in IOP is critical in open globe injuries; an inhaled induction with a full stomach may be preferable to multiple IV attempts in a crying child; and succinylcholine should be avoided if possible.
- Cataract surgery patients often have genetic syndromes; a deep plane of anesthesia is required to prevent movement, straining, or coughing

Retinoblastoma

Retinoblastoma, a malignancy of the retina, is the most common primary intraocular malignancy of childhood [61]. However, of all pediatric malignancies, retinoblastoma is rare and comprises only 3–4% of all pediatric cancers [62]. Decreased vision, eyes gazing in different directions (lazy

eye), and abnormal pupillary light reflex or leukocoria (white pupils) are the presenting symptoms. This condition is usually picked up during a routine eye examination by the pediatrician or by parents who may notice different color pupils during flash photography. Leukocoria is commonly associated with retinoblastoma (Fig. 35.4).

The management of retinoblastoma continues to evolve. The treatment is currently determined by tumor classification at diagnosis and can involve focal therapy (laser photocoagulation or cryotherapy) used alone or in combination with systemic intravenous chemotherapy, intra-arterial chemotherapy, and/or intravitreal chemotherapy [63]. Systemic intravenous chemotherapy is associated with unique toxicities including alopecia, hearing loss following carboplatin therapy, or secondary malignancies that can occur with etoposide. Chemotherapy in various forms including intra-arterial therapy can also be associated with myelosuppression [64]. Additional treatment options for retinoblastoma such as radiotherapy, radioactive plaque therapy, and enucleation are reserved for specific situations [63]. Although external beam therapy has been utilized in the management of retinoblastoma, it is associated with secondary malignancies and is rarely used today in current management. Children with retinoblastoma frequent the operating room for examinations under anesthesia to monitor tumor growth or resolution, as well as for surgical therapy. Smooth inhalational induction of anesthesia with insertion of a LMA provides adequate anesthesia for brief examinations; analgesic drugs may be warranted if surgical therapy is planned. The oculocardiac reflex may be triggered during surgery and should be adequately managed (see earlier in this chapter).

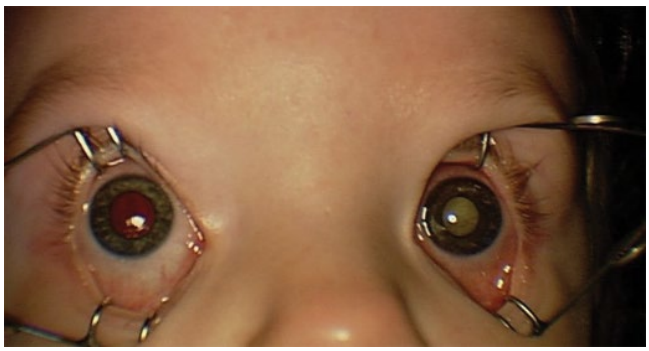

Figure 35.4 Child with leucokoria in the left eye. *Source*: Courtesy of Dan Gombos MD.

Intra-arterial chemotherapy, also referred to as ophthalmic artery chemosurgery, is a localized treatment for retinoblastoma that involves catheterization of the ophthalmic artery, a branch of the internal carotid artery, via a transfemoral approach, in order to allow for direct delivery of chemotherapy to the eye under fluoroscopic guidance (Fig. 35.5) [65]. There are limited published data on the long-term side-effects with this treatment. Thus far, experts have not reported any significant complications such as secondary neoplasms that may occur with intravenous chemotherapy or facial bony defects that can result following radiotherapy. This procedure, which is typically performed in the interventional radiology suite with the patient under general endotracheal anesthesia, is gaining popularity as it offers an alternative treatment to enucleation of the eye, thereby preserving vision (Fig. 35.6). It is also associated with a 70% 5-year survival rate [63,66,67]. Preoperative considerations include premedication for anxiolysis as these patients may have undergone several different procedures in the course of tumor management, and replacement therapy for low cell counts (neutropenia) as a result of systemic chemotherapy. While this procedure has not been associated with long-term complications thus far, it is frequently associated with adverse respiratory and hemodynamic events during the procedure. Respiratory events typically present as an acute decrease in lung compliance characterized by a decrease in tidal volumes and occasional desaturation. This may occur prior to injection of any substance into the eye, i.e. prior to injection of saline, contrast, or chemotherapeutic agent [68]. It also may occur when the microcatheter is between the internal carotid artery and ophthalmic artery [69].

Utilization of pressure control ventilation is helpful intraoperatively as a decrease of as little as 10 mL in the tidal volume can herald an impending respiratory event. This mode of ventilation will also prevent a steep increase in thoracic pressure that may accompany the decreased lung compliance and

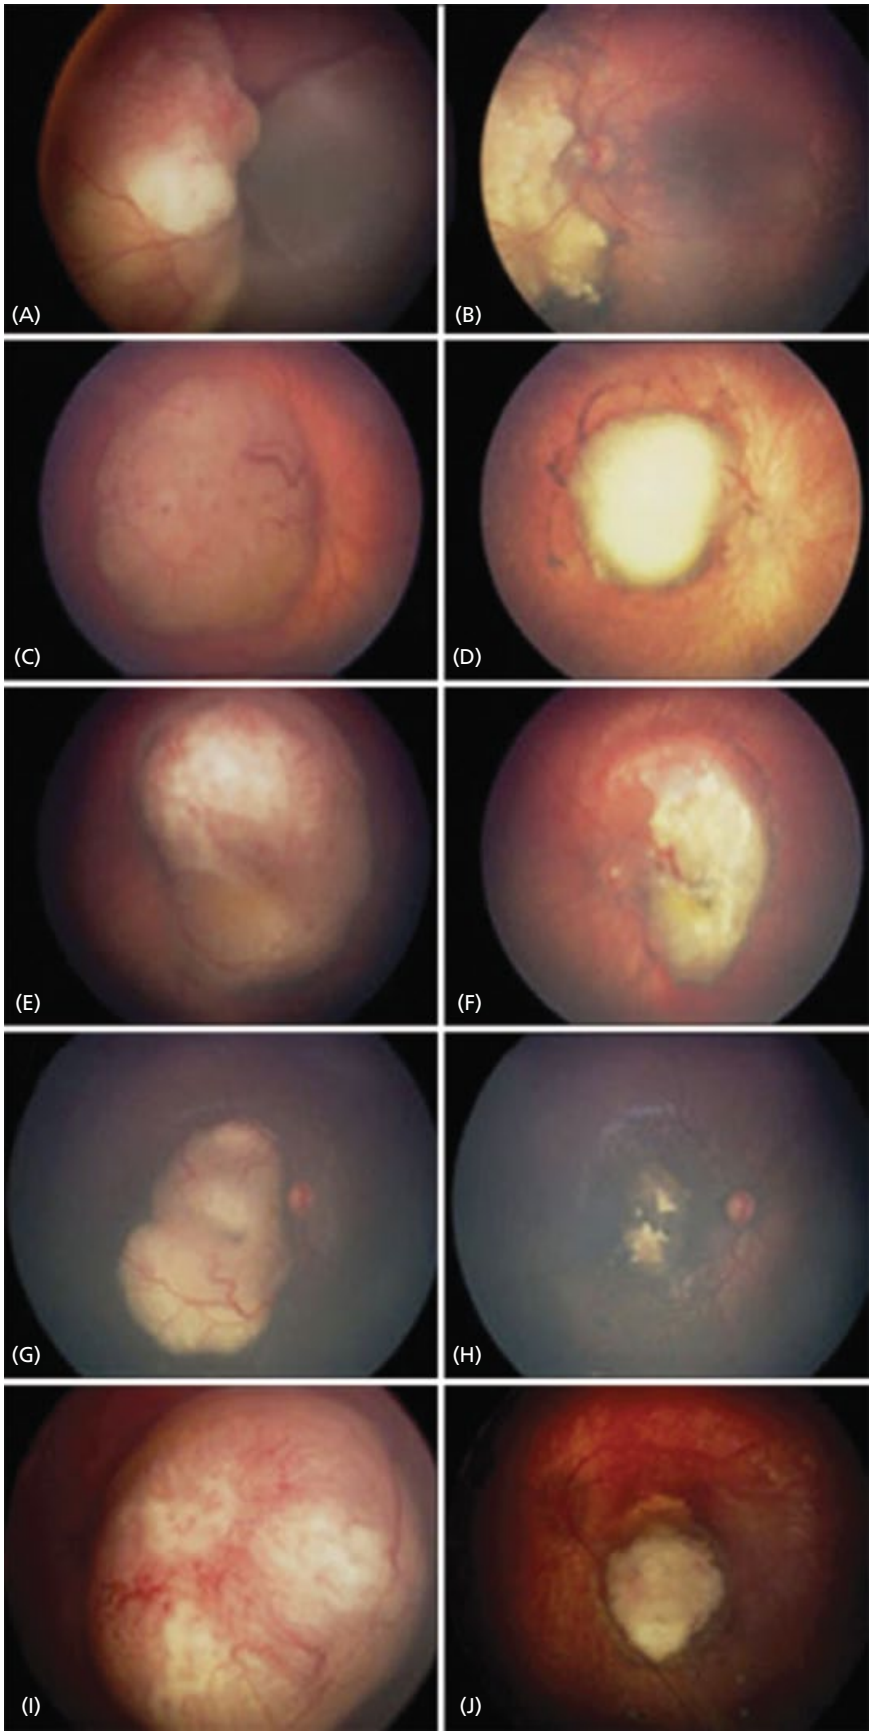

Figure 35.6 Images obtained in five cases showing the response of a solid retinoblastoma before (A, C, E, G, I) and after (B, D, F, H, J) treatment with intra-arterial chemotherapy. *Source*: Reproduced from Jabbour et al [65] with permission of Journal of Neurosurgery.

subsequent limited venous return to the heart [68]. The occurrence of this acute decompensation in respiratory mechanics has not been found to be related to the frequency of the procedure; it may occur during the first intra-arterial chemotherapy treatment or during subsequent therapies. The exact etiology of this acute respiratory decompensation is also not well defined. It can occur despite complete muscle relaxation, is not associated with wheezing, and has not been observed to have a recurring pattern. Acute respiratory decompensation is successfully resolved with the administration of intravenous epinephrine administration at bolus doses of 0.5–1 μg/kg when this is administered at the onset of the event. Hemodynamic changes that may occur during this procedure include bradycardia and hypotension. Bradycardia has been described during injection of the chemotherapeutic agent melphalan, as well as during balloon-assisted procedures [70–72]. Hemodynamic changes typically occur following the respiratory events described above [72] but may not be observed if epinephrine has been administered to treat the acute respiratory event. Epinephrine may also be used to treat the hemodynamic event if it occurs *de novo*. Since these two events often occur together during this procedure, the diving reflex has been proposed as the underlying mechanism triggering both the acute changes in respiration and hemodynamics [68]. This reflex is mediated by the ophthalmic branch of the trigeminal nerve via the anterior ethmoidal nerve. Stimulation of the anterior ethmoidal nerve results in bradycardia, hypotension, and apnea in animals [73]. It is believed that manipulation of the catheter in the ophthalmic or internal carotid artery may stimulate trigeminal afferents in the blood vessel, resulting in a reflex similar to the diving reflex in the pulmonary and cardiovascular systems and mediated, in part, by the vagus nerve.

KEY POINTS: RETINOBLASTOMA

- Retinoblastoma is the most common intraocular malignancy of childhood
- Initial treatment may involve laser photocoagulation or cryotherapy, systemic intravenous chemotherapy, intra-arterial chemotherapy, and/or intravitreal chemotherapy
- Radiotherapy, radioactive plaque therapy, and enucleation are reserved for specific situations
- Intra-arterial chemotherapy involves catheterization of the ophthalmic artery, and direct delivery of chemotherapy to the eye under fluoroscopic guidance. Acute decrease in respiratory compliance without bronchospasm, bradycardia, and hypotension may occur; treatment is with IV epinephrine

Retinopathy of prematurity

Retinopathy of prematurity (ROP), formerly known as retrolental fibroplasia, is a vasoproliferative disorder of premature infants that may result in blindness. The first phase of this disease is characterized by suppression of vascular endothelial growth factor by hyperoxia, resulting in an arrest of normal retinal vascularization. The second phase is characterized by vascular proliferation induced by hypoxia-triggered stimulation of the vascular endothelial growth factor. Hence both hyperoxia and hypoxia play a role in the pathogenesis of ROP [74,75]. Multiple risk factors for ROP have been described and these include low gestational age (strongest risk factor), low birth weight, postnatal weight gain, hyperglycemia, insulin therapy, and neonatal co-morbidities [75,76].

Oxygen supplementation and fluctuations in oxygen concentration have also been associated with ROP. Optimal oxygen saturation targets in preterm infants remain an ongoing topic of controversy and study. Multiple recent studies have compared low (85–89%) and high (91–95%) target oxygen saturations in preterm infants less than 28 weeks of gestational age to outcome measures such as death, severe ROP, bronchopulmonary dysplasia, necrotizing enterocolitis, neurodevelopmental impairment, and hearing loss [77,78]. Although a higher target oxygen saturation range of 91–95% has been associated with increased severity of ROP, this range is often recommended as the lower oxygen saturation target groups of 85–89% have been associated with an increased risk of death at discharge and at 18–24 months corrected age [79]. Nevertheless, the controversy continues, with practitioners maintaining oxygen saturations anywhere from the mid–high 80s to the low 90s range.

Retinopathy of prematurity can be classified based on disease extent, severity, and location of disease. The stages are illustrated in Figure 35.7 [80]. Severe disease can lead to retinal detachment and visual loss or blindness, therefore early intervention is advocated. Laser therapy has been found to result in better visual acuity compared with cryotherapy and is a widely accepted treatment modality for ROP [81,82]. Laser photocoagulation converts the relatively hypoxic retina into anoxic retina, reducing the stimulus for new vessel formation and disease progression. The drawback of this therapy is that it destroys retina, which can lead to significant loss of visual field. This is why antivascular endothelial growth factor treatments, with intravitreal injections of these agents, have emerged as an effective treatment for ROP. However, the safety and long-term effects of these agents remain a topic of ongoing investigation [83,84]. For late-stage ROP in which retinal detachment has already occurred, scleral buckling or vitrectomy is performed but these procedures usually fail to provide useful vision [85].

Patients with ROP have increased susceptibility to develop strabismus, cataracts, and glaucoma and should have scheduled follow-up examinations to help prevent and treat these conditions.

The anesthetic management of this patient population is challenging as multiple medical co-morbidities are usually present, including apnea of prematurity, congenital cardiac anomalies, and bronchopulmonary dysplasia, which may be associated with oxygen requirements. In addition, when ROP or its progression are diagnosed by ocular examination, laser photocoagulation is often an urgent case scheduled as soon as possible after the examination, in order to retard the progression of the disease by intervening as soon as possible. There can be institutional variation regarding the location where surgical interventions for ROP occurs. The goal is to

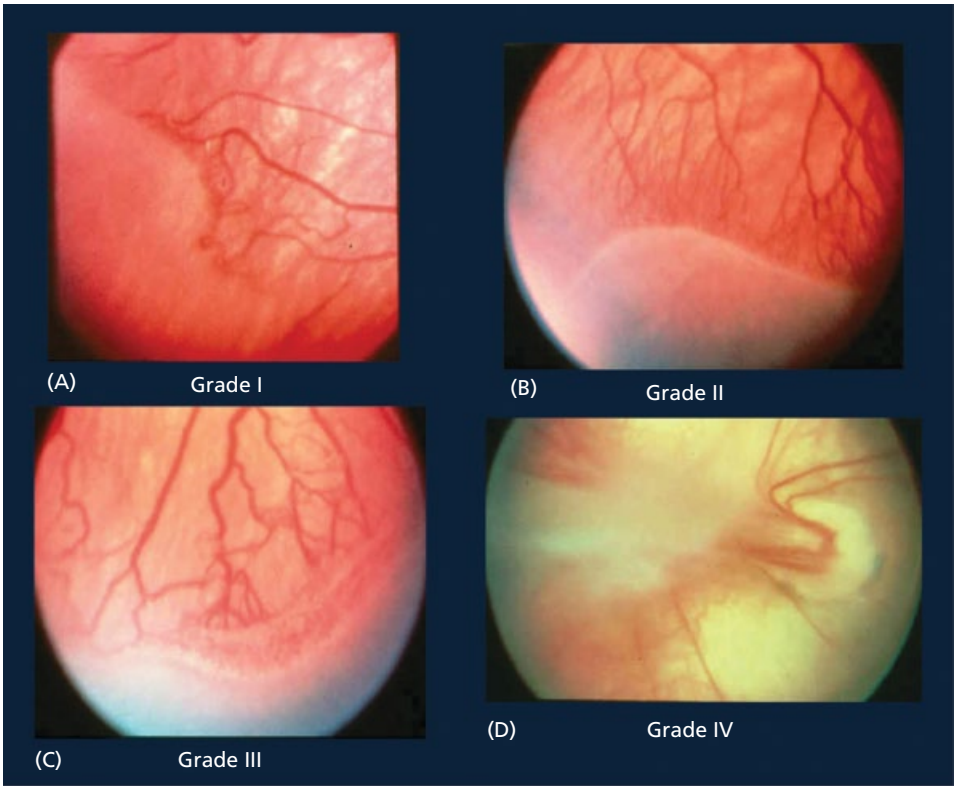

Figure 35.7 Retinopathy of prematurity stages. (A) Grade I: a demarcation line is seen between the vascular and avascular retina. It is a thin structure that lies in the plane of the retina. (B) Grade II: the demarcation line grows to occupy a volume and has a height and width to form a ridge above the plane of retina. (C) Grade III: in this stage extraretinal fibrovascular tissue is seen arising from the ridge into the vitreous. It may be continuous or non-continuous and is posterior to the ridge. (D) Grade IV: a partial detachment of the retina is seen which may be exudative or tractional. Grade V (not shown): here a total retinal detachment is seen as the child usually presents with leukocoria (white pupillary reflex). *Source*: Adapted from Vision Research Ropard Foundation, www.ropard.org. Descriptions from Shah et al [80].

provide a comfortable patient with minimal cardiorespiratory compromise and a quiet surgical field. Laser surgery may be performed in the operating room if the pulmonary status of the neonate will allow for transportation to the operating room. A general anesthetic may provide improved procedural conditions and pain management. A properly seated LMA is a viable alternative to endotracheal intubation in the occasional premature infant with mild to moderate lung disease who has not previously required tracheal intubation. In some institutions, these operations are performed in the intensive care unit which allows for seamless postintervention monitoring [86] and also avoids any interruption in respiratory support if the patient requires supplemental or mechanical respiratory support at the time of surgical intervention. Intravenous sedatives, analgesics, and topical anesthesia have been utilized in neonates who are either ventilated mechanically or are breathing spontaneously [87–89]. Retinal examinations and surgical interventions for ROP can be painful, and non-pharmacological treatments may not be effective for pain management. Nevertheless, pharmacological treatments must be cautiously administered if pain is suspected during the procedure, particularly if postoperative extubation is planned [90,91].

Prevention of ROP or its progression are important considerations when anesthetizing the premature infant for other procedures. As noted, the optimal oxygen saturation range for prevention is controversial, but these infants must not receive unnecessarily high FiO_2; it is prudent to reduce the inspired oxygen, when possible, to achieve SpO_{2in} the mid-90s percent range. The patient who is not intubated before ROP surgery and requires tracheal intubation can be extubated immediately after the procedure, but the risk of postanesthetic apnea is significant in many of these neonates, and careful monitoring in the neonatal intensive care unit setting is warranted. See Chapters 22 and 23 for further discussion of postanesthetic apnea.

KEY POINTS: RETINOPATHY OF PREMATURITY

- ROP risk factors include prematurity, hyperoxia, hypoxia, and neonatal co-morbidities
- The stages of ROP start with vascular proliferation which can increase, and lead to, partial or full retinal detachment and blindness if not treated
- Laser photocoagulation stops progression of the disease and is often performed as an urgent procedure under general endotracheal anesthesia at the bedside or in the operating room

CASE STUDY

A 2-year-old child with unilateral retinoblastoma is scheduled for intra-arterial chemotherapy. The patient was previously healthy and recently presented with unilateral strabismus and leukocoria. An ophthalmic examination under anesthesia was performed which demonstrated unilateral multifocal tumors with subretinal seeding. The patient presents from home on the day of the procedure to the interventional radiology suite. The preoperative evaluation and examination are unremarkable. The parents note that the patient is extremely anxious.

Preoperative considerations

Patients with retinoblastoma frequent the operating room for examinations under anesthesia and surgical treatment, and also non-operating room locations for diagnostic imaging and treatment. This patient may be at risk for separation anxiety due to age and repeated anesthetic encounters. Following the preoperative evaluation, the anesthesiologist should have a discussion with the family regarding possible behavioral and/or pharmacological interventions available for preoperative anxiety. Child Life personnel, may help decrease the child's anxiety if the child can be adequately engaged preoperatively. Alternatively, as this patient presents from home with no intravenous access, oral, nasal, or less commonly, intramuscular routes of medication administration should be considered. If there are no significant respiratory concerns or concerns for obstructive sleep apnea, oral midazolam 0.5–1 mg/kg is a reasonable choice for premedication. If the patient does not tolerate oral medication, intranasal dexmedetomidine 1–2 μg/kg can be considered. This has an advantage over intranasal midazolam which is associated with pain on administration. The median onset time of 1 μg/kg intranasal dexmedetomidine is slower than that of oral midazolam, however it does provide effective anxiolysis with minimal respiratory depression within 25 min of administration.

As patients with retinoblastoma often have repeated anesthetic encounters, a review of past anesthetic records is important. Some patients with retinoblastoma may have received prior systemic chemotherapy, and pertinent systemic toxicities and laboratory work should be reviewed.

Intraoperative considerations

Anesthesia provided in the interventional radiology suite should meet the same requirements as anesthesia provided in the operating room, including standardization of both anesthesia and emergency equipment (airway and code cart). The anesthesia provider should be familiar with the surroundings, equipment, and support services available in this non-operating room location. Intra-arterial chemotherapy is performed in an interventional radiology suite capable of biplane angiography under general endotracheal anesthesia. Exact medications for induction and maintenance of anesthesia are provider and patient dependent. Pressure control ventilation is the recommended mode of ventilation in order to adequately monitor respiratory mechanics as respiratory events commonly occur during this procedure. Following induction of anesthesia and prepping and draping of the patient, the femoral artery is cannulated and intravenous heparin is administered. A microcatheter is then directed under fluoroscopy to the origin of the ophthalmic artery.

Intraoperatively, an abrupt decrease in tidal volume is noted during manipulation of the microcatheter. The oxygen saturation also decreases to 88%, while the capnogram remains unchanged. The patient remains hemodynamically stable. Bilateral auscultation of the lungs reveals clear breath sounds with no wheezing.

Respiratory events typically occur when the microcatheter is advanced between the internal carotid artery and ophthalmic artery. A neural diving reflex-type mechanism has been proposed as a possible cause. A decrease in lung compliance presenting as a decrease in tidal volumes is observed and hypoxia can occur. Treatment includes hand ventilation with 100% oxygen and increased inspiratory pressure, notifying the interventional neuroradiologist to cease catheter manipulation, and administration of 0.5–1 μg/kg intravenous epinephrine. Although the event may appear similar to bronchospasm, wheezing is rarely appreciated on auscultation, and the capnogram is not typical of an obstructive pattern. Pretreatment with antihistamines, steroids, or inhaled bronchodilators are not effective. Hemodynamic issues such as bradycardia and hypotension have also been reported during this procedure. Bradycardia has been described during balloon-assisted procedures and during injection of the chemotherapeutic agent. Treatment includes an intravenous bolus of 0.5–1 μg/kg epinephrine.

Following resolution of the respiratory event, the procedure can typically resume, as recurrence of respiratory events related to catheter manipulation are rare. The anesthesia provider should also rule out other causes of respiratory and hemodynamic events such as severe bronchospasm, pulmonary edema, and anaphylactoid reactions. After catheter position is confirmed, injection of chemotherapeutic agent(s) such as melphalan, topotecan, and/or carboplatin occurs. Following femoral catheter removal and manual compression to achieve groin hemostasis, the trachea can be extubated. A smooth emergence should be prioritized. Prophylactic antiemetics should be administered during the procedure as postoperative nausea and vomiting is commonly associated with this procedure.

Postoperative considerations

The patient should remain flat for a prolonged period in the recovery area as rebleeding from the groin site is possible. Recurrence of respiratory events related to the intraoperative manipulation in the recovery area are uncommon. Periorbital and lid edema or redness may occur following the intra-arterial chemotherapy procedure but this is typically transient. Serious ocular, neurological, and femoral catheterization complications are rare. Patients are typically observed in the recovery area for a prolonged period of time and overnight admission is institutionally and patient dependent.

Multiple cycles of intra-arterial chemotherapy may be required for retinoblastoma patients. Occurrence of a respiratory event related to catheter position with subsequent procedures is unrelated to occurrence during the initial procedure. Therefore, the anesthesiologist should maintain vigilance during all intra-arterial chemotherapy procedures.

Introduction

General anesthesia has allowed surgeons to correct disfiguring lesions in infants and children since the introduction of anesthesia in the middle of the 19th century. Cleft lip and palate reconstruction was among the earliest surgical procedures for which general anesthesia was used for pediatric patients [1]. John Snow published the first report of giving an ether anesthetic to a 7-year-old boy for cleft lip reconstruction in *The Lancet* in 1847. He subsequently administered chloroform for lip reconstruction 147 times between 1847 and 1858, mostly to infants between 3 and 6 weeks of age. Cleft lip and palate repairs have also been an impetus for other innovations in anesthesia care for infants. This includes Ivan Magill's first use of endotracheal anesthesia for an infant in 1924 and Philip Ayre's introduction of the T-piece circuit in 1937 [2]. Modern developments in anesthesia and plastic surgery have permitted increasingly complex reconstruction of disfigured infants and children. The past decade has seen major advances in the understanding of anomalous development and the evolution of diagnostic and therapeutic technology. This chapter focuses on the anesthetic challenges encountered in major craniofacial reconstruction, including cleft lip and palate repair.

Craniofacial embryology

Normal development

The basic structures of the fetus are formed during the embryonic period of gestation, i.e. between postconceptual weeks 2 and 8. The skeleton of the head is composed of the neurocranium (calvaria or cranial vault), the viscerocranium (facial skeleton), and the cranial base. These structures are highly integrated, and their formation and development are closely interwoven. The cranial base is the foundation of the skull, and its formation and development greatly influence the morphology of the other components. Embryologically, the cranial base and facial complex are derived from neural crest tissues; the neurocranium arises from mesoderm [3,4].

The neural tube closes by the 3rd week of gestation. Its dorsal crests are composed of multipotent tissue that migrates widely into adjacent mesenchyme between the diencephalon and the cardiac swelling. Translocated neural crest cells undergo differentiation into a wide variety of cell types and form cartilage, bone, ligaments, muscles, and arteries of the cranial base and facial regions.

Gregory's Pediatric Anesthesia, Sixth Edition. Edited by Dean B. Andropoulos and George A. Gregory.

Cranial base

The cranial base extends from the foramen magnum to the frontonasal junction and consists of the sphenoid, petrous portion of the temporal bone, and cranial surfaces of the ethmoid bones. The pars basilaris of the clivus and the occipital bone are also part of the base. Phylogenetically, it is the oldest portion of the skull, and its development appears to be genetically determined. The bony structure is preceded by a cartilaginous structure, the chondrocranium, which first appears in the 6th week of gestation. Before chondrification, blood vessels, cranial nerves, and the spinal cord are established between the brain and extracranial sites. Centers of ossification appear during the 8th week of gestation. In contrast to the largely intramembranous bone of the cranial vault, which originates by direct ossification of mesenchyme, the osteogenic membrane, the cranial base is endochondral bone and formed from a cartilaginous prototype. Its sutures are cartilaginous joints (synchondroses), which grow by chondrocyte mitosis. The spheno-occipital synchondrosis is the principal site of growth in the cranial base during childhood.

The cranial base is an important shared junction between the cranial vault and face. Its inner surface relates to the brain and its outer surface relates to the nasopharynx and facial complex. Its shape and size strongly influence final calvarial morphology. The primary stimulus for growth of the cranial base is growth of the brain. The ventral parts of the frontal and temporal lobes determine the size and alignment of the floor of the cranial base, namely the anterior and middle cranial fossae [5]. The cranial base is, in turn, the template on which the upper face develops. Various junctures between the cranial base and facial bones, especially in the nasomaxillary complex, determine the influence of the cranial base on facial growth. The anterior cranial fossa is spatially related to the nasomaxillary complex. The middle cranial fossa is also related to the pharyngeal space and airway. The interposition of three sets of space-occupying sense organs complicates the attachment of these two skull components to each other and influences the growth of the facial skeleton in particular. These interactions become obvious in most craniofacial pathologies, e.g. in hyper- or hypotelorism, are associated with cranial vault or cranial base malformations or plagiocephaly with unilateral coronal synostosis with facial scoliosis.

Cranial vault

The cranial vault consists of the frontal, parietal, temporal, and occipital bones. The mesenchyme that precedes the cranial vault or neurocranium is derived from paraxial mesoderm and is at first arranged as a capsular membrane around the developing brain. Ossification of intramembranous calvarial bones requires the presence of the brain. According to the functional matrix concept, bone growth occurs in response to functional demands. The sutures of the calvaria can be considered interosseous ligaments that connect opposing bone surfaces. The bones of the calvaria are displaced outward by the expanding brain and deposit new bone at the contact edges of the sutures [5]. The ultimate size and shape of the cranial vault are therefore determined by internal hydrostatic pressures that the expanding brain and cerebrospinal fluid (CSF) pulsation waves exert on the cranial sutures. This stimulates compensatory sutural bone growth.

The face

Development of the head and face occurs between the 4th and 10th weeks of gestation by fusion of five facial swellings: the single frontal prominence and paired maxillary and mandibular prominences (Fig. 36.1). This depends upon the inductive activities of the prosencephalic and rhombencepahlic organizing centers, which are regulated by the expression of the sonic hedgehog gene as a signaling protein in the neural floor plate cells [6,7]. The rostral prosencephalic center induces the visual and inner ear apparatus, the upper third of the face, and the neurocranium. The caudal rhombencephalic center is responsible for the viscerofacial skeleton (i.e. middle and lower thirds of the face). Gradients of chemical and physical properties emanating from the organizing centers regulate the process of craniofacial formation [8]. The five facial swellings surround a central depression, which is the stomodeum or future mouth.

The frontal prominence encloses the forebrain from which pairs of thickened ectodermal surface placodes (nasal and optic) are derived. The nasal placodes invaginate to form the nasal passages. The surface ridges or nasomedial and nasolateral processes give rise to the nose, the philtrum of the upper lip, and the primary palate. The nasal complex is formed when the frontal prominence merges with the nasal capsule, which is part of the cranial base. The nasal capsule surrounds the olfactory organs and forms the cartilages of the nostrils and the nasal septum. Septal cartilage intervenes between the cranial base above and the palate below and plays a major role in subsequent growth of the midface. The optic placodes, which ultimately develop into eyes, are induced by lateral optic diverticula from the forebrain. Expansion of the cerebral hemispheres produces medial migration to a frontal position.

The maxillary and mandibular prominences are derived from the first branchial arch. The branchial arches are five segmented bilateral swellings of the pharyngeal foregut, consisting of a mesodermal core surrounded by neural crest tissue. The arches are separated by branchial grooves externally and pharyngeal pouches internally. The cartilaginous skeleton of the first arch, Meckel's cartilage, provides a template for development of the mandible. The ear and auditory apparatus are derived from the first and second arches and from the first groove and pouch. The external ear components migrate from an initial cervical location. The internal ear components arise from the otic placode, which is induced by the vestibulocochlear nerve. The rest of the branchial arches, grooves, and pouches form various parts of the pharynx and laryngeal apparatus.

The facial prominences and their skeletal cartilage, mesenchyme, and neurovascular bundles undergo cell proliferation, swelling, migration, and fusion in a critically timed series of events. Fusion of the paired mandibular prominences in the midline provides continuity of the lower jaw and lip. Fusion of the maxillary and mandible prominences laterally creates the commissures of the mouth. Fusion of the nasomedial processes and maxillary prominences provides continuity of the upper jaw and lip and separation of the stomodeal chamber into separate oral and nasal cavities. Fusion of the nasomedial processes in the midline forms the central upper lip, the tip of the nose, and the primary palate (Fig. 36.1).

During the 6th week of development, the secondary palate is formed from palatine shelves that initially grow inferiorly

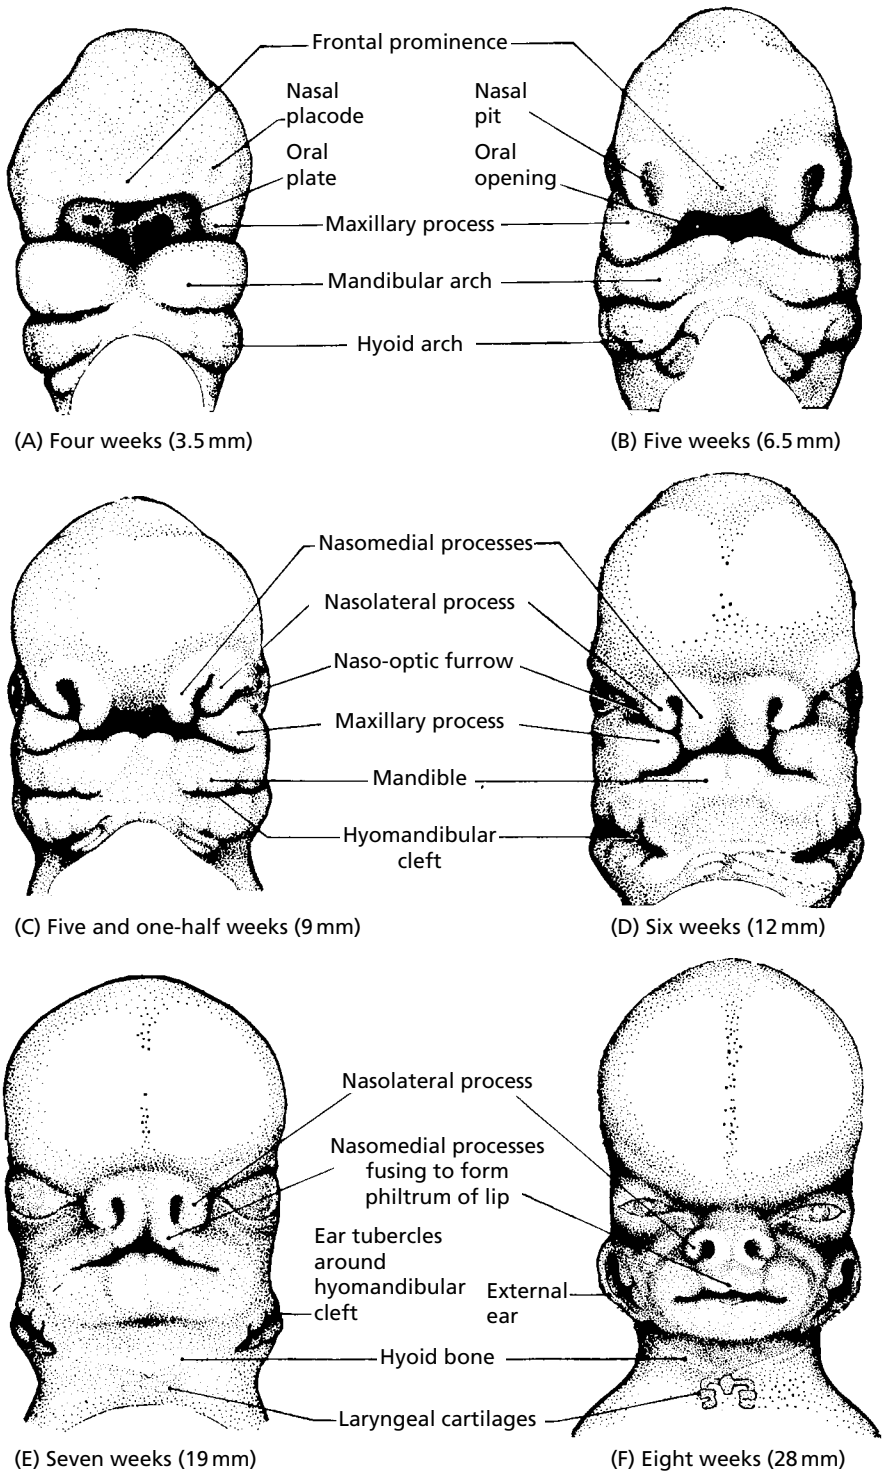

Figure 36.1 Stages in the embryonic development of the face. The median and paramedian structures from the upper lip to the forehead derive from the frontal prominence. The maxillary and mandibular regions, the ear, and the pharyngeal and laryngeal structures, derive from the branchial arches. *Source*: Reproduced from Patten [182] with permission of McGraw-Hill Companies.

from the maxillary prominences downward into the stomodeum and lateral to the tongue. Initially, these palatal shelves are widely separated from the primary palate owing to their vertical orientation on either side of the tongue. During the 7th and 8th weeks of gestation, coincident with longitudinal growth and straightening of the embryo and withdrawal of the tongue from between the shelves, the lateral palatal shelves rotate to a horizontal position and fuse with each other. The palatal mesenchyme then differentiates into bony and muscular elements that correlate with the position of the hard and soft palate, respectively. In addition to fusing in the midline, the secondary palate fuses with the primary palate and the nasal septum. These fusion processes are complete by the 10th week of embryogenesis; development of the mammalian secondary palate thereby divides the oronasal space into separate oral and nasal cavities, allowing mastication and

respiration to take place simultaneously [9]. The nature of the "intrinsic shelf force" responsible for this reorientation is unknown, although mouth-opening reflexes, which involve withdrawal of the face from against the heart prominence, have been implicated in the withdrawal of the tongue from between the vertical palatal shelves.

The neural crest tissue gives rise to the facial skeleton, and the mesoderm will form the facial muscles. Current studies demonstrate the influence of the cranial base as it adjusts to its broader structural context and provides added support for the developmental and structural integration of the cranial base with both the cranial vault and face [10]. During facial development, cells are monitored by genetically determined pathways and adjust their rates of accumulation, apoptosis, and hyperplasia to produce organs of predetermined size [11]. Forward growth of the mandible relocates the tongue more anteriorly. Successful fusion of the components of the palate by the 12th week requires a complicated synchronization of shelf movements with withdrawal of the tongue and growth of the mandible. By this time, the face takes on a human appearance.

KEY POINTS: CRANIOFACIAL EMBRYOLOGY

- The cranial base is an important junction between the cranial vault and face. Its inner surface relates to the brain and its outer surface relates to the nasopharynx and facial complex
- The ultimate size and shape of the cranial vault are determined by internal hydrostatic pressures that the expanding brain and CSF pulsation waves exert on the cranial sutures
- Septal cartilage intervenes between the cranial base above and the palate below and plays a major role in subsequent growth of the midface

Anomalous development

Various genetic and environmental factors cause anomalous craniofacial development [12]. The etiology of craniofacial syndromes and craniosynostosis is heterogeneous and multifactorial. Genetically based malformations may be caused by single-gene deficiencies or by chromosomal aberrations. Genes for several autosomal dominant craniofacial malformations have recently been defined: mutations in genes regulating fibrous growth factor receptors (FGFR-1, -2, -3, -4) and transforming growth factors (TGF-1, -2, -3) as well as *MSX2* and *TWIST* genes [13–15]. The identified gene loci associated with cleft lip and palate include regions on chromosomes 1, 2, 4, 6, 14, 17, 19, and X (*MHFR*, *TGFA*, *D4S175*, *F13A1*, *TGFB3*, *D17S250*); gene products (e.g. TGFA, TGFβ3, MSX1, IRF6, TBX22, GSTM1) also often act as growth factors [16,17]. Currently, there are no specific tests available for genetic susceptibility to orofacial clefts. Environmental factors include congenital infections, irradiation, and exposure to chemical teratogens, such as phenytoin, vitamin A analogs, and alcohol. For many malformations, the etiology is unknown.

Maldevelopment can occur through several mechanisms. Malformations that develop during the embryonic period are distinct from deformations that occur later in the fetal period and may be self-correcting with postnatal catch-up growth [6]. Fetal or postnatal head restraint can also cause premature fusion of cranial sutures [15]. Malformations can originate in anomalies of neural crest cells that may be deficient in number, may not complete migration, or may fail to cytodifferentiate. Neural crest tissues also form much of the cardiac conotruncal septum, and there is an association between craniofacial and cardiovascular malformations in syndromes in which neural crest defects play a role [18,19]. Examples include retinoic acid syndrome, DiGeorge syndrome, the CHARGE association (*C*, coloboma of the eye/central nervous system anomalies, *H*, heart defects, *A*, atresia of the choanae, *R*, retardation of growth and/or development, *G*, genital and/or urinary defects, *E*, ear anomalies and/or deafnes), and some variants of hemifacial microsomia. Malformations can also be caused by intrauterine compression of the embryo early in gestation. For example, in the amnion rupture sequence, early rupture of the amnion leads to defective morphogenesis secondary to compression of the embryo. In addition, adherence of amniotic bands to developing embryonic structures may interfere with normal development and result in simple to bizarre malformations that are not associated with embryological lines of fusion.

Malformations may result from intrauterine vascular accidents. For example, a shift in the blood supply of the face from the internal to the external carotid artery occurs during the 7th week of gestation when the normal stapedial artery atrophies. This shift occurs at a critical time of midface and palate development and has the potential to cause deficient blood supply and defects of the midface, upper lip, and palate. Malformations can also be secondary to defects in brain development because all components of the skull depend on the brain development [12–15,20,21]. Several syndromes are described below.

KEY POINTS: ANOMALOUS DEVELOPMENT OF CRANIOFACIAL STRUCTURES

- Successful fusion of the components of the palate by the 12th week requires a complicated synchronization of shelf movements with withdrawal of the tongue and growth of the mandible. By this time the face takes on a human appearance
- Genetically based malformations may be caused by single-gene deficiencies or by chromosomal aberrations
- Neural crest tissues also form much of the cardiac conotruncal septum, and there is an association between craniofacial and cardiovascular malformations in syndromes in which neural crest defects play a role like the DiGeorge syndrome and CHARGE association
- Malformations may result from intrauterine vascular accidents. For example, a shift in the blood supply of the face from the internal to the external carotid artery occurs during the 7th week of gestation. Deficient blood supply may cause defects of the midface, upper lip, and palate

Table 36.1 Nomenclature of craniosynostosis

Affected suture	Traditional name	Literal translation
Sagittal	Scaphocephaly	Boat skull
Metopic	Trigonocephaly	Triangle skull
Unilateral coronal	Plagiocephaly*	Oblique skull
Bicoronal	Brachycephaly	Short skull
Multiple sutures	Acrocephaly†	Topmost skull
	Turricephaly†	Tower skull
	Oxycephaly	Sharp skull
	Kleeblattschadel	Cloverleaf skull

* Plagiocephaly is not necessarily synonymous with unilateral coronal synostosis.
† Some authors use acrocephaly and/or turricephaly synonymously with brachycephaly to indicate bicoronal synostosis.

Craniosynostosis

Precocious brain development is reflected by rapid head enlargement, beginning in early gestation and continuing through the first postnatal year. Craniosynostosis, or premature closure of the cranial sutures, restricts skull growth in the affected region. Single suture synostosis leads to characteristic skull deformities as growth is inhibited in the synostotic suture and compensated by increased skull expansion in non-affected areas (Table 36.1). The degree of skull deformity depends on the number of sutures involved and the time at which premature fusion begins. The earlier the synostosis, the greater the deformity, which may result in a reduced intracranial volume. If the expanding cerebral structures find a restricted intracranial volume, intracranial hypertension may result. Several different mechanisms are responsible for craniosynostosis [12–15].

The causes can be multifactorial. Multiple pregnancies and other fetal head-constraining conditions are possible causes for non-syndromic craniosynostes, but also metabolic, storage or hematological disorders as well as genetic defects (Box 36.1). More than 180 syndromes with associated craniosynostosis have been described and up to 57 involved genes identified.

Table 36.2 Craniosynostosis syndromes

Syndrome	Chromosome localization	Gene
Apert syndrome	10q25.3-q26	*FGFR2*

- Thalassemia

In 85% a monogenetic background is found, mainly as multiple mutations in single genes. Only 15% of craniosynostotic conditions are caused by chromosomal aberrations. They can either be numeric chromosomal aberrations or deletions and duplications. The *FGFR2* gene is most often affected in 56.3% followed by the *FGFR3* gene (24.4%). Non-syndromic craniosynostosis may also be partially induced by genetic alterations. Genome-wide association studies may identify chromosomal susceptibility loci [22–24].

Typical craniosynostosis syndromes follow Mendelian genetic patterns and the involved genes and chromosomal localizations are well known (Table 36.2). Crouzon, Apert, Pfeiffer, and Jackson–Weiss syndromes, once thought to be separate but overlapping entities, are known to result from different mutations of the same genes [25]. In syndromic families, some members have normal phenotypes but different sutures can be affected in different individuals. Secondary craniosynostosis due to microcephaly and early CSF shunting in preterm babies are also well known conditions, as well as the influence of teratogens like diphenylhydantoin, aminopterin, methotrexate, retinoid acid, oxymetalzoline, and valproic acid (Box 36.2) [26].

Craniosynostosis may be an isolated deformation or part of a malformation syndrome. Isolated non-syndromic craniosynostosis occurs in six in every 10,000 births [12]. Sagittal synostosis is most common in more than 50%, followed by metopic synostosis and uni- or bilateral coronal synostosis. Lambdoid synostoses are very rare. Recently, a significant increase of trigonocephaly has been observed, without

knowing the underlying cause yet [27]. In single-suture craniosynostosis only deformation of the skull is obvious, although slight changes in cerebral architecture also have been described recently. Syndromic craniosynostoses most often also involve cranial base and facial structures and other parts of the skeleton.

Single suture craniosynostosis

The typical skull deformities following single-suture craniosynostosis are the result of compensatory growth (Fig. 36.2). The cephalic index (maximum biparietal diameter multiplied with 100 divided by maximum anteroposterior diameter) was introduced by the Swedish anatomist Anders Retzius and is used to measure the extent of deformity as well as for follow-up of later head development. Not all premature craniosynostoses lead to an obvious skull deformity. Typical anthropomorphic skull types are dolichocephalic (long headed), brachycephalic (broad headed), and mesocephalic (moderate head form).

Sagittal craniosynostosis

This is the most frequent form of craniosynostosis and presents the typical scaphocephalic form of skull with an elongated anteroposterior diameter and a narrowed biparietal diameter. The fused sagittal suture often forms a bony ridge and resembles the keel of a boat. The biparietal region is particularly narrow and sometimes lowered (Fig. 36.3). Frontal and/or occipital bossing can be very prominent and result from compensatory skull growth. The head circumference is generally increased, and the head is dolichocephalic. In 11% of cases, additional morphological brain changes were found on magnetic resonance imaging (MRI) studies.

Unicoronal craniosynostosis

The unilateral supraorbital ridge is retruded and the contralateral side sometimes compensates for the lack of growth and protrudes. In most cases, there is facial scoliosis that is caused by unilateral midface involvement. The deformity is described as anterior plagiocephaly. Patients may squint and have a compensatory head tilt (Fig. 36.4).

Bicoronal craniosynostosis

This entity can be syndromic and a genetic work-up is indicated. The head circumference is decreased, due mainly to a marked flattening of the forehead (Fig. 36.5). The orbits and both temporal squamae protrude. Additional turricephalic compensation

Figure 36.3 Scaphocephalic child with typical biparietal narrowing and resulting flattened head.

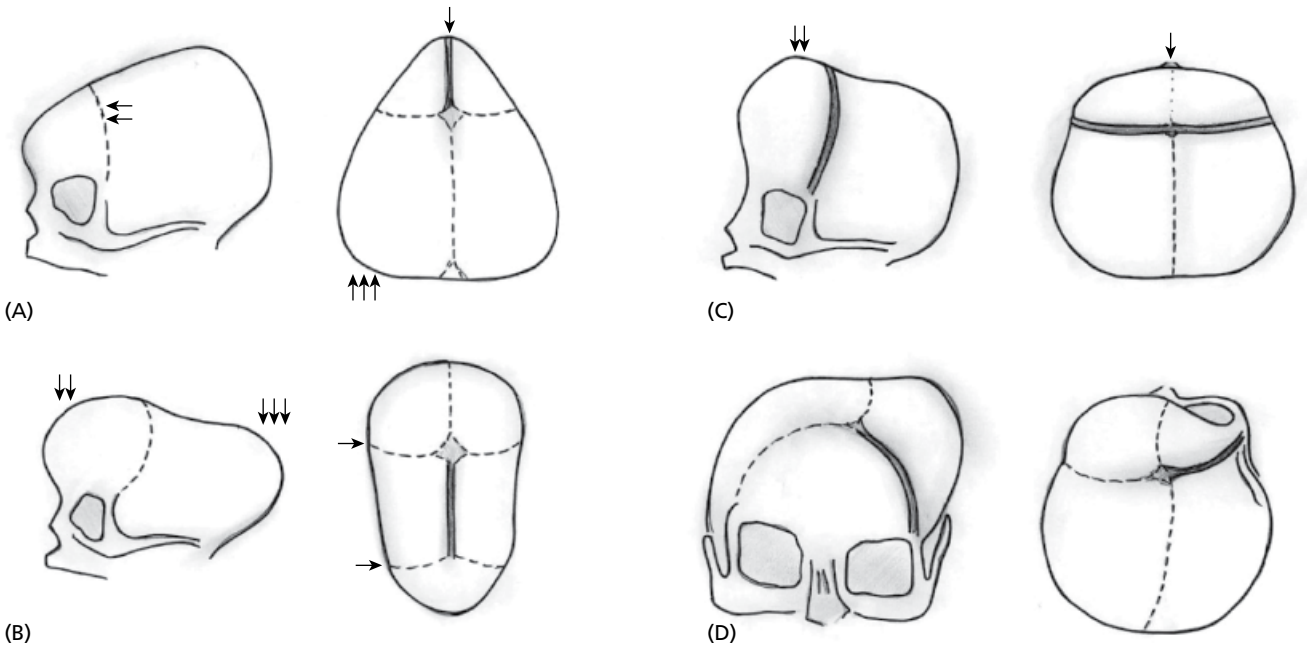

Figure 36.2 Single-suture craniosynostosis results in specific cranial deformities. (A) Trigonocephaly is the result of premature closure of the metopic suture and typical features are a frontal keel (↑), anterior displacement of the coronal sutures (↑↑), and compensatory bulging of the parietal squamae (↑↑↑). (B) Scaphocephaly is characterized by bitemporal or biparietal narrowing (↑) and frontal (↑↑) and occipital (↑↑↑) compensatory bossing. The shape of the skull resembles the keel of a boat or a saddle. (C) Brachycephaly means short skull and is the result of bicoronal craniosynostosis. The frontal region is flattened (↑) and some cases show early compensatory oxycephalic deformity (↑↑). (D) Anterior plagiocephaly results from unilateral coronal synostosis and causes asymmetrical and rotational deformity of the fronto-orbital region with additional midface and skull deformities.

Figure 36.4 Facial scoliosis in a child with anterior plagiocephaly.

Figure 36.6 (A) Hypotelorism in metopic synostosis. (B) Frontal keel.

can occur. This is the typical picture of a brachycephalic head. Early surgery is sometimes necessary to treat elevated intracranial pressure. The midface is often also involved.

Metopic craniosynostosis

The skull deformity with metopic craniosynostosis varies from a frontal ridge to severe trigonocephaly with narrowing of the frontal region and a keel-shaped forehead with hypotelorism and epicanthal folds (Fig. 36.6). It can be associated with genetic syndromes such as Opitz C syndrome or trisomy 11. The head circumference is usually decreased.

Lambdoidal craniosynostosis

Isolated lambdoidal craniosynostis is rare and accounts for only 3% of all premature synostoses. Most of the clinical forms of posterior plagiocephaly are positional deformities and do not require surgical correction. In true lambdoidal craniosynostosis, the contralateral forehead bulges forward. In cases that are caused by position, there is ipsilateral bossing.

Syndromic craniosynostosis

Craniosynostosis syndromes that are also associated with hand and feet abnormalities are described as acrocephalosyndactylies.

Apert syndrome

Apert syndrome is the most severe of several craniosynostosis syndromes that involves all the craniofacial structures: calvaria, cranial base, and face. Apert syndrome occurs in approximately one per 55,000 births due to mutations in the *FGFR2* gene on chromosome 10 [22]. Although the mode of transmission can be autosomal dominant, most cases are sporadic. Apert syndrome is characterized by craniosynostosis, midface hypoplasia, and retrusion plus symmetrical syndactyly of the hands and feet (Fig. 36.7). The dysmorphic features are listed in Box 36.3.

In Apert syndrome the craniosynostosis involves multiple cranial sutures, but most commonly involves the coronal sutures and causes brachycephaly. The occiput is usually flattened. The cranial base has a broad, flat, short contour with premature synostosis. The anterior cranial fossa is markedly shortened, which constrains development of the nasomaxillary complex. The nasal cavity, palate, and maxilla are shortened, narrowed, and retropositioned. The midface hypoplasia and brachycephaly result in proptosis because the orbits are too shallow to house the globe. The middle cranial fossa is rotated to a more vertical position than normal, which secondarily diminishes the dimensions of the pharynx. The interorbital space is always large, and the orbits may be misaligned. The shortened cranial base results in a vaulted cranium and a deep forehead. Platybasia, Chiari malformation, and hydrocephalus are relatively common. Severe dental malocclusion is typical. Lateral skull base deformities are responsible for a

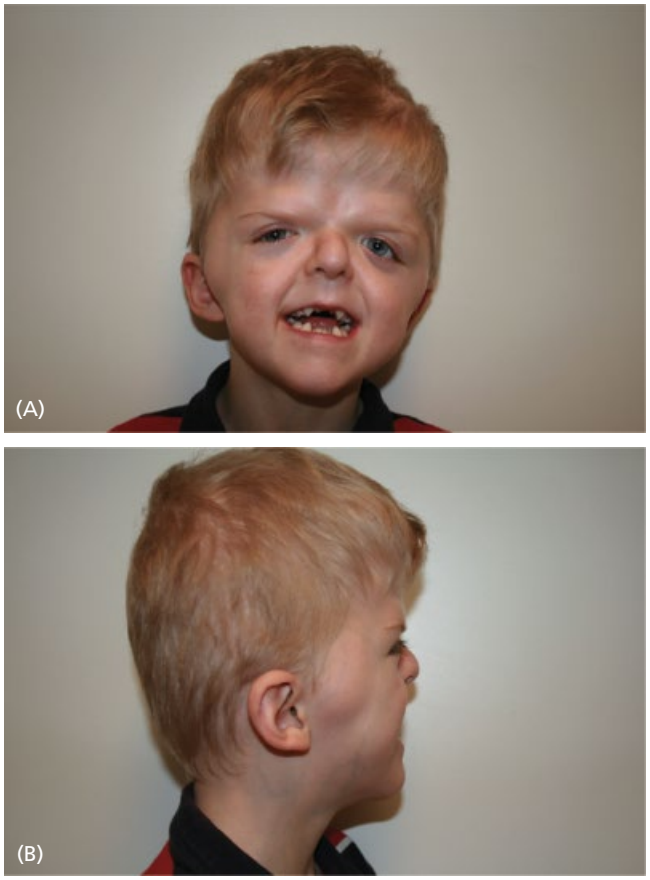

Figure 36.7 Six-year-old boy with typical features of Apert syndrome. (A) Down-slanting palpebral fissures, depressed nasal bridge, and dental malocclusion. (B) Flat facies due to midface hypoplasia.

high rate of hearing disorders. A significant number of patients are mentally retarded; most of the children have IQs below 80.

Saethre–Chotzen syndrome

Phenotypically variable, the relatively common Saethre–Chotzen syndrome is often misdiagnosed. Because mild forms may not be recognized, the true incidence is unclear. Typical features are brachy- and acrocephalic deformities, mostly due to bicoronal abnormalities and plagiocephaly (Fig. 36.8). The hairline is low and the facial appearance broad, flat, and asymmetrical. The nose is beaked, and there may be ptosis of the eyelids. The inheritance pattern is autosomal dominant.

Pfeiffer syndrome

The clinical phenotype of Pfeiffer syndrome is variable. Patients typically show a turribrachycephalic deformity that is mostly due to abnormal bicoronal sutures. Cloverleaf heads have also been reported. Hypertelorism, proptosis, maxillary hypoplasia, mandibular prognathism, and malocclusion occur as well. Ankylotic joints are typical skeletal findings. Severe skull base anomalies are associated with platybasia and Chiari malformation and also with spinal malformations and vertebral fusion. The incidence of this syndrome is about one in 210,000; its inheritance is autosomal dominant. Early surgical correction of the constraining skull structures can lead to normal neurocognitive development if brain growth is not impaired.

Crouzon syndrome

The phenotype of this syndrome is characterized by brachycephaly caused by bicoronal synostosis, maxillary hypoplasia, and shallow orbits that lead to ocular proptosis and a beaked nose. Besides coronal synostosis, scaphocephaly, trigonocephaly, and cloverleaf skull may also exist. Skull base abnormalities with platybasia and Chiari malformations are also found. Due to the midfacial deformities, nasopharyngeal airway obstruction is common and may lead to sleep apnea and impaired nose breathing. This may be a problem if the mouth is closed during a mask induction. The prevalence of Crouzon syndrome is one per 25,000 livebirths, with about two-thirds of cases being familial (autosomal dominant) and one-third sporadic. Neurocognitive development is rarely affected.

Cloverleaf skull (Kleeblattschädel)

The cloverleaf skull deformity is the most severe form of craniostenosis and is most often associated with Pfeiffer syndrome. All major sutures and the skull base are involved which produces marked constriction of intracranial structures, including the rapidly developing brain and its vessels, especially important venous structures. Early surgery is mandatory to protect the brain. Chiari malformation and hydrocephalus are common accompaniments of this lesion and need to be treated early as well. Other deformities are hypertelorism, orbital proptosis with visual impairment, and a hypoplastic skull base and midface structures that produce upper airway problems.

Other relatively common craniofacial syndromes are the Jackson–Weiss and Carpenter or Antler–Bixler syndromes.

Facial anomalies

Branchial arch malformations

Branchial arch anomalies are symptom complexes caused by deficient development of the branchial arches. They are etiologically and pathogenetically heterogeneous [12] with wide variability in expression. External ear deficiencies, auricular tags, and persistent branchial clefts or cysts are common branchial arch anomalies. Micro- or macrostomia results from abnormal merging of the maxillary and mandibular prominences. These abnormalities are examples of severe first arch anomalies. Micrognathia, also a first arch anomaly, is the result of retarded mandibular development by any mechanism; it may be an intrinsic malformation or a deformation by the chin being compressed against the chest late in gestation.

Treacher Collins syndrome (mandibulofacial dysostosis)

Treacher Collins syndrome occurs with an incidence of one in 50,000 livebirths and involves structures derived from the first and second branchial arches [12]. The major facial features include midface hypoplasia, micrognathia, microtia, conductive hearing loss, and a cleft palate that is caused by deficiencies of the maxillary and branchial arch mesenchyme (Fig. 36.9). The syndrome can be an autosomal dominant disorder with variable expressivity, but over 50% of cases are new mutations. The gene responsible for this syndrome has

Box 36.3: Features of Apert syndrome

Craniofacial dysmorphology

- Craniosynostosis:
  - Coronal synostosis most common
  - Steep full forehead (frontal bossing)
  - Flat occiput
  - ± Hydrocephalus
- Maxillary retrusion (midface hypoplasia):
  - Flat facies
- Shallow orbits:
  - Exorbitism or proptosis
- Relative mandibular prognathism
- Variable facial asymmetry
- Supraorbital horizontal groove
- Hypertelorism
- Down-slanting palpebral fissures
- Strabismus
- Parrot-beaked nose
- Depressed nasal bridge
- Cleft palate or bifid uvula
- Trapeziodal-shaped (cupid's) lips
- High arched palate
- V-shaped maxillary dental arch
- Severe tooth crowding
- Dental malocclusion
- Reduced nasopharyneal dimensions

Limb dysmorphology

- Syndactyly:
  - Osseous and/or cutaneous
  - Fingers and toes
  - Digits 2, 3, and 4 always
  - Symmetrical
- Thumb and great toe malformations

Occasional abnormalities

- Cardiovascular:
  - Atrial septal defect
  - Over-riding aorta
  - Ventricular septal defect
  - Pulmonic stenosis
  - Coarctation of aorta
  - Endocardial fibroelastosis
  - Pulmonary artery atrophy
- Skeletal:
  - Aplasia or ankylosis of joints
  - Synostosis of radius and humerus
  - Short humerus
  - Cervical spine fusion
- Pulmonary:
  - Pulmonary aplasia
  - Cartilaginous anomalies
  - Tracheoesophageal fistula
- Gastrointestinal:
  - Pyloric stenosis
  - Ectopic anus
- Renal:
  - Polycystic kidney
  - Hydronephrosis
- CNS:
  - Mental retardation
  - Hearing deficit

Figure 36.8 Infant with Saethre–Chotzen syndrome. (A) Brachycephaly. (B) Metopic ridge due to premature synostosis and turricephaly.

been mapped to chromosome 5q31.3-32. The mutation causes aberrant expression of a nucleolar protein named treacle. The abnormalities are bilateral, usually symmetrical, and confined to the craniofacial complex (Box 36.4). Besides the facial features, the patients often have choanal atresia, microphthalmia, absence of the parotid gland(s), and congenital heart disease. Mental deficiency is not common.

The characteristic facial appearance is the product of an abnormal cranial base and a dysmorphic mandible and maxillary–malar complex [28]. The face is narrow, with downsloping palpebral fissures, depressed cheekbones, and a large down-turned mouth. The cranial base angle (nasion-sella-basion angle) is reduced, which positions the posterior pharynx forward. The pharyngeal dimensions are reduced in all dimensions by several hypoplastic skeletal elements [28–31]. Some patients also exhibit a discrete area of constriction near the base of the tongue, such as occurred in an 11-year-old patient whose pharyngeal lumen was 5 mm wide [29]. Little correlation exists between the degree of pharyngeal hypoplasia and the severity of the facial deformity. The malar (cheek) bone is hypoplastic and the orbital wall is deficient. The mandible is disfigured in all dimensions.

Figure 36.9 Fifteen-year-old girl with mandibulofacial dysostosis. She has no mental deficiencies but has malar deficiencies, auricle malformation, microtia, and a retrognathic mandible.

Box 36.4: Features of Treacher Collins syndrome

Facial dysmorphia

- Skeletal hypoplasia/aplasia:
  - Malar and zygomatic bones
  - Supraorbital ridges
  - Mandible
- Facial muscle hypoplasia/hypotonia
- Eye:
  - Lower lid coloboma or notching
  - Partial absence of lower eyelashes
  - Antimongoloid slant to palpebral fissures
- Ears:
  - Auricle malformation, misplacement
  - Ear canal defects, conductive deafness
  - Inner ear malformations
  - Non-pneumatized mastoid
- Pharyngeal hypoplasia
- Dental malocclusion
- High arched palate
- Projection of scalp hair onto lateral cheek
- Bind fistulas, dimples, or tags between the ears and angle of the mouth

Occasional abnormalities

- Macrostomia
- Microstomia
- Cleft palate
- Velopharyngeal incompetence
- Upper eyelid coloboma
- Choanal atresia
- Microphthalmia
- Absence of parotid gland
- Congenital heart disease
- Mental deficiency not common

Nager and Miller syndromes are characterized by facial features that are similar to those of Treacher Collins plus limb deformities.

Robin sequence

The Pierre Robin sequence (PRS – MIM 261800) is a well-defined subgroup of the cleft lip and/or palate population with an unknown etiology of the branchial arch. PRS is characterized by cleft palate, micrognathia, and respiratory difficulties (due to glossoptosis) in the early neonatal period, and is often observed as a part of other Mendelian syndromes such as Stickler syndrome, velocardiofacial syndrome, and Marshall syndrome or fetal alcohol syndromes [32,33]. PRS is also a part of campomelic dysplasia (MIM 114290), consisting of bowing of the long bones, malformation of the pelvis and spine, rib anomalies, club feet, hypoplastic scapulae, micrognathia, and cleft palate [34]. In a "sequence," some anomalies are secondary to a primary anomaly, whereas in a syndrome, multiple anomalies have a single pathogenesis. The PRS may be the result of deregulation of *SOX9* and *KCNJ2* [35]. The pathogenesis of the Robin sequence is diverse, but the common feature is failure of mandibular development and secondary failure of the tongue to descend from between the palatal shelves. When this is an isolated finding, the deformity may be due to intrauterine mandibular constraint. The mandible is intrinsically normal and will undergo catch-up growth postnatally [6]. If the Robin sequence is associated with a syndrome that includes intrinsic mandibular hypoplasia, the mandible remains small.

Oculo-auriculovertebral spectrum: Goldenhar syndrome and hemifacial microsomia

The oculo-auriculovertebral spectrum (OAVS) is also known as the first and second branchial arch syndrome, hemifacial microsomia, Goldenhar syndrome, or facio-auriculovertebral

syndrome. This condition is caused by maldevelopment of the first and second branchial arches and is complex and heterogeneous. There is defective facial development involving the ear, eye, zygomatic bone, mandible, parotid gland, tongue, and facial muscles. Maldevelopment is not limited to facial structures: cardiac (tetralogy of Fallot, ventricular septal defect), pulmonary (hypoplasia or aplasia of lung), renal, skeletal (vertebral anomalies, commonly cervical), central structures (cranial nerve anomalies), and other anomalies, including laryngeal anomalies, also occur. The abnormalities present in various combinations, tend to be asymmetrical and are unilateral in 70% of cases [20]. Malformations of the external ear or microtia are mandatory features of the OAVS and occur as an isolated malformation (population frequency of 0.03%), or in association with other anomalies such as mandible hypoplasia, epibulbar dermoids, and spinal vertebral defects. The constellation of anomalies suggests that they originate at approximately 30–45 days of gestation.

It has been suggested that disturbances in the branchial arches or in the neural crest cells impede development of adjacent tissues. A vascular pathogenesis caused by hematoma formation at the time the stapedial artery system develops has been demonstrated in animals [36]. In this model, focal hemorrhage and an expanding hematoma destroy tissues in the ear and jaw areas. Three unrelated children have been reported with similar unilateral craniofacial defects and other structural abnormalities that had a known disruptive vascular pathogenesis [37]. The frequency of occurrence is estimated to be one in 3000–5000 births. The condition is usually sporadic, although familial instances have been reported. Several chromosomal anomalies have been associated with this condition, and it has occurred in infants born to mothers who had taken thalidomide, primidone, or retinoic acid. It is usually discordant in monozygotic twins.

Maxillary, mandibular, and auricular hypoplasia is the primary feature of this syndrome. Macrostomia is the result of a lateral facial cleft from the commissure of the mouth. Mandibular condyle deformities, present in all patients, range from slight hypoplasia to complete absence of the condyle with agenesis of the ascending ramus. When accompanied by epibulbar dermoid and vertebral anomalies it is called the Goldenhar syndrome, and when it occurs predominantly unilaterally it is called hemifacial microsomia. Most of these patients have normal intelligence.

KEY POINTS: CRANIOSYNOSTOSIS AND BRANCHIAL ARCH MALFORMATIONS

- Sagittal craniosynostosis is the most frequent form and presents the typical scaphocephalic skull with elongated anteroposterior diameter and narrowed biparietal diameter
- Apert syndrome is the most severe of several craniosynostosis syndromes involving all of the craniofacial structures: calvaria, cranial base, and face. A difficult airway is common.
- The large group of facial anomalies, including Pierre Robin sequence, and the Goldenhar, Treacher Collins, Crouzon, and Apert syndromes could make it extremely difficult to intubate the trachea due to disfigured mandibles in all dimensions, often associated with retrognathia

Hypertelorism and orbital malposition

Orbital malposition may occur in any direction and may involve different directions in each orbit. The bones and sutures making up the walls of the orbits may be primarily involved. The malposition may also be the result of craniosynostosis or craniofacial clefting. It may be associated with encephalocele, tumor, or other cranio-orbital malformations. Other cranio-orbital malformations include encephaloceles that involve craniofacial structures; with frontoethmoidal or sincipital and basal subtypes (nasofrontal, nasoethmoidal, naso-orbital, and transethmoidal) [38]. These malformations lead to significant naso-orbital deformities (Figs 36.10 and 36.11). One of the most disfiguring tumors of the orbital region is the plexiform neurofibroma that is associated with neurofibromatosis type 1. Isolated orbital hypertelorism is a skeletal deformity that consists of lateralization of the bony orbit and enlarged ethmoid sinuses. The nose may be slightly involved or severely distorted, and the nasal deformity may be difficult to correct. Dysfunction of the upper eyelid, extraocular muscles, and lacrimal system frequently occurs. Orbital hypotelorism is uncommon and is seldom present as an isolated anomaly. It is often seen in metopic craniosynostosis.

Facial clefts

Facial clefting occurs when the skeleton or soft tissues are interrupted. Clefts develop when the facial prominences fail to merge. Clefts that cannot be explained embryologically may be caused by disruptive factors [12]. The causes of most clefts are unknown, and the majority occur sporadically. Skeletal and soft tissue hypoplasia or aplasia are the anatomical defects of craniofacial clefts. Any part of the cranium or face may be involved. Various combinations of eye, ear, and central nervous system (CNS) deformities are associated with clefts.

Figure 36.10 Twelve-year-old boy with frontoethmoidal encephalocele with maxillary involvement and hypertelorism.

Tessier devised an anatomical and descriptive classification that correlates clinical appearance with surgical anatomical findings [39]. This system designates l5 locations (numbered 0 through 14) for clefts and describes their respective courses through bone and soft tissue (Fig. 36.12). Many syndromes that include hypoplastic facial dysmorphology are categorized as clefts. Treacher Collins syndrome includes clefts 6, 7, and 8 in its complete form (see Fig. 36.9) and cleft 6 in its incomplete form. Cleft 6 accounts for the eyelid coloboma; cleft 7 for the absence of the zygomatic arch, anterior displacement of the scalp hair, and mandible deformities; and cleft 8 for the defects in the lateral orbital rim. The oculo-auriculovertebral spectrum (hemifacial macrosomia and Goldenhar) is cleft 7.

Cleft lip and palate

Cleft lip and/or palate are the most frequent congenital craniofacial malformations. They occur in one in 700 births in the United States, and there is a marked racial predilection. The highest incidence is found in parts of Latin America and Asia (China, Japan), the lowest in Israel, South Africa, and southern Europe. Rates of isolated cleft palate are high in Canada and parts of northern Europe and low in parts of Latin America and South Africa [9]. Clefts may be isolated, familial, or part of a syndrome. More than 400 syndromes are associated with facial clefts [12]. Cleft lip, cleft palate, or both can be part of a syndrome, but more syndromes are associated with cleft palate than with cleft lip. They constitute a heterogeneous group of malformations with great variability in the degree of cleft formation (Fig. 36.13). A cleft lip may be complete, incomplete, or only a microform with a small vermillion notch. Osseous defects in the alveolus and the palate of patients with complete labial clefts contribute to instability of the dental arch; sometimes there is collapse of the lateral segments of the arch. For cleft classification, Kriens proposed the LAHSHAL code to represent clefts of the left and right (L)ip and (A)lveolus, as well as the (H)ard and (S)oft palate based on the anatomical structures involved [40].

Figure 36.11 Infant with frontonasal cleft and related encephaloceles and hypertelorism.

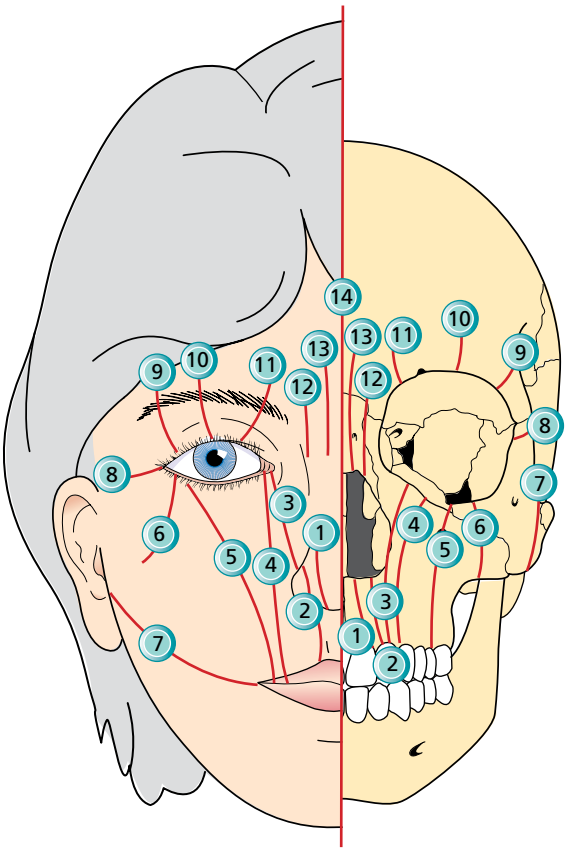

Figure 36.12 Tessier's classification of facial clefts. (Left) Locations of clefts on the face. (Right) Skeletal pathways.

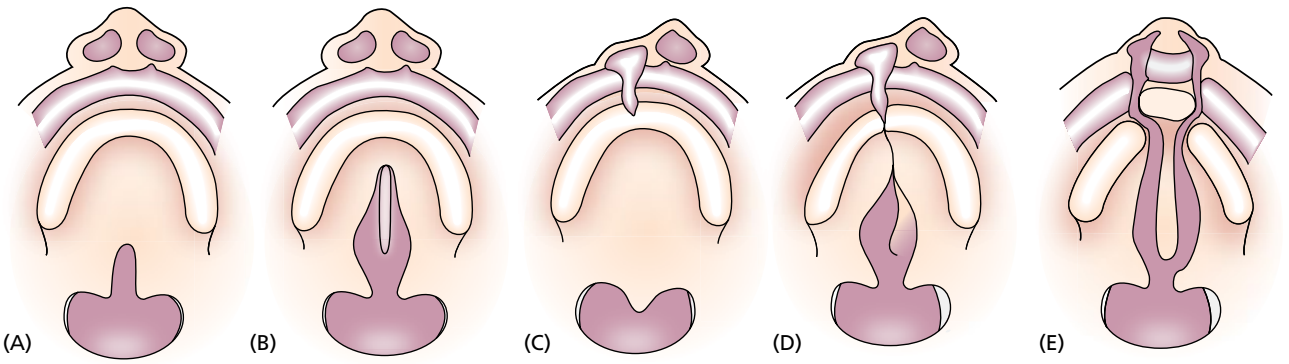

Figure 36.13 Various degrees of cleft palate and lip. (A) Cleft soft palate. (B) Cleft hard and soft palate. (C) Cleft lip and alveolus. (D) Complete unilateral. (E) Complete bilateral.

The etiology of clefting is multifactorial and has both genetic and environmental influences. The genes associated with orofacial clefting identified to date are those for non-syndromic cleft lip/palate *MSX1* (chromosome 4p16.1) and *TBX22* (chromosome Xq12-q21). Cleft palate genes are located on chromosome 14 and a locus for cleft lip (IRF6) on chromosome 1q [41,42]. Development of the upper lip and the palate is completed by postconceptional weeks 7 and 9. Maternal smoking during this time increases the risk of clefting by approximately 1.3 times.

The risk for oral clefting may be as high as 20% in some subgroups with maternal smoking (e.g. American Indians/Alaskan natives). Alcohol consumption, poor nutrition (folic acid and vitamin A deficiency), viral infection, medical drugs (e.g. anticonvulsant drugs; diazepam, phenytoin, phenobarbital, carbamazepine; retinoids; systemic corticosteroids), diabetes mellitus, and teratogenic agents (organic solvents, agricultural chemicals) also increase the risk of clefting [43].

Clefting of the upper lip and nostril is the result of failure of the nasomedial process to merge with the maxillary prominences (lateral cleft lip, either uni- or bilateral) or from failure of the two-nasomedial processes to merge (rare median cleft lip or bifid nose). Hypoplasia of the palatal shelves or mistiming of palatal shelf elevation results in cleft palate. Failure to remove the tongue from between the shelves and problems with shelf elevation and contact probably account for most human cleft palates [19]. There may be a critical time in gestation beyond which the palatal shelves cannot meet and fuse. If movement of the palatal shelves from vertical to horizontal is delayed and the head continues to grow, a widening gap is produced between the shelves, and they cannot meet. Clefting of the palate may or may not be associated with a cleft upper lip because the two conditions are separate developmental entities. However, failure of lip fusion may impair subsequent closure of the palatal shelves.

KEY POINTS: FACIAL CLEFTS

- Clefts that cannot be explained embryologically may be caused by disruptive factors. The causes of most clefts are unknown, and the majority occur sporadically
- Cleft lip and/or palate are the most frequent congenital craniofacial malformations. They occur in one in 700 births in the United States, and there is a marked racial predilection
- The risk for oral clefting may be as high as 20% in some subgroups with maternal smoking, alcohol consumption, poor nutrition (folic acid and vitamin A deficiency), viral infection, medical drugs, and many more

Physiological sequelae of craniofacial malformations

Hydrocephalus and intracranial pressure

In a retrospective review of 1727 patients treated over 20 years, hydrocephalus occurred in patients with non-syndromic craniosynostosis (1447 patients) with similar frequency to that observed in the normal population (0.3%) [44]. In patients with syndromic craniosynostosis, the frequency was 12%. Patients with Kleeblattschädel deformity and Crouzon syndrome were more likely to have hydrocephalus than those with other syndromes. Jugular foramen stenosis and crowding of the posterior fossa are two primary factors responsible for hydrocephalus in syndromic craniosynostosis [44]. Fusion of cranial base synchondroses produces alterations in the skull base and stenosis of the jugular foramen. The resulting venous hypertension increases the CSF hydrostatic pressure. If major calvarial sutures are open, the head will progressively enlarge and the ventricles and subarachnoid spaces will dilate. If the calvarial sutures are fused, intracranial pressure (ICP) will increase but ventriculomegaly may not occur until after the synostosis is surgically released. When the posterior fossa is small and crowded, especially if the lambdoidal suture is fused, cerebellar tonsillar herniation or compression of the basal cistern may produce obstructive hydrocephalus.

Intracranial pressure may be elevated without hydrocephalus in patients with craniosynostosis. Presumably, a restrictive cranium is a factor. Renier monitored ICP during sleep in 350 non-hydrocephalic patients with unoperated craniosynostosis (Table 36.3) [45]. The patients ranged in age from 6 weeks to 15 years, and 44% were less than 1 year old. The overall rate of intracranial hypertension was 23% but the proportion varied by type of craniosynostosis and age. For single sagittal synostoses (trigono- and scaphocephaly), the rates were 6% and 8%, respectively. The rate was 12% for single synostoses of a coronal suture (anterior plagiocephaly). Other authors have also reported elevated ICP with single-suture synostosis, which, in addition to cosmetics, provides a rationale for surgical correction [46,47].

In Renier's study, 26% of patients with synostoses of both coronal sutures (brachycephaly, excluding Apert and Crouzon syndromes) had intracranial hypertension. In extensive synostoses, usually involving both coronal and sagittal sutures (oxycephaly), intracranial hypertension occurred in 54% of patients. In this study, the incidence of intracranial hypertension also increased with age. After 1 year of age, the incidence was four times greater for scaphocephaly and double for plagiocephaly. With brachycephaly, intracranial hypertension was more precocious: 22% of children below 1 year of age had intracranial hypertension compared with 31% over 1 year of age. Oxycephaly is usually not seen before 3 years of age, but

Table 36.3 Intracranial pressure (ICP) before surgery

	Total no. of patients	Baseline ICP (mmHg)		
		≤10	11–15	>15
Trigonocephaly	31	21	8	2
Scaphocephaly	118	76	33	9
Plagiocephaly	65	40	17	8
Brachycephaly	34	17	8	9
Oxycephaly	66	23	7	36
Crouzon syndrome	9	3	0	6
Apert syndrome	16	3	6	7

can also be seen in very young infants, e.g. in syndromic forms. Eighty-five percent of children with oxycephaly had intracranial hypertension. However, clinical signs and symptoms of elevated ICP were uncommon. Intracranial volume measurements calculated from computed tomography (CT) scans were not a reliable indication of ICP, although markedly reduced intracranial volume did increase the likelihood of intracranial hypertension [46]. Raised ICP is also of concern after surgical correction and consecutive inappropriate skull growth and should be monitored in patients and followed up by regular ophthalmological examinations to rule out papilledema at least until 8–10 years of age. Papilledema may not be present despite significantly elevated ICP. In children without papilledema, ICP measurements may be indicated to rule out intracranial hypertension. These older children often complain of chronic headache.

In non-syndromic forms of craniosynostosis where the abnormality is confined to the calvarium, the effects of cranial vault expansion are predictable. In complex craniosynostosis, however, the effects are less certain. In Renier's series, 54 patients had postoperative ICP measurements. Before surgery the ICP was elevated in 74% and borderline in 11% of patients. After surgery 7% had elevated and 20% had borderline ICP. In another series, 22 patients had their ICP monitored postoperatively. The ICP was elevated in 45% and borderline in 32% [48]. In this series, 34 patients with complex craniosynostosis were evaluated with MRI up to 8 years after surgery. Cerebellar tonsillar herniation was found in 52% and hydrocephalus in 41% of patients, over half of whom developed the hydrocephalus after surgery. During follow-up, tonsillar herniation or Chiari malformation can develop as sequelae of insufficient intracranial space. Another report covering a 20-year period noted that the incidence of postoperative hydrocephalus was 45% for patients with syndromes and 4% for patients with isolated craniosynostosis. The incidence of shunt placement was 22% and 1%, respectively [49,50].

Upper airway obstruction

Severe malformations involving the face and cranial base are at high risk for upper airway obstruction and undetected obstructive sleep apnea (OSA). Almost 50% of patients with craniofacial dysostosis develop OSA and require airway intervention at some time [51–53]. OSA can be treated pharmacologically, non-surgically (continuous positive airway pressure (CPAP), nasopharyngeal tube) or surgically, depending on its severity and cause [17,54]. Fifty percent of patients with craniofacial dysostosis are treated with tracheostomy, but nearly 7% in the early and 5% in the late postoperative phase have complications [55–59]. Beside a high incidence of tracheal cartilaginous sleeve, laryngomalacia, tracheomalacia, and bronchomalacia, a reduced cranial base angle positions the pharyngeal wall forward and produces anteroposterior shortening of the nasal and oral airway [30]. In addition, the temporomandibular joint may be drawn posteriorly so that the mandible is positioned retrusively [31]. When the mandible is small and retrognathic (e.g. Pierre Robin sequence), the tongue is positioned posteriorly and impinges on the oro- and hypopharynx [28]. Midface hypoplasia and retroposition also diminish the dimensions of the nasal airway. Neurological dysfunction, such as pharyngeal hypotonia or incoordination, worsens airway obstruction in children with abnormal anatomy [60]. Other skeletal abnormalities, such as turbinate hypertrophy, septal deviation, and choanal narrowing or atresia (e.g. CHARGE syndrome), contribute to upper airway obstruction.

Obstructive sleep apnea is common in craniofacial syndromes [29,30,61–64]. Sher and colleagues [60] used flexible fiberoptic nasopharyngoscopy to identify the mechanisms of pharyngeal obstruction in patients with OSA. Four mechanisms were identified.

1. Posterior movement of the tongue against the posterior pharyngeal wall (Fig. 36.14).
2. Posterior movement of the tongue with compression of the soft palate or cleft palatal tags posteriorly against the

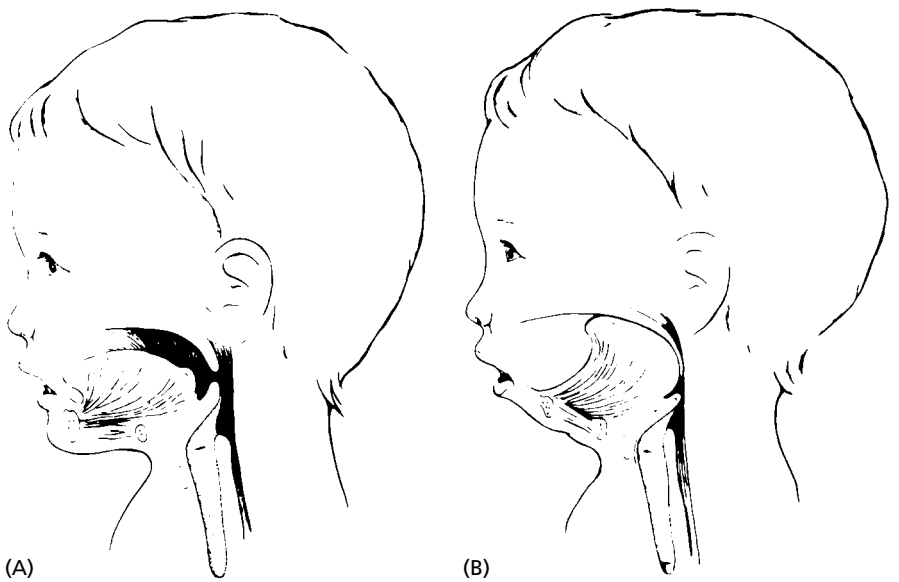

Figure 36.14 Anatomical features of the larynx. (A) Normal child. (B) Child with mandibular hypoplasia. Posterior placement of tongue makes the larynx appear to be more anteriorly situated than normal. Reproduced from Handler and Keon [183] with permission of SAGE.

posterior pharyngeal wall; the tongue, velum, and posterior pharyngeal wall meet in the upper oropharynx.
3. Movement of the lateral pharyngeal walls medially to appose each other.
4. Pharyngeal constriction in a circular or sphincteric manner.

Sleep apnea may occur from brainstem compression in children with Chiari malformation.

Some patients are successfully managed with nasal CPAP during sleep [63]. Others with severe airway obstruction may require tracheostomy. Of 251 patients with craniofacial anomalies who underwent surgery over a 5-year period, 20% required tracheostomy to relieve chronic airway obstruction or to manage the airway in the perioperative period [65]. Patients with craniofacial synostosis (Crouzon, Pfeiffer, or Apert syndromes) had the highest rate of tracheostomy (48%). Those with mandibular facial dysostosis (Treacher Collins or Nager syndromes) had the next highest rate (41%). Twenty-two percent of patients with OAVS (Goldenhar and hemifacial microsomia) required tracheostomy. The mean duration of cannulation in infancy or in early childhood was 4 years. Patients who had tracheostomy after 4 years of age required cannulation for less than 6 months, and 60% underwent decannulation 1 week after tracheostomy.

Ear, nose, and throat consultation is recommended to determine if an adenoidectomy or tonsillectomy is required prior to craniofacial surgery. Some cases of sleep apnea are effectively treated by adenotonsillectomy.

Patients with Robin sequence, especially non-syndromic patients, who have airway obstruction that is unresponsive to prone or lateral positioning alone respond to nasopharyngeal/nasotracheal intubation or glossopexy (tongue–lip adhesion). These procedures often relieve airway obstruction during the first months of life while the mandible grows and the airway expands [60,66,67]. In some syndromes (e.g. Treacher Collins and Apert), the anatomical inter-relationships become progressively distorted and the obstruction may worsen, not improve [28,61,68]. To minimize morbidity, the least invasive treatment should be used first. If conservative treatment, including wearing a soft palate plaque (e.g. Tübinger type) [69], does not resolve the problem, further management should be based on the oxygen saturation, feeding difficulties, and endoscopic findings. A lip–tongue plication is done in some patients for 6–9 months to move the tongue away from the pharynx and allows time for mandibular growth. A more aggressive approach is the tongue–lip adhesion or a perimandibular fixed extension device. Distraction osteogenesis can be used in older children [70]. Finally, if all else fails, a tracheostomy might be indicated.

Associated anomalies

With syndromic craniofacial anomalies, many systems may be malformed, particularly the CNS, the cardiac, and pulmonary systems. Cranial sensory and speech organs can also be malformed, and hearing, vision, and speech may be impaired. Cervical spine anomalies, including intervertebral fusion, occur commonly in the Goldenhar syndrome and with craniosynostosis syndromes such as the Crouzon, Apert, and Pfeiffer syndromes [71–73].

KEY POINTS: PHYSIOLOGICAL SEQUELAE OF CRANIOFACIAL MALFORMATIONS

- Hydrocephalus incidence with non-syndromic craniosynostosis is not increased; it increases to 12% with syndromic craniosynostosis
- Intracranial hypertension is present in 6–12% of patients with single-suture craniosynostosis, increasing to 26–74% of children with complex craniosynostosis
- Obstructive sleep apnea is present in a high proportion of patients with face and cranial base malformations. CPAP and tracheostomy are sometimes required in these patients

Craniofacial reconstruction: surgical procedures

Paul Tessier introduced major craniofacial surgery in Paris in 1967. He developed the first craniofacial dysjunction procedures that cleaved the face away from the base of the cranium by using both an intracranial and an extracranial approach [74,75]. Over the past 50 years, these techniques have been used to treat a variety of complex congenital and acquired deformities of the face and cranium, including traumatic and neoplastic entities [76]. A coordinated interdisciplinary approach is required for this surgery to succeed. There are many reasons for doing the surgery, including improving neurological, ocular, nasal, dental, and auditory functions as well as improving cosmetic appearance and psychological function [76]. The basic objective of craniofacial surgery is to correct skeletal deformity first and soft tissue afterwards. The basic treatment of the deformed skeleton comprises cutting, disjoining, mobilizing, repositioning, augmenting, and fixing the involved bony structures. Wide exposure of the skeleton is required. Therefore, the soft tissues, including the orbital contents, are extensively dissected and mobilized away from their bony attachments. Intracranial and extracranial approaches are utilized and scalp, preauricular, and intraoral incisions are made to avoid producing scars on the face. For intracranial and for upper and midface procedures, the surgical approach is through a bicoronal scalp incision that extends from ear to ear and from which the soft tissues of the scalp and face are reflected forward over the facial mass (Fig. 36.15). This provides wide exposure of the facial skeleton down to the maxillary alveolus. A craniotomy is done, the frontal lobes of the brain are retracted, and the anterior cranial base is exposed. To effectively provide anesthesia for major craniofacial surgery, the anesthesiologist must clearly understand both the lesion and the proposed surgical procedure.

Cranial and facial remodeling

Surgery for cranial and facial remodeling is performed with the goal of normalizing the child's appearance, ensuring sufficient head size and growth, and establishing normal function of the skull structures and related organs. In most cases, these aims cannot be fully met but significant improvement is possible. In the past, surgical techniques were employed that often did not take into account the substantial variations in

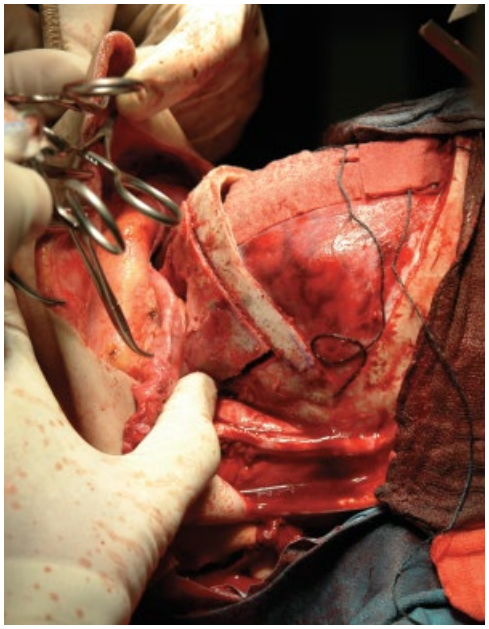

Figure 36.15 After bicoronal incision for intracranial upper and midface procedures, the face is peeled back for wide exposure of the facial skeleton bone.

the underlying pathology, the patient's age, and the skill of the surgical team. The first technique employed was to open the fused suture, with the hope that this would allow normal skull growth. In the past this method was not successful but recently Jimenez has had success with the procedure [77]. Since it became evident that cranial growth follows intrinsic pathways rather than mechanical rules, the entire cranial vault, including the skull base structures, have been addressed surgically. Whenever the fronto-orbital region is involved, additional maneuvers, such as fronto-orbital advancement, have been used to improve facial appearance and enlarge the intracranial and orbital cavity. In multisuture craniosynostosis, restricted skull growth and potential brain and orbital constriction are the major reasons for early surgery. In addition to fronto-orbital advancement and cranial vault remodeling, posterior distraction surgery can be an option.

In principle, the main surgical goals for these patients comprise three steps: opening of the cranial vault to allow the brain to expand, fronto-orbital advancement to ensure frontal brain expansion and eye protection, and midface advancement to improve nasopharyngeal pathways and dental alignment. Additional procedures may be necessary for orbital malposition and facial clefts.

The typical skin opening for cranial or craniofacial remodeling is a coronal incision. The incision can be straight, curved, or zigzag to prevent visible scarring. Attempts should be made to minimize unnecessary blood loss when dividing the galea [78].

Timing and general preparation for surgery

Timing of craniofacial repair is often controversial. As long as there is sufficient head growth, as occurs in most single-suture craniosynostoses and other craniofacial disorders that do not involve the cranial vault, surgery is scheduled in the second half of the first year, usually between 6 and 8 months of age. At that time, the hematological status is stabilized and the bony structures are firmer and easier to remodel than at younger ages. All systemic functions are checked to minimize the overall risk.

Multisuture craniosynostoses can lead to severe skull constriction and require early or even emergency procedures to relieve ICP; elevated ICP significantly increases the risks of surgery and anesthesia. These patients require early evaluation for cardiac, kidney, airway, and hematological disorders.

Parents must be informed about all aspects of craniofacial surgery, including early and late changes in the esthetic appearance of their child, potential surgical risks (mainly blood loss and the need for transfusion of blood and coagulation factors), and the possibility of infection. They should be prepared for significant facial swelling during the first postoperative days, but should also be assured that brain damage and severe complications are rare despite the extent of the surgical procedure. Long-term follow-up is important to detect late intracranial hypertension or recurrent deformity, both of which may require reoperation.

Craniectomy

The principle of craniectomy is to remove a piece of the cranial vault to permit directional skull expansion. Several forms of craniectomy have been used from simple suturectomy, to strip craniectomies, to wide vertex craniectomies in scaphocephalic patients. Barrel stave incisions and lateral strip craniectomies have been utilized to promote lateral skull expansion. Total removal of the cranial vault has been performed, with acceptable outcomes in some cases. Since craniectomies require spontaneous bone regeneration to reshape the skull and protect the brain, these techniques are not recommended in children older than 8–10 months of age.

Strip craniectomy improves craniofacial contour only for isolated sagittal synostosis. For other synostoses, removing, reshaping, and repositioning bone accomplish cranial remodeling. Cranial remodeling may involve any part of the cranium or the entire cranial vault. For complex craniosynostoses that involve the cranial base and face, the sutures involved are commonly those of the anterior cranial vault (coronal, sagittal, or metopic sutures) as well as the anterior cranial base (frontosphenoidal, frontoethmoidal, and sphenozygomatic sutures). The surgery releases the sutures and advances the upper part of the face forward (fronto-obital advancement) away from the cranial base (Fig. 36.16). The principal

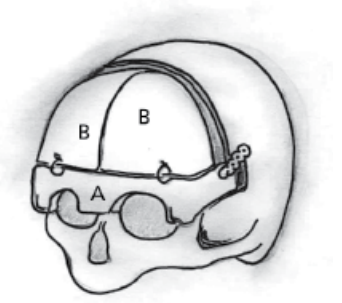

Figure 36.16 Fronto-orbital advancement. Both frontal bone flaps (B) or a coherent bifrontal flap are displaced forward together with the fronto-orbital bandeau (A). Rigid fixation with miniplates, wire loops, or tight suturing keeps the bone segments in place.

functional objectives of the surgery are to open the cranium to allow normal brain expansion, to open the nasopharyngeal airway, to provide greater support and protection for the eyes, and to achieve proper alignment of the upper and lower dental arches. This surgery usually requires at least two steps: (1) frontocranial remodeling, with release of the synostosis and advancement of the frontal supraorbital area, and (2) midface advancement. The segments are fixed in place with wires or resorbable/non-resorbable miniplates, and bone grafts are used to fill gaps. In some cases the forehead is left "floating" with a wide osseous defect.

Minimally invasive strip craniectomy

Over the last two decades, techniques for minimally invasive strip craniectomy, initially for single-suture sagittal craniosynostosis, but more recently for multisuture and syndromic craniosysnostosis, have been reported. These techniques include endoscopically assisted strip craniectomy with one or two smaller incisions, and spring-assisted craniectomy (Figs 36.17 and 36.18) [79–81]. The major advantage of this approach is less bleeding and transfusion, shorter operative and anesthetic times, and shorter postoperative length of stay. Longer term outcome studies are being reported with equivalent results in terms of head shape, brain growth, ICP, and neurodevelopmental and social outcomes; but there still remains considerable debate about the best approach. One major difference in the minimally invasive approach is that it is best performed in younger patients aged 3–6 months, when the cranial bones are softer and more flexible, rendering them more amenable to this approach.

Cranial vault reconstruction

Total or partial reconstruction of the cranial vault is the method of choice when reshaping and stability of the skull are the aim of the operation. Vault craniotomies are performed and the bony plates are remodeled and transposed to reshape the skull. Stable fixation of bone with wire loops, stitches, or miniplates (either titanium or lactic acid polymer) is

necessary. Titanium miniplates tend to grow inwards and must be removed after 3 months. Cranial expansion is another surgical aim of total cranial vault reconstruction. Again, the cranial plates are excised, transposed, and refixed, leaving substantial gaps in between the bone edges, but the intracranial cavity is enlarged [82]. This technique is indicated for children with multisuture involvement or secondary intracranial hypertension, e.g. after scaphocephaly correction. Larger bone defects (>2 cm) will not close spontaneously after the second year of life, making it necessary to do this surgery before that time. Defects in the calvarium can be filled with autologous grafts, e.g. calvarian split grafts. Children with severe occipital deformity or flattening, e.g. in brachyturricephalic heads, undergo occipital advancement, including a suboccipital bone flap. For mechanical reasons a rigid fixation is necessary.

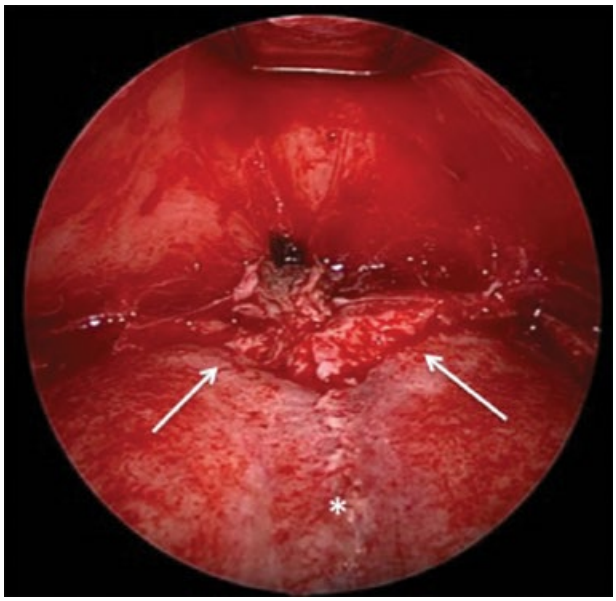

Figure 36.18 An intraoperative endoscopic view after craniectomy through a single incision demonstrating the exposed lambdoid suture on either side of the midline. White arrows represent the triangular shape of the lambda as it is approached and the sagittal sinus (asterisk) marks the midline. *Source*: Reproduced from Iyer et al [79] with permission of Springer Nature.

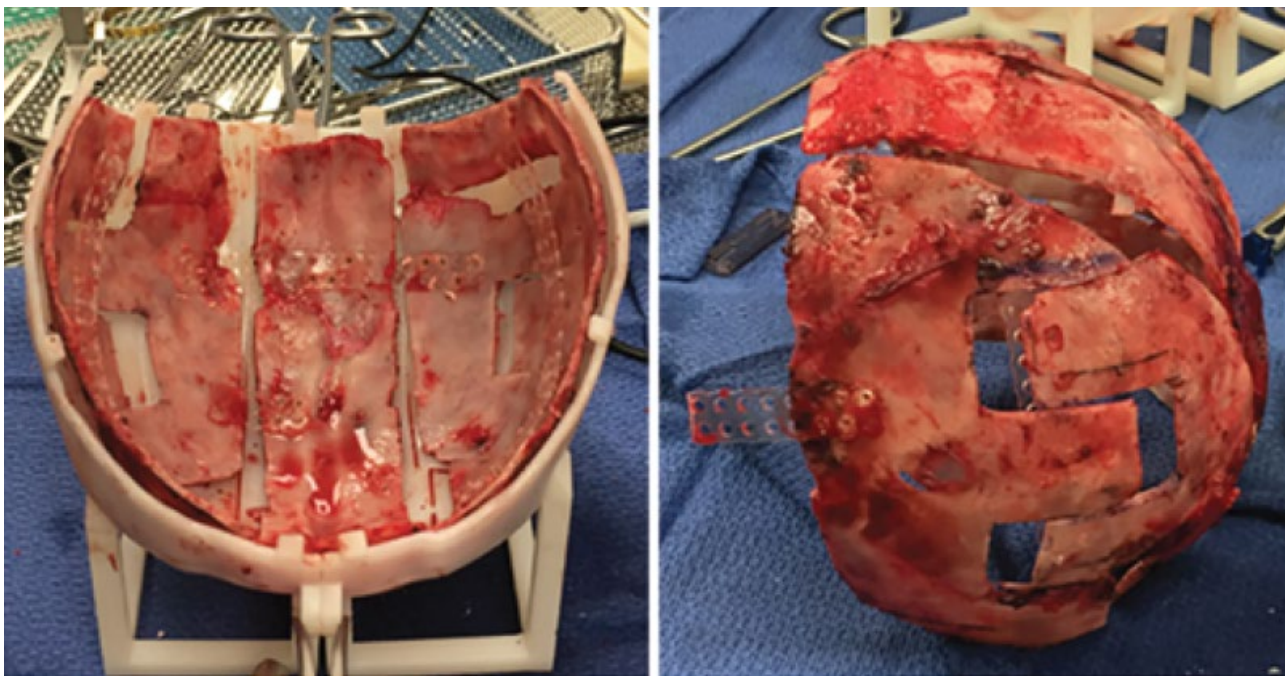
New surgical planning techniques including 3D reconstruction from CT scans, and 3D printing of the desired cranial vault shape, which can be used to produce sterile intraoperative acrylic models as a template for final osteotomies and reconstruction, are being reported (Fig. 36.19) [83]. These techniques, along with quantitative photographic techniques such as stereophotogrammetry are allowing more precise and objective surgery and follow-up of cranial vault reconstruction patients [84].

Fronto-orbital advancement

For anterior skull expansion and correction of the orbital portion, fronto-orbital advancement has been the standard technique since first described by Tessier and modified by Marchac [85,86]. First, a bifrontal flap is excised and removed, then the fronto-orbital bandeau, cutting the edges in a tongue and groove fashion. In trigonocephaly or anterior plagiocephaly, the bandeau and the frontal bones are reshaped and sometimes rotated to create the desired fronto-orbital shape. Refixation of bone may be with wire loops, miniplates, or tight stitches in older children. In multisuture synostoses, when the primary goal is to enlarge the cranial cavity,



(A) (B)

Figure 36.19 Three-dimensional printed intraoperative cranial mold. (B) Final expanded calvarial construct (middle and posterior calvarial vault). *Source*: Reproduced from LoPresti et al [83] with permission of Journal of Neurosurgery.

fronto-orbital advancement is combined with total vault reconstruction. Shallow orbits are always enlarged to protect the eyes (Fig. 36.20).

Distraction osteosynthesis

Another method of enlarging the volume of the skull is based on the Ilizarov principle of bone distraction. For midface and mandibular correction, distraction osteosynthesis has become standard. The application of distracting devices to transected vault sutures or parts of bone flaps for dynamic skull expansion is less well established.

Additional neurosurgical procedures

Hydrocephalus is relatively common in multisuture or syndromic craniosynostosis and contributes to the elevated ICP. Ventriculoperitoneal shunting is the procedure of choice in these cases, but interferes with keeping cranial sutures or newly created gaps open as long as possible after cranioplasty procedures. Alternatively, an endoscopic third ventriculostomy can be done in selected cases.

As a consequence of insufficient skull growth, the expanding brain moves downward and causes a Chiari malformation with brainstem compression and secondary hydrocephalus. In some of the affected children, a craniocervical decompression (Gardner decompression) becomes necessary.

Midface advancement

Craniofacial dysjunction and midface advancement are delayed until the patient is at least 4 or 5 years of age. Certain indications or personal preferences lead surgeons to select a specific operative procedure, which usually includes a Le Fort osteotomy (Fig. 36.21). At the beginning of the 20th century, a French surgeon, René le Fort, found that the maxilla, naso-orbital complex, and zygoma fracture in predictable ways at weak points, i.e. the linea minoris resistentiae [87]. These fracture lines are used to produce controlled osteotomies for the correction of skeletal anomalies.

The Le Fort I osteotomy is the most common and most useful midface osteotomy (Fig. 36.22). Malocclusion of the teeth

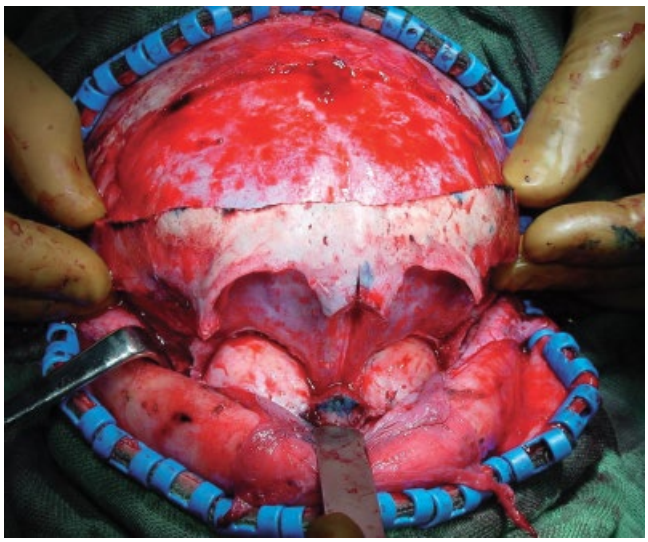


Figure 36.20 During fronto-orbital advancement, the primary goal is the enlargement of the cranial cavity which is combined with total vault reconstruction. After that both orbits are exposed.

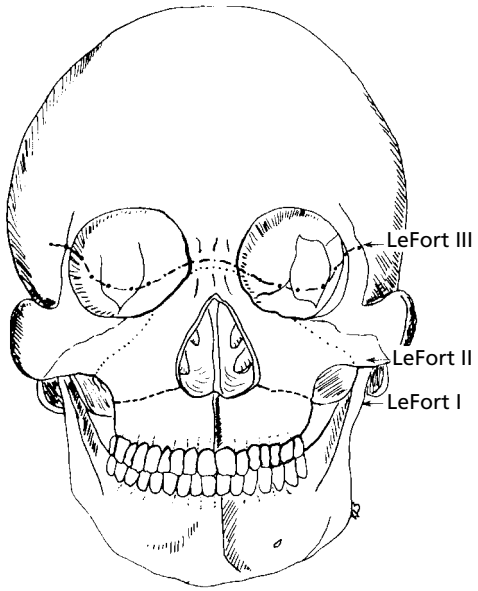

Figure 36.21 Le Fort I, II, and III osteotomies.

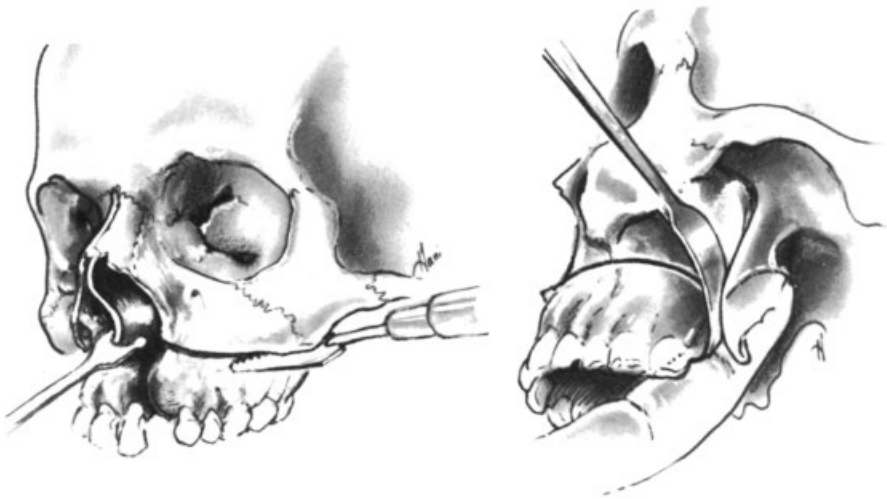

Figure 36.22 Le Fort I osteotomy. *Source*: Reproduced from Bardach and Salyer [184] with permission of Elsevier.

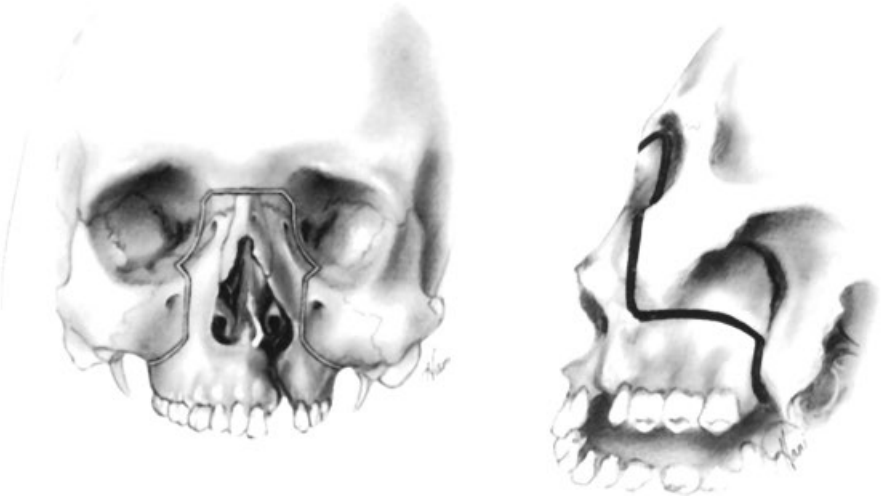

Figure 36.23 Le Fort II osteotomy. *Source*: Reproduced from Bardach and Salyer [184] with permission of Elsevier.

is always present and is treated by an interdisciplinary team of maxillofacial surgeons and orthodontists. Surgery is performed through an intraoral incision. Horizontal cuts are made across the nasal floor, the anterior maxilla, and through the pterygomaxillary junction. The maxilla is mobilized downward, advanced, and fixed. The occlusion is secured by arch bars and by a dental splint. Because of the intraoperative intermaxillary fixation, nasotracheal intubation is required. Bone grafts can be used to fill the spaces.

The Le Fort II osteotomy is done less often and is used to advance the lower maxilla and entire nose forward (Fig. 36.23). Normally, a bicoronal scalp incision and soft tissue reflection are combined with an intraoral incision to expose the midface. There are many variations of midface osteotomies. The osteotomy crosses the nasal bridge and then goes bilaterally down the lateral nasal bones through the inferior orbital rim and across the maxilla to the pterygomaxillary junction. The segment is mobilized and advanced. Bone defects are filled with bone grafts, and the entire segment is fixed with rigid miniplates or wires. Intermaxillary fixation is not really needed when rigid internal fixation plates are used.

Midface hypoplasia typically results in an Angle class III malocclusion (a relative mandibular prognathia) with an anterior overbite. A Le Fort III osteotomy is indicated, but an additional Le Fort I osteotomy is often necessary to achieve an intermaxillary relationship that enables stable occlusion. Le Fort III osteotomy (Fig. 36.24) is used for complete underdevelopment of the midface, typical of the Apert, Crouzon, Pfeiffer, and similar syndromes. It permits the nose, maxilla, and orbits to be advanced after dysjunction of the entire midface. A bicoronal scalp incision is made, the soft tissues are reflected forward over the midface, and the orbital contents are dissected free. The basic osteotomy starts at the frontozygomatic suture and then passes through the orbits below the supraorbital rim and across the nasal bridge. The pterygomaxillary junctions are separated, and the nasal septum is separated from the skull base. The facial block is advanced after down-fracture and side-to-side and rotary manipulations (Fig. 36.24). The spaces are filled with bone grafts and the bones are fixed in place. The use of rigid internal fixation plates precludes the need for intermaxillary fixation.

Figure 36.24 Le Fort III osteotomy. Rowe disimpaction forceps are used to "down fracture" the posterior maxillary wall and allow advancement of the midface. *Source*: Reproduced from Persing [185] with permission of Wolters Kluwer.

Monoblock frontofacial advancement moves the frontal and orbitofacial blocks forward simultaneously. While the early functional results are good, the complication rate is high and the poor postoperative midface growth makes a reoperation more difficult [88]. The supraorbital area and the facial mass are mobilized en bloc and advanced. The frontal bone flap is remodeled when necessary, e.g. exorbitism.

Various combinations and modifications of these osteotomies are performed either simultaneously or in stages. The transverse maxillary osteotomies (Le Fort I and II) are usually delayed until adolescence to avoid disruption of the permanent dentition.

Pediatric temporomandibular joint (TMJ) dysfunction from soft tissue or skeletal disorders may be congenital or acquired. The diagnosis and classification of TMJ disorders determine treatment options [89]. In cases of TMJ reconstruction or discontinuity defects of the mandible after trauma, hemimandibulectomy for tumor excision, condylar damage with juvenile

idiopathic arthritis, or congenital diseases (e.g. hemifacial dysplasia), the goal is to maximize function and cosmesis, preserve quality of life, and restore mastication, speech, and appearance [90]. Treatment includes autogenous bony, cartilage, and condylar grafts, free vascularized flaps, or an alloplastic TMJ prosthesis until the skeleton matures [91–94]. A variety of donor sites have been used for this purpose, including the iliac crest, radius, scapula, and fibula. TMJ diseases occurring during growth result in dentofacial deformity and require reconstruction of the occlusion plane. Surgical correction with total joint prostheses can be performed in a single-stage operation with a mono- or bimaxillary orthognathic osteotomy [95]. During surgery the occlusion has to be checked.

Surgical correction of hypertelorism and orbital malposition

Surgical correction of orbital malposition is performed to facilitate correction of strabismus, to normalize facial appearance, and to possibly achieve binocular vision. Surgery is usually performed at about 5 years of age unless there are mitigating circumstances. The orbit can be thought of as a box housing the eye. To correct hypertelorism or other orbital malposition, the box is freed from contiguous bone and repositioned (Fig. 36.25). In moderate and severe degrees of hypertelorism, an intracranial approach is employed: a bicoronal scalp incision is made; soft tissues, including orbital contents and nasal mucosa, are reflected down to the midface; a frontal craniotomy is performed; and the frontal lobes of the brain are retracted to expose the anterior cranial fossa. Intra- and extraorbital osteotomies convert the anterior orbit into a mobile box. A central block of bone (frontal, nasal, ethmoidal) is removed from between the orbits. The orbits, with the globe and other soft tissues, are then moved medially and fixed in place (Fig. 36.26). Bone grafts are inserted into the gaps created at the lateral orbital walls. The nose is rebuilt with bone grafts if necessary. For minor degrees of hypertelorism, an extracranial approach is possible; this eliminates the frontal craniotomy and brain retraction. Extensive soft tissue dissection is still required, but the osteotomies are less extensive. There is also danger of piercing the cribriform plate and causing CSF leakage.

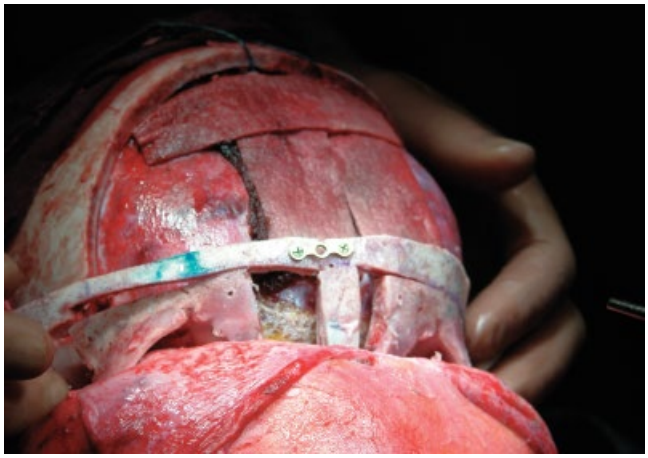

Figure 36.25 After osteotomies and removal of a central block of bone, the orbits are shifted medially. Orbits can be considered as boxes containing the eye. Each orbit can be moved in any plane.

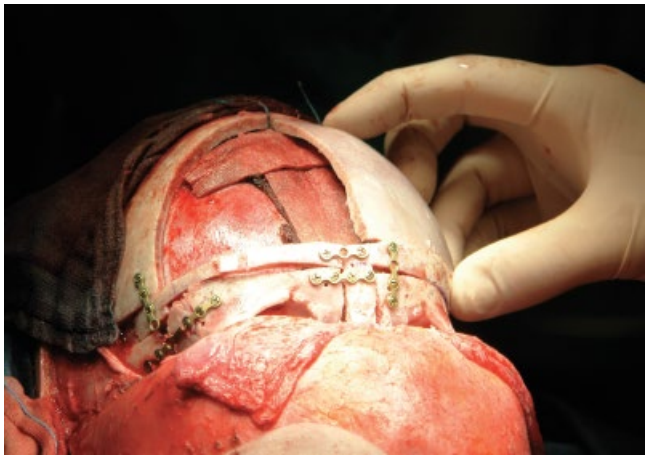

Figure 36.26 Orbits after medial shift and fixation with miniplates.

Reconstruction of facial clefts: major facial and mandibular malformations

The anatomical defects of the major facial and mandibular malformation syndromes are skeletal and soft tissue hypoplasias. Hypoplasia may involve any part of the face and cranium. Reconstruction of these lesions often requires multiple staged surgical procedures. The skeleton must be normalized, the soft tissues augmented, ears and nose reconstructed, and sometimes the face must be reanimated. For the hypoplastic skeleton, displacement osteotomies, repositioning of bones into more normal positions, and calvarial bone grafts are used to augment surfaces and fill spaces.

Soft tissue hypoplasia can involve skin, subcutaneous tissue, cartilage, and the muscles of mastication and facial expression. Various approaches can be taken to augment and restructure soft tissues. Skin and mucosal flaps from local or distant sites may be used. To add bulk and appropriate contours, dermis fat grafts from the groin can be placed subcutaneously. Contour can also be improved with inlay bone grafts. Temporal muscle transfers to the face also add bulk. These procedures may require extensive dissection of soft tissue. Facial nerve palsy can be compensated for with nerve transfer from the motor branch of cranial nerve V; if the malformation is unilateral, cross-face nerve grafts, facial–hypoglossal nerve anastomosis, and microneuromuscle transfers can be attempted.

Traditionally, mandibular reconstruction has followed the same principles as other craniofacial procedures: cut, mobilize, reposition, augment, and fix. In the past the mandible was mobilized through an intraoral incision with bilateral sagittal osteotomies and rotated and advanced into a normal position. Distraction osteogenesis is now replacing the traditional method in many cases. New mandibular parts are constructed from costochondral rib grafts or split cranial grafts. This surgery is usually done before eruption of the permanent teeth.

Distraction osteogenesis

Patients with severe craniofacial dysostosis who require early surgical correction of their deformity before skeletal maturity have clearly benefited from distraction osteogenesis compared with conventional osteotomy [96]. Distraction osteogenesis is

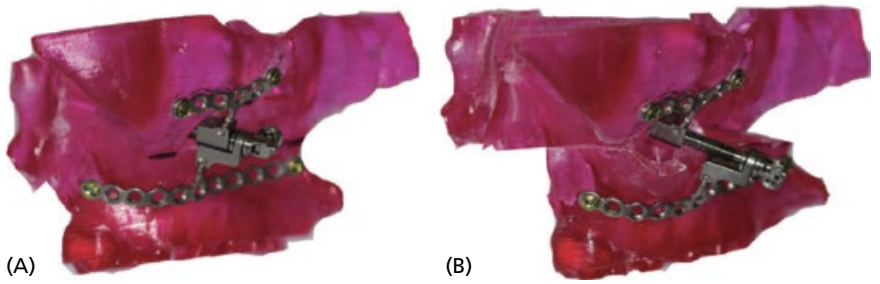

Figure 36.27 The trans-sinusoidal mandibular distractor on a stereolithographic model of the midface. Before (A) and (B) after distraction.

done by producing a bone callus (by osteotomy) and then distracting the proximal and distal ends of the callus. It has been used by some orthopedic surgeons for years to lengthen limbs but did not gain widespread acceptance because of the associated morbidity. In 1988, Ilizarov, a Russian orthopedic surgeon, described using distraction osteogenesis that required only corticotomy and minimal disruption of the periosteum and endosteum; this reduced the incidence of complications and allowed wider application of the technique [97].

Rosenthal first described distraction osteogenesis for widening the mandible in 1930 [98]. Its principal application in craniofacial surgery is for mandibular lengthening [99]. The technique consists of percutaneous insertion of pins into the mandible that are proximal and distal to a corticotomy. The pins are attached to an external fixator lengthening device, and the mandible is lengthened 1 mm/day by turning a bolt. The authors reported mandibular lengthening of 18–24 mm.

The procedure is considered minimally invasive and achieves an approximately 2–3-fold advancement compared with the conventional procedure. Using conventional osteotomy beyond the age of skeletal maturity has the advantage of a shorter treatment period and greater patient comfort. Distraction is often associated with less blood loss, less tissue exposure, and no need for bone grafting. With distraction osteogenesis the postoperative morbidity is decreased, the operation time is reduced, and the procedure can be performed on younger children. Several authors believe that mandibular distraction also induces facial soft tissue growth [100–102]. The disadvantage of this technique is the need for high patient compliance and the high psychological impact [103]. The major complication of extraoral devices is the development of hypertrophic scars when the pins migrate through the skin.

Since the original description, mandibular distraction has become increasingly popular for the treatment of mandibular hypoplasia and asymmetry [102–104]. Enoral (internal) distracters eliminate facial scars and are less likely to loosen or dislodge. Mandibular distraction has also been used to successfully alleviate the symptoms of respiratory distress and obstructive sleep apnea. A tracheostomy (if in place) can be removed. Mandibular distraction has been applied to infants as young as 14 weeks of age [105]. Both internal and external lengthening devices are being applied to distract the midface [103].

Patients with cleft lip and palate often have severe maxillary hypoplasia in the vertical, horizontal, and transverse dimensions. Traditional protocols rely on combined surgical–orthodontic treatment, including Le Fort I maxillary advancement, maxillary and alveolar bone grafting, and rigid internal fixation. Long-term results of this approach have been disappointing because relapse occurs in more than 20% of the cases. Trans-sinusoidal mandibular distractor (TS-MD) placement is a possible alternative for patients with cleft lip and palate. The major part of the TS-MD is done within the maxillary sinus and does not interfere with function during distraction and retention or with the patient's social life. Compared with headframe-based extraoral devices for midface distraction, TS-MD is easier for the patient and does not leave extraoral scars after removal of the device. Three-dimensional planning enables the surgeons to plan the distraction vector in three dimensions, but a correction of the vector by distraction is not possible, as it is with the headframe device (Fig. 36.27).

Cleft lip and cleft palate reconstruction

Surgical reconstruction of a cleft lip, palate, and/or nose is undertaken for cosmetic, psychological, and functional purposes. Functional goals are to separate the nasal and oral cavities, to improve speech and swallowing, to prevent middle ear disease, to improve hearing, and to provide normal dental occlusion (Fig. 36.28).

The treatment of children with cleft lip and palate starts during the first weeks after birth with preoperative orthopedics, such as presurgical nasal alveolar molding (PNAM) (Fig. 36.28) [106]. The PNAM appliance differs from traditional intraoral alveolar molding devices by having nasal prongs as part of the device [105]. An orthodontist adjusts the acrylic appliance by adding and removing material from the leading edge of the maxillary segments weekly. Despite the lack of long-term outcome studies, PNAM is used by many multidisciplinary cleft teams to reduce the width of the alveolar cleft and the corresponding soft tissues of the cleft lip [107].

Primary cleft lip repair is usually performed at 3–6 months of age and often includes a primary rhinoplasty (Fig. 36.29) [106]. Cleft palate reconstruction is done at 6–12 months of age before speech develops [108]. There are many ways to close the lip that have excellent results, each with its own advantages and disadvantages. The final result depends on the degree of primary dysmorphology, scarring (surgical technique), the experience of the surgeon, and the time schedule [109]. Tissue deficiency and displacement contribute to anatomical defects. Surgical reconstruction involves dissecting and freeing anatomical elements, undermining the tissue, repositioning the involved muscles in a correct anatomical position, and creating flaps for rotation and advancement of the lip. Reconstruction of the bony palate requires creating bone or mucoperiosteal flaps and also bone grafting. For example, mucoperiosteal

flaps can be made from the palatal shelves and positioned medially to fill the cleft or they can be turned off the vomer and joined to the edge of the bony cleft to close it. If the cleft is sufficiently narrow, paring of the medial palatal edges and elevation of the nasal and palatal mucosa may allow closure.

Free bone grafting is required traditionally after orthodontic palatal expansion (8–11 years of age) of the alveolar ridge. This occurs when 30–60% of the canine tooth roots have developed but before eruption of the tooth into the cleft void. Bone is generally taken from the iliac crest.

Pharyngeal flap

Velopharyngeal incompetence is failure of the velum (soft palate) and posterior pharynx to close or contact appropriately during speech and swallowing. It occurs in 10–30% of patients after cleft palate repair. It can also occur if there is any anatomical or neuromuscular abnormality of the palate or pharynx [110]. Velopharyngeal incompetence causes hypernasal, misarticulated speech. Nasal regurgitation of food and liquid occurs with swallowing.

Diagnosis of velopharyngeal incompetence has greatly improved with videofluoroscopy and nasal endoscopy, which provide a dynamic view of the velopharynx. Direct visualization can identify the closure pattern and contributions of the velum, the lateral and posterior pharyngeal walls, and Passavant ridge to speech [111]. Surgical correction of this defect is commonly attempted by creating a pharyngeal flap in which flaps of mucosa and muscle are raised from the posterior pharynx and attached to the velum (Fig. 36.30). This results in a permanent midline connection between the palate and posterior pharynx. Alternatively, a sphincter pharyngoplasty is performed, in which small lateral pharyngeal flaps are tucked under a wide medial flap to create a bulky transverse roll in the posterior pharynx, which narrows the pharynx and allows contact with the velum.

The result of these procedures is a narrowed nasopharyngeal vault and the potential for obstructed nasal airflow. Obstructive sleep apnea is not uncommon after a pharyngeal flap is created, especially with the Robin sequence [112–114]. Velocardiofacial syndrome is the most common syndrome causing palatal clefting and velopharyngeal insufficiency. It is associated with medially displaced carotid arteries that increase the risk of pharyngoplasty [115]. Velopharyngeal insufficiency can be identified by nasoendoscopy but not with endoral examination. Blind nasal tracheal intubation or insertion of a nasogastric tube should *not* be attempted in patients who have a pharyngeal flap. However, Kopp reported performing nasotracheal intubation in patients with a pharyngeal flap by first passing a flexible suction catheter to determine the patency of each naris and to identify the pharyngeal flap passages [116]. When the catheter emerges through the ostium created by the flap, it is grasped with a clamp and the endotracheal tube gently passed over it. At times it has been necessary to take down the flap due to severe postoperative airway obstruction.

KEY POINTS: SURGICAL PROCEDURES FOR CRANIOFACIAL RECONSTRUCTION

- Timing of craniofacial surgery is often controversial. As long as there is sufficient head growth, as occurs in most single-suture craniosynostoses and other craniofacial disorders that do not involve the cranial vault, surgery is scheduled in the second half of the first year, usually between 6 and 8 months of age
- More extensive midface and orbital advancement procedures, and mandibular procedures, are normally performed at older ages, usually 4–5 years or later
- Primary cleft lip repair is normally performed at 3–6 months of age, and cleft palate repair at 6–12 months of age
- A pharyngeal flap may be needed at a later date to address velopharyngeal incompetence; the nasopharyngeal airway is usually obstructed after this procedure

Anesthesia for craniofacial reconstruction

Preoperative evaluation

Many factors influence the emotional state of patients and families who face major craniofacial surgery [117–120]. Pediatric patients with craniofacial anomalies often have behavioral problems, poor self-image, anxiety, introversion, and negative social experiences. These problems are rarely profound and represent limitations rather than severe psychopathology [120]. Most children with craniofacial anomalies make social and psychological adjustments to their appearance without functioning in a psychosocially deviant range. Surgery is stressful for the patient and parents [121]. They have fear of pain and of physical jeopardy because the surgery is extensive and potentially life threatening. Older children may also fear loss of identity because of the impending changes in their appearance. Parents may be very protective. Many patients undergo multiple surgical procedures over many years, and the child and family have invested great emotion in the process.

It is important to establish rapport and gain the confidence and acceptance of the patient and parents. One can be sensitive yet open and candid in discussing the anomalies. It helps to encourage the child and parents to express their concerns and expectations. The child may have problems with sight, hearing, or speech, and these must be accommodated during preoperative preparation. Various hospital activities such as

puppet plays, movies, storybooks, and other play therapy may help to prepare the child for the coming events.

It is appropriate to be reassuring to the patient and family, because the procedure offers hope and the surgical results are usually good. Eighty-seven percent of patients report subjective improvement in appearance after surgery [122]. In addition to increased satisfaction with body image and improvement in their emotional state, some patients also have improved behavior and school performance. Ninety-one percent of parents of small children and 77% of adolescents would undergo the surgery again [118,123].

A complete preoperative medical evaluation is required. There are potential differences between craniofacial and isolated orofacial procedures. Patients undergoing craniofacial surgery should have preoperative evaluation, including sleep studies. The possible need for ICP monitoring should be discussed with the parents preoperatively. Patients with craniofacial anomalies often have syndromes and have anomalies of other systems. Relevant and comprehensive information about rare diseases is available on the internet at sites such as Orphanet, the portal for rare diseases and orphan drugs. (www.orpha.net). Associated CNS pulmonary and cardiac anomalies are especially noteworthy. Because of the nature and extent of the surgery, a careful history of bleeding tendencies should be obtained. Twenty to 37% of patients undergoing major craniofacial surgery have airway problems [124,125]; 65% of patients with mandibular dysostosis (Treacher Collins, Goldenhar, or hemifacial microsomal syndromes) and 53% of patients with craniofacial synostosis have problems with their airways.

It is important to evaluate thoroughly and comprehensively the airway because not all airway abnormities are readily apparent. Patients often undergo multiple procedures, so a history of airway problems during previous procedures and how they were managed should be reviewed. If airway management is expected to be difficult and a tracheostomy may be required, this should be discussed with the patient and parents before surgery.

Certain facial, upper airway, and neck anomalies make airway management by mask and tracheal intubation difficult. It is difficult to get a good mask fit and seal when there is facial asymmetry, malar hypoplasia, or nasal deformities. Anatomical anomalies, such as choanal atresia or stenosis, macroglossia, micrognathia, and diminished nasopharyngeal space, may cause airway obstruction. Secretions or adenoidal hypertrophy may further obstruct small air passages. Awake patients may have signs of airway obstruction, e.g. mouth breathing. Other signs, such as snoring, noisy breathing, and apnea, may be present only during sleep. Snoring with frequent sleep arousals, abnormal movements during sleep, daytime somnolence, nocturnal enuresis, and morning headaches are signs of sleep apnea. A history of sleep apnea can be elicited by asking whether the child snores and holds his or her breath between snores. Poor attention spans and school performance and/or personality and behavioral changes are also symptoms of obstructive sleep apnea. In severe cases, the child may be underweight and have pulmonary artery hypertension or cor pulmonale. The child's heart should be auscultated for a loud second heart sound and the liver for enlargement, suggesting significant elevation of right heart pressures. Patients with upper airway obstruction during sleep may have airway obstruction during premedication-induced somnolence, during mask induction of anesthesia, and after extubation of the trachea.

Airway anomalies may render direct visualization of the larynx difficult or impossible. Mandibular hypoplasia or micrognathia, microstomia, macroglossia, trismus, and restriction of TMJ movement may make laryngoscopy difficult. Certain anatomical features should be carefully studied, including shape, size, and symmetry of the mandible, anteroposterior distance from the chin to the hyoid bone, tongue size, shape of the palate, movement of temporomandibular joints during mouth opening and during anterior displacement of the jaw, and mouth size when open (interincisor distance). Range of motion of the neck, especially extension, should be determined. Vertebral anomalies, such as cervical vertebral fusion in patients with Goldenhar, Apert, Crouzon, and other craniosynostosis syndromes, may limit neck motion [126]. During endotracheal intubation, retroflexion of the head may be necessary. Patients with Chiari malformation may have brainstem compression during flexion or severe extension of the head. Discussion should take place with the family and surgeon preoperatively about possible consequences of intubation maneuvers. It may be better to accomplish tracheal intubation with a fiberoptic bronchoscope without moving the head from a neutral position. It is recommended that every anesthesia department dealing with those patients have written standard operating procedures available for how to deal with expected and unexpected difficult airways. Moreover, regular simulation training in fiberoptic intubation techniques is necessary to ensure individual skills.

Laboratory evaluation

When large blood loss is expected, the minimal laboratory testing required in otherwise healthy children usually consists of hemoglobin or hematocrit determinations and type and cross-matching of blood. Tests of coagulation (e.g. prothrombin and partial thromboplastin times, platelet count, and bleeding time) should be considered, especially in young infants. Other laboratory evaluations, such as chest x-ray, electrocardiogram (ECG), pulmonary function tests, arterial blood gases, and serum electrolytes, may be required, depending on coexisting conditions. An echocardiogram is required if there is evidence of pulmonary hypertension.

Preoperative medication

Preoperative medication can be used to augment but not to substitute for psychological preparation. The use of preoperative medication must take into account the need for sedation and the presence of coexisting conditions and airway anomalies. For example, patients with increased ICP or potential airway obstruction may not safely tolerate respiratory depressants. Optimal sedation should smooth the induction process. Oral benzodiazepines are generally well tolerated for this purpose. Benzodiazepines, pentobarbital, and chloral hydrate can be administered orally or rectally. Fentanyl can be administered in a transmucosal form. Painful intramuscular injections should be avoided when possible. A local anesthetic cream patch (2.5% lidocaine and 2.5% prilocaine) placed

above a vein can minimize the pain of inserting a venous catheter. The patch is usually removed 1 h prior to puncture. High-resolution ultrasound may facilitate peripheral venous access for those patients in whom it is required. Antisialagogues can be included with oral premedication but should be used with care because they may cause a dry mouth and fever after the procedure.

Intraoperative anesthetic management

Successful anesthetic management requires close communication between the surgeon and anesthesiologist, especially when the surgeon is working near the airway or when rapid blood loss occurs. Anesthesia management is influenced by the patient's coexisting conditions, airway anomalies, and by particular features of the craniofacial procedure. In general, standard operating procedures written by anesthesiologists and surgeons help standardize the intraoperative management of the patient and assure optimal quality of care.

Associated conditions

Associated respiratory, cardiac, and neurological anomalies or disorders will influence anesthetic management. The presence of cervical vertebral anomalies can influence head positioning or the procedure being done. If the patient has complex craniosynostosis, consideration must be given to the possibility for raised ICP, as previously discussed. Signs and symptoms of elevated ICP are uncommon. Even when the ICP is normal, intracranial complications may occur in some areas if the cranial vault inadequately accommodates the brain in all dimensions. Anesthetic induction and maintenance techniques and agents should decrease not increase the ICP of these patients.

Airway anomalies

Unexpected airway obstruction may occur during the induction of anesthesia. Physical appearance is not always a reliable indication of potential airway obstruction, and a past uneventful anesthetic course does not preclude the occurrence of airway problems this time, especially when a cleft palate has been repaired or pharyngeal flap procedure has been done in the interim. When difficulty with the airway is anticipated, a general plan of how to deal with the problem should be formulated ahead of time – no single technique is foolproof. The plan should include provision for several alternative techniques, and the availability of a variety of equipment, especially laryngeal mask airways (LMAs) and small tracheal tubes. The presence of additional personnel with experience in securing a difficult airway is recommended. It is advisable to proceed cautiously with the anesthesia induction. Spontaneous ventilation offers a margin of safety. Airway catastrophes can be avoided by allowing the patient to breathe spontaneously until it is verified that controlled ventilation is possible and easy to establish.

Difficulty with the facemask fit can be overcome by building up the face with gauze, applying a large mask over the entire face, and by using high gas flows. Clear masks with moldable air cushions often fit best, but care should be taken to assure that the cushion does not impinge on the eyes or obstruct the nares. Some patients develop upper airway obstruction during light levels of anesthesia. This can be prevented or attenuated by clearing the nasal passages of secretions before the induction of anesthesia and by maintaining the "sniffing" position, opening the mouth, applying gentle positive airway pressure (5–10 cmH_2O), and employing a "jaw thrust" when the patient is sufficiently anesthetized to tolerate it. Nasopharyngeal and oral airways may also be useful.

With mandibular hypoplasia and other oral and cervical malformations, direct laryngoscopy may be impossible or possible only with unconventional maneuvers. The larynx of these patients is often described as being "anteriorly placed." The larynx is actually in a normal position with respect to the other cervical structures but the tongue, which is attached to the hypoplastic mandible, is more posterior than normal and overhangs the larynx, giving the impression that the larynx is anteriorly p1aced [127]. It is often impossible to open the mouth adequately and displace the tongue sufficiently to allow visualization of the larynx.

Laryngeal mask airway and fiberoptic bronchoscopy are important tools for airway management of patients with craniofacial malformations. The LMA can be inserted in awake infants (with topical anesthesia) or after induction of anesthesia in infants and children to aid blind or fiberoptic-guided tracheal intubation. A mobile "difficult airway" cart, including all devices for unexpected or expected airway difficulties, is recommended (see Chapter 16) [128–130].

Many reports describe difficulty with airway management in patients with craniofacial malformations. Before LMA and fiberoptic bronchoscopy were available, some unconventional maneuvers for obtaining an airway were described, such as forcefully pulling the tongue out with a suture, forceps, or custom-made retractors or using a Jackson anterior commissure laryngoscope with an "optical stylet." Blind or tactile tracheal intubation, with and without lighted guides, has also been described [131–134]. Video-assisted rigid endoscopes are now available to facilitate tracheal intubation of patients with a difficult airway. Oxygen is insufflated via the connector tube to prevent hypoxemia during video-assisted tracheal intubation. It is also helpful to use a laryngoscope to open the airway before inserting the rigid scope (Fig. 36.31).

Some patients require a tracheostomy for airway management. In some centers elective tracheostomy is performed

Figure 36.31 Single-handed usage of a Bonfils rigid optical scope for tracheal intubation in a difficult airway situation. (A) Optical unit. (B) LED light source. (C) Tube connector with oxygen insufflation. (D) Monitor.

when extensive facial osteotomies are planned in small children or when the airway would be difficult to manage if intraoperative reintubation were necessary [135]. When rigid internal fixation with plates is used rather than using intermaxillary ligation, tracheostomy can sometimes be avoided. Some patients already have a tracheostomy in place to treat severe respiratory obstruction. The complications and hazards of tracheostomy in pediatric patients include accidental decannulation of the trachea, tube obstruction, hemorrhage, and air leaks (pneumothorax, pneumomediastinum, subcutaneous emphysema). Chapter 16 presents an extensive discussion of management of the difficult airway.

KEY POINTS: PREOPERATIVE EVALUATION FOR CRANIOFACIAL RECONSTRUCTION

- Children with craniofacial anomalies often have problems with sight, hearing, or speech, and these must be accommodated during the preoperative preparation
- There are potential differences between craniofacial and isolated orofacial procedures. Patients with craniofacial anomalies often have syndromes and/or anomalies of other systems
- Airway anomalies may render direct visualization of the larynx difficult or impossible. Mandibular hypoplasia or micrognathia, microstomia, macroglossia, and trismus, may make laryngoscopy very difficult
- Range of motion of the neck, especially extension, should be determined and needs to be discussed with the surgeon. During endotracheal intubation patients with Chiari malformation may have brainstem compression during flexion or severe extension of the head
- Patients with increased intracranial pressure or potential airway obstruction may not safely tolerate respiratory depressants for anxiolytic premedication

Features of the craniofacial procedure

Several features of craniofacial surgical procedures will influence anesthetic management: the procedure may be long with extensive tissue exposure; massive blood loss may occur; the procedure may be intracranial; and the airway may be in the surgical field.

Long procedure with wide tissue exposure

Major craniofacial procedures average 4–5 h but can last for more than 12 h; operating time is reduced with an experienced surgical team [136,137]. Meticulous attention must be paid to protecting the anesthetized patient during prolonged surgeries. This includes proper positioning with the joints comfortably flexed, peripheral nerves protected, and pressure points, including the head, adequately padded. The patient may be in a supine, prone, or modified prone position for the surgery (Fig. 36.32).

During a long period of wide tissue exposure, large amounts of body heat are lost. Temperature homeostasis is maintained by employing measures to conserve and provide heat, including minimizing the amount of time the patient is exposed to cold air before draping, warming the room to 23–24°C, and using a heat lamp before draping. A warming blanket or forced-air warming device should be used, along with passive insulation (plastic or cloth covers) around the body. Irrigation and intravenous fluids and blood should be warmed, and airway gases should be heated and humidified. When large portions of the cranium are exposed, the skull should be repeatedly bathed in warm irrigation fluid. Corticosteroids are often administered before craniofacial surgery to reduce postoperative facial swelling, but there is little evidence to support doing so.

Excessive blood loss

The magnitude of blood loss is related to the extent and duration of the surgical procedure and may equal multiples of the patient's blood volume for major craniofacial surgery. Blood loss reportedly decreases with greater experience of the team [136,137]. In one study, patients undergoing craniosynostosis repair had a mean estimated red cell volume loss of 91% of total estimated volume (range, 5–400%) [138]. The amount of red cell volume loss was greater for infants less than 6 months of age, for complex versus simple synostosis, and for complex vault remodeling compared with forehead reconstruction and strip craniectomy. Infants who underwent strip craniectomy lost about 60% of their blood volume [139].

Bleeding from the osseous venous plexus is generally continuous and may be quite brisk during osteotomy and bone mobilization. Rapid loss of large volumes of blood can occur with uncontrolled arterial bleeding or inadvertent opening of a dural sinus. For example, the internal maxillary artery may be divided during mandibular osteotomy, and the palatine artery may be cut during a Le Fort I procedure. The severed artery may be difficult to identify and clamp if it retracts into an inaccessible location. Irregularities on the internal surface of the cranium (e.g. bone spurs invaginating the dural sinuses) can cause dural sinus tears and hemorrhage that often cannot be controlled rapidly. Other sources of major bleeding are the major extradural and pharyngeal veins. Scarring and adhesions increase persistent bleeding and make major arterial, sinus, and venous bleeding more likely during repeat operations [140–143].

Blood loss should be aggressively replaced milliliter for milliliter in infants. It is unwise to fall behind in blood replacement as sudden, rapid blood loss may occur. For larger children and adolescents, initial blood loss replacement can be with appropriate volumes of crystalloid or colloid solutions until a reasonable level of hemodilution is achieved. Much of the blood loss is unmeasurable because it is hidden in the surgical field and drapes. Close communication with the surgeon about the pace of bleeding and close monitoring of the patient's intravascular volume are necessary. Normovolemia should be maintained with a combination of packed red blood cells and fresh frozen plasma (FFP). Because the child's blood volume is small, serial blood gas analyses should be made and include hematocrit and the level of lactic acidosis to detect decreased tissue perfusion.

Blood and blood components should be available close to the operating room. At least two relatively large-bore intravenous catheters should be in place to permit swift infusion of blood. Blood transfusion may be rapid and massive and have

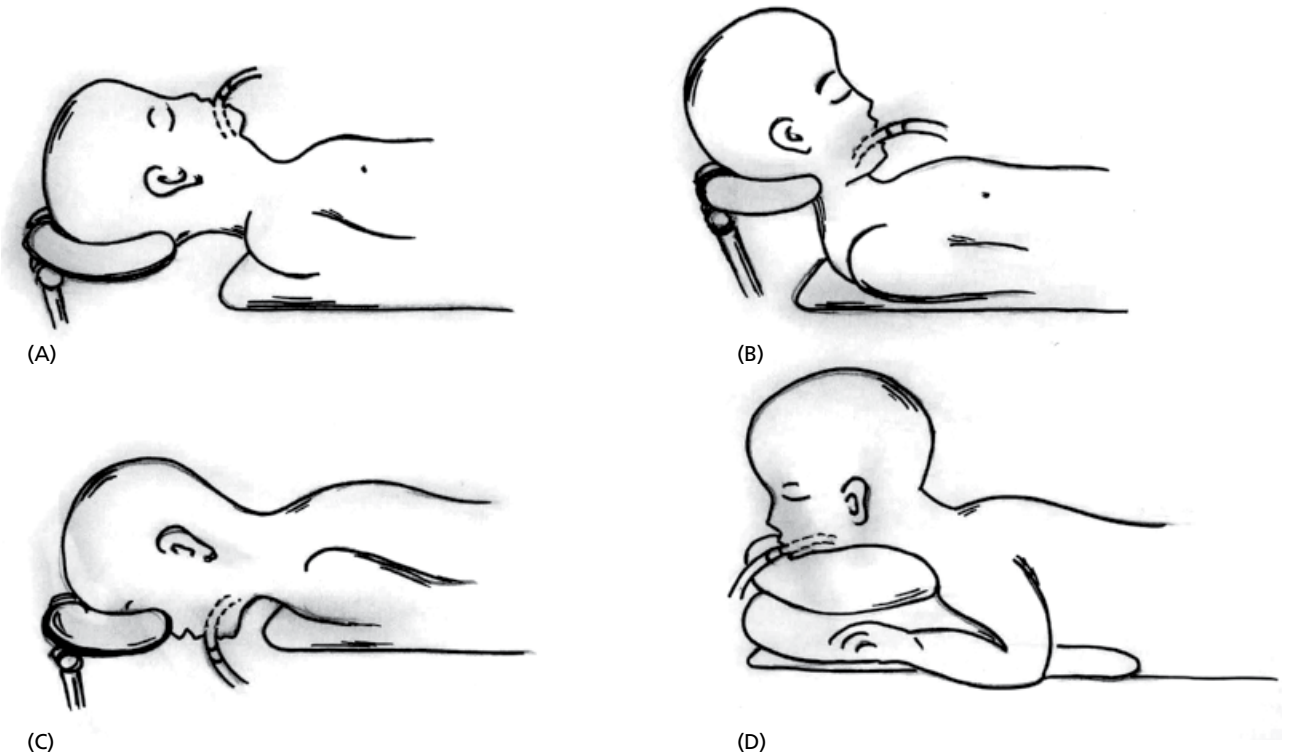

Figure 36.32 Positions in craniosynostosis surgery. (A) Supine position for frontal, frontoparietal, and orbitofacial lesions. (B) Supine with head inclination for frontal, parietal, and frontobasal lesions. (C) Prone position for parieto-occipital and suboccipital lesions. (D) Prone position with head reclination for total cranial vault exposure.

all the attendant problems (e.g. hypocalcemia, hyperkalemia, coagulopathy). When blood replacement exceeds one blood volume, coagulation factors, especially platelets, may need replenishment. Osteotomies, especially of the maxilla, may continue to ooze after surgery, so the child's hematocrit should be adequate when they leave the operating room. Induced hypotension is used to limit blood loss and create a drier surgical field, but there is no consensus on its utility and no objective data to support its use in cranial surgery.

Both induced hypotension and hyperventilation can cause cerebral hypoxia [144,145]. Therefore, it is probably unwise to combine the two. Regional brain ischemia may occur even when global perfusion is normal (e.g. when the frontal lobes are retracted). For these reasons, deliberate hypotension may be better suited to extracranial rather than intracranial procedures, although it has been used for both. Nowadays these techniques are seldom used. Other techniques that have been used to reduce or eliminate homologous blood transfusion during craniofacial surgery include preoperative administration of erythropoietin and intraoperative autologous blood salvage [146]. The cost of erythropoietin treatment makes its routine use prohibitive. The usefulness of intraoperative autologous blood salvage in small children is limited because transfusion is usually required before sufficient autologous blood can be collected. Further miniaturization of the available devices may make this technique more attractive.

For many years, antifibrinolytic agents such as aprotinin and tranexamic acid (TXA) were used to decrease intraoperative blood loss [147]. Since the withdrawal of aprotinin from the market, only TXA and ε-aminocaproic acid (EACA) are available for this purpose. A randomized, double-blind, placebo-controlled study of TXA in 46 children aged 2 months to 6 years undergoing craniosynostosis surgery revealed a dramatic decrease in blood loss (65 versus 119 mL/kg, $p < 0.001$) and blood transfusion (33 versus 56 mL/kg, $p = 0.006$) with TXA [148]. New pharmacokinetic data about TXA use in craniofacial surgery has recently been published [149]. Using data from 23 patients who received TXA in the randomized controlled trial described, a two-compartment pharmacokinetic model was devised, with co-variates of bodyweight and age in the final model. A loading dose of 10 mg/kg TXA, followed by 5 mg/kg/h infusion, was predicted to achieve and maintain plasma concentrations above the 16 μg/mL threshold for adequate inhibition of fibrinolysis and plasminogen activity. This regimen avoids the high plasma levels seen with higher loading doses, and presumably reduces risk for seizures. A recent report of 1638 patients undergoing cranial vault reconstruction from the multicenter Pediatric Craniofacial Surgery Perioperative database, in which 36% received TXA, 23% EACA, and 40% no antifibrinolytic, found a seizure incidence of 0.6%, with no difference between those receiving TXA and the remainder of patients in the database [150].

There are recent reports of the use of point of care thromboelastography (TEG®, Haemonetics Corp., Braintree, MA, USA) and thromboelastometry (ROTEM®, Instrumentation Laboratory, Bedford, MA, USA) to both predict the risk of a significant blood loss of >60 mL/kg, and to direct coagulation factor replacement [151,152]. Specifically, the TEG maximum amplitude <55 mm was the best predictor of massive blood loss, and the ROTEM measure of fibrinogen concentration, FibTEM, maximum clot firmness with a value of <8 mm, as a trigger to transfuse fibrinogen concentrate reduced the transfusion of FFP and costs of transfusion significantly.

If there is excessive bleeding, recombinant factor VIIa can be administered. This factor is not approved for

intraoperative use in coagulation disorders but is frequently used off label. It is an interesting substance that has promising effects on refractory non-surgical bleeding [153]. Chapter 12 presents an extensive discussion of intraoperative bleeding, blood transfusion, and coagulation factor therapy.

Intracranial procedures

Anesthetic techniques that decrease intracranial volume should be employed for intracranial procedures. Fronto-orbital procedures require brain manipulation and retraction to allow adequate exposure of the anterior cranial fossa and facial bones. Reducing the brain bulk decreases the amount of brain retraction necessary. Therefore, anesthetic agents such as ketamine, which increase intracranial volume, should be avoided. Opioids, benzodiazepines, thiopental, propofol, isoflurane, sevoflurane, and desflurane, in combination with mild hyperventilation (end-expiratory measured CO_2 between 30 and 35 mmHg) are preferred. Other measures used to decrease intracranial volume include 20–30° head-up positioning and the use of diuretics (mannitol and furosemide) [154,155]. The respiratory pattern during mechanical ventilation should not inhibit intracranial CSF and venous drainage. Therefore, positive end-expiratory pressure should be avoided, and mean airway pressure should be maintained as low as is consistent with adequate oxygenation by using a long expiratory time, if possible.

Potential hazards during intracranial procedures include dural sinus tears, cerebral edema, and venous air embolism. Dural sinus tears may produce rapid, massive blood loss. Manipulation and retraction of the brain may cause cerebral injury and edema. Air embolism occurs through open venous channels because the open cranium is usually positioned above the central circulation [155–157]. Meticulous surgical technique may prevent this complication.

Intraoperative airway management

During a Le Fort midface advancement, the surgeon must work around the airway. With maxillary osteotomy and down-fracturing maneuvers, the nasotracheal tube may be lacerated, transected, or dislodged from the trachea. Pilot tubes for endotracheal tube cuffs are easily cut. A plan should be formulated ahead of time between the surgeon and anesthesiologist for how an endotracheal tube will be replaced should this become necessary. Usually, the surgical field is quickly covered with sterile drapes, and the anesthesiologist is allowed access to the airway. Replacement tubes, catheter guides, and other appropriate equipment for reintubation must be readily available.

When the tracheal tube is in the surgical field, care must be taken to ensure an adequate airway despite lack of access to the face. The anesthesia circuit should be lightweight and all connectors should be well secured. The head of the operating table may be turned 180° from the anesthesia machine. Consequently the airway circuit must have adequate length to allow this. If the surgeon will move the head during the procedure, it must be ensured that the endotracheal tube and circuit are unencumbered. Care must be taken when initially positioning the endotracheal tube to avoid either tracheal extubation when the neck is extended or when the maxilla is advanced or endobronchial intubation when the neck is flexed. The maxilla or mandible can be advanced by as much as 3 cm with neck flexion. The tracheal tube should be secured with wires or sutures tied around teeth, nasal septum, mandible, or alveolar ridge. Nasotracheal intubation is required when the procedure is intraoral or when intermaxillary fixation is required. Armored tubes prevent compression of the airway by surgical manipulation. Close communication between the surgeon and anesthesiologist is required prior to tracheal intubation to determine the best position for the tracheal tube. Care must be taken to prevent nasal necrosis when a nasotracheal tube will be in place for hours. The hypopharynx should be packed to prevent intraoperative aspiration of blood, bone chips, and tissue. At the end of the procedure, the nose, mouth, and pharynx should be cleared and the stomach aspirated of gas, blood, and other material.

Postoperative swelling of the face and scalp may be severe. The swelling after bilateral midface and mandibular osteotomies may dictate that the tracheal tube remains in place for 12–48 h. This is especially true when intermaxillary fixation and occlusive intraoral prostheses limit access to the airway. Persistent oropharyngeal bleeding, cerebral edema, or pulmonary disease may also delay tracheal extubation. Tracheal extubation should occur when the patient is fully awake, has intact airway reflexes and an empty stomach, and is able to follow commands. Ensuring that an air leak is present around the endotracheal tube with the cuff deflated is a method often used to predict an unobstructed airway after extubation. Provisions should be made for immediately re-establishing an artificial airway (including wire cutters to release intermaxillary fixation wires) should this become necessary.

Other anesthetic considerations

Anesthetic drugs should be chosen on the basis of the preceding considerations. Depth of anesthesia can be balanced with muscle relaxation to prevent coughing, bucking, or patient movement with erratic surgical stimuli. Preferably, the patient should be awake and comfortable at the end of the procedure so that neurological assessment can be made. This can be accomplished by using a potent narcotic or "balanced" technique or by titrating narcotics when the patient is emerging from anesthesia. Extracranial bone graft sites (rib or iliac crest) may cause more postoperative pain than the cranial sites.

Fluids should provide maintenance requirements, replace interstitial and evaporative losses, and maintain urine output above 0.5 mL/kg/h. The exact amount of fluid required to accomplish these goals will depend on the extent of tissue dissection and exposure. For small infants, electrolyte solutions, like Ringer acetate with 1% of glucose, provides optimal maintenance of fluids and blood glucose concentrations. A urinary bladder catheter should be placed to prevent bladder distension and for intravascular volume monitoring. Serial blood analyses of arterial pH and blood gases, hemoglobin, electrolytes, ionized calcium, glucose, and coagulation parameters are made.

A high level of physiological monitoring is required. Routine anesthesia monitors, such as ECG, pulse oximeter, temperature, and airway gas and pressure monitors, are used. In addition, an intra-arterial catheter is placed to allow direct blood pressure monitoring and blood sampling. A central venous catheter is useful for monitoring intravascular volume and for

rapidly infusing drugs and fluids. Central venous oxygen saturation can be used to estimate cardiac output in children. A central venous oxygen saturation of <50–60% should prompt detailed evaluation of the patient's circulatory condition. Arterial blood pressure and waveform are good indicators of intravascular volume. A broad-based pressure wave, with the dichrotic notch in the upper half of the downslope of the curve and little or no variation with respiration, is a good indicator of normovolemia. During intracranial procedures, evidence of venous air embolism should be sought with capnography (see Chapter 19) and a precordial Doppler because the open cranium is generally above the central circulation. A central venous catheter may occasionally allow aspiration of entrained air, although early detection and prevention of further entrainment are more important than trying to aspirate the gas.

Perioperative hazards, complications, and outcomes

Although large series of major craniofacial surgery attest to its relative safety, significant morbidity and mortality can occur [158]. Intraoperative death has occurred with massive blood loss and air embolism. Postoperative death has resulted from cerebral, respiratory, and circulatory causes (e.g. cerebral edema, massive extradural hemorrhage, respiratory arrest, respiratory obstruction or tracheal extubation, tracheostomy blockage, and hemorrhage) [159–161]. A recent study analyzed 8101 major craniofacial procedures and determined the mortality rates and major morbidity. The authors found that serious complications have significantly decreased and suggested that protocols for airway management, blood salvage and replacement, age-appropriate deep venous prophylaxis, and timing of subcranial midfacial advancements might further reduce the mortality rate [162].

Other reported intraoperative complications include cardiac arrest from severe blood loss, air embolism, and pneumomediastinum (a complication of tracheostomy), pneumothorax during rib graft procurement, subdural hematoma, and bradycardia from the oculocardiac reflex [163–165]. Stimulation of any sensory branch of the 5th cranial nerve (maxillary, mandibular, ophthalmic) can cause reflex bradycardia and asystole. Reflex bradycardia and asystole have also been noted during maxillofacial and temporomandibular surgery [165]. Ocular pressure should be avoided because it too can cause severe bradycardia.

Several complications related to the endotracheal tube have been reported, including intraoperative tracheal extubation (usually during midface advancement), endotracheal tube blockage by kinking (also during midface advancement), and endotracheal tube laceration [127]. Pilot tubes for cuffed endotracheal tubes have also been lacerated. There are several reports of emergency endotracheal tube replacement intraoperatively. Complications of tracheostomy have included tube kinking, laceration of the posterior tracheal wall, esophageal perforation, and cardiac arrest from pneumoperitoneum [127,166,167]. Subgaleal or epidural drains require special care, especially when placed next to venous sinuses. The vacuum used for drains is related to the size of the used subgaleal or epidural drains. Rapid opening of the suction can cause significant blood loss. Non-fatal postoperative complications have included respiratory obstruction after tracheal extubation, pulmonary edema, cerebral edema, extradural hematoma, subgaleal hemorrhage, seizures, infection, blindness, CSF leaks, facial nerve damage, bone resorption, and hydrocephalus [168].

A recent report of the Pediatric Craniofacial Surgery Perioperative Registry of 1223 cases of complex cranial vault reconstruction gives a comprehensive picture of the challenges that the anesthesiologist faces in caring for these patients (Table 36.4) [169]. This same group also reported a case–control study of endoscopic versus open craniosynostosis repair [170]. Using a 2:1 matching by propensity scoring of control open surgeries versus endoscopic surgeries in a total of 933 patients, major intraoperative parameters (such as transfusion volume and anesthesia and surgery time) and postoperative events (including postoperative intubation and length of stay in the intensive care unit (ICU) and in hospital) were significantly improved in the endoscopic group. Incidence of critical intraoperative events such as hypothermia, hypotension requiring pressors, venous air embolism, and cardiac arrest, was not different between groups.

Postoperative care and outcomes of major craniofacial surgery

Many patients undergoing major craniofacial surgery will require postoperative ICU care for one to several days. Criteria for ICU admission vary by institution, but a recent study by Goobie and colleagues of 225 patients undergoing open craniosynostosis repair in a single center developed a risk prediction model for clinically significant cardiorespiratory or hematological postoperative events, such as reintubation, or significant postoperative blood transfusion [171]. Fifteen percent of this cohort had cardiorespiratory events, and 30% had hematological events. Major risk factors were weight <10 kg, American Society of Anethesiologists (ASA) physical score (PS) 3 or 4, intraoperative transfusion of >60 mL/kg blood products, or TXA not administered (Fig. 36.33) [171].

KEY POINTS: FEATURES OF THE CRANIOFACIAL PROCEDURE

- Major craniofacial procedures average 4–5 h but can last for more than 12 h. Meticulous attention must be paid to proper positioning with the joints comfortably flexed, peripheral nerves protected, and pressure points, including the head, adequately padded
- Blood loss is greater for infants <6 months of age, for complex versus simple surgery, and for complex vault remodeling compared with forehead reconstruction and strip craniectomy. However, even infants who undergo strip craniectomy may lose up to 60% of their blood volume
- Although large series of major craniofacial surgery attest to its relative safety, significant morbidity and mortality can occur. Intraoperative death has occurred with massive blood loss and air embolism
- Recent registry and large single-center studies have demonstrated risk categories for adverse intraoperative events, excessive bleeding, and need for ICU care. These include weight <10 kg, ASA PS3 or 4, intraoperative transfusion of >60 mL/kg, and not using intraoperative TXA.

Anesthesia for cleft lip and cleft palate reconstruction

Preoperative evaluation

The anesthesiologist's approach to patients with a cleft lip and palate is similar to that described in the preceding section for patients with other craniofacial deformities. In this case, however, the surgical procedure is less extensive. By the time the infant with a cleft lip comes for surgery at 3 months of age, the parents have usually overcome their initial reactions to their infant with a craniofacial anomaly and are hopeful that surgery will restore normal appearance and function. Preoperative preparation must accommodate the older child with a cleft palate who may have communication problems due to poor speech and hearing. Many children require multiple procedures. Every effort should be expended to ensure that the anesthetic experience is not unpleasant for either the parent or child.

A complete medical evaluation should be made, with special attention to the presence of other anomalies and syndromes. All patients with a cleft palate have Eustachian tube dysfunction and usually have chronic serous otitis with clear rhinorrhea. Acute otic infections should be resolved before surgery. Preoperative sedation is appropriate for children who have no airway compromise.

Intraoperative management of anesthesia

Induction

Most patients with an isolated cleft lip or palate present no difficulty with airway management. Only 3% of 800 patients undergoing repair of cleft lip and palate had difficult laryngoscopy [172]. Those with a difficult airway had retrognathia and/or were less than 6 months of age [173]. The protruding premaxilla associated with extensive bilateral clefts of the lip and alveolus sometimes prevents visualization of the larynx. While the incidence of failed intubation is low [167], it does occur. Therefore, it may be wise to induce anesthesia while the patient is spontaneously breathing. It is useful to have a second anesthesiologist to help with the airway management. The ability to manage the airway should be assessed before the patient is rendered apneic. Airway obstruction may occur if the tongue is impacted in a palatal cleft. This is easily remedied when recognized. Care must be taken to avoid injuring a protruding premaxilla during laryngoscopy. Antisialagog drugs are useful for oral procedures. Inserting a preformed, curved tracheal tube (Ring–Adair–Elwyn tube) that lies flat against the face minimizes the potential for tube kinking and dislodgment. A stylet can be used to facilitate tracheal tube insertion when necessary. The tube should be fixed in the midline, with the lip immobile and not distorted (Fig. 36.34).

Maintenance

There are several intraoperative special anesthetic considerations for cleft lip and palate reconstruction procedures. The first is that the airway is shared with the surgeon. Thus, the tracheal tube must be well secured to prevent inadvertent

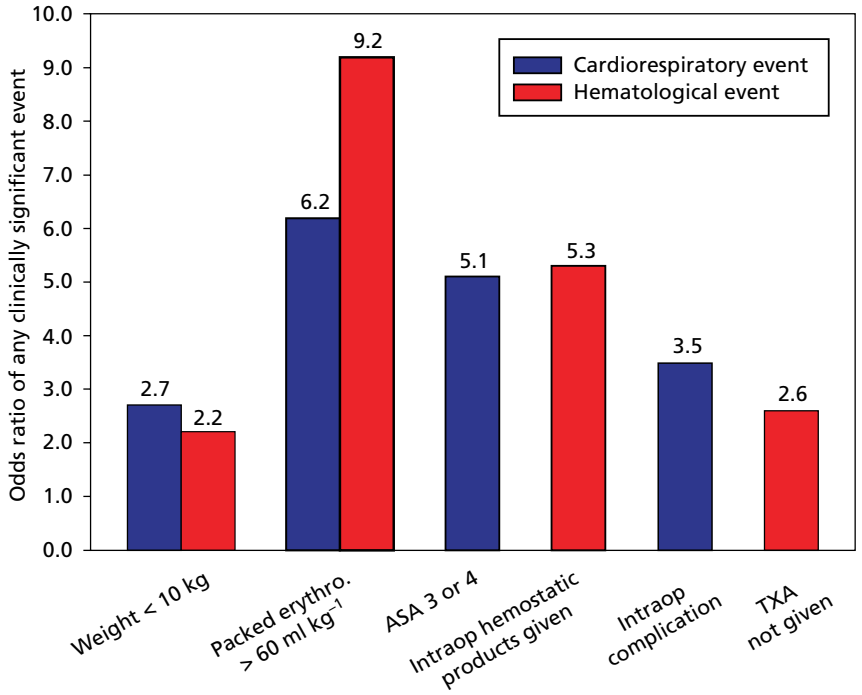

Figure 36.33 Odds ratios for the six multivariate predictors of any clinically significant postoperative event requiring ICU admission. The multivariate risk factors include bodyweight <10 kg, packed erythrocyte transfusion >60 mL/kg, ASA class 3 or 4, hemostatic blood product transfusion (platelets, fresh frozen plasma, and/or cryoprecipitate), intraoperative complication, and tranexamic acid (TXA) not given. *Source*: Reproduced from Goobie et al [171] with permission of Wolters Kluwer.

Figure 36.34 "Kilner Dott" mouth gag in place for cleft palate repair in a patient with Pierre Robin sequence (bifid uvula). The metal armored tube is safely secured under the lower part of the mouth gag.

dislodgment. Adequacy of the airway should be continuously assessed, especially after patient positioning and placement of a mouth gag or pharyngeal packs. For palate and pharyngeal procedures, correct positioning may require exaggerated neck extension, which may bring the endotracheal tube up and out of the trachea. A mouth gag provides surgical exposure and stabilizes the endotracheal tube, but it may also occlude the tracheal tube (Fig. 36.34). Pharyngeal packs are placed to prevent aspiration of blood. Compression or kinking of the tube may occur with these maneuvers. Care should be taken by the surgeon to avoid contacting the tracheal tube with a cautery, as this may cause an airway fire. The FiO_2 should be <0.3 when possible.

Other anesthesia considerations are routine. Fluid and temperature homeostasis must be maintained. Blood loss is rarely sufficient to require transfusion, although it is occasionally necessary in palate and pharyngeal procedures, especially when the hemoglobin concentration is at least 10 g preoperatively. Inhalation anesthesia is commonly used, but the choice of anesthetic agent is not crucial as long as the considerations outlined here are accommodated.

KEY POINTS: ANESTHESIA FOR CLEFT LIP AND CLEFT PALATE RECONSTRUCTION

- Patients with a cleft palate have Eustachian tube dysfunction and usually have chronic serous otitis with clear rhinorrhea
- Most patients with an isolated cleft lip or palate present no difficulty with airway management
- For palate and pharyngeal procedures, surgical positioning may require exaggerated neck extension, which may displace the endotracheal tube out of the trachea
- The most common acute postoperative problems are bleeding and airway obstruction

Postoperative management

The most common acute postoperative problems are bleeding and airway obstruction. At the conclusion of palate and pharyngeal surgery, the pharynx must be inspected for bleeding and the presence of pharyngeal packs. Leaving a pharyngeal

pack in place can be lethal when the endotracheal tube is removed. Some surgeons place a heavy silk tongue suture which is secured to the face, to allow for rapid opening of the airway with traction on the suture for anterior displacement of the base of the tongue. Placing the infant or child in the lateral position permits drainage of blood and secretions from the pharynx. Extubation of the trachea should be delayed until the patient is fully awake and has regained normal neuromuscular function to minimize potential airway obstruction from either anatomical causes or from bleeding. Applying a mask or artificial airway may damage a lip or nose repair, so it is advisable to delay extubation until the patient can maintain a patent airway without assistance. After lip procedures, infants are restrained with arm boards to prevent them from disrupting the repair.

After a palatoplasty or pharyngoplasty, the infant or child awakens from anesthesia with an altered upper airway. The presence of constricting flaps and nasopharyngeal edema compromises the nasal airway and may abruptly convert the child to a mouth breather. This problem is magnified in patients who have Pierre Robin complex. After pharyngoplasty, 10% or more of patients experience temporary obstructive sleep apnea [173]. Sleep apnea is completely eliminated when the surgical technique is modified and a nasopharyngeal airway is kept in place for the first 48 h after surgery. Fifty-seven percent of patients are predominantly or exclusively mouth breathers after palatoplasty or pharyngoplasty [174]. Up to 72% of patients develop sleep apnea after pharyngoplasty.

Pharyngeal anomalies are common with craniofacial syndromes and place the patients at high risk for airway obstruction, especially after pharyngoplasty [174]. The anomalies may be structural (pharyngeal narrowing related to malformation of the basicranium (Treacher Collins syndrome) or mandibular (Robin sequence). They may also be functional, e.g. the pharyngeal hypotonia of the velocardiofacial syndrome. One patient died 4 weeks after surgery [175].

Acute postoperative airway obstruction caused by massive lingual swelling has also been reported after palatoplasty. The mouth and tongue should be carefully inspected before tracheal extubation, particularly if the mouth gag has been in place for more than 2 h. If the mouth gag must be in place for 2 h, it should be let down for a few minutes to allow the tongue to be perfused. The lingual swelling is often the result of a reperfusion injury.

Infiltration of local anesthetic will decrease the need for postoperative analgesia. Non-narcotic analgesics are preferred, but when narcotics are required they should be titrated to effect. Infraorbital nerve blocks can be performed while the patient is asleep to prevent pain after cleft lip surgery [176,177]. Postoperative pain therapy can be guided by using pain scales [178–180].

CASE STUDY

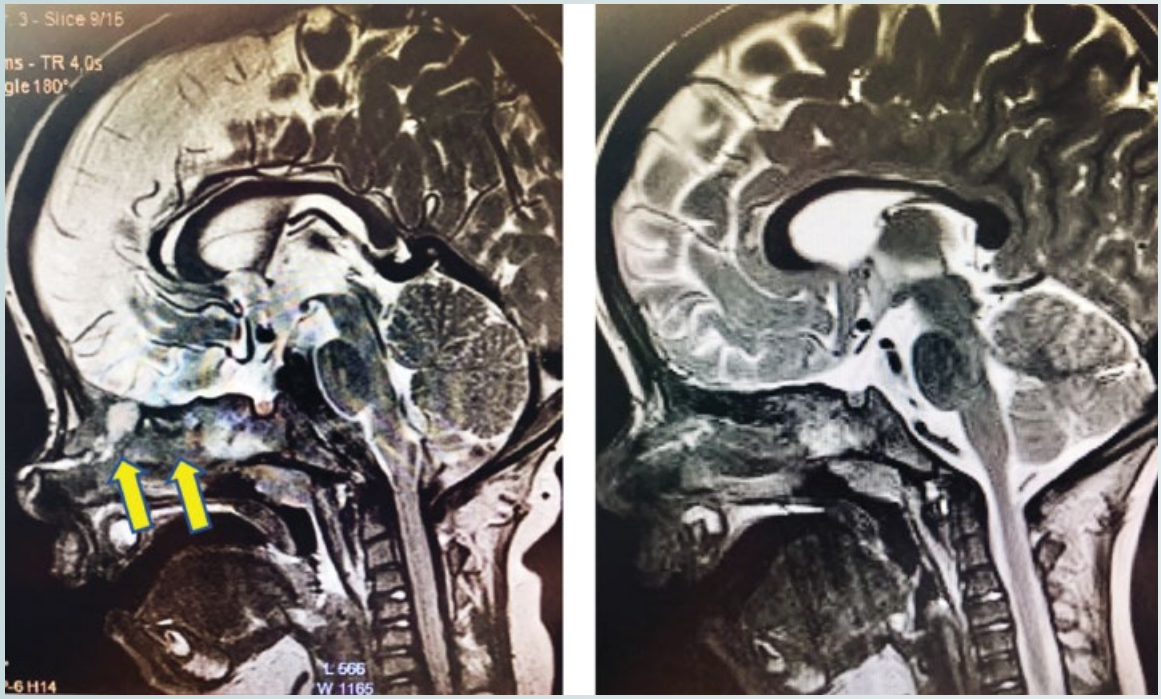
A 2-year-old, 10.8 kg, 84 cm tall, male patient was scheduled for resection of a congenital dermal sinus of the nose together with a resection of an epidermoid tumor located subcranially at the base of the scull (Fig. 36.35A). The planned procedure was a cranioplastic surgery with a fronto-orbital advancement. There were no congenital genetic disorders, but the patient had undergone multiple surgeries due to a congenital heart defect. The boy was a preterm infant (34 weeks of gestation, birthweight 2200 g). The primary diagnosis at that time was a tricuspid atresia type Ib. The patient underwent a cavopulmonary anastomosis ("Glenn" operation) at the age of 5 months. Since then he was doing well hemodynamically with routine cardiology follow-up. Another problem was that the child had chronic, multiple episodes of aspiration and pneumonias of unclear etiology. Bodyweight gain and overall development were normal. Baseline pulse oximeter saturation of the child was between 79% and 85%. He was receiving anticongestive medication together with a low dose of aspirin. The preoperative echocardiography revealed normal myocardial function, no mitral regurgitation, and a patent cavopulmonary anastomosis.

Considerations for anesthesia

Because it was suspected that a large amount of blood might be lost during surgery, 4 units of packed red blood cells (PRBC) and 2 units of FFP were available for the patient preoperatively. Additionally, the patient was on anticoagulants and therefore platelets were ordered too. The use of an antifibrinolytic agent, e.g. TXA (initial dose 10 mg/kg bodyweight by bolus followed by 5 mg/kg/h), was planned. Because of the cyanotic congenital cardiac disease the goal was to maintain a high hemoglobin (14–15 g/dL) throughout the procedure. The anesthesiologist decided to administer blood and blood components (FFP) early in the case to prevent low hemoglobin in order to maintain patient-adjusted "normal" oxygen carrying capacity. Because patients with cavopulmonary anastomosis benefit from spontaneous breathing rather than mechanical ventilation, early extubation was the primary goal. Normally it is preferred to perform nasal intubation in small children because of improved tube fixation and ease of weaning ventilation in the emerging patient. In this case, the nose had to be free so oral intubation was preferred. Meticulous attention to prevention and detection of venous air embolism is important for all craniofacial surgery, and even more so in cyanotic congenital heart disease. In this patient, venous air from the surgical site would travel down the superior vena cava and enter the pulmonary arteries, potentially causing obstruction. Systemic air in the arterial circulation would not be expected.

Induction of anesthesia

Anesthesia was induced with propofol (2.5 mg/kg) and remifentanil (1 μg/kg) with oxygen. Special care was taken to keep the intrathoracic pressure as low as possible to ensure unobstructed venous backflow to the heart. Tracheal intubation with direct laryngoscopy was facilitated by



(A) (B)

Figure 36.35 Preoperative (A) and postoperative (B) MRI scans of a dermal sinusoid together with a skull based epidermoid tumor. The arrows in (A) point to the tumor.

administering rocuronium (1 mg/kg). No further muscle relaxation was needed during the case. An orogastric tube and a urinary catheter and temperature probe were placed into the urinary bladder after induction of anesthesia. Sevoflurane and remifentanil (0.3–0.5 μg/kg/min) were used to maintain anesthesia. The inspired oxygen fraction was 0.3 to maintain a SaO_2 between 75% and 85%. Thirty minutes before the end of anesthesia, a longer acting opioid, together with a NSAID, was administered.

Cardiovascular monitoring

A double-lumen 4 Fr central venous catheter was inserted in to the right femoral vein to measure cardiovascular pressure continuously. The internal jugular vein was avoided because of the cavopulmonary connection with its high venous pressure equal to pulmonary artery pressure, to not take any chance of obstructing cerebral venous drainage. Another large-bore peripheral IV was added after induction. The right radial artery was cannulated with a 22-gauge catheter for on-line arterial blood pressure monitoring and blood sampling. Monitoring in the perioperative period consisted of continuous measurement of arterial and venous pressures, temperature (via the urinary catheter), oxygen saturation by pulse oximetry, end-expired CO_2, and urine output. Blood gases, pH, electrolytes, and glucose and lactate concentrations were measured every 1 h or more frequently, as required. Venous oxygen saturation was determined from central venous blood samples and used to estimate cardiac output and blood volume status, although it must be remembered that in patients with a femoral venous catheter with its tip in the inferior vena cava, the measured venous saturation is not equal to the central venous saturation in the superior vena cava – it is normally higher. For this case the trend over time was most important, not the absolute values.

Airway management

Preoperatively there was no concern that oral tracheal intubation might be difficult. The patient's mouth opening was not limited and he had been intubated easily for previous surgery. Therefore, equipment for fiberoptic tracheal intubation was not necessary for this patient. It was known from his previous surgeries that facemask ventilation was without problems. Because the patient would be in the prone position, free access to the nose and airway was not possible due to fronto-orbital advancement (see Fig. 36.20), so an armored oral tracheal tube was inserted. Care was taken to fix the tracheal tube securely to the face with liquid adhesive and tape to avoid accidental tracheal extubation during surgery. Because surgery would last several hours, great care was taken to prevent the compression of soft facial tissues (eyes, nose) when the patient was placed in the prone position (see Fig. 36.32).

Body temperature

Care was taken to prevent intraoperative hypothermia for several reasons. First, to prevent inhibition of the coagulation system; second, to prevent hypoperfusion and local ischemia (e.g. metabolic acidosis and lactate production); and third, to prevent hypoventilation and respiratory acidosis once spontaneous ventilation returned and the trachea was extubated. Prevention of hypothermia would also avoid the negative effects of shivering and cardiovascular depression after surgery.

Intraoperative management

After induction of anesthesia and insertion of the tracheal tube, the surgeons and anesthesiologists together positioned the patient for surgery. Maintenance fluid consisted of acetate buffered Ringer solution with 1% dextrose added (4 mL/kg/h) to maintain a normal glucose concentration. Volume losses were initially replaced with 4 mL/kg/h of Ringer solution without dextrose as needed. During reflection of the scalp, packed red blood cells and FFP (5 mL/kg each) were administered. The primary goal was to maintain a supranormal hemoglobin concentration of >14 g/dL due to the palliated congenital heart defect. Once the scalp and bone were reflected and surgical coagulation was accomplished, PRCBs and FFP were given as needed to maintain the hemoglobin concentration and to prevent bleeding. Despite prophylactic administration of PRBCs, the hemoglobin concentration decreased below initial values (Table 36.5). The estimated blood loss during surgery was 340 mL, about 40% of the patient's blood volume. These losses were initially replaced with Ringer solution and then with PRBCs and platelets (15 mL/kg) at the end of the procedure. Heat loss was prevented by wrapping the patient's extremities with sheet wadding and by actively warming him with a thermal blanket and warmed-humidified inspired gases. Despite this he initially lost about 1°C in body temperature. Anesthesia was maintained with a combination of sevoflurane and remifentanil, as described earlier.

Because the intraoperative period was uneventful and because spontaneous ventilation returned and was adequate, the trachea was extubated in the operating room once the child was awake as planned before the operation. The oxygen saturation measured with pulse oximeter was 90% 15 min after extubation. He was transferred to the PICU to monitor for bleeding and for signs of elevated intracranial pressure. Postoperative blood loss was 75 mL, which was replaced with PRBCs. Tracheal extubation occurred at the end of surgery because (1) it was superior to positive pressure ventilation to ensure unobstructed venous backflow through the cavopulmonary anastomosis, and (2) it was felt that it would be easier to monitor for signs of increased intracranial pressure if the patient was awake and spontaneously breathing, remembering that because of the cavopulmonary connection with its elevated pressure, the margin of safety for elevated ICP is smaller. The patient was positioned with head elevated 30°, both to minimize edema and bleeding, and to facilitate venous drainage through the cavopulmonary connection. Postoperative fluid administration was restricted to that which maintained urine output at about 1 mL/kg/h. This fluid restriction was done to reduce the likelihood of increasing ICP and of causing pulmonary edema. The day after surgery all monitoring lines were removed, and the patient was transferred to the ward in good condition. He was discharged home several days later and has done well. The postoperative MRI several months later revealed a good surgical result (Fig. 36.35B).

Conclusions

This case demonstrates several important points.

- Because of the underlying additional congenital heart defect the oxygen content of the blood needed to be maintained throughout surgery. Patient-adjusted "normal" hemoglobin values (>14 g/dL) were required. Blood loss is common in these cases, especially when there has been previous surgery. This child lost 340 mL of blood during the case despite an infusion of PRBCs and plasma at the beginning of the case and attempts to maintain normal coagulation. Adequate fluid and blood products were administered to maintain normal arterial and central blood pressures and to prevent metabolic acidosis.
- Patients with cyanotic heart defects may have coagulation disorders due to platelet dysfunction (see Chapter 27). In those cases the use of an antifibrinolytic agent,

e.g. tranexamic acid (initial dose 10 mg/kg bodyweight by bolus followed by 5 mg/kg/h), is recommended. Additionally, platelets must be available because the patient was on anticoagulants preoperatively. There is a fine balance required. One does not want to have excessive bleeding, and at the same time one does not want to cause excessive clotting that may obstruct the child's cavopulmonary shunt.

- It is important to take measures to maintain a normal body temperature during surgery, especially when it is desirable to extubate the trachea at the end of the surgery. Hypothermia may cause hypoventilation, increased $PaCO_2$, and increased intracranial pressure. If the case lasts long enough, hypothermia may cause clotting abnormalities and increase intraoperative bleeding. Maintaining a normal body temperature must be balanced against the fact that a 1–2°C reduction in brain temperature is neuroprotective (see Chapter 8).
- Measuring intravascular pressures and urine output during surgery helped determine the adequacy of fluid and blood products replacement. Urine glucose concentrations were measured several times during the case because high concentrations of glucose in the blood may cause an osmotic diuresis that gives the false impression of normal urine flow, even in hypovolemic patients.

CHAPTER 37
Pain Management in Children

Christine Greco and Charles Berde
Department of Anesthesiology, Perioperative, and Pain Medicine, Children's Hospital, Boston; and Harvard Medical School, Boston, MA, USA

Introduction

The management of pain and related symptoms is part of the daily practice of pediatrics, pediatric anesthesiology, and pediatric intensive care. In this chapter, we will outline aspects of how the experience of pain changes with age, how analgesics act at different ages, and how to treat some common acute and chronic pain conditions in pediatrics.

Developmental neurophysiology of pain

Studies by Fitzgerald and others have shown that there is considerable maturation of peripheral, spinal, and supraspinal neurological pathways necessary for nociception by late in the second trimester of human gestation [1]. Although the general architecture of the sensory nervous system is established by midgestation, there are some differences in preterm and term neonates compared with older infants as patterns of connections and functions mature over the first months of life. Peripheral sensory fibers involved in nociception have larger, more overlapping, receptive fields and lower thresholds for impulse activation in infant animals, compared with mature animals [2]. Descending pain inhibitory pathways, such as the dorsolateral funiculus [3], tend to develop postnatally. This has been interpreted to suggest that neonates and young infants may perceive pain more intensely or have hyperresponsiveness to pain compared with older infants and children with a more mature nervous system.

Many of these initial studies emphasized maturation of peripheral and spinal mechanisms and simple withdrawal reflexes. More recently, attention has focused on cortical representation of responses to injury in neonates and young infants [4]. Studies of brain activation using near-infrared spectroscopy have shown that a noxious stimulus to the heel of a neonate evokes increased signals overlying the contralateral cerebral cortex [4]. This implies that a specific pattern of activation occurs in response to a noxious stimulus as opposed to the global, non-specific pattern of activation seen with autonomic arousal. This and other evidence suggests that painful stimuli reach the cerebral cortex in infants although this evidence does not establish that pain is perceived as a conscious experience or as suffering in neonates. Despite the delay in the development of spinal descending pathways and neurotransmitters, α-adrenergic agonists and opioids administered via epidural or spinal routes exert analgesic effects in newborn animals [5,6] and humans [7,8]. Adult functional magnetic resonance imaging (fMRI) studies of cortical networks involved in pain have emphasized activation of both somatosensory pathways as well as pathways involved in salience, emotion, learning, and fear. Recent fMRI studies of brain activation from noxious events have found extensive overlap of regional brain activation, but with some differences [9–11].

Several studies have been interpreted as providing evidence that infants are able to form implicit memory of pain and that there are potentially negative behavioral consequences of untreated pain in infants. Taddio showed that infants who were circumcised with little or no analgesia had significantly increased pain behaviors at their 2-, 4-, and 6-month immunizations when compared with infants who were uncircumcised or who had received adequate analgesia [12]. Studies of adult rats who had received persistent inflammatory stimuli as neonates showed long-term changes in the dorsal horn synaptic organization and nociceptive functioning [13]. Newborns undergoing major surgeries when

Gregory's Pediatric Anesthesia, Sixth Edition. Edited by Dean B. Andropoulos and George A. Gregory.

randomized to relatively light versus relatively deeper anesthetic techniques showed better suppression of stress responses with deeper anesthetic techniques, as well as some reductions in postoperative morbidities [14–17]. Conversely, studies of critically ill newborns undergoing mechanical ventilation have not shown a clear benefit from routine administration of morphine infusions compared with controls who just received intermittent morphine prior to suctioning or other painful procedures [18].

Pain assessment in infants and children

Assessing pain in infants and children is a fundamental aspect of pediatric care and serves as the foundation for treating pain. Most pain assessment tools for infants, toddlers, and preschool children are based on the developmental age of the child and often combine behavioral and physiological parameters, since self-report measures may not be possible in preverbal children or accurate in hospitalized young children. Readers interested in this topic are referred to a consensus statement on pediatric pain measurement [19]. Studies indicate that healthcare providers tend to underestimate pain using observational measures compared with parents' or children's own ratings. Children who are ill, hospitalized, and confronted with strangers may not participate with self-report measures; pain assessment tools designed for younger children may be more useful in these cases.

Pain assessment in infants and preterm babies is particularly challenging. Infants rely on caregivers to interpret their behavior and other signs in determining whether they have pain. Numerous studies have examined pain responses in infants and have shown that infants exhibit predictable response patterns with respect to stress hormone levels, behavior patterns, and changes in heart rate, oxygen saturation, blood pressure, and other physiological patterns. Neonates who are subjected to repeated heel lancing for blood analyses consistently swipe at the affected foot, indicating their ability to localize to the site of pain. Infants display gradations in heart rate, blood pressure, and oxygen saturation in response to varying intensities of pain, indicating their ability to discriminate severity of pain. Nevertheless, physiological parameters are non-specific indicators of pain and can reflect fear, hunger, anxiety, and emotional distress as well as pain [20]. As a result of these studies and others, pain assessment tools in infants are typically composite pain scores that combine observed distress behaviors such as facial grimacing, sleep–wake cycles, and body posture with physiological parameters, including heart rate, oxygenation, and blood pressure measurements. Behavioral responses to pain in premature infants may be much more subtle than those observed in full-term infants. In addition, behavioral and physiological pain scales are not applicable to critically ill infants who may be septic, hemodynamically unstable, or mechanically ventilated. The premature infant pain profile (PIPP) is a pain assessment tool for procedural pain that has been validated in premature and full-term infants (Table 37.1) [21]. The PIPP is unique in that gestational age is included in the scoring system in addition to distress behaviors, heart rate, and oxygen saturation. The FLACC scale combines five types of pain behaviors, including facial expression, leg movement, activity, cry, and consolability, and has been shown to have good inter-rater reliability and validity in children (Table 37.2) [22]. It is widely used because it is quick, versatile, and can be applied to infants and older children, including those with developmental disabilities [23].

Concrete thinking and variations in cognitive and language development in toddlers and preschool-age children can make pain assessment challenging in this age group. Preschool age children are often able to give simple measures of self-report such as location of pain but cannot provide more abstract details such as quality of pain. It is generally useful to involve parents or other familiar caregivers when questioning young children about their pain. A variety of pain assessment tools have been developed for young children. Studies indicate that many children tend to prefer faces scales where pictorial representations of faces are used to denote varying degrees of pain. Young children are able to differentiate pain intensity when presented with facial expressions, although more than five choices seems to interfere with the child's ability to reliably indicate pain. The Oucher scale (Fig. 37.1),

Table 37.1 Premature infant pain profile (PIPP)*

Indicators	0	1	2	3
Gestational age in weeks	≥36 weeks	32–35 weeks and 6 days	28–31 weeks and 6 days	<28 weeks
Observe the NB for 15 s alertness	Active	Quiet	Active	Quiet
	Awake	Awake	Sleep	Sleeping
	Opened eyes	Opened eyes	Closed eyes	Closed eyes
	Facial movements present	No facial movements	Facial movements present	No facial movements
Record HR and SpO_2				
Maximal HR	↑ 0–4 bpm	↑ 5–14 bpm	↑ 15–24 bpm	↑ ≥25 bpm
Minimal saturation	↓ 0–2.4%	↓ 2.5–4.9%	↓ 5–7.4%	↓ ≥7.5%
Observe NB for 30 s†				
Frowned forehead	Absent	Minimal	Moderate	Maximal
Eyes squeezed	Absent	Minimal	Moderate	Maximal
Nasolabial furrow	Absent	Minimal	Moderate	Maximal

* In this scale, scores vary from 0 to 21 points. Scores equal to or lower than 6 indicate an absence of pain or minimal pain; scores above 12 indicate the presence of moderate to severe pain.

† Absent is defined as 0–9% of the observation time; minimal, 10–39% of the time; moderate, 40–69% of the time; and maximal as 70% or more of the observation time.

bpm, beats per minute; HR, heart rate; NB, newborn.

Table 37.2 The faces, legs, activity, cry, and consolability (FLACC) scale

Category	Scoring		
	0	1	2
Face	No particular expression or smile	Occasional grimace or frown, withdrawn, disinterested	Frequent to constant quivering chin, clenched jaw
Legs	Normal position or relaxed	Uneasy, restless, tense	Kicking, or legs drawn up
Activity	Lying quietly, normal position, moves easily	Squirming, shifting back and forth, tense	Arched, rigid or jerking
Cry	No cry (awake or asleep)	Moans or whimpers, occasional complaint	Crying steadily, screams or sobs, frequent complaints
Consolability	Content, relaxed	Reassured by occasional touching, hugging, or being talked to, distractable	Difficult to console or comfort

Each of the five categories face (F), legs (L), activity (A), cry (C), and consolability (C) is scored from 0 to 2, which results in a total score of between 0 and 10.

Figure 37.1 Oucher pain scale.

the Wong–Baker scale (Fig. 37.2) and the Bieri faces scale (Fig. 37.3) are examples of face scales that have been validated for use in children as young as 4 years of age. The Oucher scale, developed for use with children of all ethnicities, uses actual photographs of children and is available in several versions, each tailored to child ethnicity. Among the different face scales, in our view there are some psychometric advantages to the revised faces pain scale by Hicks et al [24]. Parental responses can affect a child's levels of observed behavioral distress and increased parental anxiety tends to correlate with increased levels of self-report pain scores in children undergoing painful procedures. Older school-age children and adolescents usually have the emotional and cognitive maturity as well as the language development to use self-report scales, although self-report is sometimes not accurate in this age range due to issues regarding behavioral control and self-esteem. Illness, hospitalization, and separation from parents may cause some older children and adolescents to regress emotionally, making pain scales designed for younger children more applicable. The meaning that pain has for a child also can influence their self-report. The color analog scale (Fig. 37.4) is a slide-rule device where gradations of color are used to denote degree of pain which has been validated for use in children as young as 5 years [25].

Pain assessment should be part of everyday practice in caring for hospitalized children. A successful, hospital-wide pain assessment program requires a committed, multidisciplinary team of healthcare providers, standard protocols of assessment methods and documentation, staff and parental education programs, and protocols for reassessment after pain treatment interventions. Essential to pain assessment is the use of validated, age-appropriate pain assessment tools as well as consideration of the child's developmental level, presence of fear and anxiety, parental factors, and the context of the child's pain.

KEY POINTS: PAIN ASSESSMENT IN CHILDREN

- Pain assessment for preverbal children is based on developmental age and combines behavioral and physiological parameters
- The FLACC scale and PIPP system are validated for young infants
- Faces scales, including Oucher, Wong–Baker, and Bieri, are validated for children as young as 4 years
- Visual or color analog scales can be used for older children

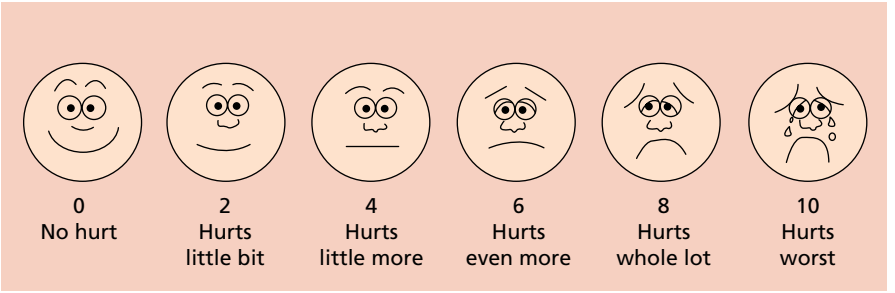

Figure 37.2 Faces (Wong–Baker) pain scale.

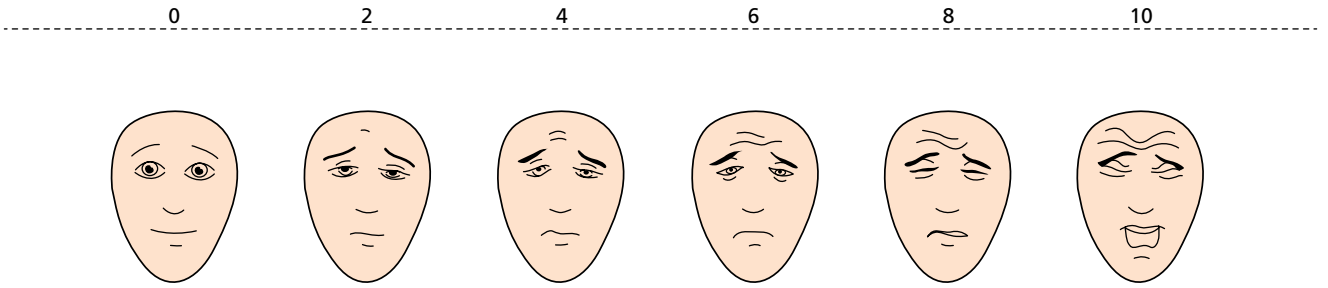

Figure 37.3 Faces pain scale revised (FPS–R) version.

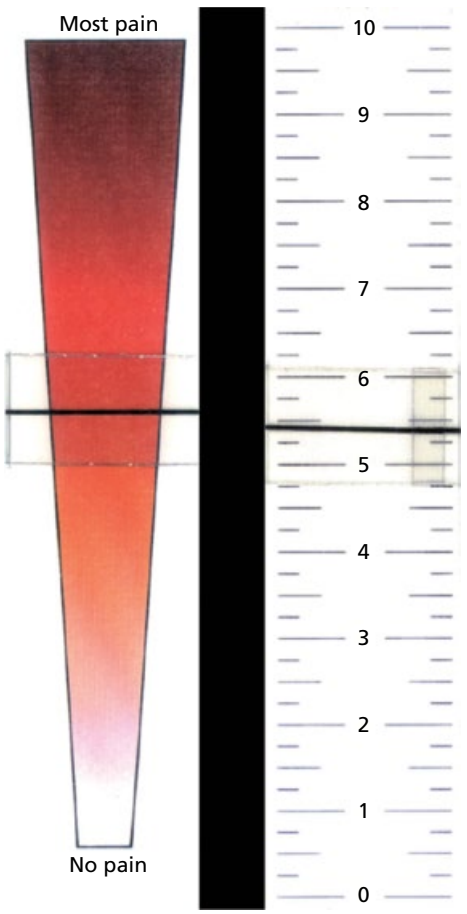

Figure 37.4 Color analog pain scale.

Developmental analgesic pharmacology in infants and children

A number of pharmacokinetic and pharmacodynamic factors produce age-related differences in responses to analgesics [26]. Neonates and young infants have immature hepatic enzyme systems involved in conjugation, glucuronidation, and sulfation of analgesics such as opioids and amide local anesthetics, causing prolongation of the elimination half-life and increasing the risk of drug accumulation. Rates of maturation of individual enzyme functions vary, but for most analgesics, metabolism has matured by around age 6 months. Glomerular filtration and renal tubular secretion are reduced in the first several weeks of life. Along with slower elimination of some native drugs that depend primarily on renal clearance, renal immaturity also results in a slower elimination of glucuronides of morphine and hydromorphone (which produce analgesia, sedation, respiratory depression, and excitatory reactions) and slow elimination of MEGX, a principle metabolite of lidocaine, which can cause seizures. Neonates and young infants have reduced levels of α1-acid glycoprotein and albumin, leading to decreased plasma protein binding for many drugs and increased concentrations of free, pharmacologically active, unbound drug. Infants have immature ventilatory reflexes in response to hypoxia [27,28] and hypercarbia [29]. The increased risk of hypoventilation in response to opioids in infants observed in clinical case series [30] probably reflects a combined effect of pharmacokinetic and pharmacodynamic immaturity, as well as the impact of disease states that are over-represented in hospitalized infants.

Non-opioid analgesics

Non-opioid analgesics refer to acetaminophen, aspirin, the non-steroidal anti-inflammatory drugs (NSAIDs), and the selective cyclo-oxygenase 2 (COX-2) inhibitors. COX enzymes convert arachidonic acid to various prostaglandins that have diverse physiological roles, contributing to pain, hypersensitivity, inflammation, thermoregulation, vasodilation, and protection of gastric mucosal integrity. The COX isoenzymes differ in their distribution and function in a variety of peripheral tissues and in the central nervous system. Aspirin and NSAIDs act on a broad spectrum of COX enzymes. Aspirin's irreversible inhibition of COX-1 in platelets contrasts with the reversible action of NSAIDs; this accounts for the much longer duration of aspirin's antihemostatic actions. The COX-2 inhibitors were

developed to specifically inhibit the COX isoenzyme subtype 2, which is expressed preferentially in leukocytes and other cell types involved in inflammation, as well as in neurons and glial cells in the peripheral and central nervous systems. While these drugs are commonly regarded as "peripheral" analgesics, analgesia from all of these drugs involves a combination of peripheral and central actions [31].

Ontogeny of prostanoid biosynthesis and cyclo-oxygenases

Studies by Ririe and co-workers have shown that administration of a COX-1 inhibitor does not reduce hypersensitivity to mechanical stimuli in infant rats. This lack of efficacy of COX-1 inhibitors in infant rats appears to be a result of developmental differences in the COX-1 expression in the spinal cord [32]. The data raise the question of whether commonly used analgesics acting on COX isoforms might be ineffective in infants due to delayed maturation of COX-mediated processes in spinal microglia.

Acetaminophen

Acetaminophen is one of the most widely used analgesics and has a good safety record for use in pediatric patients. It is often combined with opioids for additional analgesic effect. Acetaminophen is also sometimes dosed alternating with ibuprofen, although there are no clinical trials examining the effectiveness of this approach. Although the actual mechanism of analgesic and antipyretic action is somewhat controversial, acetaminophen seems to have an effect on the COX-3 isoenzyme, on endogenous cannabinoid receptors, and on TRPV1(transient receptor potential cation channel subfamily V member 1) receptors [33]. Cannabinoid receptor type 1 (CB1) and TRPV1 receptors are involved in pain and thermoregulatory pathways. Acetaminophen's analgesic actions appear to occur largely via sites within the central nervous system, though there is controversy regarding the importance of central COX-3 inhibition in acetaminophen's analgesic effects [34]. When compared with NSAIDs, acetaminophen exerts minimal peripheral anti-inflammatory effects and is associated with significantly less gastropathy, platelet dysfunction, and anti-inflammatory effect. Approximately 90% of acetaminophen undergoes sulfation and glucuronidation to water-soluble products, which are then eliminated by the kidneys. A small percentage of acetaminophen is metabolized by the CYP450 system to a toxic metabolite that binds to glutathione to form a non-toxic conjugate. Inadvertent dosing errors have led to fulminant hepatic necrosis and failure in infants and children when large doses overwhelm the binding capacity of existing hepatic glutathione stores. Therapeutic oral doses of 10–15 mg/kg result in peak plasma concentrations after 2–3 h. Pharmacokinetic studies show that peak plasma concentrations of IV acetaminophen are greater and are achieved more rapidly compared to oral dosing with evidence of good cerebrospinal fluid penetration [35,36]. The use of IV acetaminophen has been shown to be cost effective for pediatric tonsillectomy and idiopathic scoliosis surgery due to reduced adverse events and reduced postanesthesia care unit or hospital length of stay [37,38].

Because rectal absorption is inefficient and variable, peak drug levels with rectal dosing generally peak at 70 min but can vary considerably. Some studies have recommended much higher dosing than traditionally prescribed: rectal dosing with a first dose of 30–45 mg/kg followed by 20 mg/kg every 6–8 h produced generally therapeutic blood concentrations in several studies [39]. Even though the overall bioavailability of rectal acetaminophen is roughly half that of oral formulations, previous recommendations by the American Academy of Pediatrics have listed the same daily maximum doses for oral and rectal acetaminophen.

The analgesic efficacy of acetaminophen in newborns has not been established in controlled clinical trials. One study of rectal dosing of acetaminophen in infants following major surgery was negative [40,41], while a subsequent study by the same group of investigators found evidence for an analgesic/opioid-sparing effect of intravenous acetaminophen in a similar population [42].

It remains unclear whether some of these negative results reflect a true lack of efficacy due to any of the following: delayed maturation of the analgesic targets of acetaminophen, variable absorption, inadequate sensitivity of the pain models used, insensitivity of the pain measures used, or wash-out of treatment effects by the choice of an overly generous rescue analgesic regimen [43].

Non-steroidal anti-inflammatory drugs

The NSAIDs are widely prescribed as antipyretics, analgesics, and anti-inflammatory agents in children and, considering their widespread use, have a very good safety margin. They are often combined with opioids for improved analgesic effect and to reduce opioid use and side-effects. They are often first-line therapy for inflammatory pain. They produce their anti-inflammatory effect by reversibly inhibiting COX-1 and COX-2 isoenzymes and inhibiting the conversion of arachidonic acid to prostanoids. The clearances of several NSAIDs are slower in neonates and infants but more rapid in young children aged 3–10 years when compared with adults [44]. In postsurgical patients randomly assigned to receive an NSAID or placebo, with parenteral opioids as rescue analgesics, the NSAID groups typically show both lower pain scores and a 30–40% reduction in opioid use. Other studies have shown that standard doses of NSAIDs produce more effective analgesia than 30–60 mg of codeine in adults following surgery [45].

The incidence of serious side-effects from NSAIDs is very low in children 6 months and older, particularly with short-term use. A large-scale study in young children less than the age of 2 years of age receiving ibuprofen showed a very low incidence of serious side-effects [46]. There are few efficacy data on the use of NSAIDs in neonates. Many of the pharmacokinetic and safety data for use in neonates come from the use of ibuprofen and indomethacin in treating patent ductus arteriosus; ibuprofen appears to have less renal toxicity and less risk of hyponatremia than indomethacin in this age group. Many of the safety data for long-term use of NSAIDS are based on experience in treating juvenile rheumatoid arthritis [47]. Although children frequently complain of mild gastrointestinal upset with long-term NSAID use, serious gastropathy, gastrointestinal bleeding, and renal toxicity appear to be less common in children than adults. The risk of NSAID-induced renal toxicity can be increased in states of dehydration, concomitant use of other nephrotoxic drugs, use in pre-existing renal disease, and hypotension.

The use of NSAIDs in children undergoing tonsillectomy has become increasingly common over the past 10 years. NSAIDs are an attractive choice in patients with obstructive sleep apnea who are at risk for airway obstruction and hypoventilation with opioids after a tonsillectomy. Moreover, in a large number of analgesic trials and meta-analyses for tonsillectomy, NSAIDs provide good analgesia. Previously, there had been concern

regarding the impact of NSAIDs on immediate and delayed postsurgical bleeding that can occur after a tonsillectomy. While results of initial meta-analyses gave conflicting results, subsequent meta-analyses have largely found no significant impact of NSAIDs on clinically important bleeding events [48–50]. At Boston Children's Hospital, as with many pediatric centers around the USA, practice has changed towards the use of NSAID–acetaminophen combinations as a routine analgesic regimen for pain after tonsillectomy. COX-2 inhibitors for tonsillectomy are reviewed in a subsequent section.

Another controversy surrounding the use of NSAIDs is the concern of bone healing in postsurgical patients who require active bone formation, such as children with scoliosis who have undergone posterior spinal fusion and instrumentation. NSAIDs and COX-2 inhibitors clearly provide good analgesia and reduced opioid requirements for several types of orthopedic surgery [51]. NSAIDs are thought to interfere with bone healing since prostanoids produced by osteoblasts are associated with new bone formation and are involved with the balance between bone formation and bone resorption. Meta-analyses of case–control and cohort studies have suggested that the effects of short-term use of NSAIDs in most patient groups are clinically minor [52]. Reviews of heterotopic bone formation in adult patients after hip replacement have suggested a higher frequency of non-union; however, the number of patients studied was small and other risks for non-union may have been present. A meta-analysis of the effects of NSAIDs in adult patients with spinal fusions showed that short-term use of normal-dose NSAIDs appear to be safe after spine fusion but high-dose ketorolac increased the risk of non-union, implying that the risk may be in part dose dependent [53,54]. In general, children seem much less likely than adults to have impaired bone healing after surgery. In many pediatric centers, there is a growing trend towards use of NSAIDs following most types of orthopedic surgery, including scoliosis surgery, based on their opioid-sparing effects and major role in enhanced recovery after surgery (ERAS) protocols [55,56], as discussed further later in this chapter.

These authors' recommendation is to adopt a middle course pending more specific data on clinical outcomes and risks. For children at high risk for non-union or impaired bony fusion, NSAIDs probably should be avoided. Conversely, for children who are at comparatively low risk of non-union, who have had severe and difficult to control side-effects from opioids, or who have significantly increased risks from opioids, an NSAID or COX-2 inhibitor can be administered for 1–2 days postoperatively. Some studies suggest that selective COX-2 inhibitors are less likely to inhibit bone formation than traditional NSAIDs.

Ketorolac is a commonly prescribed parenteral NSAID often used as an adjuvant to opioids in the postoperative period. Despite the common belief regarding the "magic" of a parental route, ketorolac provides no stronger analgesia than other NSAIDs when given in recommended or equitoxic doses. Typical doses are 0.25 mg/kg every 6 h for a maximum of approximately 5 days. The recommendation duration of 5 days is based on the pivotal adult studies used to obtain US Food and Drug Administration (FDA) approval for postoperative use and because of an impression that more prolonged use further increases the risks of adverse events, especially gastropathy. In a randomized controlled trial of infants and children undergoing cardiac surgery, ketorolac did not increase the risk of surgical bleeding or gastrointestinal bleeding [57]. Small case series have not reported harm with use after surgeries in neonates and young infants [50,51], though larger prospective studies are needed to better define the risks of NSAIDs in those age groups.

Prostanoids produced by COX-1 isoenzymes are associated with the protection of the gastric mucosa and platelet aggregation. Randomized controlled trials in adult patients show that COX-2 inhibitors provide the anti-inflammatory effects of traditional NSAIDs but with a lower incidence of gastrointestinal symptoms and bleeding. Anti-inflammatory effects, analgesic efficacy, and incidence of renal toxicity with COX-2 inhibitors are comparable to other NSAIDs. NSAIDs and COX-2 inhibitors both alter the balance of pro- and antithrombotic products of arachidonic acid. For adults with risk factors for coronary artery disease, peripheral vascular disease, and carotid artery disease, COX-2 inhibitors appear to increase risks of cardiovascular events. Rofecoxib and valdecoxib were withdrawn from the US market due to reports of cardiovascular complications in adult patients; celecoxib and meloxicam remain available in the USA, but with warnings regarding these potential risks. With a few exceptions (e.g. children with genetically based hypercoagulability, children with Moya Moya disease), there is little basis to anticipate significant cardiovascular risks from COX-2 inhibitors in children [44]. We consider them to have a potentially favorable risk–benefit ratio for selected children with inflammatory pain who have severe gastrointestinal side-effects with traditional NSAIDs or those with underlying bleeding disorders, such as children with hemophilia. Certain modified non-acetylating salicylates with relatively mild gastric effects, including salsalate, diflunisal, or choline-magnesium salicylate, may also be considered in children who have gastrointestinal side-effects with NSAIDs. Since COX-2 inhibitors have minimal antiplatelet/antihemostatic effects, they should in principle be ideal analgesics for children undergoing tonsillectomy. Available data on COX-2 inhibitors regarding efficacy are mixed; some trials found COX-2 inhibitors equal to NSAID comparators and better than placebo [52], while other trials found COX-2 inhibitors either inferior to an NSAID or not distinguishable from placebo [53,57]. Overall numbers of subjects in these trials were small, and there is the potential for failing to identify analgesic effects due to type II error, or for study designs washing-out treatment effects by scheduled use of other analgesics. We could not identify a meta-analysis to assign a confidence interval for their odds ratio for post-tonsillectomy bleeding.

See Table 37.3 for dosing guidelines of commonly used non-opioid analgesics.

Table 37.3 Dosing guidelines for non-opioid analgesics

Analgesic	Dose <60 kg	Dose >60 kg
Acetaminophen	10–15 mg/kg q 4 h PO/IV	650–1000 mg q 4 h PO/IV
Naproxen	5 mg/kg q 12 h PO	250–500 mg q 12 h PO
Ibuprofen	6–10 mg/kg q 6–8 h PO	400–600 q 6 h PO
Celecoxib	2–4 mg/kg q 12 h PO	100–200 mg q 12 h PO
Ketorolac	0.5 mg/kg q 6–8 h IV, not for >5 days	30 mg q 6–8 h IV, not for >5 days

Dosing guidelines listed refer to children >1 year of age. Further modifications in dosing are required for use of these agents in term and preterm neonates and in infants. Modifications are detailed in the text.
IV, intravenous; PO, orally; q; every.

KEY POINTS: NON-OPIOID ANALGESICS

- Non-opioid analgesics refer to acetaminophen, aspirin, NSAIDs, and the selective COX-2 inhibitors
- Acetaminophen affects the COX-3 isoenzyme, cannabinoid, and TRPV1 receptors; has minimal anti-inflammatory effects; and IV doses are effective for mild pain or adjuncts to moderate–severe pain
- NSAIDs ketorolac and ibuprofen reversibly inhibit COX-1 and -2 isoenzymes and are effective in moderate pain; side-effect risk is low but includes renal dysfunction, gastropathy, bleeding, and bone non-union
- Celecoxib and meloxicam are COX-2 inhibitors with a low risk of side-effects, and are effective for inflammatory pain in children who have gastrointestinal and bleeding side-effects

Opioids

Opioids are widely used for the treatment of moderate to severe pain in infants and children, particularly in the immediate postoperative period. Safe and effective administration of opioids requires careful patient selection, knowledge of age-related differences in metabolism, dose titration, and aggressive treatment of opioid side-effects. Opioid prescribing for children over the past 30 years has undergone "pendulum swings." Case series from the 1960s and 1970s indicated that pediatric patients, particularly infants and young children, received inadequate doses of opioids for pain after surgery or advanced cancer, partly because of a lack of understanding of how opioids are metabolized and limitations in ability to assess pain in children. A greater understanding of the pharmacokinetics of opioids, developmental neuroanatomy, and validated pain scores have led to more appropriate dosing and the widespread use of opioids for pain management in infants and children. Over the 1980s and 1990s, opioids were prescribed more liberally for postoperative pain and cancer pain in many developed countries. In the past 15 years, opioid misuse has emerged as a major public health concern, especially in the USA. Aside from issues around misuse, opioid sparing has emerged as a major theme in postoperative analgesic management, because of the adverse effects of opioids on aspects of postoperative recovery [58,59].

There has been growing interest in multimodal approaches to pain management and ERAS programs for children. There is good evidence to support opioid-sparing effects and postoperative analgesic efficacy for acetaminophen–NSAID combinations combined with regional anesthesia [60,61]. Studies of gabapentin and low-dose ketamine as part of a multimodal regimen has shown mixed results [56,62–65]. Although there are limited multicomponent ERAS studies in children, outcomes among adolescents with idiopathic scoliosis having posterior spine fusions show early postoperative mobilization and reduced length of hospital stay using different care bundles [55,66].

Ontogeny of opioid actions

Opioid receptors are present by midgestation in a widespread distribution in the forebrain, brainstem, and spinal cord. Functional maturation occurs gradually in prenatal and postnatal life. For example, while the infant rat (postnatal day 5) has an extensive complement of opioid receptors in brainstem and forebrain distributions, coupling to Gi/o proteins, as assayed by the ratio of guanosine triphosphate binding to DAMGO binding in brain striosomal preparations, is less than 5% of that seen in adult rat brain preparations [67].

There is an extensive series of animal studies of the effects of acute or chronic opioid administration on subsequent development. For example, chronic opioid exposure in the prenatal and early postnatal life in the rat can lead to reductions in brain size, neuronal packing density, and dendritic development, with corresponding functional impairments in learning and locomotion [68]. Chronic opioid exposure in infant rats produces tolerance, withdrawal syndromes, and opioid-induced hyperalgesia [69]. The effects of opioids, ketamine, and other drugs on the developing animal are also modified by the presence of pain, injury, and/or inflammation [70]. In some models, there are apparent long-term benefits of administering opioids prior to injury or inflammation. Thus, extrapolations from animal studies regarding either benefit or harm of analgesics for newborns undergoing intensive care should be very cautious, in part because most animal models do not fully simulate all the types of perturbations seen with prolonged intensive care in humans.

Newborns undergoing intensive care are subjected to a large number of noxious procedures and mechanical ventilation, which per se produces stress and distress. Several studies have examined analgesia, side-effects, and potential long-term consequences of opioids for ventilated newborns, given either on schedule or around specific noxious procedures. In the NEOPAIN trial, infants receiving chronic morphine infusions did not show more long-term neurological impairments compared with controls, but there was essentially no evidence of benefit on distress measures, and increased open-label episodic morphine administration for distress was associated with worse outcomes [71]. Moreover, morphine has only mild effect on behavioral indices of distress during painful procedures in preterm neonates [72]. At present, there is very little consensus regarding either benefit or harm from opioids or sedatives in critically ill neonates [73]. Prolonged opioid therapy in critically ill neonates and children often leads to opioid tolerance; withdrawal can occur as opioids are weaned or discontinued [74].

The specific choice of opioid depends on numerous factors including the ability to tolerate oral intake and gut absorption, side-effects, severity of pain, and whether pain is escalating. Oral routes are preferred for mild to moderate pain in children who are able to tolerate oral intake and who have adequate gastrointestinal absorption. Intravenous routes should be used for children who have severe pain that needs to be rapidly controlled, for rapidly escalating pain, and for those who cannot tolerate oral opioids.

Codeine is considered a weak opioid and is often combined with acetaminophen to improve analgesia. It is also used as an antitussive agent; the FDA recently restricted the use of any opioid-containing antitussive to adults. Compared with other opioids, codeine seems to be associated with higher risk of nausea. Analgesic effect is through the hepatic metabolism of codeine to morphine by CYP2D6 although there is significant variability in both the pharmacokinetics and pharmacodynamics of codeine. Studying a British cohort of children coming for surgery, 47% of children studied had reduced CYP2D6

enzyme concentrations and 36% had no detectable levels of morphine or metabolites after a parenteral dose of 1.5 mg/kg of codeine [75]. In children who lack or have significantly reduced enzyme levels, codeine is essentially inactive and provides no analgesia. Conversely, for patients with CYP2D6 gene duplication or with an ultrarapid metabolizing allele, codeine may cause respiratory depression or death [76]. In the USA in 2012, the FDA began a series of positions and then black box warnings against the use of codeine as an analgesic for children. At Boston Children's Hospital and many other pediatric hospitals, codeine is no longer prescribed. In 2015 and again in 2017, the FDA issued a warning regarding pediatric use of tramadol, based on a somewhat smaller number of pediatric adverse events. Tramadol is a complex drug with multiple actions. It acts in part via monoamine pathways and in part as a prodrug by conversion to an opioid agonist. Metabolism involves both CYP3A4 and CYP2D6, so even though genetic variants can alter production of active products, it is overall probably less susceptible to extreme pharmacogenomic effects compared with codeine.

Oxycodone is a frequently used oral opioid for children with mild to moderate pain and is often used in the postoperative setting of converting from parenteral to enteral opioids. While historically oxycodone was used for moderate pain in relatively fixed doses, studies in adults showed that the dose of oxycodone, like morphine, can be escalated for moderate to severe pain. Oxycodone undergoes hepatic metabolism by CYP3A enzymes to normoxycodone and to a lesser extent to oxymorphone by CYP2D6 enzymes. Genetic variability of CYP2D6 enzymes results in a less profound effect on analgesia and adverse effects for oxycodone compared with codeine since CYP3A pathways to normoxycodone are predominant [77]. A pharmacokinetic study of oxycodone in infants showed great variability in both clearance and in the elimination half-life, especially in neonates [78]. Oxycodone is available as an elixir for children unable to swallow pills and as a controlled-release preparation for a small subset of older children with severe or prolonged postoperative pain, e.g. for pain due to cancer or other serious illnesses. Dosing for immediate release is 0.1–0.2 mg/kg/dose every 4 h as needed.

Hydrocodone is an oral opioid used for mild to moderate pain and is often formulated with acetaminophen. Metabolism is primarily through CYP2D6 and CYP3A4 pathways to hydromorphone and norhydrocodone, respectively, and to a lesser extent by non-CYP pathways. Although patients with genetic polymorphism of CYP2D6 enzymes resulting in "slow metabolizers" have lower peak concentrations of hydromorphone compared with "rapid metabolizers", there are insufficient data to conclude whether analgesic response and potential for toxicity can be predicted based on the CYP2D6 phenotype [79–81].

Morphine is generally considered a first-line opioid for parenteral use. Metabolism occurs in the liver, primarily through glucuronidation to morphine-3-glucuronide, which has neuroexcitatory actions, and morphine-6-glucuronide, which has analgesic, sedative, and respiratory depressant actions. Both glucuronides are renally eliminated and can accumulate in patients with renal failure, which accounts for the prolonged response and increased side-effects seen in patients with renal failure. Accumulation of morphine-3-glucuronide can contribute to delirium, myoclonus, agitation, and seizures. There is some evidence that morphine is preferentially metabolized in neonates to morphine-3-glucuronide and has an increased risk of seizures in this age group [82]. The elimination half-life of morphine in neonates and young infants is more than twice that of older children and is even more prolonged in premature infants [82]. Clearance of morphine in premature infants is less than half that measured in adults. Studies of morphine efficacy in neonates have yielded mixed results with some studies showing no apparent analgesic effect of morphine infusion in ventilated neonates in response to endotracheal suctioning. Because of the significant variation in pharmacokinetics of morphine among patients, dosing should be based on age, weight, side-effects, and careful dose titration [82]. Erythema and local urticaria at the site of intravenous administration is sometimes seen and does not imply an allergy to morphine. Morphine is generally well tolerated with minimal hemodynamic changes during infusions in blinded studies [83], but rapid bolus dosing can be associated with hypotension. Morphine and other opioids produce dose-dependent depression of ventilation by decreasing the brainstem response to hypoxia and hypercarbia and by interfering with central ventilatory centers. Morphine reduces the sense of air hunger in children with cancer and end-stage lung disease and can be given sublingually in this setting for ease of administration and for more rapid onset than enteral dosing. Dosing guidelines for morphine can be found in Table 37.4.

Hydromorphone has similar duration of action to morphine and is frequently used in patient-controlled analgesia (PCA) and epidural analgesia. Like morphine, it is commonly given orally and intravenously, although there is no long-acting preparation available. It differs from morphine in that it is slightly more lipid soluble and approximately five times more potent in steady state when given intravenously [84]. Like morphine, it is metabolized principally by glucuronidation. Hydromorphone is often prescribed for patients with renal insufficiency but this practice is not evidence based. Excitatory effects of either morphine or hydromorphone in patients with renal insufficiency correlate poorly with plasma concentrations of glucuronides [85]. While individual patients may report differences in analgesia or side-effects between morphine and hydromorphone, randomized blinded comparisons have found few clinically meaningful differences in the frequency of side-effects [86].

Methadone is a long-acting opioid that is supplied as a racemic mixture of d- and l-isomers. It has a prolonged elimination half-life, resulting in a long duration of analgesia. There is, however, wide variation in elimination half-life, ranging from 6 to 30 h. The bioavailability is quite high, approximately 70–90%. Because of these unique properties, methadone can be dosed intermittently, either orally or intravenously, and can provide prolonged, steady-state analgesia similar to a continuous infusion or controlled-release preparations of other opioids.

The l-isomer of methadone acts as a mu opioid; the d-isomer acts as a non-competitive antagonist at the N-methyl-D-aspartate (NMDA) subgroup of excitatory amino acid receptors in the brain, spinal cord, and peripheral nerves. NMDA receptor antagonism results in analgesia, reduction in hyperalgesia, and partial reversing of tolerance to mu opioids [87]. Methadone's

Table 37.4 Initial dosing guidelines for opioids for patients over 1 year of age*

Drug	Equianalgesic doses and intervals		Usual starting intravenous or subcutaneous doses		Parenteral: oral dose	Usual starting oral doses and intervals	
	Parenteral	Oral	Child <50 kg	Child >50 kg	Ratio	Child <50 kg	Child >50 kg
Morphine	10 mg	30 mg (long term) 60 mg (single dose)	Bolus: 0.1 mg/kg every 2–4 h Infusion: 0.03 mg/kg/h	Bolus: 5–8 mg every 2–4 h Infusion: 1.5 mg/h	1:3 (long term) 1:6 (single dose)	Immediate release: 0.3 mg/kg every 3–4 h Sustained release: 20–35 kg: 10–15 mg every 8–12 h; 35–50 kg: 15–30 mg every 8–12 h	Immediate release: 15–20 mg every 3–4 h Sustained release: 30–45 mg every 8–12 h
Oxycodone	NA	15–20 mg	NA	NA	NA	0.1–0.2 mg/kg every 3–4 h	5–10 mg every 3–4 h
Methadone†	10 mg	10–20 mg	0.1 mg/kg every 6–12 h	5–8 mg every 6–12 h	1:2	0.1–0.2 mg/kg every 6–12 h	5–10 mg every 6–12 h
Fentanyl	100 mg (0.1 mg)	NA	Bolus: 0.5–1.0 µg/kg every 1–2 h Infusion: 0.5–2.0 µg/kg/h	Bolus: 25–50 µg every 1–2 h Infusion: 25–100 µg/h	NA	NA	NA
Hydromorphone	1.5–2 mg	6–8 mg	Bolus: 0.02 mg every 2–4 h Infusion: 0.006 mg/kg/h	Bolus: 1 mg every 2–4 h Infusion: 0.3 mg/h	1:4	0.04–0.08 mg/kg every 3–4 h	2–4 mg every 3–4 h

* Doses are for patients over 6 months of age. In infants under 6 months, initial per kilogram doses should begin at roughly 50% of the per kilogram doses recommended here. Higher doses are often required for patients receiving mechanical ventilation. All doses are approximate and should be adjusted according to clinical circumstances. Recommendations are adapted from previous summary tables, including those of a consensus statement from the World Health Organization and the International Association for the Study of Pain.

† Methadone requires additional vigilance because it can accumulate and produce delayed sedation. If sedation occurs, doses should be withheld until sedation resolves. Thereafter, doses should be substantially reduced, the interval between doses should be extended to 8–12 h, or both.

NA, not applicable; NR, not recommended.

combined effect of mu receptor agonist and NMDA antagonism results in incomplete cross-tolerance so that dose conversion between methadone and other opioids depends, in part, on the patient's degree of opioid tolerance [88]. In opioid-naïve patients, the average daily requirement of intravenous methadone is approximately 30% of the corresponding intravenous morphine requirement. However, in opioid-tolerant patients, the average daily methadone requirement may be as little as 10% of the total daily morphine dose. This is especially relevant when converting from morphine to methadone in children who are opioid tolerant and when weaning non-ventilated infants and children from prolonged opioid therapy [89]. Because of incomplete cross-tolerance, slow and unpredictable elimination half-life, and variability in plasma concentrations, methadone dosing requires careful titration and frequent assessment for respiratory depression. Methadone has been associated with prolongation of the QT interval, especially when combined with other drugs known to cause prolonged QT. For patients showing oversedation or mild hypoventilation, it may be necessary to hold multiple doses rather than make small incremental changes due to the prolonged duration of action.

For opioid-naïve patients in the postoperative period, one approach is to dose methadone on a "sliding scale" every 4 h where patients receive 0.075 mg/kg for severe pain, 0.05 mg/kg for moderate pain, and 0.025 mg/kg for mild pain. After 24 h of this dosing regimen, patients are then placed on a more regular dosing schedule with shorter acting opioids such as morphine or hydormorphone, offered for rescue therapy. Methadone is particularly useful in children with cancer who have nociceptive as well as neuropathic pain. It can be dosed in small children with chronic pain who are unable to swallow sustained-release pills.

Fentanyl is highly lipophilic and is 70–100 times more potent than morphine in single-dose administration and 30–50 times more potent when given as a continuous intravenous infusion. Because fentanyl has a rapid onset and brief duration, it is often used for brief painful procedures, such as lumbar punctures, bone marrow biopsies, and dressing changes either by itself or in combination with benzodiazepines or general anesthesia. Doses of 0.5-1 µg/kg, titrated every 1–3 min generally provide good analgesia for brief painful procedures in non-ventilated patients. Fentanyl primarily undergoes conversion in the liver to inactive metabolites, making it useful in patients with renal failure. The effect of a single dose of fentanyl is terminated in large measure by rapid redistribution [90,91]. However with repeated doses or continuous infusion, the termination of fentanyl effect is more determined by elimination rather than redistribution, resulting in prolonged duration of action. The context-sensitive half-life of fentanyl is particularly prolonged in neonates receiving continuous infusions [92]. Rapid administration may cause glottic and chest wall rigidity; treatment can consist of neuromuscular blockade, assisted ventilation, and in some cases administration of naloxone.

Oral transmucosal fentanyl is also used for brief painful procedures [93] and for children with cancer breakthrough pain.

The oral transmucosal dose is partially absorbed through the buccal mucosa and partially swallowed so that the overall bioavailability is approximately 50%. The peak analgesic effect occurs at 30–45 min. Most children tolerate oral transmucosal fentanyl well, although almost 90% experience facial pruritus.

Transdermal fentanyl is used in selected children with cancer pain [94]. It is also used for a very small number of children with chronic pain who require regular dosing of opioids and have a better side-effects profile with fentanyl than other opioids. Transdermal fentanyl is also used for patients who have difficulty with oral opioids or who have limited intravenous access. Following initial application or with dose escalation, approximately 12–24 h are required to reach steady-state plasma levels because of depot accumulation of fentanyl in the skin; this also accounts for continued absorption of the drug at a declining rate after the transdermal fentanyl is removed. Because of these properties, transdermal fentanyl is not useful in patients with acutely fluctuating pain. Additional short-acting opioids are required with initial application and dose escalation. Drug uptake can be influenced by a number of patient factors, including temperature, thickness, adiposity, and inflammation. Transdermal fentanyl should be used only in patients who are opioid tolerant and who have fairly constant pain. Adverse events, including deaths, have been reported among opioid-naïve adult and pediatric patients who were treated with transdermal fentanyl for acute postsurgical pain.

Meperidine is approximately 10 times less potent than morphine. It is metabolized in the liver through hydrolysis and N-demethylation to normeperidine, a metabolite that is renally eliminated. The elimination half-life is 3–4 h. Accumulation of normeperidine can cause hyper-reflexia, agitation, delirium, and seizures. Life-threatening events have occurred with the use of meperidine in patients taking monoamine oxidase inhibitors and in patients with untreated hypothyroidism. Doing so has resulted in metabolic and hemodynamic changes, excitability, seizures, and death. Meperidine is unique among opioids in that it reduces rigors associated with general anesthesia and the administration of blood products. Beyond its use in low doses for rigors or shivering, we recommend against the use of meperidine for analgesia in children.

Table 37.4 gives the initial dosing guidelines for opioid analgesics.

KEY POINTS: OPIOIDS

- Codeine and tramadol have been restricted by the US FDA because of variations in metabolism due to CYP2D6 genetic polymorphisms
- Oxycodone and hydrocodone are appropriate for oral opioid analgesia and have less variation in metabolism since they depend more on CYP3A pathways for metabolism
- Morphine is first line for parenteral opioid analgesia; young infants have both reduced metabolism and increased brain levels of morphine and dosing must be reduced
- Hydromorphone, methadone, and fentanyl are also standard drugs for parenteral opioid analgesia; methadone may prolong the QT interval

Methods of opioid administration

Intermittent opioid bolus dosing

Intermittent parenteral dosing of opioids can be useful for episodic pain or for initial loading doses in the treatment of acute pain. Particularly with longer dosing intervals, this approach results in wide fluctuations in plasma opioid concentrations and fluctuations in side-effects and pain intensity. Continuous infusions and patient (or nurse) controlled analgesia are often used instead of intermittent parenteral bolus dosing to avoid fluctuations in plasma opioid concentration, analgesia, and opioid side-effects.

Continuous opioid infusions

Continuous opioid infusions are useful for maintaining steady-state plasma opioid concentrations [82,95,96]. This approach is often used in intensive care units for ventilated patients who have relatively constant levels of pain; intermittent boluses of opioids are administered for any increases in pain, such as endotracheal tube suctioning. Although continuous infusions achieve steady-state plasma opioid levels and near-constant levels of analgesia, patients who have fluctuations in pain, such as with coughing, chest physiotherapy, or getting out of bed may have increased levels of pain which are not readily relieved by a continuous infusion of drug. In this setting, additional opioid boluses are required. Typical starting dose for continuous infusions of morphine is 0.025 mg/kg/h. Because of patient variations in opioid metabolism and pain intensity, effective starting doses vary considerably. Neonates and young infants require lower starting doses, ranging from 0.005 mg/kg/h in preterm neonates to 0.015 mg/kg/h in young infants aged 2–6 months.

Patient- and nurse-controlled analgesia

Patient-controlled analgesia takes into account individual variations in opioid pharmacokinetics and individual fluctuations in pain intensity that cannot be achieved by intermittent opioid bolus dosing or continuous infusions [97–100]. PCA involves a delivery system that administers a small preset dose of opioid, usually intravenously, when the patient depresses a button. There is a preset lock-out time during which no additional boluses can be administered, even if the button is depressed. PCA can also administer a continuous opioid infusion in addition to the intermittent boluses.

PCA has been shown to be safe and effective in children aged 7 years and older. Some children as young as 4 or 5 years are able to effectively use PCA. However, there is a higher incidence of failure in younger children because of their inability to understand the causal relationship between depressing the button and obtaining medication for pain relief. PCA is widely used for a variety of painful conditions such as postoperative pain, painful vaso-occlusive crises, and cancer pain. There are conflicting data comparing PCA with continuous opioid infusions. Some studies indicate that PCA use tends to reduce patients' overall opioid use with fewer opioid side-effects and similar or lower pain scores. Other studies did not find lower total opioid use with PCA compared with continuous opioid infusions. Many of these comparative studies were conducted in an era before a very widespread use of multimodal opioid-sparing analgesia (acetaminophen, NSAIDs, regional anesthesia, gabapentinoids, etc.). In the authors' current practice, continuous infusions have become infrequent

for postsurgical pain except for patients receiving prolonged mechanical ventilation.

Nurse-controlled analgesia (NCA) is commonly used for infants and children who are unable to push the PCA button, either due to lack of cognitive abilities or due to physical limitations. Outcome studies indicate that NCA is generally safe and effective in children with good patient, nurse, and parent satisfaction [99,100]. NCA is commonly used in pediatric hospitals for opioid administration to young children following surgery.

Parent-controlled analgesia is widely accepted for use in children with advanced cancer pain and in palliative care, both in home and hospital settings. There is, however, controversy surrounding parent-controlled analgesia for opioid-naïve children or in the setting of acute postoperative pain. Advocates of parent-controlled analgesia point out that parents know their children best, especially children with developmental or physical disabilities. The counterargument is that parents, unlike nurses, do not have the training or expertise to effectively assess risks of opioid dosing or impending respiratory depression. There have been several serious adverse events, including deaths, with the use of parent-controlled analgesia by well-meaning parents. Our view is that parent-controlled analgesia for opioid-naïve patients should be restricted to hospitals that have formal education parent programs, protocols for close nurse observation and assessment, and electronic cardiorespiratory monitoring [100].

Commonly used opioids for PCA include morphine, hydromorphone, and fentanyl. Some studies have shown that adding a basal infusion at night for postsurgical patients improves sleep and pain scores. Other studies have shown that basal infusions with PCA increase risk of desaturation episodes, especially at night. Whether to add a basal infusion depends on a number of factors, including severity of pain, tolerance to opioids, and an underlying patient condition that may increase the risk of hypoventilation or airway obstruction. In general, patients with mild to moderate pain experience good analgesia with demand-only PCA. Our practice is to use PCA bolus dosing without a background basal infusion for children who have received a peripheral nerve block intraoperatively, who have increased risks of respiratory compromise, and for those who are expected to have mild–moderate but not severe surgical pain. We do tend to include a basal infusion for children who have cancer pain or pain from vaso-occlusive crises. For these patients, we often provide approximately 40–50% of their daily opioid dosing through basal infusions to provide effective analgesia without the need for frequent demand boluses. We often add a basal infusion for 1–2 days postoperatively for patients who have had surgeries expected to result in severe postoperative pain, such as scoliosis surgery or major hip surgery. When fentanyl is chosen for PCA, such as for patients who have had side-effects to other opioids, a basal rate is often used because fentanyl is shorter acting than morphine or hydromorphone. Typical starting doses for PCA (and NCA) are listed in Table 37.5.

Table 37.5 Typical starting doses for patient-controlled and nurse-controlled analgesia

Drug	Bolus dose (μg/kg)	Continuous rate (μg/kg)	4-hour limit (μg/kg)
Morphine	20	4–15	300
Hydromorphone	5	1–3	60
Fentanyl	0.25	0.15	4

Opioid side-effects and treatment

Opioids are associated with a range of side-effects, including nausea, vomiting, constipation, urinary retention, pruritus, sedation, and respiratory depression. Although some children may experience different side-effect profiles with different opioids, there are few data to suggest that side-effects differ greatly among commonly used opioids. To many children, severe opioid side-effects, such as relentless nausea or pruritus, may be as distressing as pain. Opioid-sparing approaches to postoperative analgesia, including the use of NSAIDs, should be considered to avoid the complications of opioids on postoperative recovery [101].

Opioid side-effects occur by actions at both peripheral and central sites [102]. For example, opioid-induced nausea and vomiting involve agonist activity at receptors in the chemoreceptor trigger zone as well as in the gastrointestinal tract. Some opioids produce pruritus by peripheral release of histamine; however small doses of intrathecal morphine are associated with profound pruritus, implying a more central cause of signaling and neurotransmission in the spinal dorsal horn and nucleus caudalis.

Opioid side-effects should be anticipated and treated aggressively. A proactive program with protocols for side-effect management allows for rapid implementation of treatment. The evaluation of the patient with opioid side-effects should include assessment of the severity of side-effects, the degree of patient distress, the expected duration of opioid therapy, and careful consideration of other factors that may masquerade as opioid side-effects. For example, severe itching may be a result of opioids but may also be due to an allergic reaction to other medications.

Constipation is nearly universal among patients receiving opioids, even with short-term use. Stimulant laxatives should be routinely used for all patients anticipated to require more than one or two doses of opioids. Methylnaltrexone has a decreased ability to cross the blood–brain barrier and acts as a peripheral opioid antagonist [102]. It has been used for opioid-induced constipation that is refractory to laxatives. Doses of methylnaltrexone for children are extrapolated from adult studies.

Opioid-induced pruritus can be relentless and as distressing as pain to some patients. Pruritus occurs in approximately 13% of patients receiving parenteral opioids and 20–80% of patients receiving intrathecal or epidural opioids. Opioid-induced pruritus is thought to occur through activation of opioid receptors in the brain and substantia gelatinosa. Although antihistamines have traditionally been used to treat pruritus, there is good evidence for use of mu receptor antagonists such as naloxone infusions for both opioid-induced pruritus and opioid-induced nausea. In addition, antihistamines can exacerbate sedation, constipation, and urinary retention caused by opioids. In a prospective, randomized trial of 46 children receiving low-dose naloxone infusion (0.25 μg/kg/h) and morphine PCA postoperatively, the incidence and severity of opioid-induced pruritus and nausea were significantly reduced [103]. There was no

Table 37.6 Management of common opioid side-effects

Side-effect	Comments	Drug dosage*
Nausea	Consider switching to different opioid Use antiemetics Exclude other processes (e.g. bowel obstruction)	Ondansetron 10–30 kg: 1–2 mg IV q 8 h >30 kg: 2–4 mg IV q 8 h Naloxone infusion 0.25 μg/kg/h Metoclopramide 0.1–0.2 mg/kg PO/IV q 6 h
Pruritus	Exclude other causes (e.g. drug allergy) Consider switching to different opioid Use antipruritics	Nalbuphine 0.01–0.02 mg/kg/dose IV q 6 h Naloxone infusion 0.25 μg/kg/h Diphenhydramine 0.25-0.5 mg/kg PO/IV q 6 h
Sedation	Add non-sedating analgesic (e.g. ketorolac) and reduce opioid dose Consider switching to different opioid	Methylphenidate 0.05–0.2 mg/kg PO bid (morning and midday dosing) Dextroamphetamine 5–10 mg every day for children >6 years of age
Constipation	Regular use of stimulant and stool softener laxatives	Naloxone infusion 0.25-1 μg/kg/h Docusate: Child: 10–40 mg PO daily Adult: 50–200 mg PO daily Dulcolax: Child: 5 mg PO/PR daily Adult: 10 mg PO/PR daily Methylnaltrexone (adult) 0.15 mg/kg

* In the absence of more specific data, patients weighing >60 kg should be dosed based on a 60 kg weight-scaled dose.
bid, twice a day; PO, orally; PR, rectally; q, every.

increase in pain scores or increase in morphine use with the administration of low-dose naloxone. Ultralow-dose naloxone infusions show differential binding to opioid receptors coupled to G-stimulatory versus G-inhibitory proteins so that analgesia is not reversed. Nalbuphine is a widely used mu receptor antagonist used for opioid-induced nausea and vomiting although there are conflicting efficacy data among pediatric patients [104].

Nausea and vomiting are a major source of distress for patients, especially in the postoperative period. There is a strong relationship between postoperative nausea and vomiting and the amount of opioids used postoperatively [105], however other causes should also be considered such as electrolyte abnormalities or impaired kidney function. Ondansetron is a selective 5-hydroxytryptamine-3 (5-HT3) receptor antagonist often used in the treatment of nausea and vomiting. Phenothiazines, butyrophenones, and metoclopramide have traditionally been used but have the associated risk of extrapyramidal reactions. There is good evidence to support the use of low-dose naloxone infusions in the treatment of nausea and vomiting associated with opioids. The typical dose of low-dose naloxone used in the treatment of opioid-induced pruritus and nausea is 0.25 μg/kg/h.

Children with advanced cancer often experience fatigue and somnolence, and opioid use often exacerbates these symptoms. Other treatable causes of fatigue should be considered, such as anemia, sleep disturbances, and depression. A cross-sectional study of the parents of 141 children who died of cancer reported that 96% of children had fatigue and nearly 50% experienced significant suffering from fatigue [106]. Only 13% of children with fatigue received directed treatment. More aggressive treatment of pain with opioids may further exacerbate fatigue and somnolence [107]. Methylphenidate is a stimulant that acts as an adrenergic receptor agonist to indirectly increase the release of dopamine and norepinephrine. Studies in adults support the use of methyphenidate to antagonize opioid-associated sedation and fatigue. Methylphenidate can also provide additional analgesic and antidepressant effects, which can be particularly beneficial for children with advanced cancer.

See Table 37.6 for the management of common opioid-induced side-effects.

KEY POINTS: OPIOID DOSING AND SIDE-EFFECTS

- Intermittent IV opioid dosing is used for acute pain, but continuous opioid infusions are more effective to maintain steady-state plasma concentrations
- Both patient- and nurse-controlled opioid analgesia for children are safe and effective; parent-controlled analgesia should be reserved for advanced cancer pain and palliative care
- Opioid side-effects include nausea, vomiting, constipation, urinary retention, pruritus, sedation, and respiratory depression and should be anticipated and treated aggressively

Local anesthetics and regional anesthesia

Developmental pharmacology of local anesthetics

The amino amide local anesthetics, including lidocaine, bupivacaine, levobupivacaine, and ropivacaine, undergo hepatic metabolism more slowly in neonates and young infants, and weight-scaled clearances reach mature values generally around 6 months of age [108]. In addition, reduced renal clearance of metabolites (e.g. MEGX, the primary metabolite of lidocaine) can contribute to the risk for seizures in neonates. Although

plasma esterases involved in the metabolism of amino ester local anesthetics are present in reduced amounts in neonates, chloroprocaine clearance occurs quite rapidly in neonates [109]. Local anesthetics have somewhat larger volumes of distribution and reduced protein binding in neonates [108]. The plasma concentrations that produce cardiotoxicity or risk of seizures in human neonates, infants, and children are extrapolated from case reports, adult case series, and adult preclinical toxicological studies [110]. Infant rats tolerate a higher weight-scaled dose of either bupivacaine or ropivacaine (higher median lethal dose (LD50)) than adult rats [111]. In our view, it seems prudent to conclude that the maximum systemically safe single dose of bupivacaine, levobupivacaine, ropivacaine, or lidocaine scales directly with bodyweight, and that the hourly maximum infusion rates in neonates and infants less than 3–5 months of age should be reduced by about 50% relative to the recommended rates for older infants and children.

Topical anesthetics

Topical anesthetics are widely used in children for pain associated with immunizations, venipuncture, accessing indwelling central venous ports, and other types of needle pain [112,113]. The stratum corneum of the epidermis is a relatively impermeable barrier to local anesthetics and a variety of strategies have been developed to permit uptake of local anesthetics across this barrier.

EMLA

The eutectic mixture of local anesthetics (EMLA; lidocaine and prilocaine) was one of the first topical anesthetics commercially available for use on intact skin and has been extensively used and studied [114,115]. The physicochemical feature of this type of mixture is that it permits a higher aqueous solubility of the uncharged forms. This physical feature permits a higher effective concentration at the stratum corneum and increases the rate of uptake. A meta-analysis of controlled trials in children and adults showed that EMLA reduced pain associated with venipunctures in 85% of patients [114].

Applying a thicker layer and increasing the duration of application to 90–120 min can increase its effectiveness. Applying a thin layer (0.5 mm) compared to a thick layer (2 mm) resulted in significantly less pain relief with venipunctures. Even with longer duration of application, absorption into the epidermis was limited to no more than 6 mm. Application times of less than 45 min resulted in high failure rate, and with short application times, tetracaine gel appeared more effective than EMLA [115]. Blanching is commonly seen with EMLA and is due to vasoconstriction of superficial capillaries.

Clinical trials have shown the effectiveness of EMLA in reducing pain or distress of a number of common pediatric procedures, including venous cannulation, venipuncture, circumcision, urethral meatotomy, immunizations, allergy testing, accessing implanted central venous access ports, and laceration repair.

LMX cream

Lidocaine 4% (LMX) is a topical preparation. A randomized cross-over trial showed that LMX was as safe and effective as EMLA for reducing pain associated with venepuncture [116]. Advantages over EMLA include minimal vasoactive properties and shorter onset of action without the need for an occlusive dressing [117]. Additionally, LMX is not associated with methemoglobinemia.

S-Caine patch

The S-Caine patch™ (Synera®) is a drug delivery device consisting of a eutectic mixture of lidocaine (70 mg) and tetracaine (70 mg) integrated with an oxygen-activated heating element. The heating element enhances the delivery of the local anesthetics across the epidermis. When removed from its storage pouch, the heating element becomes activated and the patch begins to heat, warming the skin after application. Controlled trials in children and adults showed that application of the patch for 20 min produced good skin analgesia for venous cannulation [118]. A randomized, placebo-controlled trial of S-Caine Patch use showed that the majority of patients had good pain relief with vascular access procedures. The most common side-effects were local transient skin reactions, such as localized pruritus and erythema. Unlike EMLA, the S-Caine Patch is associated with mild vasodilation due to the vasodilating properties of lidocaine and mild heating of the skin.

Jet propulsion injectors

Jet propulsion injectors (J-tip system® and Powerject) are needless syringe devices that utilize compressed gas, typically carbon dioxide, to rapidly propel a predetermined amount of local anesthetic through the stratum corneum. These types of devices are attractive in that the local anesthetic effect occurs within several minutes and it is a needleless system. However, efficacy data are somewhat mixed. A randomized trial in adult patients showed that subcutaneous lidocaine infiltration was significantly more effective at reducing pain from venous cannulation. Other randomized studies in adults have found a failure rate of approximately 10%, and 17% of patients had mild bleeding at the site. A study comparing the J-tip system to EMLA in children found that the former provided better analgesia than EMLA for IV cannulation [119].

Iontophoresis

Iontophoresis employs an electrical field to drive local anesthetics in their charged ionic form across the stratum corneum. Iontophoresis produces cutaneous anesthesia in a much shorter time. The most common anesthetic used by this route is 2% lidocaine with 1:100,000 epinephrine. Skin analgesia occurs within 10–15 min and typically lasts for 15 min. Iontophoresis appears to result in deeper levels of dermal anesthesia and may penetrate deeply enough to numb both skin and veins, allowing for less painful venous cannulation. Randomized prospective studies in children comparing EMLA with iontophoresis of 2% lidocaine and 1:100,000 epinephrine found no significant differences in pain relief with venous cannulation. Superficial and partial thickness burns have been reported with lidocaine iontophoresis when placed over areas with skin defects or when high currents have been used. A mild tingling sensation often occurs during drug delivery. It is recommended that the system be removed if pain rather than tingling is experienced. Longer application

times are needed when lower currents are used, but the tingling sensation can be made almost undetectable.

Epidural analgesia

Epidural analgesia can provide excellent postoperative analgesia for infants and children undergoing a variety of surgical procedures including thoracic, perineal, lower extremity, and abdominal procedures. (Detailed discussion of peripheral nerve blocks can be found in Chapter 20.) Epidural analgesia is also used for certain chronic pain conditions such as complex regional pain syndrome, especially when used as part a rehabilitation program that emphasizes active mobilization (Figure 37.5).

An inherent difference between epidural catheter placement in adults and children is that, unlike for adults [120], most epidural catheters in children are placed while anesthetized. Most pediatric anesthesia providers agree on the safety of placing a lumbar epidural catheter in an anesthetized rather than an awake, moving child. However, there is somewhat more controversy surrounding the safety of direct needle placement in the thoracic region, particularly in infants due to concerns of neurological complications. Published case series and prospective clinical outcome studies showed generally good safety, though from available data it is difficult to ascribe confidence intervals on the risk specifically for anesthetized thoracic needle puncture in different age groups [121,122]. To avoid the potentially increased risk, an alternative method is to advance catheters from the caudal region cephalad to thoracic dermatomes. This may be performed blindly, or with additional guidance by fluoroscopy, ultrasound [123], nerve stimulation guidance [124], or electrocardiography [125]. Several reports in infants show that these techniques can be safe alternatives to direct needle placement, with success rates ranging from roughly 80% to 98%. Failure rates with blind placement are greater for infants greater than 5 kg. Infants clear amide local anesthetics more slowly than older children so that lower infusion rates are necessary and repeated local anesthetic dosing is more likely to produce systemic accumulation of drug and toxicity. Because of the limitations of using safe local anesthetic infusion rates, it is crucial in infants and young children to place epidural catheter tips in the correct surgical dermatome. When placing epidural catheters directly in a thoracic dermatome or when advancing epidural catheters cephalad to the thoracic region, our practice is to obtain confirmation of proper placement, either radiographically, through ultrasound, or by electrical stimulation. "Blind" advancement of catheters from lumbar to thoracic levels has a failure rate of approximately 30%. One method of radiographic confirmation of proper epidural catheter tip placement is an epidurogram where a small amount (0.5–1 mL) of radiocontrast dye is injected through the epidural catheter that can be detected on a plain radiograph (Fig. 37.6).

Catheters can also be advanced from lumbar or caudal routes under fluoroscopic guidance, and catheter tip positions can be confirmed by a contrast epidurogram. In our experience, lumbar-to-thoracic placement of catheters is more successful if placement occurs at L1–2 rather than lower levels, and with the epidural needle angled in a cephalad direction, rather than perpendicular to the spine. It is important to note that the distance from skin to epidural space is much shorter at the T12–L1 and L1–2 interspaces than at L3–4 or L4–5 which may predispose to inadvertent dural puncture. In our own practice, we make extensive use of electrical stimulation of epidural catheters [126], for confirming placement in the epidural space, for advancing lumbar and caudal catheters to thoracic dermatomes, and for confirming that the catheter is not wrong-sided (directed contralateral to the side of surgery). In this method, a small amount of electric current is applied to a saline-filled, wire-wrapped epidural catheter as it is advanced cephalad in the epidural space. Twitches can be observed at the myotomal level of the catheter tip in a current range

Figure 37.5 Complex regional pain syndrome presentation.

Figure 37.6 Epidurogram following placement of an epidural catheter. Note dye in the thoracic area.

usually between 2 and 15 mA. Characteristic response patterns indicating epidural, vascular, intrathecal, or dural placement can be observed as the catheter is advanced. This technique can also provide information on the sidedness of the epidural catheter so that for a unilateral surgical procedure predominant myotomal twitching on the non-operative side can be detected and the catheter repositioned. Technical success rates of 98% and analgesic success rates of 85% have been described using this method. Even in older adolescent and adults who may undergo regional anesthesia awake or under light sedation, we find that nerve stimulation is tolerated with minimal distress, provided the current is increased gradually.

It is sometimes necessary to confirm proper position of an epidural catheter postoperatively, for example, in the setting of continued pain despite adequate dosing of epidural infusions. Our common practice is to use a "chloroprocaine loading dose," particularly for infants and non-verbal children. Chloroprocaine is an ester local anesthetic that is metabolized by plasma cholinesterases. Although infants have reduced levels of plasma cholinesterases, chloroprocaine is nevertheless rapidly metabolized. Because of concerns of toxicity due to accumulation of amide local anesthetics in infants and young children, we prefer to use chloroprocaine in place of lidocaine or other amide local anesthetics to check epidural catheter placement. Since most patients will have received infusions of amide local anesthetics intraoperatively, administering a bolus of chloroprocaine avoids the possibility of reaching toxic plasma levels through additional boluses of amide local anesthetics. We inject a loading dose of 3% chloroprocaine incrementally over roughly 2 min through the epidural catheter. For this loading dose, infants receive larger weight-scaled volumes than adolescents. For example, an 8 kg infant might receive a total loading volume of 5 mL (0.62 mL/kg), while a 30 kg 7-year-old might receive a total loading volume of 12 mL (0.4 mL/kg), and patients >50 kg get a total loading volume of 15 mL. With these loading volumes, there should be clear clinical signs of sensory and motor block if the catheter is correctly positioned within the epidural space. Behavioral measures of pain relief, such as relaxed posture and ceasing of crying, are helpful in determining whether preverbal patients are experiencing relief, but objectives measures should also be present, such as a motor block and a return of vital signs to baseline values.

The selection of drugs for epidural injection should be individualized and will vary with site of surgery, location of epidural catheter tip, and patient-specific risk factors. For most postoperative children, we recommend infusions of local anesthetics in combination with opioids, clonidine, or both rather than local anesthetics alone because of the synergistic effect of combining local anesthetics with adjuvants. Bupivacaine is a commonly used amide local anesthetic in epidural local anesthetic infusions because it has a prolonged duration of action and produces more sensory than motor block. As previously discussed, the clearance of bupivacaine and other amide local anesthetics is reduced in neonates and young infants. Pharmacokinetic studies measuring unbound: pharmacologically active bupivacaine in infants receiving continuous epidural bupivacaine infusions showed plasma bupivacaine levels rise after the first 48 h and some infants will have plasma bupivacaine levels nearing or exceeding safe levels. Although most infants had an increase in their serum α1-acid glycoprotein concentrations after surgery, the increase did not fully buffer the unbound bupivacaine fraction. Based on these studies, epidural bupivacaine infusion rates in neonates and infants younger than 4 months of age should be limited to 0.2 mg/kg/h. Even at this low infusion rate, accumulation and drug toxicity are possible for infusions lasting more than 72 h [127]. Epidural bupivacaine infusion rates of 0.4 mg/kg/h appear to be safe for children over the age of 6 months.

Ropivacaine is an amide local anesthetic that in adult studies was found to be safer and more sensory selective than bupivacaine. Studies of IV ropivacaine in adult volunteers showed less central nervous system and cardiovascular toxicity than bupivacaine. In double-blind comparisons, ropivacaine and levobupivacaine both produced similar analgesic effects as racemic bupivacaine but less extensive motor block [128]. Pharmacokinetic data in infants and children show that the clearance of bupivacaine is slightly more than the clearance for ropivacaine in all ages but, as with bupivacaine, clearance of ropivacaine is reduced in neonates and young infants compared to older children [129–131]. Our practice is to use ropivacaine infusion rates up to 0.3 mg/kg/h in infants younger than 6 months and up to 0.5 mg/kg/h for older children.

Lidocaine is used as an epidural local anesthetic for neonates and infants in some centers because of the relative ease of monitoring lidocaine blood concentrations and because of reduced cardiotoxicity relative to bupivacaine. Note that even with lidocaine concentrations in a safe range, there is the potential for seizures due to an accumulation of MEGX [132].

Epidural infusions rates of amide local anesthetics are limited in young infants because of the increased risk of toxicity, as detailed earlier. Chloroprocaine infusions have been used as an alternative to continuous amide local anesthetic infusions to allow for sufficient epidural infusion rates without the associated toxicity concerns of amide local anesthetics. Studies of continuous epidural infusions of chloroprocaine showed good surgical anesthesia without neurotoxicity [109]. Higher weight-scaled infusion rates of chloroprocaine are necessary to achieve a similar extent of sensory block that is seen with bupivacaine and ropivacaine. Our practice is to use 1.5% chloroprocaine at a rate of 0.5 mL/kg/h for midthoracic epidural catheters and 0.6–0.8 mL/kg/h for lumbar and low thoracic catheters in neonates and young infants who are monitored in the intensive care unit.

Because of weight-based scaling constraints of local anesthetic infusion rates, one rationale for combining opioids, clonidine, or both along with epidural local anesthetic infusions is to provide a stronger analgesic effect while remaining in a safe local anesthetic dosing range. The addition of opioids, either neuraxially or systemically, will intensity the analgesia, but will increase the frequency of side-effects. Hydromorphone and fentanyl are the most commonly used epidurally administered opioids. In studies in adults, hydromorphone produces analgesia similar to morphine, but with less pruritus. The hydrophilic property of hydromorphone results in more cephalad spread, which can be effective for extensive surgeries that cover multiple dermatomes. The cephalad spread of hydromorphone increases the risk of respiratory depression and we tend to restrict the use of hydromorphone in epidural infusions for infants older than 4 months, infants who are opioid tolerant, or infants who require ventilatory support for a period of time postoperatively. For older children, we favor hydromorphone over other additives especially for extensive

and painful surgery, for patients who have pre-existing chronic pain and hyperalgesia, and for most cancer surgeries. Fentanyl is used in epidural infusions in infants less than 4 months of age and in children whose surgery does not involve multiple dermatomes or is associated with relatively less pain intensity. In general, slightly lower starting infusion rates should be used when epidural catheter tips are located in the thoracic region or when using hydrophilic opioids. All neuraxial opioids cause similar opioid side-effects, which are treated in much the same way as side-effects caused by systemically administered opioids. Pruritus is one of the most common side-effects of neuraxial opioids. It is most likely the result of modulation of neurotransmission in the dorsal horn and the trigeminal nucleus caudalis. Low-dose naloxone infusions in doses of 0.25 μg/kg/h are effective at treating opioid-induced pruritus and nausea without reversing analgesia or precipitating withdrawal symptoms.

Clonidine enhances and prolongs the analgesic effect of local anesthetics without contributing to respiratory depression, nausea, urinary retention, pruritus, and other opioid-related side-effects. We tend to employ clonidine most commonly for patients who have persistent epidural opioid side-effects despite standard treatments. Hypotension can occur, particularly in adolescents or in patients with inadequate blood and volume replacement.

Table 37.7 details recommended epidural infusion rates.

KEY POINTS: LOCAL ANESTHETICS AND EPIDURAL ANALGESIA

- Bupivacaine, levobupivacaine, ropivacaine, or lidocaine dose should scale with bodyweight, and hourly maximum infusion rates in infants less than 3–5 months of age should be reduced by 50%
- Topical anesthetic combinations of lidocaine, tetracaine, and prilocaine are effective but need adequate time to be effective; prilocaine is associated with methemoglobinemia
- Epidural analgesia is a versatile technique for perioperative pain; placement of the tip of the catheter at the dermatome of pain, and infusing dilute local anesthetics with opioids and clonidine, is effective

Peripheral nerve blocks and plexus blocks

The use of peripheral nerve blocks in the pediatric population has increased dramatically over the past 15 years to provide acute postoperative and chronic pain management with relative opioid sparing. Large databases have shown very low rates of complications, establishing the safety of performing peripheral nerve blocks in anesthetized pediatric patients [122,133]. In a recent meta-analysis, there was good evidence that the use of ultrasound guidance increases success rates and block duration in children [134]. Our practice has shifted in the past 10 years to largely placing peripheral nerve catheters for extremity and unilateral thoracic procedures and epidural catheters for extensive bilateral thoracic procedures or for procedures involving multiple sites where safe local anesthetic infusion volumes would prevent use of multiple peripheral nerve catheters. Chapter 20 presents an extensive discussion of peripheral nerve and plexus blocks.

Acute pain services

Over the past 30 years, there has been much focus on the development of acute pain services, in part because of the recognition of the undertreatment of postoperative pain, particularly in children. The Joint Commission has mandated specific hospital-wide standards for the treatment of pain and related symptoms in healthcare settings. There is evidence that acute pain services reduce patient reports of pain intensity and reduce delays in relieving severe pain, however the effect on other outcomes, such as incidence of side-effects, critical events, and length of hospital stay are equivocal. Other studies, however, did not consistently show similar outcomes. The specific organization of pain management programs varies depending on numerous factors including the average number of postoperative patients, the type of surgical procedures performed, and availability of subspecialists. Although the particular model of pain management program is unique to each hospital, there are common features that should be considered in the organization of acute pain services.

- Multidisciplinary group of clinicians dedicated to pain management, including anesthesiologists, nurses, surgeons, pediatricians, and pharmacists

Table 37.7 Recommended epidural infusion rates*

Solution	<1 month	1–4 months	>4 months†
Bupivacaine 0.1% ± fentanyl 2 μg/mL ± clonidine 0.4 μg/mL	Rarely used	0.2 mL/kg/h	0.4 mL/kg/h
Ropivacaine 0.1% ± fentanyl 2 μg/mL ± clonidine 0.4 μg/mL	Rarely used	0.3 mL/kg/h	0.4–0.5 mL/kg/h
Bupivacaine 0.1% + hydromorphone 10 μg/mL	Rarely used	Rarely used	0.3–0.4 mL/kg/h
Ropivacaine 0.1% + hydromorphone 10 μg/mL	Rarely used	Rarely used	0.3–0.4 mL/kg/h
Chloroprocaine 1.5% + fentanyl 0.2 μg/ml ± clonidine 0.04 μg/mL	0.5 mL/kg/h (mid-thoracic) 0.6–0.7 mL/kg/h (lumbar and low thoracic)	0.5 mL/kg/h (mid-thoracic) 0.6–0.7 mL/kg/h (lumbar and low thoracic)	Rarely used Rarely used

* Infusion rates and solutions should be modified according to clinical circumstances. Little information is available on how best to adjust these rates based on degrees of prematurity. Rates shown reflect the upper end of the usual infusion rates, based largely on both systemic accumulation of local anesthetics and on expected extent of sensory and/or motor blockade. Solutions containing hydrophilic opioids such as hydromorphone may pose a higher risk for delayed respiratory depression, so appropriate frequency of observation and continuous electronic monitoring is recommended. Higher concentrations of opioids may be considered for selected patients who are opioid tolerant.

† Weight-scaled infusion rates should plateau at values recommended for patients weighing around 45 kg, i.e. maximum infusion rates for larger patients should rarely exceed 15 mL/h.

- Designated personnel to provide 24h pain management services
- Hospital-wide protocols or algorithms for pain assessment, analgesic therapy, monitoring of pain and vital signs, treatment of side-effects, and documentation of pain-related information
- Hospital-wide standards for management of more specialized analgesic treatments such as epidural catheters, patient-controlled epidural analgesia, spinal catheters, peripheral nerve catheters, baclofen pumps, and implanted spinal/epidural ports
- Education program for clinicians (including pre- and post-tests)
- Education program for parents and children about risks, benefits, and treatment options
- Quality assurance program and outcome tracking system
- Ongoing review of pain management practices.

Formal measures of pain intensity should be assessed at regular intervals and recorded as is routine for vital signs measurement. Specific pain assessment tools are chosen based on the patient's age and cognitive and emotional ability as is detailed above in the section on pain assessment in infants and children. In general, a visual analog scale or numerical rating scale is generally used for children ages 7 years and older. Faces scales such as the Bieri or Wong–Baker faces, are appropriate for younger children aged 3–7 years. Ideally, education regarding the use of appropriate pain assessment tools should be reviewed with children and their parents at the preoperative visit. Composite pain scales that include behavioral observations, such the FLACC scale, are used for toddlers and non-verbal children. The FLACC and PIPP scales are commonly used pain scales for infants and for preterm newborns, respectively.

Protocols for pain and symptom management are the foundation to a comprehensive pain management program. Depending on the type of surgery, patients' medical condition, and the degree of postoperative pain, most postoperative pain is treated by combinations of NSAIDs, opioids, and regional analgesia. For mild postoperative pain, short-acting opioids such as oxycodone, alternating with doses of NSAIDs, generally provides good pain relief. Oral dosing is preferred when patients are able to tolerate oral intake postoperatively. Parenteral opioids are used in patients with more severe pain or when patients are restricted in their oral intake. PCA or NCA is widely used for infants and children with acute postoperative pain who require parenteral opioids. Regional analgesia including peripheral nerve catheter infusions and epidural infusions can provide excellent postoperative analgesia with opioid sparing and a subsequent decrease in opioid side-effects. Protocols for analgesic administration include standardized PCA, epidurals, and peripheral nerve catheter order sets so that range-dosing of opioids and local anesthetics solutions are standardized and somewhat independent of prescriber. Nevertheless, dosing parameters and choice of specific opioid or combined local anesthetic/opioid solutions should be individualized and based on the patient's prior opioid use and side-effect profile, severity of pain, location of surgical pain, medical condition, and psychological state. Inherent in pain management protocols are algorithms and order sets for treatment of side-effects so that patients do not experience delays in receiving treatment for common side-effects, such as pruritus, nausea, and vomiting.

All patients receiving opioids, either systemically or through regional catheters combined with local anesthetics, should be assessed for signs of respiratory depression. Protocols for monitoring level of consciousness and respiratory depression should involve nursing assessment and documentation of levels of sedation at regular intervals. Our practice is to provide electronic cardiorespiratory monitoring for all patients who have a basal rate added to their PCA, patients with risk factors for respiratory depression with opioids, such as those with certain airway diseases or neurological impairments, and young infants who are at risk for apnea with opioids. There have been reports of hypoventilation and critical events among healthy patients receiving epidural analgesia postoperatively, even when fentanyl was used as the opioid in the epidural infusion. We routinely place all patients receiving epidural infusions on cardiorespiratory monitors. While oximetry may be imperfect in detecting hypoventilation, especially when supplemental oxygen is administered, it probably facilitates rescue before serious harm occurs in many cases [135]. Other routine nursing assessment and documentation should include regular assessment of side-effects, extent of sensory and motor block for patients with regional catheters, and total daily amounts of opioids administered so that day-to-day comparisons can be made.

Hospitals with acute pain services need to have available an immediate response system to critical events. The structure of the immediate response system varies among hospitals but it is essential to have clinicians involved who have expertise in pediatric airway management and who are knowledgeable in the pharmacology of local anesthetics, opioids, and sedatives.

Quality assurance programs should analyze data pertaining to clinical practice, including general outcome measures of PCA, epidural, and other regional techniques. Data concerning adverse events should also be analyzed at regular intervals. Based on analyses of data, quality assurance programs can review institutional policies and practices and make practice guideline recommendations for improvement in safety and patient satisfaction.

Painful conditions in infants and children

Cancer pain

Children with cancer experience a variety of types of pain related to their disease process and resulting from the cancer treatments [136]. Studies of cancer pain in children have shown that as successful treatment protocols evolve, pain related to cancer treatments are the more predominant source of pain and suffering, including painful mucositis, postamputation pain, and peripheral neuropathies [137]. Repeated needle procedures, such as bone marrow biopsies, lumbar punctures, and repeated venous access, are particularly distressing for children. Tumor-related pain is often present at the time of the initial diagnosis and also results from disease progression with tumor spread to bone, spinal cord, and nerves plexuses. Children with hematological malignancies often present with bone pain from bone marrow infiltration and abdominal pain from capsular stretch of liver and spleen; those who show a good response to induction chemotherapy generally experience resolution of pain. However, a subgroup

of children will continue to experience somatic, visceral, and neuropathic pain.

Children undergoing treatment of cancer frequently need diagnostic imaging studies, radiotherapy, and brief needle procedures. Aggressive and proactive management will help decrease pain and anxiety associated with these procedures. Cognitive behavioral therapies, such as guided imagery, are useful for children with procedural pain. Topical analgesics should be routinely used for minor needle procedures such as accessing implanted vascular ports or intravenous line insertions. Depending on age, associated medical problems, and severity of pain and other symptoms, general anesthesia or moderate sedation is generally used for more invasive needle procedures, such as bone marrow biopsies and lumbar punctures. Safe sedation protocols have been established by the American Academy of Pediatrics and serve as guidelines for procedural sedation by oncologists and other subspecialists. Children with risk factors for conscious sedation or those who failed prior attempts at conscious sedation require consultation by pediatric anesthesiologists. Daily radiotherapy or diagnostic imaging, such as magnetic resonance imaging (MRI), is not typically painful but does require children to be immobile and brief general anesthesia is usually required.

Mucositis is painful inflammation of the mucosa caused by chemotherapy or radiation. It is a common side-effect in children receiving chemotherapy and is especially intense and prolonged with bone marrow transplantation. Topical agents are often used for symptomatic relief in mild mucositis, but there are limited data showing efficacy. Parenteral opioids through PCA or NCA are generally used for moderate to severe pain from mucositis. Oral opioids are not typically used initially since most children experience painful swallowing from mouth and esophageal involvement. Since many children experience significant pain from mucositis for weeks, our practice is to provide approximately 60% of the total daily opioid dose through a basal rate to provide sustained analgesia without requiring the patient to use the PCA button repeatedly throughout the day and night. For patients with mucositis whose pain is poorly controlled with standard PCA or NCA opioids, a recent trial supports the addition of low-dose ketamine to the mixture [138].

Nearly all children who have had amputations experience phantom sensations and many experience phantom pain [139]. Postamputation pain occurs more often in children who have had amputations due to cancer rather than trauma, and administration of chemotherapy may be a risk factor in the development of phantom pain. Regional analgesia, including epidural and peripheral nerve catheters can provide very effective postoperative analgesia after limb amputations. Although severity of early postop amputation pain correlates with likelihood of longer term pain, studies of pre-emptive actions of several regional anesthetic approaches have yielded mixed outcomes. Treatment with antidepressants, anticonvulsants, NMDA-antagonistic drugs, gabapentin, opioids, and clonidine has shown some success; however, there are limited data from large, controlled clinical trials. Mirror box therapy and other forms of visual feedback therapies have been used with some success in the treatment of postamputation pain [140]. A mirror is positioned so that the reflection and movement of their limb appears as if the amputated limb is intact.

A stepwise program of analgesic therapy proposed by the World Health Organization can provide good treatment of pain in adults with advanced cancer without intolerable side-effects in a large majority of patients. A similar stepwise analgesic approach has been advocated for the treatment of children with cancer pain where NSAIDs, acetaminophen, and low-dose opioids, such as oxycodone, are initially used for the treatment of mild pain. Morphine, hydromorphone, and other opioids are titrated to effect as pain escalates. The use of oral opioids is recommended when possible. For patients with persistent pain, an effective opioid regimen includes the use of long-acting opioids, such as methadone or sustained-release formulations of morphine or oxycodone. Short-acting morphine, oxycodone, hydromorphone, or other opioids are added for breakthrough pain. Oral methadone is useful as a long-acting elixir for children who are unable to swallow pills. Conversion from morphine and other short-acting opioids to methadone requires individualization and close observation because of the incomplete cross-tolerance mentioned earlier. A rough guide for conversion can be found at www.globalrph.net/narcoticconverter. Several sustained-release opioid preparations contain microbeads and it is common practice to open the capsule and sprinkle the microbeads into food just prior to use. However, if the microbeads are chewed or left in contact with food for an extended period of time, they release their contents. Not only does this reverse the sustained-release property, it can also increase the risk of overdose. Parenteral opioids are used when pain is rapidly escalating and oral opioids are not effective or when patients are unable to tolerate oral opioids due to nausea, vomiting, gastrointestinal processes, or the inability to swallow. In this setting, PCA or NCA is used, generally with a basal rate. Opioid side-effects should be aggressively treated and in cases of intolerable side-effects, opioid rotation can be helpful.

Although standard dosing of opioids adequately treats cancer pain in most children, a subgroup of children with cancer will have persistent, severe pain despite an enormous escalation of opioid dosing (e.g. 500 mg/kg/h) [141]. Refractory pain despite massive opioid doses is typically seen with tumor metastases to the spinal cord and major nerves, causing unrelenting neuropathic pain. For some of these patients, low-dose ketamine infusions and intravenous lidocaine infusions may provide an improved therapeutic window [142–144].

Many children with severe cancer pain who are resistant to opioids can be made comfortable through the use of regional anesthetic techniques, such as implanted intrathecal or epidural catheters or ports [145,146]. The choice of drugs should be individualized and depends on a number of factors, such as location and nature of pain, bowel and bladder function, and level of alertness. In most cases, dilute solutions of local anesthetics and opioids provide good pain relief, although other agents are sometimes added, such as clonidine or ketamine. Our general preference is use intrathecal rather than epidural placement in most cases, because this permits versatile dosing as pain escalates over time, and because over time epidural dosing of local anesthetics is limited by tachyphylaxis and systemic toxicity. We generally prefer placement of ports to facilitate skin care, reduce the risk of infection, and reduce the chance of catheter dislodgment at home. These procedures are performed under general anesthesia and with

fluoroscopic guidance. There are a number of technical and management issues involved, and clinicians are encouraged to consult with the authors or with others with experience in this area, since many aspects are not readily extrapolated from either perioperative regional anesthesia or adult chronic pain management. For a very small percentage of children with advanced disease and refractory pain or terminal dyspnea, there may be a role for administration of sedative infusions. However, in our view, use of sedatives near the end of life should never become routine, and efforts should be made whenever possible to preserve clarity of sensorium and interactiveness [147]. The ethical principle of double effect is commonly invoked to guide prescribing of opioids and sedatives at the end of life. While this principle has become nearly universally accepted, critics have pointed out some difficulties with its justification and application [148].

In addition to pain, children with cancer experience a range of other symptoms, such as fatigue, somnolence, and depressed mood. Some data suggest that the prevalence of symptoms is higher among children who are undergoing chemotherapy, who are hospitalized, and who have solid tumors compared with those with hematological malignancies. One study suggested that, as pain is treated more aggressively with opioids, the likelihood of fatigue and somnolence are increased [107]. Studies in adults support the use of stimulants, such as methylphenidate, to counteract somnolence from opioids.

KEY POINTS: CANCER PAIN

- Children with cancer undergo frequent needle and diagnostic imaging procedures and radiotherapy; cognitive behavioral therapies, topical analgesia, and moderate sedation/general anesthesia are used to prevent and treat pain
- Mucositis often requires parenteral opioids via PCA, and phantom limb pain can be treated with regional analgesia, analgesics, or visual feedback therapies
- Severe cancer pain resistant to opioids can be improved through implanted regional anesthetic techniques

Sickle cell vaso-occlusive episodes

Painful vaso-occlusive episodes are the most common cause of pain in children with sickle hemoglobinopathies [149]. Other acute processes can also present with pain, such as pneumonia, stroke, priapism, acute cholecystitis, splenic sequestration, and avascular necrosis. Fever can be associated with an uncomplicated pain episode or may be a sign of pneumonia, appendicitis, or other infection. The pain from vaso-occlusive crises can be unpredictable in severity, location, and frequency – ranging from occasional, mild episodes to frequent, severe, and prolonged episodes requiring repeated hospitalizations. Approximately 5% of children with sickle cell disease account for over 30% of hospitalizations and those patients with the highest rate of painful episodes and hospitalizations have the highest mortality rates [150]. Painful vaso-occlusive crises can occur in children as young as 6 months of age as the protective effects of fetal hemoglobin decreases. Dactylitis is a painful episode involving the hands and feet and is more common in younger children. Adolescents tend to experience back, limb, and chest pain, although the location can be variable. Priapism is caused by sickling of hemoglobin in the sinusoids of the penis and causes prolonged, painful erection.

Children with occasional mild to moderate painful episodes are typically managed at home with NSAIDs and oral opioids. Severe, escalating pain is generally managed in the hospital with NSAIDs and PCA with basal infusions. Opioids should be titrated to effect with close observation for hypoventilation and signs of excessive sedation. Surveys suggest that even with generous PCA dosing, pain scores remain quite high and a considerable percentage of hospitalized patients with vaso-occlusive episodes experience pain on a regular basis [151]. For some patients with severe chest pain, the high doses of opioids necessary to treat pain can result in somnolence, hypoventilation, and inability for effective coughing and incentive spirometry, leading to worsening hypoxemia and further pulmonary decline. There is some evidence that low-dose ketamine infusions may provide analgesic and opioid-sparing effects [152,153]. In selected cases, continuous epidural analgesia or peripheral nerve infusions may provide improved analgesia and reduce the need for further systemic opioids and reduce opioid-induced somnolence.

Cystic fibrosis

Patients with cystic fibrosis (CF) experience a spectrum of recurrent or persistent pain, particularly chest pain and headaches in the final year of life [154]. Other commons sites of pain include abdominal pain, recurrent limb pains that are sometimes associated with arthritis, and back pain, which is multifactorial [155,156]. Chest pain is typically the most commonly reported pain in patients with CF, regardless of severity of lung disease. Coughing and chest wall muscle strain from increased work of breathing leads to chronic musculoskeletal chest pain. Severe coughing can result in rib fractures or periosteal tears that produce pinpoint tenderness on exam and severe pleuritic chest pain.

Headaches may be due to a range of causes, including musculoskeletal strain, chronic sinusitis, migraine, hypoxia, and hypercarbia. Over 50% of patients with CF report chronic headaches. Headaches due to muscular contraction and strain are very common and are worsened by excessive coughing and increased use of accessory muscles of respiration. Sinus disease is found in the majority of patients with CF and can contribute to headache pain. In some cases, surgery can reduce pain from sinus-associated headaches. Migraines can be intractable and particularly difficult to treat in patients with CF; many patients do not experience good relief with typical abortive migraine treatments, such as NSAIDs or 5-HT1 receptor-specific agonists. With disease progression and worsening of pulmonary function, hypercarbia and hypoxia play a more predominant causative role.

Patients with CF experience a number of other musculoskeletal chronic pain conditions. Chronic back pain is generally a result of chronic muscle strain from severe coughing; however thoracic and lumbar compression fractures can

occur and are often under-recognized. The incidence of CF-associated episodic arthritis in children seems to be similar to that seen in older patients with CF, while hypertrophic pulmonary osteoarthropathy is more prevalent in adult patients.

Treatment of children with chronic pain from CF depends in part on location and severity of pain, severity of lung disease, the degree to which pain interferes with good pulmonary toilet, and response to opioids. There are no controlled clinical trials of non-pharmacological therapies in children with CF, although many patients find acupuncture, biofeedback, and other cognitive behavioral therapies helpful [157]. NSAIDs are often used either alone or combined with opioids without contributing to respiratory depression, somnolence, or constipation and may allow for opioid-sparing effects. There may be a role for COX-2 inhibitors for patients who experience gastrointesinal side-effects with traditional NSAIDs and they may be less likely to contribute to hemoptysis. If patients with CF receive opioids postoperatively, there is a very high incidence of constipation; aggressive and pre-emptive use of stimulant laxatives should be considered. The indications for chronic opioid therapy for children and adults with CF is a subject of controversy. CF is now associated with a median survival that exceeds 40 years of age in many centers, so chronic opioid administration should be undertaken with consideration of long-term consequences. We commonly employ thoracic epidural analgesia or paravertebral infusions for major thoracic and abdominal surgery in patients with CF, especially those undergoing lung transplantation. Patients with CF may benefit from thoracic epidural analgesia or paravertebral infusions for (1) severe chest pain due to rib fractures or a chest tube, and (2) impending bowel obstruction associated with meconium ileus equivalent [158]. For CF patients with meconium ileus, a thoracic epidural infusion of local anesthetic has several benefits: it relieves pain and reduces the requirement for opioids, which further slow the bowel, and it provides thoracic sympathectomy, which directly accelerates bowel motility. Many patients undergoing lung transplantation have had chronic, severe chest pain prior to transplantation, and we have found that infusing higher concentrations of local anesthetics (e.g. ropivacaine 0.2%) in combination with hydromorphone is sometimes necessary to achieve adequate analgesia.

KEY POINTS: SICKLE CELL AND CYSTIC FIBROSIS PAIN

- Painful vaso-occlusive crises in sickle cell disease often include back, limb, and chest pain, and can be treated with oral NSAIDs or opioids
- Opioid PCA and low-dose ketamine infusions are effective for severe sickle cell pain; epidural or nerve block catheters may also be used
- Chest pain, headaches, and sinus pain are common in cystic fibrosis; NSAIDs and COX-2 inhibitors are often effective

Neuropathic pain

Neuropathic pain refers to pain associated with injury or altered excitability within the peripheral or central nervous system. Unlike nociceptive pain, neuropathic pain can persist independently of ongoing tissue injury or inflammation. Aδ- and C-fibers can become activated through a range of mechanisms, including infection, inflammation, ischemia, and transection. Other causes include tumor involvement of nerves, metabolic disorders, and chemotherapeutic drugs such as vincristine. Neuronal reorganization and central sensitization occur through sustained C-fiber discharge and "wind-up" in the dorsal horn. An array of complex mechanisms induce central neural changes, including ectopic firing of dorsal root ganglion, decreases in magnesium blockade of NMDA receptors, and changes in afferent Aδ-fibers that facilitate pain [159]. Pathways containing opioid receptors and endogenous opioids, serotonin, and norepinephrine project to the rostral ventromedial medulla and spinal dorsal horn. Input from the hypothalamus, amygdala, anterior cingulate area, and insular cortex modulates the pathways and can facilitate or inhibit the transmission of pain signals.

Many adult neuropathic pain conditions such as diabetic neuropathy, central poststroke pain, and trigeminal neuralgia are quite rare in children. There may be an age dependence to the nervous system's responses to several types of nerve injury. For example, while traumatic brachial plexus injury commonly produces severe pain in adults, perinatal brachial plexus injury in human neonates rarely appears painful, except for a subset of infants who subsequently undergo nerve grafting procedures [160]. In two models of painful peripheral nerve injury, infant rats show markedly reduced allodynia and other pain behaviors compared with older rats [161]. The age dependence of neuropathic pain may be related in part to the ontogeny of microglial inflammatory responses to nerve injury [162–164].

The classic description of neuropathic pain in adults of burning, shooting, or pins and needles pain is sometimes seen in children, but younger children often have difficulty describing their pain. A thorough neurological examination should help detect underlying disease and should assess the whether there are dermatomal deficits. Characteristic physical exam findings include allodynia and hyperalgesia. Allodynia refers to previously non-painful stimuli, such as light touch of the skin, causing pain. The presence of allodynia implies abnormal sensory processing and is an important clinical sign of neuropathic pain. Hyperalgesia refers to normally noxious stimuli, such as a light pinprick, producing abnormally exaggerated pain. The history and physical examination should guide any additional studies such as testing for thyroid dysfunction, vitamin B12 deficiency, or heavy metal toxicity. Electromyography can detect signs of denervation in muscles, and nerve conduction studies are useful for objectively assessing function of myelinated large nerve fibers, but these do not measure function of smaller C- and A-δ-fibers commonly involved in neuropathic pain. Neuropathic pain may occur in a range of static or progressive neurological disorders in childhood, including mitochondrial disorders. Heterozygous Fabry disease can produce painful small-fiber neuropathies that may begin during late childhood or adolescence [165,166]. Quantitative sensory testing is a non-invasive method of assessing the function of

small as well as large sensory nerve fibers. Unlike nerve conduction studies, quantitative sensory testing is well tolerated by children and does not require sedation.

Adults with neuropathic pain are commonly treated with anticonvulsants and antidepressants. While randomized trials show efficacy for conditions such as postherpetic neuralgia and diabetic neuropathy, it should be noted that effect sizes (based on changes in pain scores) are comparatively small, and benefit is often achieved at doses that would be expected to cause significant somnolence or impaired cognition in many patients [167].

The use of drugs for the treatment of neuropathic pain in children is extrapolated from adult studies since there are very few pediatric prospective trials [168,169]. Tricyclic antidepressants are among the most established analgesics in the treatment of diabetic neuropathy, postherpetic neuralgia, and central poststroke pain in adult patients. Tricyclics can also be helpful in promoting sleep in patients with sleep disorders due to pain. For children and adolescents with neuropathic pain, we generally use tricylics and anticonvulsants as first-line drugs. Gabapentin, oxcarbazepine, nortriptyline, and amitriptyline are most commonly used. In a randomized controlled study comparing gabapentin with amitriptyline in 34 children and adolescents with neuropathic pain, both drugs had similar effects on reducing pain intensity and improving sleep without significant side-effects [170]. Tricyclics are often prescribed in twice daily dosing with a larger portion of the dose give at bedtime. A baseline electrocardiogram is recommended prior to initiation. A typical starting dose for nortriptyline is 0.2 mg/kg with dose titration every 3–5 days. Common side-effects are related to anticholinergic effects including dry mouth, sedation, tachycardia, constipation, and urinary retention. There is less robust evidence for the use of selective serotonin reuptake inhibitors (SSRIs) in the treatment of neuropathic pain in children, but they are often used as an adjuvant in the treatment of associated mood disorders. Overall, antidepressants, including SSRIs, appear less effective for treatment of major depressive disorders in children compared with adults. In randomized trials, placebo responses are common and substantial; effect sizes relative to placebo are relatively small, and numbers needed to treat (NNTs) average 8 or greater [171]. NNTs are somewhat better (lower) for the treatment of anxiety disorders in children [171,172]. Gabapentin and pregabalin are widely prescribed, in part because of historical concerns about risks of antidepressants exacerbating suicidal ideation or attempts. However, meta-analyses of clinical trials of anticonvulsants suggest that multiple anticonvulsants also may increase these risks, even in patients without epilepsy or known severe mood disorders [173]. Parenthetically, anesthesiologists should note that lipid emulsions, which are used to treat bupivacaine cardiotoxicity, also appear to be effective in reversing cardiotoxic effects of several classes of antidepressants and anticonvulsants [174]. While the overall excess risk of severe mood or behavioral changes from antidepressants or anticonvulsants appears relatively low, in our view clinicians should titrate these medications gradually, should alert parents to report any concerning changes in behavior or affect, and should employ a system of phone and clinic-based follow-up to detect adverse effects of these medications.

Lidocaine 5% transdermal patches are widely prescribed for neuropathic pain and for other forms of pain. Plasma concentrations of lidocaine are quite low. While these formulations appear quite safe, and there are studies supporting efficacy for several types of neuropathic pain in adults, in our view there is a high likelihood that placebo responses contribute substantially to their reported benefits for many patients [175].

The use of opioids in the treatment of chronic pain not associated with a life-limiting condition remains controversial. Opioid prescribing for chronic pain in adults increased enormously over the past 30 years, with a concomitant increase in overdose deaths in adults and adolescents due to apparent non-medical use or diversion of prescribed opioids. Diversion of prescribed opioids has increased rapidly as a problem among adolescents, however most recent data indicate a downward trend in medical and non-medical use of prescription opioids among adolescents [176,177]. In recent years, heroin and street fentanyl have increased more than prescribed opioids as causes of fatal overdoses. In adult studies for chronic non-cancer pain, evidence for long-term benefit of opioids on pain scores is limited, and most studies show no benefit for measures of functioning or disability. As a result, Centers for Disease Control and Prevention guidelines for the treatment of chronic pain emphasize non-opioid therapies [178]. For children and adolescents with non-life-limiting chronic pain conditions there are additional concerns. First, as noted above, opioid tolerance is probably more rapid in childhood compared to in adults. Secondly, adolescence appears to be a time of unique vulnerability to addiction to multiple classes of substances. Long-term opioid prescribing for children is relatively infrequent [179]. Methadone and buprenorphine may play a role for a very small subgroup of patients with refractory neuropathic pain in the context of a multidisciplinary treatment approach.

KEY POINTS: NEUROPATHIC PAIN

- Neuropathic pain can persist independently of tissue injury or inflammation
- Allodynia and hyperalgesia are components of neuropathic pain
- Tricyclic antidepressants, anticonvulsants, gabapentin, opioids, and transdermal lidocaine are all frequently utilized for neuropathic pain

Complex regional pain syndromes

Complex regional pain syndrome type 1 (CRPS1) is characterized by neuropathic limb pain with associated sensory characteristics and neurovascular and sudomotor findings. The term CRPS1 overlaps with what was previously called reflex sympathetic dystrophy or reflex neurovascular dystrophy [180]. Diagnostic criteria for clinical and research purposes have undergone refinement [181]. The classic clinical presentation is burning pain in an arm or leg with allodynia, hyperalgesia, mottling, coolness, swelling, and abnormal sweating, although the clinical presentation can vary widely. Various motor findings can also occur such as tremors, fasciculations,

and dystonia. CRPS2 refers to this pattern of clinical findings with signs of specific peripheral nerve injury; this is similar to what was traditionally called causalgia. In our view, although there may be important roles for peripheral and autonomic mechanisms, it is useful to view CRPS as being maintained at least in part by abnormal information processing in the brain. These functional brain abnormalities are not purely sensory, but also involve pain modulation [182] and motor representation [183,184].

CRPS has unique epidemiological features in children. Multiple cases series have found a high female to male ratio (approximately 5–8:1) and a preponderance of lower extremity involvement (75–90%) [180,185,186]. The peak age of onset is 10–12 years of age. It is rarely seen in children less than the age of 6 years. Twenty percent of children have a remote or contralateral limb affected. About 90% of patients recall an inciting trauma but it is usually vague and minor. Some children can present as extremely disabled, have significant school absences, and are unable to ambulate independently, however the degree of disability seems to vary widely. fMRI has been used to study CNS activation in children with CRPS [187,188]. Some functional and structural changes normalize after the pain from CRPS resolved, while other changes are persistent [187–190].

Retrospective case series and prospective studies in children have indicated that the majority of children with CRPS will have improvement in both function and pain through an aggressive rehabilitative approach without the use of nerve blocks or pharmacological agents [191,192]. The frequency of recurrent episodes may range from 20% to 50% of cases, although most recurrences of symptoms appear to be milder than the initial episode and more readily responsive to reinstitution of aggressive physical therapy, occupational therapy, and cognitive-behavioral therapies. Our practice in treating children with CRPS involves a rehabilitation program with these therapies. A significant aspect of the approach involves patient and parent education about the non-protective nature of neuropathic pain and recognizing factors that reinforce disability and fear of pain. Physical and occupational therapies are directed at active mobilization of the affected limb, resuming independent weight-bearing, and aggressive desensitization techniques [172,192]. For some children, this program can be accomplished as an outpatient but those who continue to have severe pain and limb dysfunction may need an inpatient or partial hospitalization program. Results of an interdisciplinary day hospital treatment program comprised of physical, occupational, and cognitive-behavioral therapies with medical and nursing services for pediatric CRPS showed significant improvements in pain, functional disability, emotional functioning, and use of assistive devices [192]. Functional gains were maintained or further improved at follow-up at 10 months postdischarge [192]. Continuous epidural or peripheral nerve local anesthetic infusions are used for a comparatively small subgroup of patients who fail to make good progress with good rehabilitation efforts or for those with severe limb swelling or dystonia that persists after an active multidisciplinary treatment program [193]. If the distribution of pain, allodynia, and autonomic abnormality is appropriately limited, there are advantages to the use of peripheral or plexus catheters. Our practice is to use an indwelling catheter technique for several days rather than repeated single injections. We tend to place continuous popliteal–sciatic catheters for lower extremity CRPS and either supraclavicular or infraclavicular catheters for upper extremity CRPS [194]. Patients are then hospitalized and receive continuous local anesthetic infusions of ropivacaine. During their 3–5-day hospital stay, they receive intense rehabilitation with twice daily physical therapy and cognitive-behavioral therapy. In a review of 102 children who received continuous regional analgesia and inpatient pain rehabilitation for CRPS, 75% had significant benefit, including pain reduction and improved function [193].

KEY POINTS: COMPLEX REGIONAL PAIN SYNDROMES

- CRPS presentation includes burning pain in an arm or leg with allodynia, hyperalgesia, mottling, coolness, swelling, and abnormal sweating
- CRPS1 occurs without antecedent peripheral nerve injury (reflex sympathetic dystrophy); CRPS2 occurs in association with peripheral nerve injury (causalgia)
- CRPS treatment incudes an aggressive rehabilitation approach; continuous epidural or peripheral nerve local anesthetic infusions are used for a small subgroup of patients

Back pain

Back pain in adults is a major cause of suffering as well as economic loss due to work-related disability. Non-disabling episodic back pain is relatively common in children and adolescents, but daily persistent back pain is overall much less common than in adults [195]. Since persistent severe back pain is relatively less common in younger children, it is appropriate to evaluate for specific serious causes including infections (osteomyelitis, diskitis, pyelonephritis), tumors, benign abnormalities such as osteoid osteoma, and congenital abnormalities, such as tethered cord and diastematomyelia.

Back pain in our referral practice is more commonly seen in adolescents who are competitive athletes, such as gymnasts, dancers, and cheerleaders. A thorough neurological and musculoskeletal exam is necessary to determine likelihood of conditions such as lumbar disk disease, spondylolysis, spondylolisthesis, sacroiliitis, and muscular strain. Patients with muscular pain without evidence of radiculopathy are treated with an exercise program of core strengthening and reducing repetitive stress and trauma to the spine. With proper patient selection, fluoroscopically guided epidural steroid injections appear to provide intermediate-term benefit in adults with lumbar radiculopathy. Our recent review of experience with fluoroscopically guided epidural steroid injections for children and adolescents with lumbar radiculopathy showed that the majority of patients reported significant reductions in pain with an excellent safety profile. In 2–5 years of follow-up, fewer than 40% of patients required diskectomy [196]. In adults, extension-related back pain is commonly associated with facet arthropathy. In adolescents, this pattern of pain is commonly seen with spondylolysis and spondylolisthesis. These conditions are commonly treated with a trial of bracing. Adults with

cervical or lumbar facet disease commonly receive median branch blocks and, if they provide short-term benefit, with radiofrequency denervation procedures [197]. In our practice, we perform some of these injections using local anesthetic and low doses of steroids. To date, we have been reluctant to perform radiofrequency denervation procedures on patients with a developing spine except in extraordinary circumstances.

Functional gastrointestinal pain

Functional gastrointestinal disorders are common in pediatric populations and include a range of symptoms such as nausea, vomiting, constipation, and pain [198,199]. Functional abdominal pain disorders refers to persistent or episodic abdominal pain occurring among children and adolescents for whom symptoms cannot be attributed to another medical condition [198,200]. Functional abdominal pain disorders present in distinct patterns, as codified most recently by the Rome IV classifications, and include functional dyspepsia, irritable bowel syndrome, abdominal migraine, and functional abdominal pain not otherwise specified [198]. These conditions account for a high frequency of pediatric office visits, and may account for up to 20% of school days missed due to illness in the USA. Most children who present in this manner remain medically well and few eventually are found to have an identifiable structural or inflammatory disorder.

There are common features of functional abdominal pain with respect to clinical characteristics. Most children are between the ages of 4 and 16 years and report episodic, diffuse, or periumbilical pain. Children younger than 4 years should prompt further investigation into underlying causes. Children are otherwise generally medically well without systemic signs of disease. Rarely do children report that pain awakens them at night. The diagnostic approach in primary care should be guided by a careful history and physical examination and should avoid unfocused laboratory testing beyond basic studies, such as a complete blood count and urinalysis, and as appropriate, such as testing for gluten sensitivity, lactose intolerance, amylase, lipase, and stool examination [201]. A psychosocial history is important for identifying reinforcing pain behaviors and other behaviors that suggest disability. In general, extensive testing, routine radiographic studies, and unfocused laboratory testing are not helpful and may heighten parental and patient anxiety. For children who have fevers, weight loss, or poor growth, a family history of inflammatory bowel disease, and localized pain that is not periumbilical, these are concerning signs and warrant further evaluation. Abnormalities on physical examination should also guide additional investigation.

Treatment of functional abdominal pain disorders depends in part on the pattern of clinical presentation and the degree of distress or disability involved. As guided by the history and examination, some clinicians favor empirical trials of treatment of constipation, lactose avoidance, or lactose enzyme supplementation, dietary alterations such as the FODMAP (fermentable oligo-, di-, and monosaccharides, and polyols) diet, or acid suppression [202–204]. Education of parents and patients should include discussion about the non-protective character of the pain, and should discourage catastrophizing and overmedicalizing. Cognitive-behavioral interventions are supported by evidence, and should be used early in the course of treatment [205]. In our view, medications form only a part of the management and should not be used in lieu of lifestyle change, rehabilitative interventions, and cognitive-behavioral interventions. Controlled trials of medications such as amitriptyline have yielded both positive and negative results [206]. Many medications are commonly prescribed based on uncontrolled pediatric case series or extrapolation from adult studies [207,208].

Headache

Episodic headaches are also common in children and adolescents. The frequency of both migraine and tension-type headaches increases through childhood. Prior to adolescence, boys and girls are similarly affected. With the onset of adolescence, the prevalence increases more in girls than in boys, particularly with migraine. Patients and parents are often worried that headache is associated with serious conditions, such as tumors. As with abdominal pain and chest pain, diagnostic evaluation should emphasize the history, including a psychosocial history, and physical examination, including a systematic neurological examination. Practice parameters on imaging for recurrent headaches in childhood have been published. In the absence of features of the clinical presentation that suggest higher risk, imaging studies are generally of low yield [209], or they identify incidental findings [210] that further increase worry but are of generally limited clinical significance.

While recurrent tension-type headaches or episodic migraine are common, for the majority of children in the general population they do not dramatically impair daily functioning. The subgroup of children who may be referred to pediatric neurologists or pediatric pain physicians tends to be those with more frequent or more severe headaches, or those who have pathological but not readily "fixable" headaches. Examples of the latter include headaches following head trauma or following multiple ventricular shunt procedures with slit ventricles. The occurrence of more disabling recurrent headaches [211] or chronic daily [212] headaches is more prevalent with certain lifestyles, including obesity, smoking, and lack of physical exercise, with some psychological comorbidities, including anxiety and depression, and with overuse of analgesic medications.

For children with relatively infrequent migraine episodes, there is evidence to support episodic use of NSAIDs and several triptans for abortive treatment [213]. For children and adolescents with disabling recurrent or chronic daily headaches, in our view, treatment should begin with identification of triggering factors, lifestyle modifications, and avoidance of overly frequent use of acetaminophen and NSAIDs. A number of approaches to cognitive-behavioral therapy show strong evidence of efficacy for both migraine and tension-type headaches, and they should be used widely [214].

The use of prophylactic medications for pediatric migraine is often based on custom and on extrapolation from adult studies. For example, cyproheptidine is widely used, despite absence of controlled trials. While several anticonvulsants are widely used, evidence for efficacy is sparse for most anticonvulsants [215]. There is some support for topiramate in recent placebo-controlled pediatric migraine prophylaxis trials [216]. There are positive trials for amitriptyline, trazodone, and several calcium channel blockers, and trials of propranolol have yielded mixed

results [213]. A double-blinded, placebo-controlled trial of amitriptyline and topiramate for pediatric migraine prophylaxis showed no significant differences in headache frequency or related disability compared with placebo [217]. Patients receiving amitriptyline and topiramate had higher rates of adverse events. Nerve blocks such as occipital blocks and trigger point injections are commonly used in the management of pediatric headaches, however there is limited evidence on efficacy [218]. In young adults with persistent transformed migraine, we occasionally do scalp injections of botulinum toxin, based on adult studies [219].

KEY POINTS: BACK, FUNCTIONAL GASTROINTESTINAL, AND HEADACHE PAIN

- Back pain in adolescents is commonly seen with spondylolysis and spondylolisthesis; fluoroscopically guided epidural steroid injections are effective for patients with lumbar radiculopathy
- Functional gastrointestinal pain is primarily treated with cognitive-behavioral interventions
- Muscle tension headaches are treated with cognitive-behavioral interventions and mild analgesics; migraines may require avoidance of triggers, triptans, and other preventive drug strategies, and occasionally scalp injections of botulinum toxin

Summary

The management of acute, recurrent, and chronic pain in children has made considerable progress over the past 30 years. While pain assessment is more challenging in infants and preverbal children, pragmatic measures are now available for all age groups. Treatment should be individualized and may involve combinations of pharmacological, regional, rehabilitative, and cognitive-behavioral interventions. Multicenter clinical trials will be helpful for conducting adequately powered clinical trials for many forms of acute and chronic pain in pediatrics.

CASE STUDY

You are working in a pediatric chronic pain clinic when you are paged by one of the emergency room physicians who asks if you would urgently evaluate a patient who has severe foot pain and is currently being seen in the ER. You agree to see the patient who then shortly arrives in your office. The patient is an 11-year-old competitive gymnast who is accompanied by her mother. The child has an 8-week history of left foot pain, which she attributes to tripping over a gymnastic mat; this event produced a small laceration of her foot and a sprain. An orthopedic surgeon evaluated her after the fall. Her plain radiographs did not show an obvious fracture, but she did wear an aircast boot for 4 weeks without significant improvement. A recent bone scan showed osteopenia of the affected limb. An MRI showed no significant findings. Her pain is significantly worse this morning since falling last night after her left foot "gave out" as she was walking up stairs. She reports that her foot often "gives out" and feels like she has no strength in it. She is otherwise medically well. She describes her pain as a numb, burning sensation over her entire left foot with shooting pains into her lower calf. She has noticed occasional swelling and redness of her foot and has also noticed that her foot seems to shake involuntarily. She has difficulty falling asleep due to pain and is unable to have the blankets touch her painful foot. She and her mother are tearful as she explains how she will miss the state competitions in 1 month if she cannot participate fully. Her mother explains how difficult this has been for the entire family and how she has had to take a leave of absence from her job since the onset of her daughter's pain 2 months ago. She does describe how supportive the teachers at her child's school have been by allowing her to attend classes only when she is able to make it.

On examination, she is a small-appearing female who is ambulating with the use of crutches. The lateral aspect of her left foot has a 3 × 3 cm area of slight ecchymosis and edema, which the patient reports comes and goes. Her foot has a mottled appearance. When you lightly touch her foot, she withdraws, begins to cry, and explains that it feels like an intense burning and pins and needles sensation. Her foot and lower leg feel cool to touch up to the lower calf. She has noticeable atrophy of her gastrocnemius. She refuses to bear weight on her foot during the examination or to place her left foot on the floor. You explain to the patient and her mother that her history and physical examination findings are most consistent with a diagnosis of complex regional pain syndrome (CRPS). Her allodynia and pain in a nondermatomal distribution are typically seen in CRPS. Neurovascular and motor findings such as edema, intermittent color, and temperature changes, and involuntary spasms and tremors are also consistent with CRPS. A bone scan and MRI have ruled out other worrisome conditions such as osteomyelitis or an occult fracture.

Your discussion with the patient and her mother involves extensive education about CRPS and treatment options. CRPS is rare before the age of 8 years and peaks around the age of 12–13 years. Girls are six times more likely than boys to have CRPS and the lower extremity is much more commonly involved than an upper extremity by a ratio of 8:1. Twenty percent of children experience spread of their symptoms to a contralateral or remote limb, which is presumably due to central sensitization. The majority of children report an antecedent injury, although in most cases the injury seems vague and minor, such as the injury that occurred in this patient. Studies have shown that children with CRPS have similar scores on depression and anxiety testing compared with other children with chronic pain conditions. Plain radiograph findings in children with CRPS are variable and can show diffuse osteopenia or can appear normal,

even with long-standing CRPS. Bone scans also show variable results and have little to no predictive value in CRPS but, as in our patient, can exclude other pathology such as infection. Although CRPS is a clinical diagnosis, quantitative sensory testing has been used in children to provide more objective evidence of sensory abnormalities. It is used to assess function of cutaneous somatic small fibers and is particularly applicable to children since it is painless and does not require sedation.

In discussing various treatment options, you explain that studies of children with CRPS show that the majority will show a good improvement with respect to function and pain intensity through a multidisciplinary approach of active physical therapy, occupational therapy, and cognitive-behavioral therapy. You explain that in some cases a nerve block is indicated so that patients are able to participate in physical therapy or if you are concerned about limb perfusion. The patient's mother asks for a medication such as oxycodone that will alleviate her daughter's pain quickly so that she can participate in the state gymnastics competition. You explain that data showing efficacy of medications are lacking and there is no "quick fix." However, since the patient is having difficulty with sleep, you do prescribe 10 mg of nortriptyline at night. You order a baseline ECG to detect any underlying dysrhythmia that would place her at additional risk in taking a tricyclic antidepressant. You explain that in most cases, you do not prescribe opioids for patients with CRPS. You emphasize to the patient and her mother that cognitive-behavioral techniques such as biofeedback are important to her overall recovery and that therapy will be directed at improving her coping skills, maintaining regular school attendance, and normalizing behavioral responses to pain. She will need to have active participation in physical therapy, particularly to regain strength, to ambulate without the use of assistive devices and for desensitization techniques. You discuss the non-protective nature of neuropathic pain in that, unlike nociceptive pain which is protective, neuropathic pain is abnormal processing of nerves and pain does not imply tissue injury. If outpatient therapy is not effective, you discuss the possibility of an inpatient or partial hospitalization program for intense rehabilitation.

The patient and her mother return for a follow-up visit in 3 weeks after an outpatient trial of physical therapy and cognitive-behavioral therapy. She has made very little progress. She refuses to participate in physical therapy because of her severe pain. In fact, she is using a wheelchair almost exclusively now and will not allow anyone or anything to touch her foot, even to examine it. She is tearful throughout the evaluation and keeps her knee flexed to protect her foot. Her foot and lower calf have a duskier and diffusely mottled appearance with significant worsening of muscle atrophy. Because of her refusal to participate in physical therapy and her severe neurovascular findings, you offer the patient an admission to a partial hospital pain rehabilitation program which is available to her in 3 weeks. In addition, you offer her a nerve block with an inpatient rehabilitative hospital stay prior to her admission to the pain rehabilitation program to which the patient and her mother agree. Since her pain is unilateral and involves the foot and ankle, you recommend placing a popliteal–sciatic peripheral nerve catheter.

Under general anesthesia, she has a left popliteal–sciatic catheter placed using ultrasound guidance. You inject 7 mL of 0.2% ropivacaine which results in a motor and sensory response. She is taken to the recovery room where a continuous sciatic catheter infusion of 0.1% ropivacaine is started at 8 mL/h; she is then admitted for an anticipated 4–5-day hospital stay. During her hospitalization, she will receive twice daily physical therapy and daily cognitive-behavioral therapy. She will have a strict schedule each day consisting of physical therapy, psychology therapy, "home" exercises, and school tutoring. She will have to dress each morning in regular clothes and wear her shoes and socks. She progresses well during the hospitalization and shows increasing participation in her therapies and activities. No new medications are started. During the course of her psychology sessions in the hospital, it becomes apparent that the demands of school and competitive gymnastics have been very stressful for her, particularly given her perfectionistic tendencies. On hospital day 5, the catheter is removed. She continues to experience intense allodynia and neurovascular symptoms, but feels that overall her symptoms have improved. She is discharged home with physical therapy and psychology follow-up with a planned admission to the partial pain rehabilitation program when an opening is available.

In 2 weeks she is admitted to the partial hospital pain rehabilitation program. During her stay, she receives intense multidisciplinary treatment consisting of 8 h per day of physical therapy, occupational therapy, and psychological therapy with nursing and physician involvement. There is a significant focus on learning active coping skills, family and individual education, desensitization, independent ambulation, and regaining full function despite the presence of pain. By the end of her first week in the partial program, she is able to tolerate shoes, socks, and partial weight bearing on her left leg. By the end of week 2, she is fully weight bearing with no crutches and is able to walk on a treadmill. Sleep is greatly improved through the use of cognitive-behavioral sleep strategies. She has discontinued nortriptyline. Desensitization techniques are still very painful although she is compliant with all aspects of the program. She stays an additional 2 weeks in the partial program. She makes good progress in regaining muscle strength and bulk. Her foot and ankle appear pink and well perfused. Through family therapy with the psychologist, it has been decided that she will still participate in gymnastics but not at a competitive level. Results of neuropsychological testing indicate that she has a mild learning disability and appropriate accommodations will be provided to her when she returns to school. A school reintegration plan is made with her school and her team at the partial program prior to discharge. At discharge, she is able to run, dance, and participate in a full school day, although continues to report some pain in her left foot and ankle.

At her 4-week follow-up appointment, she walks into the office without the use of assistive devices, wearing her shoes

and socks. She and her mother report she is back to school full time with no absences or early dismissals due to pain. She is socially active and involved in an upcoming school play. She reports having no functional limitations.

Teaching points

1. In evaluating children with painful conditions, it is important to perform a thorough history and physical examination to detect underlying or sometimes overlooked causes of pain. For example, other causes of pain in this patient include an isolated nerve injury resulting from her fall or osteomyelitis, since she had erythema, pain, and swelling associated with an open laceration and a presumed fracture. Most children with allodynia in a non-dermatomal pattern associated with motor and neurovascular changes will have CRPS. However, an underlying malignant tumor causing nerve compression can also cause exquisite neuropathic pain and a careful history and physical examination with attention to neurological signs, lymphadenopathy, and distribution of pain will help to clarify possible etiologies.
2. There are numerous classes of drugs used in the treatment of chronic pain, including tricyclic antidepressants, anticonvulsants, and serotonin reuptake inhibitors. It is necessary to understand the wide range of side-effects of these medications and possible interactions as different classes are combined. Our practice is not to use opioids for chronic pain not due to a life-limiting illness.
3. Evidence shows that the majority of children with CRPS will show good response to a conservative approach of intense physical therapy and cognitive-behavioral therapy and many children will never require a nerve block. Nevertheless, treatment must be individualized for each patient. The 11-year-old girl described in this case had a brief trial of outpatient physical therapy and cognitive-behavioral therapy. It was apparent at her initial follow-up visit that she was unable to actively engage in the physical therapy and cognitive-behavioral therapy necessary to recover. It was therefore decided to provide more intense treatment in a partial hospital pain rehabilitative program. Prior to her admission to the program, it was decided to pursue a nerve block and initiate aggressive physical therapy and cognitive-behavioral therapy in the hospital. Because she still had significant functional deficits at discharge, it was necessary for her to continue treatment in a partial hospital pain rehabilitation program.

Introduction

One of the most significant changes in medical practice over the past two decades has been the rapid and enormous expansion of outpatient surgery. For the purposes of this chapter, this includes only day case surgery or other procedures, where the procedure and the discharge home are on the same calendar day, and does not include so-called short stay, i.e. "23-hour admission" surgery where an overnight stay in a medical setting, with nursing care, is included. This growth has been largely fueled by escalating healthcare costs and an imperative need for efficient utilization of shrinking healthcare resources. Recognition of the numerous benefits of outpatient surgery including less disruption of family schedules, decreased inconvenience to patients, fewer psychological disturbances, decreased exposure to nosocomial infections, and greater patient satisfaction have further driven the shift toward performing surgery in the ambulatory setting. This change in practice has affected both adults and children. Indeed, in the year 2006, over 2.3 million ambulatory anesthetic procedures were performed in children under 15 years of age in the United States alone which translates to 38 procedures per 1000 children and represents an approximately 50% increase over procedures performed in 1996 [1]. By 2010, this number had increased to 2.9 million procedures, and of these, approximately half were performed in hospital outpatient settings, and half in ambulatory surgery centers (Table 38.1) [2]. A breakdown of surgical procedures by outpatient versus inpatient status at Texas Children's Hospital in 2017 is shown in Figure 38.1. Of 45,663 total anesthetics, 33,786 (74%) were outpatients.

Historically, the practice of outpatient surgery was first reported in 1909 more than a century ago [3] and the first outpatient surgical center was established in Sioux City, Iowa in 1918 [4]. However, it was not until 1984 that outpatient anesthesia became recognized as a specialty and the Society of Ambulatory Anesthesia was formed. The growth of the specialty of ambulatory anesthesia was accompanied by significant advances in anesthetic techniques including the availability of better anesthetic agents that enabled patients to recover faster. Improved analgesic agents and the practice of regional analgesia techniques allowed patients to be discharged home in reasonable comfort, or with mild to moderate pain that could be adequately managed at home. Such advances coupled with improvements in surgical techniques including minimally invasive procedures made it possible to move procedures from the inpatient to the ambulatory setting. These developments have also resulted in patients with more complex co-morbidities being considered for ambulatory surgery. The ongoing challenge is the provision of efficient, high-quality, and safe perioperative care to patients with complex medical histories for a large variety of surgical procedures in diverse venues. Continuous scrutiny of existing systems along with critical ongoing evaluation of outcomes is necessary to provide a framework that will guide care that is safe, effective, patient centered, and efficient in the ambulatory surgery setting.

Gregory's Pediatric Anesthesia, Sixth Edition. Edited by Dean B. Andropoulos and George A. Gregory.

Design and setting for outpatient surgery

Outpatient surgery in the pediatric population may be performed safely and efficiently in a variety of settings. Such environments include hospital-associated ambulatory care facilities such as operating room suites within hospitals or satellite surgery centers, unaffiliated freestanding facilities, as well as individual physician's offices. One of the most significant reasons for implementing outpatient or day surgery is to maximize efficiencies while decreasing costs. Previous investigators have suggested that the ambulatory surgery center (ASC) model by virtue of its bias toward high volume provides more efficient, higher quality care at a lower cost as compared with hospital-based facilities [5].

Table 38.1 Estimates for outpatient surgery and other outpatient procedures in the USA in children 0–15 years of age, 2010

Procedure	Number
All procedures	2,916,000
Operations on the eye	93,000
Operations on the ear	847,000
Myringotomy with insertion of tube	699,000
Operations on the nose, mouth, and pharynx	903,000
Tonsillectomy with or without adenoidectomy	289,000
Adenoidectomy without tonsillectomy	69,000
Operations on the urinary system	67,000
Operations on the musculoskeletal system	173,000
Reduction of fracture	52,000
Operations on the integumentary system	131,000
Miscellaneous diagnostic and therapeutic procedures	228,000

Estimates are for both ambulatory surgery centers and outpatient procedures in hospital settings.
Source: Data from US Centers for Disease Control Ambulatory Surgery Data [2].

The Institute of Medicine has described high-quality care as care that is safe, effective, patient-centered, timely, efficient, and equitable [6]. These goals may be achieved by focusing on a select population with as few complicating factors as possible.

To ensure the most efficient operation, facilities and personnel should be dedicated solely to pediatric patients as well as outpatient or day surgery. Administrative and medical personnel at such a center are able to provide a uniquely effective care plan that is perhaps hindered, disadvantaged, or even unobtainable when such children are mixed with adults or a more complicated inpatient pediatric patient population. Resource and space constraints may nevertheless force the comingling of various patient groups in a single surgical environment. In such cases, special consideration should be given to the needs of pediatric patients and parents. The separation of inpatient (hospital setting) and outpatient waiting and recovery areas is highly desirable. Likewise, where children and adult patients are mixed, special attention should include the incorporation of child life experts, playroom facilities, changing stations, feeding considerations, and progressive care into the pre- and postoperative setting.

Generally speaking, outpatient surgery requires the same anesthetic and recovery equipment that would be required for any hospital patient. At autonomous surgical sites or physicians' offices, certain other minimal capabilities should be available on site: basic laboratory functions, processing facilities for equipment sterility and maintenance, and an informatics system to accommodate medical record utilization. Standard resuscitation equipment specific to pediatric patients of all ages must be available. A fully stocked cart addressing difficult airway scenarios should also be available, and should minimally include some form of video or fiberoptic assist as well as materials for an emergent cricothyrotomy. Finally, clearly delineated plans and prearrangements must be conceived and implemented to accommodate any patient who

Table 38.2 Summary of the American College of Surgeons Childrens' Surgery Verification Program scope of practice

Level	I	II	III
Age	Any	Any	>6 months
ASA	1–5	1–3*	1–2
Multidisciplinary management of co-morbidities	Multiple medical and surgical specialties; pediatric anesthesiology	Typically single surgical specialties; neonatology; pediatric anesthesiology	None
Operations†	Major congenital anomalies and complex disease, including those that are uncommon or require significant multidisciplinary coordination	Common anomalies and diseases typically treated by most pediatric surgical specialists and that do not require significant multispecialty coordination	Common, low-risk procedures typically performed by a single specialty
Ambulatory‡	ASA 1–3 Full-term infants and preterm infants may be cared for as ambulatory patients based on written guidelines established by the pediatric anesthesiologist in charge of perioperative care. Institutional guidelines generally require full-term infants <44 weeks or preterm infants <50 weeks PMA to be monitored for at least 12 h postoperatively	ASA 1–3 Full-term and preterm infants may be cared for as ambulatory patients based on written guidelines established by the pediatric anesthesiologist in charge of perioperative care. Institutional guidelines generally require full-term infants <44 weeks or preterm infants <50 weeks PMA to be monitored for at least 12 h postoperatively	Otherwise healthy (ASA 1–2) Age >6 months

* Emergent procedures in some patients >ASA 3 may be appropriate in neonatal patients such as those with necrotizing enterocolitis.
† Depending on patient age, co-morbidities, and need for multidisciplinary surgical approach, these may be appropriate for either level I or level II centers.
‡ Ambulatory sites of care are included in these recommended levels of institutional designation when the on-site provider team possesses the requisite pediatrie training and experience. The site of care may be physically attached/integrated into the hospital or may be a component of a demonstrably integrated healthcare delivery system that provides these defined resources.
ASA, American Society of Anesthesiologists; PMA, postmenstrual age.

develops complications requiring more extensive care including emergent transportation and hospital admission [7].

The American Academy of Pediatrics Section on Pediatric Anesthesiology has published recommendations for the perioperative environment for anesthesia and surgery in children [7]. The facilities should include a separate preoperative unit or an area within a general preoperative unit that is available and designated to accommodate pediatric patients and caregivers. It should have age- and size-appropriate pediatric equipment required for the preoperative evaluation and preparation of the infant or child. In the operating and procedure rooms, a full selection of pediatric-sized equipment for all phases of anesthesia care, including airway and monitoring equipment, and drug dosing and resuscitation carts, should be available for pediatric patients of all sizes. A pediatric difficult airway cart with devices of all sizes needs to be available. Warming devices, i.e. forced-air warming systems and heat lamps, also need to be available. The postanesthesia care unit (PACU) environment similarly should be equipped with pediatric devices of all sizes and appropriate recovery beds for the pediatric population, i.e. high-top cribs for patient safety. There needs to be a set of written pediatric guidelines for treatment, and drug dosing information specific to pediatric patients. Anesthesiologists caring for pediatric patients should have significant training and experience in the care of pediatric patients; and patients of higher risk should have the services of an Accreditation Council for Graduate Medical Education (ACGME) trained, and preferably American Board of Anesthesiology (ABA) certified pediatric anesthesiologist. Minimum case volume standards for pediatric anesthetics should be in place for anesthesiologists. Similarly, nursing staff in all phases of care should have specific training and experience caring for pediatric patients. In the case of freestanding ASCs, detailed, specific transfer agreements to an inpatient hospital with pediatric capabilities must be in place.

The American College of Surgeons, in conjunction with the Society for Pediatric Anesthesia and American Academy of Pediatrics, has recently instituted a voluntary Children's Surgery Verification (CSV) program, with the goal of improving pediatric surgical, procedural, and perioperative care [8]. Included in this program are standards for the delivery of pediatric anesthesia care across a variety of practice settings. The scope of practice requirements are summarized in Table 38.2. The definition of a "pediatric anesthesiologist" is one who is certified or eligible for the ABA pediatric anesthesiology certification or equivalent, i.e. ACGME fellowship trained (Table 38.3). An alternative pathway for this designation requires significant ongoing pediatric anesthesia practice and additional continuing medical education requirements. An "anesthesiologist with pediatric expertise" is defined as certified or eligible for basic ABA certification, and is performing at least 25 anesthetics per year on patients <24 months of age. Of note, in level III of this program, only patients >6 months of age, and of American Society of Anethesiologists (ASA) physical status (PS) 1 or 2 should be cared for in the institutions with this designation. This verification program requires an extensive application and a site visit for inclusion. As of this writing, there were only seven ACS CSV centers in the USA, and all were level I. It remains to be seen whether this program will be widely adopted, especially by potential level II and III centers. This program may have significant implications for pediatric anesthesia practice in the outpatient setting in the USA.

Table 38.3 Summary of classifications of pediatric anesthesiologists in the American College of Surgeons Childrens' Surgery Verification Program

Type of anesthesiologist	Board certification and licensing requirements	Pediatric cases/year	Other requirements
Pediatric anesthesiologist	Certified or eligible for certification in pediatric anesthesiology (prerequisite is ABA certification)		
Anesthesiologist with pediatric expertise	Certified or eligible for certification by the ABA	25 patients per anesthesiologist per year (patients <24 months old)	Ongoing care of patients <18 years ≥10 pediatric CME credits annually (category 1)
Alternative pathway for pediatric anesthesiologist designation	Completion of residency in anesthesiology with letter detailing the pediatric component Licensed to practice medicine and credentialed by hospital to care for children <2 years of age	30% or more of practice averaged over past 5 years devoted to pediatric cases including neonates, children <2 years, high-risk patients	PALS certified 48 h in 3 years of pediatric anesthesia-related CME Membership or attendance at children's anesthesia meetings Case list of patients <2 years of age during reporting period

ABA, American Board of Anesthesiology; CME, continuing medical education; PALS, Pediatric Advanced Life Support.

Appropriate procedures

Outpatient or day surgery should be restricted to procedures that combine expeditious and efficient throughput with patient safety that obviates the need for lengthy observation or involved inpatient care. Such procedures must meet minimal criteria [9–11] that would:

- Include a relatively limited duration (usually less than 4 h, however this may vary from state to state or institution to institution)
- Comprise a low hazard of surgical or anesthetic complication
- Encompass minimal or easily regulated physiological derangements (including minimal blood loss)
- Involve minimal or moderate postoperative pain that may be easily treated and finally managed with oral analgesics (necessitating the ability to resume oral fluids or nutrition in the immediate postoperative period).

By and large, the majority of common pediatric surgeries fit the described ambulatory surgery parameters (Box 38.1). It should be noted that whereas most adults do not, children do often require significant sedation or anesthesia along with comprehensive monitoring for certain brief exams and minor or rather superficial procedures. As such, myringotomies, circumcisions, cystoscopies, biopsies, and ophthalmological exams, among others, are often scheduled as outpatient procedures. The fact that the most recent data regarding free-standing ASCs reveal the top three pediatric procedures to be. myringotomy (699,000), tonsillectomy with/without adenoidectomy (289,999), and adenoidectomy (69,000) (see Table 38.1) only confirms the shift in thought when considering appropriate procedures for the ambulatory setting [8].

Ear, nose, and throat procedures

Historically, pediatric ear, nose, and throat (ENT) surgery (most commonly adenotonsillectomy) required overnight admission due to concerns for hemorrhage and airway compromise. Hence day surgery was previously practiced on a relatively limited population of older, healthy ASA PS1 and 2 patients without obstructive sleep apnea (OSA). Today, despite the fact that OSA has become a primary indicator for these procedures, the push to attain advantages in efficiency, cost containment, and better resource utilization has made outpatient surgery much more appealing [12,13].

Recent studies have substantiated the general safety of adenotonsillar procedures in children 4 years and older [13,14]. An analysis of national data for pediatric ambulatory ENT surgery confirms the relative safety of such procedures, with minor complications occurring at rates of approximately 1%; however, complication rates for patients younger than 4 years were significantly higher with 2.5% of patients ($p < 0.001$) returning to the surgery center and 9.3% ($p < 0.011$) having an unplanned admission [15]. Likewise, a systematic review noted a statistically significant increase in both complication rates (odds ratio 1.64) as well as unplanned admissions (odds ratio 1.71) in children younger than 3 years of age [13].

Children with OSA encompass a growing portion of the ENT practice, and these patients present augmented risks (see section "Obstructive sleep apnea"). For the predisposed patient, tonsil or adenoid surgery inherently creates the potential for worsened airway obstruction or pulmonary complication in the postoperative period. Data suggest that OSA may markedly accentuate risk; however, it is difficult to independently separate this effect from the more clearly substantiated age effects. Regardless, the literature supports hospital admission for children aged 3 years and younger in whom tonsillectomy and adenoidectomy (T&A) is indicated for OSA [16]. Indeed, outpatient T&A is less cost effective than planned hospital admission for children in this age range [17].

Presenting indications for scheduled ENT surgery may include pathologies that increase risks. Whether suffering from OSA, obesity, central sleep apnea, facial or oral dysmorphism, or even recurrent or continual upper respiratory tract infections (URIs), each patient must be evaluated individually when considering their selection for day surgery, especially in a free-standing ASC. Those patients under 4 years old or possessing multiple co-morbidities should be seen at a hospital centered practice allowing for the possibility of lengthier observation or admission.

Box 38.1: Commonly performed outpatient surgical procedures

Otolaryngology
- Myringotomy and insertion of tubes
- Adenoidectomy
- Tonsillectomy and adenoidectomy (unless contraindicated)
- Frenulectomy
- Laryngoscopy
- Closed reduction of nasal fracture
- Foreign body removal
- Brachial cleft cysts
- Endoscopic sinus surgery
- EUA including some DL/bronchoscopies

Ophthalmology
- EUA
- Eye muscle surgery (strabismus)
- Nasolacrimal duct probing
- Excision of chalazion
- Insertion of lens or prosthesis
- Trabeculectomy

Dentistry
- Extraction
- Restoration

Orthopedics
- Cast change
- Arthroscopy
- Closed reduction of fracture
- Manipulation
- Hardware removal
- Percutaneous tenotomies
- Arthrograms

Urology
- Cystoscopy
- Meatotomy
- Orchiopexy
- Circumcision
- Hydrocelectomy
- Testicular biopsy
- Hypospadias repair

General surgery
- Hernia repair
- Excision of cyst
- Ganglion
- Skin lesion
- Suture of lacerations
- Removal of sutures
- Dressing change
- Muscle biopsy
- Sigmoidoscopy
- Bronchoscopy
- Esophagoscopy
- Incision and drainage of abscess
- Proctological and vaginal procedures

Plastic surgery
- Otoplasty
- Septorhinoplasty
- Scar revision
- Cleft lip and some cleft palate repairs
- Placement of tissue expanders

DL, direct laryngoscopy; EUA, examination under anesthesia.

Continuing the trend toward outpatient surgery for an increasing number of ENT patients, a recent combined review concluded that tympanomastoidectomy, and even cochlear implantation in children older than 2 years, could be done safely as outpatient surgery [18].

KEY POINTS: DESIGN, SETTING, AND APPROPRIATE PROCEDURES

- Ideally, facilities should be dedicated solely to pediatric patients and outpatient surgery
- Appropriate procedures are generally <4 h, have a low risk of surgical or anesthetic complication, have minimal blood loss and physiological derangements, and have easily managed pain
- ENT surgery comprises about one-third of outpatient surgical procedures

Patient selection

In order to accomplish the workflow goals implicit in the outpatient surgery process, patient selection (and preparation) is paramount. Generally healthy ASA class 1 and 2 children are excellent surgical candidates who can go home soon after surgery. Initial ambulatory practices focused on these patients. However, with the evolution of healthcare practice (medications, equipment, interventions), ASA 3-classified children with stable systemic disease may also now be seen in the ambulatory setting. Even more than other patients, these children should be rigorously screened and ought to have prior approval from their surgeon specialist and anesthesiologist.

Congenital heart disease

The recent increase in survival after congenital heart disease (CHD) surgery means that these patients are increasingly presenting for outpatient anesthesia. With a population incidence of about one in 100, there are approximately 1 million children in the USA with CHD. Outpatient surgery can be done safely in these patients, but in general they should be surgically anatomically corrected two-ventricle patients with no or minimal residual defects [19]. These patients would be considered ASA 2 and do not have an increased risk over other ASA 2 patients without CHD. When a patient has a single functional ventricle at any stage of repair, or has unrepaired two-ventricle defects or significant residual cardiac disease after surgery, great care must be taken with evaluation, and the patient's cardiologist must be contacted, and echocardiography and other studies must be reviewed [20]. Most of these patients will be considered ASA 3 and should not have outpatient procedures, particularly in a freestanding ASC. The well-documented increased risk of anesthetic complications,

especially cardiac arrest, in CHD patients warrants extreme caution, and procedures are best done in a tertiary hospital setting where appropriate expertise and back-up are available. If the decision to proceed with outpatient anesthesia is made, consideration for infective endocarditis prophylaxis is needed. See Chapters 27 and 28 for more information on CHD.

Resource management

The focal point of the outpatient or ambulatory facility centers on resource allocation. Even a single patient requiring increased attention or unplanned efforts may compromise the overall flow or function of the unit. Such a patient might be a normally healthy child with a history of asthma and a new URI who is more prone to laryngospasm and postoperative bronchospasm; or an otherwise healthy child with micrognathia and previously difficult intubation; or an obese child with known OSA who might need prolonged postoperative monitoring or even positive pressure ventilation. It is not that such patients cannot be safely cared for, it is that their care may be more easily accommodated at a larger center possessing greater resources and readily available admission. As such, it is crucial to recognize and triage these patients before they arrive at an ambulatory practice setting.

A surgical scheduling system for ENT cases in a large tertiary children's hospital is displayed in Table 38.4 [21]. Category I patients could be scheduled at an outlying ambulatory surgery center, and of 8478 procedures in a 12-month period, 3454 (48%) were deemed suitable for category I ASC scheduling. Of these, 93% were actually performed in an ASC. Unfortunately, outcomes were not reported in this publication [21].

Table 38.4 Surgical scheduling categorization system for ear, nose, and throat procedures

Category	ASA*	Description
I	1 or 2	Full-term infant 4 months of age or older Must be acceptable based on anesthesia criteria†
II	1 or 2	Category I patients that must be done in main OR due to family/social issue
III	1 or 2	Category I patients that must be done in main OR due to coordinated case
IV	2–4	Patients that do not qualify for satellite based on anesthesia criteria† or fit exclusion criteria‡

* American Society of Anesthesiologists (ASA) physical status classification: ASA 1, no systemic disease; ASA 2, single systemic disease (mild or well controlled); ASA 3, two or more systemic diseases or single moderately controlled systemic disease; ASA 4, poorly controlled systemic disease(s).
† Well-controlled gastroesophageal reflux disease, developmental delay, or mild cerebral palsy without coexisting medical conditions; well-controlled asthma; cardiac lesions with minimal hemodynamic effects (atrial septal defect, ventricular septal defect, patent ductus arteriosus); well-controlled or resolved seizures; malignancy in remission; simple uncomplicated diabetes mellitus; and von Willebrand disease considered on an individual basis.
‡ Known or anticipated difficult airway; immediate or one-degree relative with history of malignant hyperthermia; bleeding disorder requiring possible transfusion; less than 1 year of age and former prematurity less than 35 weeks' gestation; and corrected complex cardiac disease.
OR, operating room.

KEY POINTS: PATIENT SELECTION

- Generally, outpatients should be of ASA 1 or 2; occasionally ASA 3 patients with stable systemic disease can be anesthetized in the outpatient setting
- Patients with CHD can be anesthetized as outpatients, but generally they must be ASA I or II, and have repaired or minimal two-ventricle disease
- Patients with a known risk of increased intervention such as new URI with asthma, a difficult airway, or known significant OSA should be cared for in a hospital setting

Preoperative evaluation/screening

While there are specific conditions or pathologies that would seemingly be in conflict with ambulatory procedures, creating a definitive list is debatable. Much depends on the specific environment of the surgical suite – ASC or physician office versus hospital or tertiary care setting. Likewise, such decisions must be informed by the comfort level of the assigned staff or anesthesia provider. The conditions listed in Box 38.2 warrant careful preoperative evaluation and screening in order to determine appropriateness for ambulatory surgery. They provide a framework from which medical directors may develop guidelines appropriate for their site.

There are clearly conditions that should generally be avoided in such centers – a patient with a previously difficult airway, or with a coagulopathy previously requiring considerable blood products, or with an unstable congenital heart defect. However, even patients with such conditions may appear on a spectrum. There are two basic areas of concern when evaluating such cases. The first and most important is patient safety. For example, if the ASC or outpatient site does not possess the capability to procure or administer blood products, then the hemophiliac or brittle sickle cell anemia patient should probably not be a surgical candidate there.

As noted above, after patient safety, the goal of the ambulatory practice is to optimize throughput and efficiency. Any patient condition that increases the probable perioperative complexity also increases the potential drain on the ambulatory unit's resources. A severely autistic or developmentally delayed child often requires greater resources or attention in

Box 38.2: Patient co-morbidities that require special considerations for ambulatory surgery

- Prematurity/exprematurity
- Obstructive sleep apnea
- Obesity
- Uncorrected or hemodynamically significant congenital heart disease
- Known difficult intubation, airway obstruction
- Myopathy
- Inborn errors of metabolism
- History of malignant hyperthermia
- Down syndrome
- Known coagulation disorders
- Sickle cell disease
- Diabetes mellitus

the pre- and postoperative setting and thus impedes unit throughput. The difficulty is deciding at what point the potential for unanticipated problems outweighs the benefit of caring for such a patient in the ambulatory setting.

Apnea in the infant

Patient age is not regarded as the limiting factor for outpatient procedures; however, full-term neonates in the first 4–6 weeks of life require special consideration due to concerns stemming from the transition from fetal and neonatal physiology to a more mature homeostatic state. Most significantly, these infants, whose brainstem breathing regulation remains immature, are at increased risk of apnea after anesthesia.

With improvements in neonatal intensive care, a greater number of premature infants (less than 37 weeks' gestation) now survive through the neonatal period, and a proportionally larger number present for surgery in early infancy. Regarding these infants, studies clearly demonstrate an increased risk of postanesthetic apnea in ex-premature babies with hazard stratified by postconceptual age. In the most significant analysis (combining eight prospective studies) a postconceptual age of 56 weeks was required to reduce the postanesthetic risk of apnea to less than 1% (95% statistical confidence) in infants with a gestational age of 32 weeks. For those with a gestational age of 35 weeks, the required postconceptual age was 54 weeks [22]. Despite the suggestion that regional techniques might reduce or eliminate this risk [23–25], there have been published case reports of apnea after spinal anesthesia [26,27] and a Cochrane Review of this topic determined that there was no reliable evidence to demonstrate a reduction in postoperative risk of apnea with spinal versus general anesthesia in former premature infants [28,29].

As noted, even the healthy full-term infant may be prone to periods of apnea and hence it is prudent to delay outpatient procedures in such patients. Most institutions set a 4–6-week age requirement for term infants [30]. Alternatively, scheduling such patients earlier in the day also allows for an extended observation period if indicated. Regarding former premature infants, the recommended cut-off postconceptual age for outpatient consideration varies from 46 to 60 weeks [9,31,32]. Of course any complicating medical conditions must be considered, and the more premature the infant, the lower the threshold for admission. Likewise, if apnea is documented during the recovery period, the patient should be admitted for observation. These patients are not candidates for surgery at freestanding centers due to their need for admission and continuous cardiorespiratory monitoring for apnea.

Obstructive sleep apnea

Beyond its significance as the primary indication for T&A, OSA and its associated risks must be appreciated and understood in the greater context of all pediatric procedures. Peak prevalence occurs in 3–6-year-olds, but rates are on the rise due to the rapid rise in pediatric obesity. OSA is also more prevalent in children with respiratory disease, prematurity, craniofacial anomalies, hypotonia, myelomeningocoele, cerebral palsy, and other disorders such as Down syndrome and Arnold–Chiari malformation. Among its most significant manifestations are neurocognitive and behavioral dysfunction as well as cardiopulmonary sequelae including pulmonary hypertension and cor pulmonale [33].

Children with OSA are clearly at increased risk during the perioperative period and those with severe OSA must be assessed closely before proceeding [34,35]. Clinical practice guidelines released by the American Academy of Pediatrics describe risk factors for respiratory complications in children with OSA undergoing T&A including: age <3 years, severe OSA on polysomnography, cardiac complications of OSA such as right ventricular hypertrophy, failure to thrive, obesity, prematurity, recent respiratory infection, craniofacial anomalies, and neuromuscular disorders [36]. These guidelines also recommend T&A as the first-line treatment for children with severe OSA although they do not define the exact polysomnography criteria that are indicative of high risk. Finally, these guidelines recommend that patients deemed as high risk be monitored as inpatients following T&A.

Polysomnography is the recognized gold standard to diagnose and quantify the severity of OSA; however, it cannot predict postoperative clinical outcomes. In one study, its positive predictive value for respiratory complications was only 25% [37]. Postoperative complications in children with OSA include laryngospasm, apnea, pulmonary edema, pulmonary hypertension, and pneumonia [38]. Even the incidence of respiratory complications in such children is significantly higher than in the general pediatric population (21% versus 1–2%) [37].

Studies also show that children with moderatet o severe OSA (SpO_2 nadir <85%) have increased sensitivity to opioids and are more prone to postoperative apnea [39]. While these patients should be considered on a case-by-case basis, significant or severe OSA should be considered a contraindication to the outpatient management of all procedures, not just ENT cases.

Obesity

With a prevalence of 16%, representing a threefold increase in the past 30 years, obesity is a growing concern in the pediatric population and a significant risk factor in pediatric ambulatory procedures [40,41]. Compared with the non-obese population, these children are significantly more predisposed to complicating co-morbidities including asthma, hypertension, gastric reflux, type 2 diabetes, and OSA. More importantly, obesity has been associated with an increased incidence of adverse perioperative respiratory events including difficult mask ventilation, airway obstruction, bronchospasm, significant oxygen desaturation, and overall critical events [42]. Various studies have demonstrated similar perioperative risks and obesity has been identified as an independent predictor for the likelihood of admission after T&A [43]. Keeping these concerns in mind then, the obese patient with any comorbidity must be evaluated carefully before scheduling for outpatient surgery. Indeed, before being considered for procedures at freestanding ambulatory centers, such patients should be evaluated and approved by the anesthesiologist or the medical director of the center.

Malignant hyperthermia

Children with suspected or confirmed malignant hyperthermia (MH) susceptibility present special challenges for outpatient anesthesia [44]. Undoubtedly these children should

receive a trigger-free anesthetic with the use of continuous temperature and end-tidal carbon dioxide monitoring. Arterial blood gas monitoring and dantrolene must be available for the management of a rare case of MH. Additionally, children with MH susceptibility may require extended monitoring of temperature and heart rate in the PACU. In the ambulatory setting, an important question is whether the MH-susceptible child should be routinely admitted for overnight monitoring following a trigger-free anesthetic. A retrospective study of 285 MH-susceptible children undergoing 406 procedures reported no cases of intraoperative pyrexia [44]. The sample included 25 children with biopsy proven MH and none of them developed pyrexia; however, six of these children had received routine preoperative dantrolene. Of 10 children who developed postoperative pyrexia, none were believed to be experiencing an MH reaction and none were treated with dantrolene, although four of them had received dantrolene prophylactically. These data suggest that it may be safe to discharge children with MH susceptibility home following a trigger-free anesthetic. However, the facility must be prepared to monitor them for an extended period of time (4 h or more) and have the ability to transfer the child to an inpatient setting in the rare but unexpected case of an MH reaction. It remains questionable whether the surgical care of these patients is best handled in a hospital-based facility rather than a freestanding ASC, given the throughput goals at the latter site.

Upper respiratory infection

Among the most difficult scenarios confronting the anesthesia provider in the ambulatory setting is the otherwise healthy child who presents with a new URI. Rather benign, recurrent viral illnesses may be ubiquitous in the preschool and primary school population and should not necessarily delay surgery. However, more severe symptoms, including fever, lethargy, purulent secretions, a productive cough, or pulmonary involvement, should mandate procedure postponement for a minimum of 4 weeks. Likewise for a suspected bacterial infection where an antibiotic may be prescribed; the patient can then be assessed by their primary care physician before returning for surgery. The difficulty resides in those URI cases that fall in between the toxic appearing child and the bright, interactive child.

These infections, whether viral or bacterial, may increase airway inflammation, irritability, and respiratory tract secretions to a degree that may persist up to 6 weeks. This airway hyper-reactivity during anesthesia can lead to adverse respiratory events, a protracted recovery time, or even hospital admission. Indeed, much of the literature on this topic confirms that an active or recent URI increases the risk of perioperative complications including atelectasis, hypoxemia, laryngospasm, and bronchospasm in the pediatric population [45–49]. Furthermore, certain factors raise the perioperative risk when combined with a URI: endotracheal intubation, history of prematurity, history of reactive airway disease, airway surgery, the presence of copious secretions, nasal congestion, and passive smoking [48]. Despite such increased risk, there is little evidence of long-term sequelae; the vast majority of adverse events are manageable under the judicious care of experienced practitioners [50].

Decisions regarding whether to proceed with elective surgery in a child harboring a URI should be based on findings from a detailed history and physical examination. Parents are often clear in differentiating their child's condition from their "typical runny nose" or "allergic symptoms." They should be able to provide lucid differentiation between a chronic symptomology and an acute illness exacerbation. Indeed, previous investigators have found that confirmation of a URI by the parent was a more reliable predictor of laryngospasm than symptom criteria alone [51]. A 3-year-old with recurrent ear infections presenting for myringotomy and tube placement may exhibit symptoms such as fever and congestion. Waiting for an asymptomatic window in such a child may be unrealistic given the waxing/waning course of the patient's pathology (e.g. otitis media). With a detailed history regarding the frequency of the symptoms and in the absence of findings on auscultation, it may be reasonable to proceed with the surgery in this case. If persistent concerns remain, such patients should be referred to a hospital-based center with greater flexibility for observation and admission.

Preoperative evaluations or phone interviews may help identify patients with URI in whom it is prudent to delay elective surgery. Postponement of such cases before they arrive in the hospital or ASC will avoid a wasted trip for the family and prevent interruptions in the surgical schedule at the ambulatory facility. Elective surgery is usually delayed 2–4 weeks for simple nasopharyngitis; 4 weeks for more severe infections including antibiotic prescription; and a minimum of 4–6 weeks, including a follow-up with a primary care physician before rescheduling, for any URI including a lower respiratory tract component (bronchitis, pneumonia, asthma exacerbation, etc.). Ultimately, each of these patients must be evaluated on an individual basis keeping in mind the severity of their symptoms, the urgency of the scheduled procedure, the presence of identifiable risk factors, and finally the comfort level and experience of the involved anesthesia provider. For children difficult to diagnose due to the ambiguity of their presentation or the existence of multiple risk factors, a more conservative approach should be taken when considering proceeding at a freestanding surgery site or physician's office.

Asthma

Asthma, afflicting approximately 9% of children in the USA, is the commonest serious childhood illness and the leading cause of school absenteeism. In its severe form, it carries substantial morbidity and mortality. Asthma accounts for about 3% of all pediatric hospital admissions and emergency department (ED) visits [52]. Despite its associated hazards, in the absence of active wheezing and with appropriate patient evaluation, preparation, and perioperative management, children with asthma may be safely anesthetized in an ambulatory setting.

Patient history is crucial when evaluating a child with asthma. The severity of their condition must be assessed on a spectrum. How frequent and/or severe are their wheezing episodes or exacerbations? How often must they visit the ED? Have they ever required admission to the intensive care unit? What is their current medication regimen? Only patients with well-controlled mild to moderate reactive airway disease should be considered for outpatient surgery.

Children with mild or intermittent symptoms who do not require continuous medications and who may only require sporadic rescue treatments are usually excellent candidates for surgery. The moderate asthmatic requiring regular medications to manage their symptoms must continue these medications or treatments through the morning of their procedure. Inhaled steroids and other treatments (e.g. leukotriene inhibitors or cromolyn) necessitate continual use in order to be effective. A short course of systemic steroids starting the day before the planned procedure may be appropriate for those patients who have required systemic steroids previously. Preoperative prophylactic treatment with a β-agonist may attenuate increase in airway resistance with intubation.

Due to the isolated nature of the freestanding ASC or physician office, a conservative approach is advocated for those patients who appear well but have evidence of suboptimal disease control: hospitalization for asthma within 3 months of scheduled procedure; an exacerbation within 1 month; wheezing during exercise; more than three wheezing episodes in the past 12 months; the need for systemic steroids within 1 month; or a room air O_2 saturation of <96% [9,49]. Caution should be practiced for those patients who are actively wheezing, especially in conjunction with a URI or other respiratory symptoms (e.g. cough or tachypnea). Elective surgery in these patients should be postponed and rescheduled for a time when they are symptom free and fully optimized. Severe asthmatics (baseline wheezing) are at increased risk despite optimization through consultant care and assertive preoperative treatments including systemic steroids and increased bronchodilator therapy. Even with aggressive perioperative management, they should only be scheduled at a hospital-based practice in the event that an exacerbation requires admission.

KEY POINTS: PREOPERATIVE EVALUATION/ SCREENING

- Risk of apnea limits outpatient anesthesia to full-term infants who are 4–6 weeks of age or older; and former premature infants of 46–60 weeks' postconceptional age
- Significant or severe OSA should be a contraindication to outpatient anesthesia
- URI is frequent; an acute infection with fever should result in cancellation of elective surgery; an improving URI without fever should be considered for anesthesia

Preoperative preparation

The prospect and actual process of any surgical procedure is inherently stressful and anxiety provoking. The potential trauma experienced by a child may be transmitted to the caregivers or family. Ambulatory surgery may in fact diminish this trauma by minimizing the separation time between parents and child as well as avoiding a disruptive hospital stay. Yet, the ambulatory model's very emphasis on efficiency and throughput may end up limiting the time and effort allowed for preparation, understanding, and acceptance of the prospective perioperative experience. Fast tracking patients through outpatient surgical settings restricts the ability to address each patient's psychological needs, which may be pronounced in younger children. Ultimately, consideration of these varying child/family requirements (the basis for family-centered care) is integral to the success of the ambulatory model. Ignorance, anxiety, and uncertainty in the preoperative holding area may lead to confusion, patient agitation, delays, and/or staff interventions that strain the surgery center's resources. Moreover, there is evidence that preoperative pediatric patient anxiety is related to emergence delirium (agitation), increased pain (hence, opioid requirements with attendant side-effects), and postoperative behavioral problems [53,54]. These outcomes may postpone discharge and further stress the ASC's timetable and resources.

Among the most cited methods for ameliorating surgery's attendant anxieties are the use of sedative premedications, parental presence at induction, and specific presurgery preparation programs for children as well as their parents.

Premedication

Sedative premedication, in most circumstances, effectively reduces preoperative anxiety, and may reduce perioperative recall and postoperative agitation or maladaptive behavior. Oral midazolam is the most commonly used agent and benefits from a relatively rapid onset and reliable effect. A dose of 0.25–0.5 mg/kg should be administered 20–30 min prior to taking the child to the operating room (the lower dosing requires a longer interval to achieve effect). Establishing protocols and maintaining communication between the preoperative area and the operating room should allow for timely medication administration and mitigate possible delays in anesthetic induction due to premedication. A particular concern in the ambulatory setting is the possibility of an extended sedative effect delaying patient discharge. While there are studies indicating protracted sedation at the higher dosing regimen, most studies have failed to demonstrate a prolonged effect that delays patient discharge [55,56]. In any case, most parents and anesthesia providers will accept the infrequent short delay in order to moderate any psychological trauma.

Alternative agents are available. Oral ketamine (5 mg/kg) or fentanyl (15–20 μg/kg) may be given although these are sometimes associated with prolonged recovery (ketamine) and nausea, vomiting, and pruritis (fentanyl). For those patients unable to cooperate with oral administration, midazolam (0.2 mg/kg) may be given via intranasal or intramuscular routes where the onset of action is more rapid (5–10 min). In the exceptionally uncooperative patient, ketamine (3–4 mg/kg), often combined with midazolam and glycopyrrolate, may be given via intramuscular injection. The resultant nystagmus of the latter method may not be a good option in strabismus surgeries. The intramuscular route, however, should be reserved for situations when all other measures have failed since most children have an inherent phobia for needles. Dexmedetomidine, given intranasally at a dose of 0.5–2 μg/kg 30 min before induction, is an effective technique for patients who will not take an oral premedication [57]. Involvement of a child life specialist and use of distraction techniques may permit children with a high degree of anxiety to cooperate.

Parental presence at induction

Much of the parents' and child's anxiety centers on the separation that occurs at the time the child departs to the operating room. Indeed, sedative premedication is administered in part to facilitate this separation. Intuitively, allowing parents to be present during their child's induction should help to calm the child while simultaneously allaying parental uncertainty and fear. It may also increase cooperation and parental satisfaction with the entire perioperative experience. This approach, while still somewhat controversial, has garnered a great deal of support and has been implemented in many institutions and surgery centers. Nevertheless, most current evidence does not support parental presence at induction [55,58] and in most cases, has not reliably alleviated children's or parents' anxiety. Indeed, for those instances where parental presence did seem to benefit the involved participants, sedative premedication is shown to be a viable alternative and similarly efficacious.

There are clearly cases where parental presence can and does afford benefit; however, this depends on an accurate assessment of individual personalities as well as interpersonal dynamics between patient and parents/caregivers. Experienced anesthesia providers quickly evaluate and build rapport with the patient and parents, but the limited preoperative interaction necessitated by day surgery scheduling militates against clearly or effectively appraising such complex interactions and advocating for or against parental presence. Notwithstanding, children who may benefit are older, less impulsive or active in temperament, and typically have calmer parents who value preparation and coping skills in stressful situations [59].

Preoperative preparation programs

The increased focus on family-centered care often includes preoperative preparation programs incorporating a variety of techniques and activities designed to allay child anxiety and assuage parental concern. Among those activities for the children are non-medical play, medical play, tours of the operating rooms and PACU, videos or movies relating to the perioperative course, and teaching of relaxation or coping techniques. Parental involvement is encouraged throughout and may additionally involve parental tours, presence at induction, and early admittance to the PACU to be with their child.

Feeling inadequately prepared leads to increased parental anxiety [60], and there appears to be a relationship between parental anxiety and an increased risk for the child to manifest anxiety, postoperative agitation, and maladaptive behavior [53]. Hence, methods to mitigate parental concerns such as preoperative preparation programs may expedite and facilitate patient care and the ambulatory process. Furthermore, ancillary benefits may be attained by integrating such programs into an ambulatory process that already requires preoperative evaluation and education as well as the administrative procurement of records and financial/insurance information.

Due to the increased interest in the family-centered care model, many institutions and pediatric-centered facilities have initiated varying forms of these preparation programs. While there are indications that such programs can make a substantive difference in the overall experience of patients and families, and by association the workflow ease and productivity of the ASC, it is still unclear how effective they are in specifically addressing patient anxiety and subsequent sequelae. Study results are mixed when assessing the efficacy of various measures; yet even when patient anxiety is reduced, there is evidence that preoperative benefits fail to translate to the induction or postoperative recovery period [61]. This may be due to the unstructured and piecemeal implementation of many plans that rely on specific or uncoordinated measures.

Recent evidence has demonstrated that a highly integrated and evolved preoperative program can successfully reduce preoperative anxiety (significantly reduced when compared to control and parental presence cohorts; similar when compared to a premedication cohort) and improve postoperative outcomes (decreased analgesic consumption, decreased emergence delirium, decreased time to discharge) [54]. Such a fully developed program, however, requires significant resources in staffing and expertise and thus would be very expensive to implement and run. Likewise, to be effective it would require parental enrollment and a large commitment of time. These constraints may limit the application of such programs to larger, hospital-centered practices that have more resources and can benefit from economies of scale. Chapter 14 presents additional discussion of preoperative preparation.

KEY POINTS: PREOPERATIVE PREPARATION

- Premedication may delay emergence for short cases, but, if needed, oral midazolam is preferred; intranasal dexmedetomidine is an alternative
- Parental presence at induction does not reliably reduce anxiety in the patient or improve induction quality
- Preanesthetic education programs can be effective in reducing anxiety in selected children

Preoperative fasting

Standard nil per os (NPO) guidelines are followed for outpatient surgery [62]. The ASA guidelines were updated in 2017 for patients of all ages and allow ingestion of clear liquids (water, fruit juices without pulp, carbonated beverages, carbohydrate-rich nutritional drinks, clear tea, and black coffee) up to 2 h before procedures requiring general or regional anesthesia, or procedural sedation (Table 38.5) [62]. Breast milk may be ingested up to 4 h before the procedure, and infant formula or non-human milk or a light meal up to 6 h before the procedure. Additional fasting time, i.e. 8 h, may be needed for intake of fatty foods, fried foods, or meat. Gastrointestinal stimulants (e.g. metoclopramide), histamine-2 receptor antagonists to block gastric acid secretion (e.g. famotidine), and antacids (e.g. sodium citrate), and proton pump inhibitors (e.g. omeprazole) are only indicated in patients at significant risk of pulmonary aspiration. If patients are taking these medications, they should continue to take them as usual preoperatively. In general, obese children and teenagers who do not have symptoms of gastrointestinal

Table 38.5 Fasting guidelines for all ages in healthy patients undergoing elective procedures*

Ingested material	Minimum fasting period†
Clear liquids‡:	2 h
Breast milk	4 h
Infant formula	6 h
Non-human milk§	6 h
Light meal**	6 h
Fried foods, fatty foods, or meat	Additional fasting time (e.g. 8 or more hours) may be needed

* These recommendations apply to healthy patients who are undergoing elective procedures. Following the guidelines does not guarantee complete gastric emptying.
† The fasting periods apply to all ages.
‡ Examples of clear liquids include water, fruit juices without pulp, carbonated beverages, clear tea, and black coffee.
§ Since non-human milk is similar to solids in gastric emptying time, the amount ingested must be considered when determining an appropriate fasting period.
** A light meal typically consists of toast and clear liquids. Meals that include fried or fatty foods or meat may prolong gastric emptying time.

reflux are not treated prophylactically with agents to decrease pulmonary aspiration risk.

In actual practice, although patients can and should ingest clear liquids until 2 h before the induction of anesthesia, because of scheduling considerations – i.e. the possibility that preceding cases could cancel or be completed ahead of schedule – this period may be extended to 3–4 h so that a case can start earlier if needed. Under no circumstances should infants and young children undergoing outpatient anesthesia be fasted for long periods of time, i.e. more than 4 h. Although healthy patients will tolerate this, it is very uncomfortable for the patient and upsetting for the caregivers. If a procedure is significantly delayed, clear liquids are offered to infants and young children while awaiting the start of the procedure.

Anesthetic agents and techniques

Apart from the economic advantages of ambulatory surgery and anesthesia, there are psychosocial benefits to a child recuperating at home following surgery. Hospital admission is associated with behavioral problems possibly due to separation from parents and disruption of family life [63]. To this end, rapid and short-acting drugs for induction and maintenance of anesthesia have been developed to facilitate early recovery following day case surgery. The ideal anesthetic agent for ambulatory surgery should provide smooth and rapid induction of general anesthesia, allow prompt recovery, have minimal side-effects, have analgesic properties, and be free of postoperative nausea and vomiting (PONV). Such an agent does not exist. Since induction of anesthesia is a very important component of the overall ambulatory surgery experience, it is important to use the most acceptable and least distressing technique for the child. While induction of anesthesia is most commonly achieved via the inhaled or the intravenous routes, maintenance is often exclusively by the inhalational method. In some centers outside the USA, rectal administration is sometimes used for sedation or induction of anesthesia [64].

Monitoring

The ASA monitoring standards must be applied to all children undergoing an anesthetic regardless of the setting in which the surgery is performed including office-based settings.

Induction technique

Inhalational induction of general anesthesia is arguably the most common technique used by pediatric anesthesia providers in North America. However, what constitutes the "gentlest" induction method for children remains unclear [65]. Very often, induction method is guided by personal preference of anesthesia providers, institutional practice, and cultural factors. For example, because of prevailing "needle phobia" in many children, anesthesia practitioners in the USA often avoid IV induction [66]. However, in many other parts of the world, including Europe, IV induction appears to be more favored [67]. Very few investigators have compared the induction characteristics of intravenous and inhalational techniques. Some investigators contend that because inhalational induction is not always "smooth," it may be associated with long-term negative memories for children and may be a source of severe stress for parents [65]. Still others claim that IV induction can be a pleasant experience for the child provided topical anesthetic cream is applied to the venepuncture site and the cannulation is performed by a skilled practitioner [63].

Inhalational agents

The ideal inhalational agent should have many of the following desirable characteristics: it should be pleasant to inhale (permitting a smooth induction and emergence), potent (allowing the concomitant administration of high fractional oxygen concentration), produce rapid induction and emergence (low solubility), and it should be easy to administer and analyze (infrared). Such an agent should also be stable in storage, should have minimal to no reaction with soda lime, and should not be significantly biotransformed in the body. It should have little or no cardiac or respiratory irritant or depressant effects and should possess some analgesic properties. With the almost total withdrawal of halothane from clinical anesthesia in developed countries, sevoflurane has become the prototype inhalational agent.

Sevoflurane

Sevoflurane, by virtue of its non-pungent smell and relative lack of airway irritant properties, has become the agent of choice for induction of anesthesia via the inhaled route in children. Due to its low blood gas solubility, sevoflurane causes rapid induction of anesthesia and recovery making it particularly suitable for the ambulatory setting. Other advantages of sevoflurane include its lack of major side-effects, the ability to induce and maintain anesthesia with one drug, better conditions for laryngeal mask airway (LMA) insertion, and ability to induce anesthesia without IV access. Notable

disadvantages of sevoflurane-based anesthesia, however, include possible increased pollution of the operating room with anesthetics and excitatory movements during anesthetic induction [68]. A recent meta-analysis comparing the induction characteristics of sevoflurane with propofol concluded that the two drugs had similar efficacy for anesthetic induction but sevoflurane use was associated with a higher incidence of PONV [68]. Sevoflurane induction and maintenance of anesthesia is also associated with excitatory motor movements on induction and emergence agitation [69]. These side-effects may be distressing to parents and may potentially delay discharge from the PACU. The practice at the University of Michigan is to induce anesthesia with sevoflurane and change to isoflurane for the maintenance of anesthesia. In many cases, we begin inhalational induction with a N_2O/O_2 mixture and gradually introduce sevoflurane into the gas mixture. This practice has been shown to dampen the fairly strong odor of sevoflurane and may reduce some of the anxiety and excitement associated with inhalational induction [70].

Isoflurane

Isoflurane has a pungent odor and causes considerable airway irritation making it a poor choice for induction via the inhaled route. Indeed previous investigators have reported a higher incidence of coughing, breath holding, excessive salivation, and laryngospasm in children who underwent induction of anesthesia with isoflurane compared to those who were induced with halothane for myringotomy and tube placement [71]. Isoflurane is excreted predominantly in the lungs with very little hepatic biotransformation. It is possibly the most popular inhalational agent for anesthesia maintenance due to its lower cost compared with sevoflurane.

Desflurane

Due to its low blood gas solubility (about 0.42 lower than all currently available volatile anesthetics, and slightly lower than nitrous oxide), induction of and recovery from desflurane anesthesia is rapid with a prompt return of protective airway reflexes [72]. The rapid emergence and recovery from general anesthesia provided by desflurane has been associated with a frequent incidence of emergence agitation in children [73,74]. In some patients emergence agitation may be severe enough to require treatment with supplemental analgesic or sedative medications in the PACU. The use of these medications and the need for additional observation prolong and complicate PACU care and delay discharge. Some investigators have determined that the administration of 2.5 μg/kg of fentanyl, given after induction, successfully reduced the incidence of severe agitation associated with desflurane anesthesia in children without delaying emergence [75].

Desflurane may prove useful in overweight and obese patients. Recent data indicate that desflurane use is associated with faster return of protective airway reflexes in otherwise healthy overweight and obese adults [76]. Similar data indicating rapid wash-out of desflurane compared with sevoflurane in morbidly obese patients have also been published [77]. The rising prevalence of childhood obesity in the general and pediatric surgical population may indicate that desflurane is the agent of choice for obese children undergoing prolonged anesthesia. Studies comparing the emergence characteristics of desflurane between obese and normal weight children are warranted.

Due to its pungent odor and associated airway irritability, however, desflurane is unsuitable for inhalational induction. Several pediatric studies [78–80] have demonstrated a high incidence of airway irritation and/or reactivity, including breath holding, coughing, excessive secretions, and laryngospasm.

Intravenous agents

Although inhalational induction is more popular with outpatient anesthesia, IV induction and (less commonly) maintenance of anesthesia is sometimes preferred or indicated. There is a smooth, rapid loss of consciousness and emergence is rapid with currently available agents.

Propofol

This has rapidly become the most popular IV induction agent because it has many of the properties of an ideal intravenous agent. Induction of anesthesia is smooth and recovery is rapid even after prolonged infusion making it suitable for total intravenous anesthesia (TIVA). Propofol is also becoming the agent of choice for most procedural sedation, especially with recurrent procedures such as radiotherapy or chemotherapy. It is a good antiemetic agent (another desirable characteristic in ambulatory anesthesia) and very often some clinicians may opt for propofol TIVA in patients with a compelling history of PONV. It is important to keep in mind that due to their large central volume of distribution and rapid clearance of propofol, children have a higher dose requirement for induction and TIVA than adults. The typical induction dose of propofol in children is 2.5–3.5 mg/kg.

Perhaps the biggest drawback to the use of propofol is pain on injection. The incidence is as high as 70% [81] and various techniques have been tried to reduce this rather distressing side-effect. These authors commonly co-administer lidocaine (1 mg to 1 mL of propofol) and inject the mixture very slowly.

A recent systematic review of propofol-based TIVA versus sevoflurane for outpatient pediatric anesthesia reported a total of 16 trials involving 900 children [82]. Propofol TIVA was associated with a significantly lower risk of PONV (16.1% versus 32.6%), and postoperative behavioral disturbances (11.5% versus 24.7%). There was no difference in incidence of respiratory or cardiovascular complications, time to anesthesia recovery, or discharge from hospital.

Dexmedetomidine

Dexmedetomidine is a presynaptic α2-agonist that binds to the locus ceruleus in the brain and to receptors in the spinal cord to provide sedation, anxiolysis, and some analgesia, while preserving normal respiratory patterns and reducing doses of opioids and inhalational agents when utilized as an adjunct to general anesthesia [57]. In the outpatient surgery setting, dexmedetomidine can be utilized as a single loading dose of 0.25–1 μg/kg at the start of the anesthetic, and the anesthesia can then be maintained with inhaled agents or propofol. This approach has been effective at reducing opioid requirements for pediatric patients undergoing T&A [83]. Other intraoperative applications in the outpatient setting

include airway procedures such as direct laryngoscopy and bronchoscopy, magnetic resonance imaging sedation as a sole agent or combined with propofol for bone marrow biopsy/intrathecal chemotherapy.

KEY POINTS: ANESTHETIC AGENTS AND TECHNIQUES

- Inhaled induction and maintenance with sevoflurane is by far the most common technique for outpatient anesthesia; a high risk of emergence delirium in young children is seen if mitigation strategies are not used
- Propofol as a component of TIVA is associated with smooth emergence and low risk of PONV
- Dexmedetomidine as an adjunct in outpatient anesthesia can reduce opioid requirement and risk of emergence delirium

Emergence agitation and delirium

Rapid-acting anesthetics and an emphasis on avoiding opioids, and providing analgesia with non-steroidal anti-inflammatory drugs (NSAIDs) and regional anesthesia (see section "Regional blockade"), often translates into a significant incidence of emergence agitation and possibly delirium for outpatient surgery [84]. Emergence agitation and delirium are a continuum, with agitation in the early recovery period, and delirium persisting after about 30 min of recovery; both terms are frequently used interchangeably. Emergence delirium is a state of dissociated consciousness in a child who is crying inconsolably, and thrashing about after anesthesia, who typically does not recognize parents or caregivers, or familiar objects like their favorite stuffed animal. The patient is typically preschool aged and is disoriented and does not seem to be aware of their environment. He/she is difficult or impossible to console. The time course is normally early in recovery, usually in the first 5–15 min, and resolves spontaneously in most cases. Emergence agitation lasting longer than 30 min is referred to as emergence delirium. Needless to say this is very upsetting to parents and caregivers, and with an emphasis on smooth recovery and discharge from anesthesia, and parent and family satisfaction of the perioperative care process, minimizing delirium is an important outcome for outpatient surgery programs to strive for.

It is very important to rule out pain or physiological disturbance (e.g. hypoxia) as a cause of emergence delirium. Factors associated with such delirium include age 2–5 years, preoperative anxiety and anxious temperament, pain, and anesthetic technique. A comprehensive review of 158 studies involving 14,045 children clearly associated sevoflurane with a higher incidence of emergence delirium than a halothane or propofol-based anesthetic [85]. No clear difference was found in the use of desflurane or isoflurane versus sevoflurane. Effective pharmacological adjuncts to reduce the incidence of delirium include dexmedetomidine, clonidine, opioids (fentanyl), a propofol bolus at the end of the anesthetic, ketamine, or midazolam. Parental presence on induction and midazolam premedication did not reduce the risk of emergence delirium. A later systematic review and meta-analysis of delirium incidence with desflurane versus sevoflurane identified 14 randomized studies in 1194 patients [86]. The incidence and severity of delirium was the same in both groups, but the emergence and awakening times were shorter with desflurane by 2–3 minutes. See Chapters 14 and 17 for further discussion of emergence delirium.

Pain management

The strategy for postoperative pain management is an integral part of any anesthetic plan; however it becomes particularly important in children undergoing outpatient surgery in order to ensure that parents are able to manage their child's analgesia effectively at home. The intraoperative analgesic regimen should under ideal circumstances allow the child to emerge from anesthesia in reasonable comfort since it is easier to maintain analgesia in a pain-free child than to achieve analgesia in one with severe pain. Effective analgesia is best achieved using multimodal therapies including non-opioid and opioid analgesics, as well as appropriate regional techniques based on the surgical procedure and the child's comorbidities. Education of parents and caregivers regarding assessment of their child's pain and analgesic needs following discharge in addition to detailed instructions regarding the timing and dosage of prescribed analgesics are other important facets of care for children undergoing outpatient surgery.

Non-opioid analgesics

Non-opioid analgesics may be used alone for the treatment of mild pain or as important adjuncts in combination with opioids or regional techniques for the multimodal treatment of moderate to severe pain. Non-opioid analgesics produce dose-dependent responses, but are limited by a ceiling effect, i.e. a concentration is reached above which no additional analgesia is achieved. Therefore, moderate to severe pain is rarely managed with these drugs alone.

Acetaminophen

Acetaminophen is the commonest analgesic and antipyretic used in children. The recommended dose for oral administration is 10–15 mg/kg every 4 h. An oral loading dose of 30 mg/kg followed by a maintenance dose of 10–15 mg/kg may result in an earlier onset of action. Rectal administration results in unpredictable absorption with variable peak blood concentrations being achieved in 60–180 min [87–89]. One study reported a greater morphine-sparing effect with a less frequent need for additional rescue analgesics for 24 h in children who received 40 or 60 mg/kg of rectal acetaminophen compared with those who received 20 mg/kg or placebo during outpatient surgery [90]. Intravenous formulations of paracetamol (acetaminophen) and its prodrug propacetamol have been available in Europe and Australia for many years. Intravenous administration of paracetamol results in an onset of analgesia in 15 min and of antipyresis in 30 min [91,92]. One controlled randomized trial reported good analgesia for the first 6 h after surgery in children undergoing T&A who

received either rectal acetaminophen 40 mg/kg or IV acetaminophen 15 mg/kg after induction of general anesthesia [93]. However, children who received acetaminophen rectally required rescue analgesics later than those in the intravenous group. The intravenous formulation of acetaminophen has been approved by the US Food and Drug Administration (FDA) for use for analgesia and fever in patients 2–18 years of age, and for fever in infants 0–2 years of age since 2010. The maximum daily dose of acetaminophen via any route should not exceed 75 mg/kg for children and 60 mg/kg for infants. Oral acetaminophen is available in a wide variety of over-the-counter and prescription formulations. These include cold remedies and opioid combination products that place children who may inadvertently receive more than one such formulation at risk of an overdose. A careful review of medications and parental education is needed to minimize this risk. In addition, if IV acetaminophen has been administered intraoperatively it is important to communicate this to the PACU staff so that postoperative acetaminophen-containing products are not given too early or in doses exceeding recommended limits.

Non-steroidal anti-inflammatory drugs

NSAIDs provide excellent analgesia for mild to moderate pain due to surgery, injury, and disease. *Ibuprofen*, one of the oldest orally administered NSAIDs, has been used extensively for the treatment of fever and pain derived from a variety of etiologies including surgery, trauma, and arthritis. The recommended dose of ibuprofen is 10–15 mg/kg PO every 6 h. IV ibuprofen is now FDA labeled in the USA for patients older than 6 months for treatment of pain and fever. In a randomized, placebo-controlled trial of a single 10 mg/kg IV dose versus saline placebo for T&A in 161 pediatric patients, ibuprofen demonstrated a significant reduction in the total fentanyl dose and number of doses in the postoperative period [94]. Surgical complications, including bleeding, were not different than with placebo. Ibuprofen may prove to be an attractive choice because of a lower risk of bleeding and gastrointestinal and renal effects.

Diclofenac in a dose of 1 mg/kg every 8 h PO, PR, or IV also provides effective analgesia after minor surgical procedures in children. In the USA it is only available as an oral tablet; however, rectal and injectable formulations are available in other countries. Previous studies have reported that children who received diclofenac during inguinal hernia repair experienced comparable analgesia to those who received caudal bupivacaine or IV ketorolac [95–97]. Diclofenac also yielded better analgesia with a reduced need for supplemental opioids, less nausea and vomiting and earlier resumption of oral intake compared with acetaminophen in children undergoing tonsillectomy and/or adenoidectomy [98,99]. However, diclofenac use has been associated with above average bleeding in children during tonsillectomy [100].

Ketorolac provides postoperative analgesia comparable to opioids in children of all ages. Its lack of opioid side-effects including respiratory depression, sedation, nausea, and pruritis make it a very attractive choice for the treatment of postoperative pain, especially in the ambulatory setting. However, like other NSAIDs, it does carry the risks of platelet dysfunction, gastrointestinal bleeding, and renal dysfunction. Some studies that evaluated the safety and benefits of ketorolac in children undergoing tonsillectomy reported a 2–5-fold increase in bleeding complications including measured blood loss, ease of achieving hemostasis, and bleeding episodes in the PACU necessitating re-exploration and hospital admission in some cases [29,101–103]. Two studies were terminated early when preliminary analysis found an unacceptably greater risk of bleeding in children who had received ketorolac [29,103].

A systematic review of the literature included 25 studies related to the use of NSAIDs for T&A and found that compared with opioids, NSAIDs were equianalgesic, caused significantly less nausea and vomiting, but were associated with more frequent reoperation for bleeding [104]. This study found that the use of NSAIDs avoided PONV and its attendant complications in 11/100 patients, but 2/100 were exposed to the risk of postoperative bleeding requiring reoperation. A Cochrane review involving 13 studies related to the use of NSAIDs and peritonsillectomy bleeding found no statistically significant increase in the risk of bleeding but reported a significant decrease in the incidence of PONV in children who received NSAIDs compared to other analgesics [105]. A follow-up to this review, with 15 studies and 1101 children, confirmed these findings [106]. Taken together, this suggests that until further data become available, it may be prudent to avoid the use of NSAIDs during or after tonsillectomy, and alternative analgesics such as acetaminophen and tramadol should be considered as adjuncts in order to reduce opioid requirements.

Corticosteroids

The role of dexamethasone as a co-analgesic is becoming increasingly recognized in both adults and children [107]. The use of dexamethasone provides the added benefit of antiemesis, which is highly desirable in ambulatory surgery. The mechanism of steroid-based analgesia appears to be related to their powerful anti-inflammatory effect and reduction of prostaglandins at sites of tissue injuries [108]. Recent studies raising concern over the possibility that dexamethasone increased post-tonsillectomy bleeding were assessed in a systematic review and meta-analysis of 61 pediatric studies, and no increased risk of post-tonsillectomy hemorrhage, with or without concomitant NSAID administration, was identified [109].

Opioid analgesics

Opioids play a fundamental role in the management of postoperative pain. Unfortunately, their use is associated with a number of side-effects, including nausea, vomiting, pruritus, sedation, and respiratory depression (particularly undesirable in ambulatory surgery). The high incidence of PONV and concern for respiratory depression often prompts many clinicians to avoid opioids or to use them sparingly [110].

Oral opioids are suitable for children experiencing mild to moderate pain, those who undergo outpatient surgery, or as adjuncts to a regional anesthetic technique. In fact, administration of an oral opioid dose upon awakening in the PACU prior to a regional block wearing off may provide a virtually pain-free recovery period. If dosed appropriately and at regular intervals, reasonably constant blood levels can be achieved with oral opioids. In most cases, oral opioids are better

tolerated after the resumption of oral intake. Codeine now has a US FDA "black box" warning, and is contraindicated in children after T&A. Codeine formerly was the commonest opioid prescribed for pediatric outpatients. It is a weak analgesic and, being a prodrug, it requires conversion to morphine to be effective. Because of polymorphisms in the hepatic metabolizing enzyme CYP2D6, a large percentage of children either have no analgesia from codeine or are at risk of respiratory depression from rapid metabolism to morphine. Codeine has been removed from many children's hospital formularies. *Oxycodone*, with or without acetaminophen, is now one of the most commonly prescribed oral opioids available in liquid form making it easy to prescribe for infants and young children. Oxycodone causes significantly less nausea and vomiting than codeine and appears to be better tolerated by the postoperative child just resuming oral intake.

Children who wake up in moderate to severe pain may require IV opioids such as fentanyl or morphine to achieve rapid and effective pain relief. However, careful titration of dosing and frequent assessment of the child are required to ensure adequate analgesia without excessive opioid side-effects such as respiratory depression, excessive sedation, or PONV that may prolong the PACU stay and delay discharge. Children with obstructive sleep apnea have documented increased sensitivity to opioids and investigators have recommended a 50% reduction in morphine doses for children undergoing T&A who experienced a pulse oximetry nadir to <85% on preoperative sleep studies [39]. See Chapter 37 for additional information about opioids and pain management.

Regional blockade

Regional blocks with long-acting local anesthetics provide excellent postoperative analgesia, particularly for genitourinary and orthopedic procedures performed in the outpatient setting. Both peripheral nerve blocks and central neuraxial blocks (caudal or lumbar epidural) may be used. The techniques are discussed in detail in Chapter 20. Peripheral nerve and plexus blocks provide relatively long periods of analgesia lasting for 8–12 h in most cases and sometimes exceeding 24 h. Depending on the nature of the surgery, this may permit the child to transition to non-opioid analgesics at the time the block wears off, thereby eliminating or reducing the use of opioids and their potential untoward effects. However, appropriate analgesic plans must be made for the parents to follow at home to ensure the comfort of the child once the block wears off.

The optimal time to place the block remains a subject of debate; however, there are several purported advantages to placing the block before the onset of surgery [111]. In addition to the potential benefit of pre-emptive analgesia, the effectiveness of a block placed after induction of anesthesia can be assessed during the procedure so that the block can be repeated at the end of the procedure if ineffective. An effective block may decrease general anesthetic requirements, facilitating a faster recovery. On the other hand, placing the block at the end of the procedure requires a deeper level of anesthesia to be maintained for block placement, resulting in delayed awakening. Lastly, a block placed at the end of surgery may require some time to become effective causing the patient to wake up in pain. A single caudal injection of local anesthetic prior to incision does not shorten the duration of postoperative analgesia after procedures lasting 1 h or less. Investigators have reported similar times from recovery until the first request for analgesics in children undergoing inguinal herniorrhaphy who had caudal blocks placed before incision or after surgery [112]. For prolonged procedures, a second caudal block using half the original volume of local anesthetic may be placed prior to emergence. For central neuraxial blocks in the setting of outpatient surgery, dilute concentrations of local anesthetic (0.1–0.15%) may be preferable since they provide effective postoperative analgesia while avoiding motor blockade and urinary retention. Additives such as clonidine have also been shown in some studies, but not in others, to prolong the action of "single shot" central neuraxis and some peripheral blocks.

Ilioinguinal-iliohypogastric nerve blocks provide excellent postoperative analgesia for genitourinary procedures such as inguinal herniorrhaphy and orchidopexy. They are technically easy to perform (see Chapter 20) and they appear similar in efficacy to caudal blocks with a duration of analgesia of at least 4 h when bupivacaine with epinephrine is used. A randomized, blinded study found that an ilioinguinal nerve block was as effective as caudal blockade to the T10 level in children undergoing orchidopexy [113]. However, pain following procedures that involve considerable manipulation and traction on the spermatic cord and testis may be better managed with caudal blockade. While a penile block is effective for both circumcision and distal, simple hypospadias repair; a caudal block provides more effective analgesia for more extensive procedures on the penis such as the repair of penile/scrotal hypospadias [114]. Infiltration of the incision site with local anesthetic provides effective analgesia for 4–6 h after surgery and should be used at the end of virtually every operation [115,116].

With the widespread application of ultrasound-guided regional anesthesia and the greater numbers of pediatric anesthesiologists who are skilled in this technique in recent years, the repertoire of nerve blocks for outpatient surgery has expanded considerably [117,118]. This includes upper extremity blocks: all approaches to the brachial plexus, and axillary, musculocutaneous, elbow, and wrist blocks. In addition, lower extremity blocks such as lumbar plexus/psoas compartment blocks, and fascia iliaca, femoral, sciatic, popliteal fossa, and saphenous blocks are feasible in the outpatient setting. Truncal blocks including the transversus abdominus plane, rectus sheath, paravertebral, and quadratus lumborum blocks have all been described in the outpatient setting.

A relatively recent addition to regional analgesia techniques in the outpatient setting has been ambulatory peripheral nerve block (PNB) catheters, which go home with the patient and remain in place for 1–5 days postoperatively, delivering dilute concentrations (e.g. 0.1% ropivacaine or bupivacaine) via a disposable infusion pump (Fig. 38.2) [119]. Several large series demonstrate the effectiveness and safety of this approach. In a series of 1285 outpatient PNB catheters, 35% were discharged home on the day of surgery [120]; 82% of these catheters were femoral or sciatic catheters; most patients were in the 11–18-year age group and had arthroscopic knee surgery for anterior

cruciate ligament or menisceal repair. The median duration of infusion was 50 h, with a range of 0 to 168 h. Analgesia was good, with 13% of patients requiring no opioid medication, and median time to first opioid dose was 16 h; 5% of patients had complications, most of which were accidental catheter removal or excessive leakage. There were no serious complications, although five patients had local anesthetic-related side-effects. Another series of 403 patients with brachial or lumbar plexus, femoral, sciatic, or paravertebral catheters reported good pain relief and patient/parent satisfaction; 14.4% of patients had complications, the majority were nausea/emesis, with leaking or accidental removal also observed [121]. All authors in this field stress the requirement for a well-organized service, including detailed education and instruction written material for parents, with at least daily telephone follow-up and established procedures for returning to the hospital for problems and for removal of the catheter.

A potential future development in regional anesthesia for outpatients is long-acting local anesthetic drugs, where a single injection could provide many hours, or even days, of local anesthetic blockade. One approach is liposomal bupivacaine, either by local intra-articular infiltration for knee surgery, or as the agent used for a regional block, for example a transversus abdominus plane block. Reports in adults have indicated safety and long-lasting analgesia equivalent to a PNB catheter [122,123]. No reports specific to pediatric patients have been published. A second approach is neosaxitoxin, a site-1 sodium channel blocker that exerts its local anesthetic effects by binding to the outer pore of the voltage-gated sodium channels, blocking impulse generation and propagation [124]. A phase I study of dosing and safety for cutaneous anesthesia reported 30–47 h of duration of action for neosaxitoxin combined with bupivacaine with or without epinephrine. Additional clinical trials in pediatric patients are needed before this approach can be adopted.

KEY POINTS: PAIN MANAGEMENT

- Non-opioid analgesics are a mainstay for outpatient surgery; IV acetaminophen, ibuprofen, and ketorolac are all available
- Opioid analgesics include standard intraoperative drugs; codeine should not be used in children; hydrocodone with or without acetaminophen is a good choice for oral postoperative analgesia
- Regional blockade is increasingly used in outpatient anesthesia; ambulatory peripheral nerve block catheters are effective with low complication rates

Postoperative nausea and vomiting

Postoperative nausea and vomiting is a major concern in pediatric outpatient surgery because it may increase patient discomfort, delay patient discharge, increase the incidence of wound dehiscence, and increase the cost of patient care [125]. PONV, the commonest cause for delayed discharge from the PACU, can be a source of frustration to parents/caregivers and is a frequent cause of unplanned hospital admission or an early postoperative visit to the emergency department secondary to dehydration and electrolyte derangement [126]. Many adult patients rank PONV as the number one complication of surgery they wish to avoid [127].

Young children often have difficulty describing the occurrence or severity of nausea and, for this reason, many investigators use vomiting as a more definite endpoint [128]. Older children may be instructed preoperatively to report any nausea experienced in the postoperative period. It is not clear whether these "suggestions" may increase the reported incidence of nausea in children who may simply answer the way they think the investigators want. Despite these limitations, the incidence of postoperative vomiting in children is between 8.9% and 42%, approximately twice the incidence for both nausea and vomiting after surgery in adults [129]. PONV rates may be as high as 50–89% following tonsillectomy possibly due to swallowed blood, pharyngeal stimulation, and the use of opioids [130]. Risk factors for PONV may be broadly grouped thus: patient factors, surgical factors, and anesthetic factors. Patient factors include age greater than 3 years, gender (female > male), previous history of PONV, and a family history of PONV and motion sickness [129,130]. Commonly described surgical factors include type of surgery (strabismus surgery, tonsillectomy, laparoscopic surgery, and certain urological procedures) and prolonged surgery [131]. Anesthetic factors although well described, are controversial and include the use of nitrous oxide, difficult mask ventilation, use of opioid medications, and reversal of neuromuscular blockade [132]. Many investigators agree that a propofol-based anesthetic technique is associated with the lowest incidence of PONV [68,133]. A simplified risk score for postoperative vomiting in children is presented in Figure 38.3 [134].

Management of PONV is based on primary prevention and pharmacotherapy. Primary prevention includes a careful history to identify risk factors and tailoring the anesthetic technique to patient and surgical risk factors. Ensuring adequate hydration and nasogastric suctioning following tonsillectomy and/or adenoidectomy are other non-pharmacological techniques that have been employed to reduce the incidence of PONV.

Pharmacotherapy

This may be divided into prophylactic or rescue therapy. It is presently unresolved whether routine prophylaxis is warranted in all patients undergoing general anesthesia or whether prophylaxis should be based on risk stratification. Very often economic considerations and risk–benefit analysis determine the choice and use of prophylactic PONV medications [135]. An international panel of experts compiled comprehensive evidence-based guidelines for the management of PONV under the auspices of the Society for Ambulatory Anesthesia [134]. These guidelines suggest that the use of prophylactic antiemetics should be based on valid assessment of risk factors for postoperative vomiting as detailed in the algorithm in Figure 38.4 [134]. These guidelines recommend that children deemed at moderate to high risk for PONV should receive combination therapy with two or three prophylactic

Risk factors	Points
Surgery ≥ 30 min	1
Age ≥ 3 years	1
Strabismus surgery	1
History of POV or PONV in relatives	1
Sum =	0 to 4

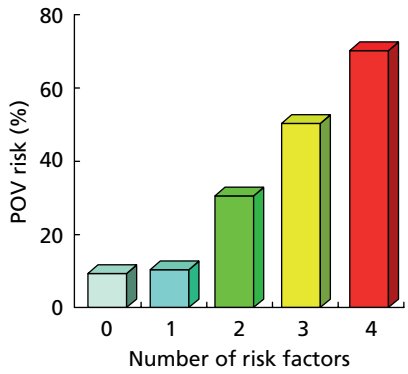

Figure 38.3 Risk factors for postoperative vomiting (POV) in children showing a simplified risk score to predict the risk for POV in children. When 0, 1, 2, 3, or 4 of the depicted independent predictors are present, the corresponding risk for POV is approximately 10%, 10%, 30%, 55%, and 70%. drugs from different classes. Additionally, patients who experience PONV despite prophylaxis should receive additional antiemetics from a pharmacological class different to that of the prophylactic drug since repeating the same drug within 6 h of the original dose does not confer any benefit.

Commonly used medications include serotonin (5-hydroxytryptamine-3 or 5-HT3) receptor antagonists (ondansetron, granisetron, dolasetron), steroids (dexamethasone), antihistamines (promethazine, benadryl), metoclopramide, and droperidol. It should be noted that droperidol has a "black box"

warning from the US FDA against its use for PONV due to fatal cases of QT interval prolongation and torsade de points. In addition, promethazine has a similar warning against use in children less than 2 years of age because of cases of fatal respiratory depression, especially when combined with opioids. A systematic review reported good evidence that dexamethasone and the serotonin receptor antagonists ondansetron, granisetron, and tropisetron were clinically effective for PONV prophylaxis in children undergoing tonsillectomy with or without adenoidectomy [136]. Furthermore, this review found that dimenhydrinate, perphenazine, droperidol, gastric aspiration, and acupuncture were not efficacious in reducing PONV in this population. The 5-HT3 receptor antagonists are rapidly becoming the most frequently prescribed agents for both prophylaxis and treatment of PONV [130]. Recent data indicate that ondansetron (0.1 mg/kg, up to 4 mg) was effective in preventing early and delayed PONV in children undergoing various types of surgeries [137]. Due to its efficacy and safety profile, ondansetron has become the most commonly prescribed antiemetic for prophylaxis and treatment of PONV. Despite its established safety record, it is important to be aware of some of the fortunately rare but serious side-effects of ondansetron, which may cause a lethal outcome. Recent data indicate that ondansetron may cause QT prolongation leading to ventricular tachycardia [138]. Rarely, ondansetron may be associated with serotonin syndrome [139] and malignant hyperthermia reaction in patients with muscular dystrophies [140,141].

Two novel antiemetic agents are now available that will likely have an increasing role in the treatment of PONV. Palonosetron, a second generation 5-HT3 antagonist, was approved by the FDA in July 2003. Due to its unique binding properties and greater binding affinity for the receptor, it has a substantially longer half-life of approximately 40 h. A study of adult patients undergoing outpatient laparoscopic surgery with two or more risk factors for PONV found that a single IV dose of 0.075 mg of palonosetron prior to induction significantly increased the complete response rate, i.e. no emetic episodes and no rescue medication, compared with placebo [142]. Furthermore, patients who received palonosetron reported less severity of nausea and less interference in their postoperative function due to PONV. Pediatric data with the use of palonosetron are limited to its use for chemotherapy-induced nausea and vomiting. A study that compared children who received ondansetron before the administration of chemotherapy and every 8 h through the hospitalization with those who received a single dose of palonosetron prior to chemotherapy reported significantly reduced intensity of nausea and a significant reduction of emetic events for 3 days of treatment, with some benefits for up to 7 days in the palonosteron group [143]. Palonesetron has been found to be superior to other agents in preventing nausea and vomiting in highly emetogenic chemotherapy regimens [144,145]. Its long duration of action makes it an excellent choice for patients undergoing outpatient surgery and further studies are needed to evaluate its benefits in this setting.

Aprepitant is a neurokinin-1 receptor antagonist that crosses the blood–brain barrier and blocks the emetic effects of substance P [146]. Studies in adults have reported its efficacy in reducing PONV following joint arthroplasty and abdominal surgery [147,148]. However, no pediatric data are available for this indication. A single oral dose of 40 mg given 1 h prior to surgery has been recommended for adults. An IV formulation is now available but its only indication is for chemotherapy-induced nausea and vomiting. A recent review of the literature in pediatrics revealed no PONV studies, but a number of studies have documented the effectiveness of aprepitant when added to highly emetogenic chemotherapy regimens [149].

KEY POINTS: POSTOPERATIVE NAUSEA AND VOMITING

- Risk factors for PONV include age >3 years, being female, a family history or previous history of PONV and motion sickness, and surgical procedures like ENT, eye, and laparoscopy
- High-risk patients should receive dexamethasone and ondansetron for the prophylaxis of PONV
- Reducing opioid dose and employing regional anesthesia may reduce the risk of PONV

Recovery and discharge

Recovery from anesthesia is a complex process encompassing several outcomes including normalization of physiological end-points, return to baseline sensorium and activity, and emotional and psychological recovery. For the patient undergoing ambulatory surgery, assessment of recovery has largely focused on a return of acceptable physiological parameters, ability to ambulate, and recovery of consciousness such that the patient may be safely discharged home. To that end, a number of simple clinical scoring systems that assess recovery have been developed and tested [150–154]. The scoring system that is perhaps most widely used is the Aldrete score which was first described in 1970 [150]. The original Aldrete score was a 0–10 point scale comprising of five recovery parameters, each of which was scored from 0 to 2, similar to the Apgar score. Subsequently, a number of modifications of this score have been made that incorporate fast-track criteria and oxygen saturation rather than observation of color to identify hypoxemia, in addition to consideration of developmental stages in children [151,153,155]. Table 38.6 describes a version of the Aldrete score suitable for use in children.

Another score that is easy to use and is well suited for use in children is the Steward postanesthetic recovery score which incorporates three recovery parameters scored from 0 to 2 yielding a maximum achievable score of 6 (Table 38.7). In addition to monitoring of physiological variables such as vital signs, oxygen saturation, and level of consciousness, a standardized recovery score should be calculated for each patient on admission, at appropriate intervals during the PACU stay, and on discharge. Each facility must select the recovery score that works best in their setting taking into consideration the psychometric as well as pragmatic qualities of the scoring system to facilitate its repeated use.

Recently, the limitations of such scoring systems in evaluating the broader and potentially long-term impact of anesthesia and surgery have been recognized [156,157]. In attempts to assess early and long-term recovery across multiple domains, including cognition, emotional recovery, and activities of

Table 38.6 Modified Aldrete score for children

Box 38.3: Items included in the post-hospital behavior questionnaire.

I. Does your child need a pacifier?
Does your child seem to be afraid of leaving the house with you?
Is your child uninterested in what goes on around him (or her)?
Does your child bite his (or her) fingernails?
Does your child seem to avoid or be afraid of new things?
Does your child have difficulty making up his (or her) mind?
Is your child irregular in his (or her) bowel movements?
Does your child suck his (or her) fingers or thumbs?

II. Does your child get upset when you leave him (or her) alone for a few minutes?
Does your child seem to get upset when someone mentions doctors or hospitals?
Does your child follow you everywhere around the house?
Does your child spend time trying to get or hold your attention?
Does your child have bad dreams at night or wake up and cry?

III. Does your child make a fuss about going to bed at night?
Is your child afraid of the dark?
Does your child have trouble getting to sleep at night?

IV. Does your child make a fuss about eating?
Does your child spend time just sitting or lying and doing nothing?
Does your child have a poor appetite?

V. Does your child have temper tantrums?
Does your child tend to disobey you?

VI. Does your child wet the bed at night?
Does your child need a lot of help doing things?
Is it difficult to get your child interested in activities (like playing games, with toys, and so on)?
Is it difficult to get your child to talk to you?
Does your child seem to be shy or afraid around strangers?
Does your child break toys or other objects?

Source: Reproduced from Vernon et al [160].

daily living, studies in adults have evaluated the reliability, validity, precision, and pragmatic qualities of instruments that measure postoperative recovery outcomes at various time periods following surgery. [156–159]. These studies evaluated instruments that were designed for use in adults and most would not be suitable for use in children. The post-hospital behavior questionnaire comprises of 27 items across six categories of anxiety including: general anxiety, separation anxiety, sleep anxiety, eating disturbances, aggression against authority, and apathy/withdrawal (Box 38.3) [160]. This instrument was designed specifically to evaluate maladaptive and negative behavioral changes in children and has been widely used to assess postoperative behavior changes in the pediatric surgical population [53,161,162].

Discharge criteria

The ASA practice guidelines recommend that each patient care facility should develop suitable recovery and discharge criteria and provide guidance for the development of such criteria (Box 38.4) [163]. Box 38.5 summarizes the ASA stance on specific discharge criteria that have been traditionally mandated in some settings, such as requiring that patients void or tolerate oral liquids prior to discharge. These practices prolong recovery stay and evidence to support their benefits in reducing adverse outcomes is insufficient. Indeed, a previous study reported a lower incidence of vomiting and a shorter stay in the day surgery unit in children who were allowed to drink electively compared to those who were required to drink prior to discharge [164]. No child in either group required readmission for vomiting or dehydration. However, the intravenous fluid regimen was liberalized to supply a calculated 8 h deficit in addition to maintenance fluids and intraoperative losses. Adequate intravenous hydration and correction of fluid deficits prior to discharge may be prudent in children who refuse oral fluids in the PACU.

Discharge before voiding has also not been found to result in readmission for urinary retention. In one study, 30/1719 ambulatory patients who were unable to void but met other discharge criteria were discharged home and followed by a home care nurse [165]. Three of these patients required catheterization at home and all three had undergone rectal or inguinal surgery under spinal anesthesia, and none required readmittance. Risk factors for postoperative urinary retention in children include a history of urinary retention or urethral surgery. In the absence of these risk factors children may be discharged before voiding with instructions to the caregivers to call if they have not voided within a given timeframe.

Sample PACU discharge criteria are presented in Box 38.6. The responsibility of discharge to inpatient settings when specific discharge criteria are met may be delegated to the PACU

Box 38.4: Summary of recovery and discharge criteria

General principles
- Medical supervision of recovery and discharge is the responsibility of the supervising practitioner
- The recovery area should be equipped with appropriate personnel and monitoring and resuscitation equipment
- Patients should be monitored until appropriate discharge criteria are satisfied
- Level of consciousness, vital signs, and oxygenation should be recorded at regular intervals
- A nurse or other individual trained to monitor patients and recognize complications should be in attendance until discharge criteria are fulfilled
- An individual capable of managing complications should be immediately available until discharge criteria are fulfilled

Guidelines for discharge
- Patients should be alert and oriented. Patients whose mental status was initially abnormal should have returned to their baseline
- Vital signs should be stable and within acceptable limits
- Discharge should occur after patients have met specified criteria
- Use of scoring systems may assist in documentation of fitness for discharge
- Outpatients should be discharged to a responsible adult who will accompany them home and be able to report any postprocedure complications
- Outpatients should be provided with written instructions regarding postprocedure diet, medications, activities, and a phone number to be called in case of emergency

Source: Data from American Society of Anesthesiologists Task Force on Postanesthetic Care [163] with permission of Wolters Kluwer.

Box 38.5: Summary of recommendations for discharge.

Requiring that patients urinate before discharge
- The requirement for urination before discharge should not be part of a routine discharge protocol and may only be necessary for selected patients

Requiring that patients drink clear fluids without vomiting before discharge
- The demonstrated ability to drink and retain clear fluids should not be part of a routine discharge protocol but may be appropriate for selected patients
- Replacement intravenous hydration is recommended

Requiring that patients have a responsible individual accompany them home
- As part of a discharge protocol, patients should routinely be required to have a responsible individual to accompany them home and to monitor for complications

Requiring a minimum mandatory stay in recovery
- A mandatory minimum stay should not be required
- Patients should be observed until they are no longer at increased risk for cardiorespiratory depression
- Discharge criteria should be designed to minimize the risk of central nervous system or cardiorespiratory depression after discharge

Source: Data from American Society of Anesthesiologists Task Force on Postanesthetic Care [163] with permission of Wolters Kluwer.

Box 38.6: Sample postanesthesia care unit (PACU) discharge criteria

Criteria for discharge to general care inpatient units
- Stable respiratory status (patent airway, adequate respiratory function, adequate oxygen saturation)
- Stable vital signs within an acceptable range for patient's age, condition and preoperative status
- Awake or easily arousable. Level of consciousness appropriate for preoperative developmental age/status
- Operative area without evidence of significant bleeding
- Adequate analgesia so that comfort needs can be easily managed by resources available at the discharge location
- Normothermic or core temperature that is minimally 36°C or temperature within an acceptable range of preoperative status
- Patients who have received spinal or epidural anesthesia must demonstrate maximum sensory block at the T12 dermatome level and be free of orthostatic hypotension
- Patients who receive racemic epinephrine will be admitted or monitored for at least 8 h

Criteria for discharge to home
- Tolerate oral fluids with minimal nausea or vomiting or have received adequate intravenous fluid replacement to deter dehydration
- Parents or caregivers have adequate understanding of discharge instructions and are able to provide postoperative care
- Patients who have received spinal or epidural anesthesia must be able to transfer with assistance
- Patients who receive regional anesthesia will be instructed to call the PACU or surgical service if they have not voided within 6 h

nurse. In the USA, all patients who are to be discharged home must be evaluated for discharge readiness by an anesthesiologist in accordance with guidelines from the Centers for Medicare and Medicaid Services [166].

Fast-tracking

Fast-tracking is the process of bypassing the PACU and transferring the patient who has met specific criteria directly to the step-down or phase II recovery unit. The goals of fast-tracking are to improve efficiency without compromising patient safety or satisfaction. Table 38.8 describes suggested criteria for fast-tracking children that take into consideration the adequacy of pain relief [155]. A randomized study found that children who were fast-tracked had a 20 min shorter recovery time compared with those who were sent to PACU even though both groups met fast-track criteria in the operating room [155]. Children in the fast-track group were less likely to be given analgesics postoperatively (41% versus 62%) and were more likely to be restless in the phase II recovery unit (31% versus. 16%) compared with the children who were sent to the PACU. Yet no child experienced a clinically significant adverse event. A previous study that included patients >12 years of age found that ASA PS3 compared with ASA 1, age <60 years, and general surgery compared to orthopedics and ophthalmology were risk factors for fast-track ineligibility [167]. Consideration of such factors in addition to standard criteria may enhance efficient and cost-effective utilization of PACU resources. As stated in the American Society of Perianesthesia Nurses standards, "Phase II is a level of care, not a physical place. The decision to fast-track a patient should

Table 38.8 Criteria for fast-tracking children

Criterion		Score*
Level of consciousness	Awake and oriented	2
	Arousable with minimal stimulation	1
	Responsive only to tactic stimulation	0
Physical activity	Appropriate for age and development	2
	Weak for age and development	1
	Unable to move extremities	0
Hemodynamics	BP <15% of baseline MAP	2
	BP 15–30% of baseline MAP	1
	BP >30% below baseline MAP	0
Respiratory stability	Coughing, crying, deep breaths	2
	Hoarseness with crying or coughing	1
	Stridor, dyspnea, wheezing	0
SpO_2	>95% on room air	2
	90–95% on room air	1
	<90% on room air	0
Pain	None/mild discomfort	2
	Moderate to severe controlled with IV analgesics	1
	Persistent severe pain	0

* A minimum score of 10 (with no score <1 in any individual category) is required for fast-tracking children.
BP, blood pressure; IV, intravenous; MAP, mean arterial pressure.

be based on patient needs, clinical assessments, and desired patient outcomes" [168].

KEY POINTS: RECOVERY AND DISCHARGE

- The modified Aldrete score is the most common and reliable assessment of recovery from anesthesia; versions modified for pediatrics are in common use
- Requirements to ingest oral fluids or to void prior to discharge are unnecessary
- Fast-tracking bypasses the standard PACU and admits the petient to a phase II step-down recovery to improve efficiency and discharge the patient home earlier

Complications of outpatient anesthesia

Adverse postoperative outcomes are usually multifactorial in origin and occur due to the patient's underlying comorbidities, due to anesthetic techniques, or due to the surgical procedure itself. Fortunately, major morbidity and mortality are extremely rare following ambulatory anesthesia, with a reported death rate of approximately two per 100,000 procedures [169,170]. However, minor sequelae such as drowsiness, uncontrolled PONV, unrelieved pain, bleeding complications, and respiratory complications may lead to delayed discharge, unplanned hospital admission, or readmission following discharge.

Unrelieved pain is the commonest symptom reported by parents following discharge, with an incidence of 25–91% [171–177]. One study found that tonsillectomy was a predictor for postoperative pain. Pain lasted for 7 days or longer in 33% of children in this study and 12% of the parents believed that postoperative instructions for pain management at home were inadequate [172]. The incidence of PONV following discharge is reportedly 5.9–59% [171–175,178]. Predictors for PONV include emetic symptoms in the hospital, pain at home, age >5years, and administration of postoperative opioids [172]. Other symptoms after discharge include drowsiness, headache, dizziness, fever, hoarseness, mild croup, and difficulty voiding. Adequate preparation of the family/caregivers with individualized discharge education regarding the potential complications and symptoms may alleviate parental anxiety following discharge and promote satisfaction.

Unplanned admission

Unplanned hospital admission for the ambulatory surgery patient increases utilization of resources, poses inconvenience to patients and their families, and has been viewed as a measure of outcome and quality of care. Previous investigators have reported that approximately 2% of children scheduled for outpatient surgery required hospital admission [179–181]. One study found that almost 4% of children undergoing ambulatory surgery required a prolonged PACU stay (>3 h) and 1.9% required hospital admission [179]. Prolonged PACU stay occurred most frequently due to PONV (19%) or respiratory complications (16%) including bronchospasm, oxygen desaturation, stridor, and apnea. Hospital admission was most commonly required due to respiratory complications and surgical reasons including more extensive surgery than was originally planned. Similarly, other investigators reported a 1.8% unplanned admission rate most commonly due to PONV, postoperative bleeding, or unexpected difficulty of the procedure [181]. Another study reported a 2.2% incidence of unplanned hospital admission in children that occurred most commonly due to surgical reasons including uncontrolled pain, surgical complications, need for extensive surgery, and bleeding [180]. In this study, hospital admission also resulted from: anesthesia-related causes including PONV, oxygen desaturation, bronchospasm, and somnolence; social causes including surgery ending late in the day; and medical causes including underlying medical problems or undiagnosed medical disease. Notably, in the latter two studies, orchidopexy was the commonest surgical procedure resulting in unplanned admission. Taken together these data suggest a need for careful and frequent re-evaluation of selection criteria for outpatient surgery and vigilant monitoring for potential complications in the PACU.

A recent study of 21,957 ambulatory surgery cases in children documented a 0.97% hospital admission rate; 47% of the admissions were anesthesia related [182]. Factors associated with admission were age <2 years, ASA 3, surgery duration >1 h, completion of surgery after 3 p.m., orthopedic, dental, or ENT surgery, OSA, and intraoperative events. Leading anesthetic causes for admission were inadequate pain control in 24% and PONV in 21%.

Summary

As we enter an era of healthcare reform, it is inevitable that the pressures to provide low cost, yet efficient and high quality surgical care will become increasingly relentless.

The practice of ambulatory surgery will likely expand further and at a more rapid pace than it has over the past 30 years. The need for development of innovative delivery models that capitalize upon low-cost organizational structures and prudent management of resources will call upon the resourcefulness of healthcare professionals and administrators alike. In the setting of ambulatory surgery, it will become increasingly important to prevent such pressures from constraining clinical judgment regarding the safest and most appropriate patient care.

CASE STUDY

A 22-month-old male child presented for hypospadias repair as an outpatient.

History

The patient had been healthy since birth and had been followed regularly for his well child visits. He was up to date on his immunizations and his growth and development had been normal. The parents reported a history of a "cold" with a runny nose and cough that started 7 days prior to the scheduled surgery. His skin was warm to touch, and he had decreased appetite and activity on the first day of his symptoms. Most of his symptoms had resolved without any treatment but he continued to have an occasional cough. This was his second upper respiratory infection since he started going to daycare 6 months ago. His review of symptoms was otherwise negative. The child was on no medications. He had not undergone any previous surgery.

He was born at 41 weeks' gestation by emergent cesarean section for fetal bradycardia. His neonatal course was complicated by hyperbilirubinemia that was treated with phototherapy and caused him to stay in the newborn nursery for an extra day.

His family history was negative for anesthesia-related problems. His mother received an uneventful epidural anesthetic for his birth and his father had undergone a tonsillectomy as a child that was uneventful to the best of his knowledge.

Physical examination

The child was active and alert, playing with toys in the surgical waiting room but started crying and clinging to his mother when being examined. His vital signs were normal for age and his weight was 13.2 kg. He had no dysmorphic features and while it was impossible to perform a detailed airway examination, he had normal neck mobility and anatomy and his mouth opening was adequate. His breath sounds were initially coarse but cleared when he was distracted and stopped crying. He had normal heart sounds and no murmurs, extra sounds, or clicks.

Anesthetic management

The child was fearful of strangers and resisted changing into the hospital gown. His mother was concerned that he would not cooperate with induction of anesthesia by mask. He was therefore premedicated with 7 mg of midazolam orally. He also received 200 mg of acetaminophen suspension orally for pre-emptive analgesia. Within 15 min, the child appeared visibly calmer but resisted being carried by the anesthesia team. He was wheeled into the operating room in a wagon. Anesthesia was induced by the inhaled route using sevoflurane and intravenous access was secured after induction. Due to the potential airway hyper-reactivity from the recent upper respiratory infection, a laryngeal mask airway was placed and anesthesia was maintained with oxygen, nitrous oxide, and sevoflurane. After induction of anesthesia, a caudal block was placed using 7 mL of 0.125% bupivacaine with 1:200,000 epinephrine. The surgery was completed uneventfully and the LMA was removed in the operating room prior to transfer to the PACU.

Postoperative management

The child was asleep but readily arousable on arrival in the PACU. He had stable vital signs and his oxygen saturation was 98% on blow-by oxygen. The oxygen was discontinued and he maintained saturations >95% on room air. His pain score on awakening was 3/10 by the FLACC (face, legs, activity, crying, consolability) scale and since 4 h had elapsed after his initial acetaminophen dose, he was given an additional 150 mg of oral acetaminophen. He was reunited with his parents in the PACU. The child had two episodes of emesis in the PACU after he drank apple juice. He was given 2 mg of ondansetron and no further emesis occurred. The child refused additional fluids but was able to void in the PACU. He had complete return of motor function and was able to stand prior to discharge. He was discharged home with a prescription for oxycodone suspension when he met institutional discharge criteria. Telephone follow-up the next day revealed that the child had an uneventful recovery at home and had required one dose of oxycodone upon awakening the morning after the surgery.

Conclusion

This case describes the perioperative care of a child undergoing a common urological procedure. It illustrates the effective use of a sedative premedication that facilitated separation from the parent. The use of a regional block allowed the child to awaken in minimal pain and significantly reduced the need for opioids.

A review of over 21,000 ambulatory surgery cases with an admission rate of 0.97%; anesthesia causes accounted for about half of these, with pain and PONV the leading causes.

CHAPTER 39
Anesthesia for Trauma

Monica S. Vavilala and Sarah A. Lee
Department of Anesthesiology and Pain Medicine, University of Washington School of Medicine, Seattle, WA, USA

Introduction

Trauma is the leading cause of death in children older than 1 year of age. In children, trauma accounts for approximately 65% of deaths and more than 35% of all non-fatal injuries (Table 39.1) [1]. Trauma resulting in death is higher in males than in females in all age groups from age 0 to age 18, with fatal trauma rates in males nearly double that of females [2]. Non-fatal injury rates are highest for Native Americans and lowest for Asian and Pacific Islanders; Caucasian and African-American rates of non-fatal injury are similar [3]. Blunt force trauma is significantly more common than penetrating trauma, and traumatic brain injury (TBI) constitutes 80% of pediatric trauma, followed by intra-abdominal and intrathoracic trauma. Motor vehicle trauma and other transportation-related traumas (e.g. cycling, pedestrian) are a leading cause of fatal injury across all age groups and genders, but is most substantial in adolescents 15–18 years of age. According to the Centers for Disease Control and Prevention (CDC), falls are the leading cause of non-fatal injuries in children under the age of 15 years; they occur predominantly in children 4 years of age and younger and are highest in infants less than 1 year in age. Penetrating trauma, occurring largely in the form of animal bites, accounts for a high number of non-fatal injuries in children aged 0–9 years of age, and occurs more commonly in the form of firearm-related injuries in adolescents aged 15–18 years.

Prehospital care

Critically ill children represent approximately 10% of emergency medical service transport cases. However, children utilizing emergency medical services for transport to an emergency department are of higher acuity than adults, require care in the emergency department more promptly, and have significantly higher rates of admission [4][. The "golden hour" represents the early critical period during which crucial managements can directly increase the patient's chance of survival.

While emergency medical service systems have recently undergone fundamental improvements with regards to pediatric trauma care, there still exists a significant gap in quality of prehospital care for pediatric patients compared to that of adults [4]. Vella et al studied 154 pediatric trauma patients who presented at level 1 trauma centers and found that 70% of the patients either did not receive or received inadequate fluid resuscitation. Half of the patients did not have a second intravenous line, as per the Advanced Trauma Life Support (ATLS) guidelines, which may be a result of the perception that the patients did not require significant resuscitation [5]. There is a higher rate of failed tracheal intubation in children receiving prehospital care, even when tracheal intubation is performed by skilled, hospital-based providers [6]. Similarly, intravenous placements by prehospital providers have a higher complication or failure rate in pediatric patients versus adult patients [7]. Prehospital pediatric intubation carries a much higher rate of tube malposition and left lung atelectasis, with less than one-third of tracheal tubes placed in a safe position [8]. Of note, Gausche et al demonstrated that there is no significant difference in survival rate or neurological outcome among pediatric trauma patients who were randomized to bag–mask ventilation verses tracheal intubation in the prehospital setting. Their study raises the question whether prehospital providers should be educated in managing the airways of appropriately selected patients using a bag–mask rather than placing all patients at risk for multiple intubation attempts or incorrectly placed tracheal tubes [9].

Fewer sets of vital signs are obtained in children under the age of 15 years, and children under 4 years of age are significantly less likely to have a complete set of initial vital signs taken than all other age groups combined. Blood pressure and respiratory rate, two principle components of field triage assessment for identifying children needing the resources of a

trauma center, are the most frequently missed vital signs by prehospital providers in the pediatric population, leading to the undertriaging of more than half of pediatric trauma patients [10]. The IMPACT prospective randomized trial demonstrated that pediatric trauma patients who had enhanced monitoring during transport had shorter lengths of hospital stay and lower rates of multiorgan dysfunction [11]. These findings underscore the need for focus on pediatric-specific education and skills training, especially in situations where providers do not have regular encounters with pediatric patients. Without the consistent use of these skills in the field, a disparity in the provision of care for injured children is created [12]. In addition to emergency medical services, medical direction and oversight, protocol development, and implementation, education is paramount for continued prehospital process improvement [13]. Baker et al demonstrated that there was a significant increase in vascular skill performance in emergency medical service providers trained in pediatric advanced life support (PALS) versus those not trained in PALS (100% versus 77% for intravenous, 100% versus 55% for intraosseous) [14].

Organization of trauma services

Trauma centers are assigned levels I–III, designated by the American College of Surgeons (ACS) based on capability. Pediatric trauma centers may be present in either level I or II trauma centers. Level I trauma centers require the continued presence of specialized providers with a dedicated trauma operating room (OR) that is available 24 h a day, in concert with the immediate availability of supportive services such as radiology and blood banks. Level II trauma centers require the prompt availability of these services [15]. Advances in prehospital care has been focused on early identification and stabilization of the critically ill patient and rapid prehospital transport during the "golden hour" to specialized centers capable of definitive intervention. The regionalization of trauma centers has permitted early referral of severely injured children to facilities equipped with specialized pediatric-trained providers. Nevertheless, pediatric trauma patients still suffer a relatively increased number of inappropriate delays during transport to definitive care in the current trauma system in the United States [16].

Furthermore, despite the existence of regional referral networks, there is evidence that a significant number of injured children are not treated at pediatric trauma centers, likely due to geographical limitations of such specialized providers and care [17]. Compared with non-pediatric trauma centers, care at pediatric trauma centers increases the percentage of non-operative management of solid organ injuries, and data suggest that children with splenic injuries treated at non-pediatric trauma centers have up to five times the odds ratio of having a splenectomy compared with those treated at pediatric centers [18]. Evidence exists that treatment at pediatric trauma centers improves functional outcomes and mortality of severely injured patients, and, in particular, improves outcomes of patients with severe traumatic brain injury [20,23]. With regard to older children, a recent analysis of the National Trauma Data Bank between 2007 and 2011 revealed that severely injured adolescents have improved outcomes and decreased imaging and invasive procedures when treated at pediatric versus adult trauma centers [23]. However, the data are not entirely unequivocal and remain a topic of controversy.

Primary and secondary evaluation

The ATLS guidelines for the initial assessment of an injured child involves identification and stabilization of the most immediately life-threatening issues. The primary survey consists of immediate management of the patient's airway, breathing, circulation, and disability (ABCD). A sizing, length-based resuscitation tape, such as the Broselow® tape, is used for rapid weight approximation in order to size equipment and work out dose fluids and medications (Fig. 39.1) [24]. If necessary, cardiopulmonary resuscitation should be performed in accordance with the PALS guidelines. Of note, the pediatric Basic Life Support for non-medical professionals advises beginning with an assessment of airway and breathing, and performing ventilation at a rate of one breath every 3–5 s. If the patient has no pulse, or their heart rate is less than 60 beats/min (bpm), chest compressions should be conducted at a rate of 100–120 bpm. However, the modified Advanced Life Support (ALS) algorithm prioritizes circulation or perfusion as the primary step, following a circulation, airway, and breathing sequence. Therefore, the healthcare provider should

Figure 39.1 The Broselow® tape used for rapid estimation of pediatric patient sizing and dosing. *Source*: Broselow, https://commons.wikimedia.org/wiki/File:BTape1.jpg. Licensed under CCBY 3.0.

first determine the presence of a pulse and immediately initiate chest compressions if necessary, prior to establishing an advanced airway. Of note, the survival rate for pediatric trauma victims who have undergone cardiopulmonary resuscitation is low (8–16%), with extraordinarily high morbidity rates for those receiving cardiopulmonary resuscitation on arrival at the emergency room [25].

Management of airway, breathing, and circulation, as described below in greater depth, should aim to maintain age-appropriate normal vital sign values. ATLS guidelines suggest that an approximate systolic blood pressure goal can be calculated using the formula 90 mmHg plus twice the age in years. As soon as possible, monitoring of urine output through placement of a Foley catheter allows for assessment of end-organ perfusion and adequate circulatory resuscitation, as well as serving as an indicator of bladder trauma and increasing the accuracy of an abdominal physical examination. Ensuring that the patient is normothermic is of high priority, especially since infants and children are at significantly higher risk of hypothermia due to their larger surface area to volume ratio, increased metabolic rate, thin skin, and decreased subcutaneous tissue and fat. Temperature should be maintained through warmed fluids and blood, increased ambient temperature, and the use of warmed blankets and heat lamps. Evaluation of disability involves a rapid assessment of neurological function. It is important to emphasize that regular, frequent reassessment of the primary survey be repeated as the patient's condition can change rapidly.

Once the primary survey is completed, the secondary survey involves a head-to-toe evaluation of other injuries. When possible, a more detailed history should be attained and should include the patient's allergies, medications, past medical and surgical history, last oral intake, and events related to injury (mechanism, timing, prior medications, and resuscitative procedures). If the patient remains stable enough for further evaluation, areas with a high index of suspicion for injury, identified by the physical examination, should be radiographically scanned. The primary trauma survey consists of radiographs of the chest and affected extremities. Computed tomography (CT) is the gold standard for the assessment of hemorrhage in the intraabdominal, thoracic, and cranial spaces. Because of the risk of malignancy from childhood CT radiation exposure, approximately 1:10,000 after a single CT scan, ATLS guidelines advise that radiation be as low as reasonably achievable (ALARA), and that CT should be limited to the affected area, with risks weighed against its prognostic value and ability to guide management [26]. During the secondary survey, treatment of pain should not be overlooked, and sequential doses of fentanyl (1 μg/kg) should be administered and redosed to achieve comfort, while ensuring that hemodynamic status and adequate respiratory drive is maintained. It is important to note that the undertreatment of pain can lead to an inability to perform an adequate physical exam, as well as lead to an increased incidence of post-traumatic stress conditions [27].

KEY POINTS: PRIMARY AND SECONDARY EVALUATION

- ALS guidelines mandate that chest compressions be initiated in a pulseless patient, prior to establishing an advanced airway
- The primary survey should be frequently repeated throughout the patient evaluation as the patient's condition can change rapidly
- CT radiation should be as low as reasonably achievable (ALARA) to decrease the risk of malignancy

Airway management

As per ATLS guidelines, an immediate priority of the anesthesiologist is to evaluate and, if necessary, manage the airway of the pediatric trauma patient. Indications for urgent intubation include hypoxia, respiratory distress, hemodynamic instability, airway or pulmonary injury, and decreased cognition leading to an inability to protect the airway [28]. Hypoxemia is detected by a decrease in oxygen saturation on pulse oximeter, but can also be observed by the patient's color, which is most apparent in infants and neonates. Respiratory distress is evident by signs of increased work of breathing, use of accessory and intercostal muscles, chest retractions, grunting, nasal flaring, and tachypnea. If upper airway obstruction exists as a result of airway edema, blood, or decreased pharyngeal tone, suprasternal retractions and stridor will be apparent [29]. Hemodynamic instability, often a result of hypovolemia and bleeding in the trauma patient, is reflected in the blood pressure, heart rate, capillary refill, and moistness of the mucous membranes. Patients with a modified Glasgow coma scale (GCS) score below 8 cannot protect their airways and are at risk for aspiration due to abated airway reflexes.

There are a number of factors that render the airway management of pediatric trauma patients especially challenging. From an anatomical standpoint, compared with adults, smaller children and infants tend to have larger tongues, shorter jaws, longer palates and epiglottises, a narrower cricoid cartilage, and an increased risk for laryngospasm. The relatively larger head to body ratio results in natural neck flexion when an infant is lying flat, making the "sniff position" more difficult. Moreover, as Pouiseuille's law dictates, the naturally smaller diameter of the pediatric airway means that even small decreases in size resulting from edema from

chemical injury or burns, swelling from direct airway injury, or adherent blood or secretions results in large increases in airway resistance. Infants tend to be obligate diaphragmatic breathers, and in the setting of respiratory distress, tire more rapidly. Hypoxia is precipitous even in healthy infants because of their increased oxygen demand and their decreased oxygen reserve (functional reserve capacity). The predisposition for infants to become quickly hypoxic is further exacerbated in cases where there is direct trauma to the lungs or pulmonary compromise from concomitant edema, transfusion-related acute lung injury, or acute respiratory distress syndrome. Furthermore, at baseline, infants have increased chest wall compliance but decreased lung compliance. Direct or indirect trauma can cause sudden decreases in pulmonary compliance and problems with ventilation [30].

Unlike in adults where cardiac problems remain the primary cause of cardiac arrest, in children hypoxia is the most common cause. Positioning of an infant's head and neck is very important, and because of the larger occiput, a small towel roll can be placed under the infant's shoulders in order to extend the neck into an ideal "sniff position" (Fig. 39.2). As many infants will have or be at risk for cervical spine injury, it is recommended that the cervical collar be removed prior to intubation and manual inline stabilization be performed by another provider. Preoxygenation for 3–5 min is imperative if possible, given the decreased oxygen reserve. As with adults, pediatric trauma victims are considered to have full stomachs and are at high risk for aspiration. Therefore, a rapid-sequence intubation should be performed and should include a slight reverse Trendelenberg (head up) position when possible (and provided the patient has a reasonable blood pressure) and cricoid pressure. Cricoid pressure should be reduced compared to that used in adults, as the softer tracheal cartilage of children is more collapsible, and can impede intubation. Succinylcholine (2.0 mg/kg) should be used to deliver intubating conditions as soon as possible. It is also prudent to have atropine readily available in the event that the succinylcholine coupled with vagal stimulation from intubation leads to sudden bradycardia, particularly in infants less than 1 year of age.

Cuffed tracheal tubes should be used instead of uncuffed tubes in the setting of trauma. Uncuffed tubes often lead to large leaks in ventilation, especially since, in children, pulmonary compliance can quickly deteriorate with pulmonary and airway injury in the setting of rapid fluid resuscitation. Studies show that the use of uncuffed tracheal tubes leads to an increased need for reintubation and subsequent airway trauma [31]. To avoid tracheal injury and subsequent tracheal stenosis, when the tracheal tube cuff is inflated, an air leak should be audible at 20–25 cmH_2O. As with any potentially difficult intubation scenario, emergency and back-up equipment should be immediately available. Such equipment includes appropriately sized laryngeal mask airways, oral and nasal airways, bougies, videolaryngoscopes, and fiberoptic bronchoscopes. ATLS guidelines recommends that oral airways should not be placed using a backward, 180° rotation technique as this can cause trauma to the more fragile oral tissue. For the same reason, these guidelines advise against nasotracheal intubation in children.

Videolaryngoscopy has become increasingly popular in both the OR and emergency room settings. Several studies have shown that videolaryngscopes have the potential to improve the view of the glottis in anterior or challenging airways, but generally increase time to intubation compared to direct laryngoscopy [32]. In cases of difficult intubation, fiberoptic scopes can be used. However, depending on the size of the tracheal tube, the smaller size and decreased rigidity of small-caliber or "spaghetti" flexible scopes make it more difficult to navigate past swollen pharyngeal tissue. Secretions and blood in the oral pharynx, common in trauma patients, can obscure or obstruct the view of the glottis, and can block small size tracheal tubes (Fig. 39.3). Smaller scopes do not have suction capability to remove secretions and mucous which can hinder visibility. While airway bougies can be helpful, especially in situations where there is an acute angle or small mouth opening or oropharyngeal space, they can be associated with very rare but devastating complications such as tracheal injury or perforation [33]. The extra fragility of the tracheas of small children means that special caution should be taken when using an airway bougie to ensure that it is not advanced too far past the vocal cords, and that advancement is without resistance. End-tidal CO2 should be continuously monitored to ensure that ventilation achieves normocapnea, and because changes in ventilation is an early indicator of tube malplacement. The tracheal length in infants is approximately 5 cm and grows to 7 cm at 18 months. The shorter tracheal length results in easy malpositioning of the tube. Reassessment and repeat auscultation should be performed after intubation, after the patient is moved or repositioned, or whenever there appears to be a change in the ventilation, as the probability of unrecognized inadvertant dislodgment or mainstem intubation of the tracheal tube is inversely proportional to the size of the child.

Figure 39.2 Towel rolls used to stabilize the cervical spine prior to intubation. *Source*: Courtesy of Dr Sanjay Bhananker, University of Washington, Harborview Medical Center.

KEY POINTS: AIRWAY MANAGEMENT

- Hypoxia is the most common cause of cardiac arrest in children
- Cuffed tracheal tubes should be used in preference to uncuffed tracheal tubes in pediatric trauma patients
- Reassessment and repeated auscultation should be performed after an airway is secured, when the patient is moved or repositioned, or when an acute change in ventilation manifests; malpositioning of the tracheal tube is increasingly likely in smaller children and infants

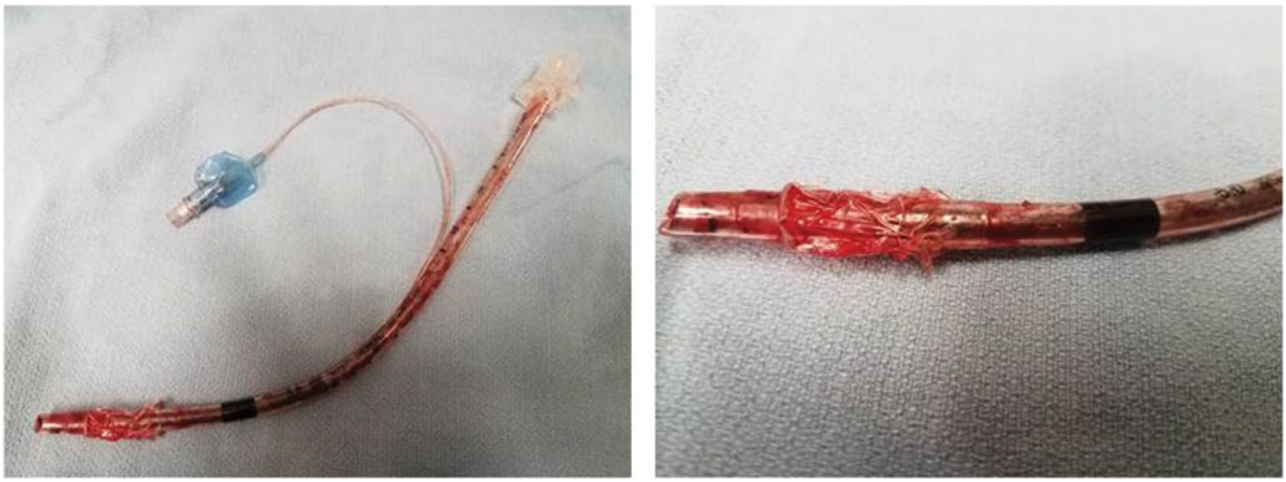

Figure 39.3 A smaller tracheal tube diameter increases the risk of airway obstruction by blood and secretions.

Vascular access

Establishing intravenous access is an immediate priority in both the prehospital and hospital settings. The smaller size of pediatric vessels and increased subcutaneous fat on the extremities of infants and toddlers can make intravenous catheter placement challenging. Peripheral access should consist of at least two intravenous lines, and should be placed in the upper extremities (preferably antecubital fossa) in situations when there is likely abdominal or thoracic trauma. Other common sites include the saphenous veins and external jugular veins, although the latter should be avoided in patients who have cervical spine collars or who exhibit signs of airway distress. Small increases in the radius of the intravenous catheter results in large increases in flow rate (by a power of 4). Placement of intravenous catheters as large as is feasible, and no smaller than 20 gauge in size (22 gauge in infants), allows for optimal rapid fluid and blood resuscitation (Table 39.2). There is evidence that rapid transfusion systems confer no significant benefit to flow rates or warming capacities of fluids through IV catheters of size 20 gauge or smaller [34].

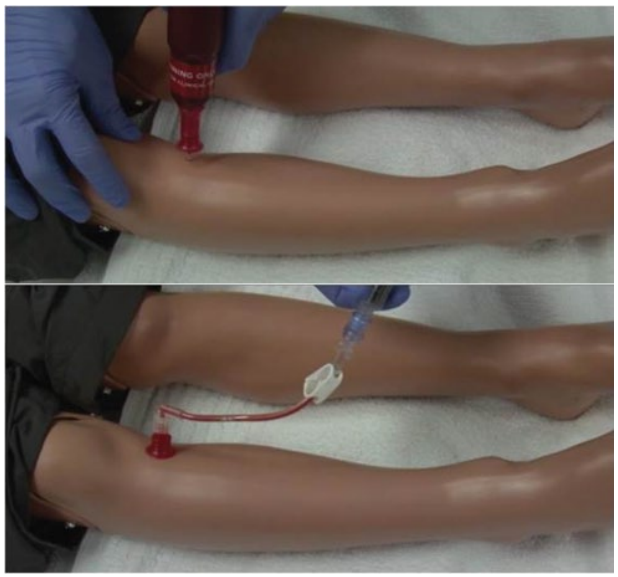

Figure 39.4 Placement of an intraosseous line in the anteromedial tibia and confirmation by line aspiration. *Source*: Courtesy of Dr Sanjay Bhananker, University of Washington, Harborview Medical Center.

Difficult intravenous access may require the use of ultrasonography or the blind saphenous technique. However, the severe hypovolemia and vasoconstriction in patients suffering from shock may render adequately sized intravenous access impossible within minutes of patient arrival. In situations where intravenous access cannot be successfully obtained within three attempts or 90 s, an intraosseous cannula should be placed. According to ATLS guidelines, the intraosseous catheter size should be 18 gauge in infants and 15 gauge in young children. Intraosseous cannulation is possible in long bones, although the most common site is the anteromedial aspect of the tibia, just below the tibial tuberosity (Fig. 39.4), followed by the distal femur. Complications include possible fluid extravasation but studies have shown that the incidence of complications is consistently low, and intraosseous lines offer a fast, safe method of fluid resuscitation, although they are often underutilized [35].

After the initial resuscitation, central venous access (either femoral or internal jugular) may be required as intraosseous access is life saving but temporary. Studies in the critical care setting have assessed techniques and complication rates associated with the placement of central venous lines in children. A recent evaluation of over 5000 patients demonstrated that although complication rates for central venous access was low among anesthesiologists (1.3%), failure was more likely in children <3 kg [36]. The use of ultrasound-guided techniques have improved first-pass success and decrease rates of complications. Evidence from a recent study demonstrated ultrasound-guided subclavian vein cannulization conferred a 98% first-pass success in patients weighing over 5 kg and a 92% first-pass success in neonates weighing under 5 kg, within a median time of 40 s [37]. When possible, confirmation of correct central line catheter placement through visibility by cross-sectional and longitudinal ultrasound, radiography, and pressure transduction should be ascertained prior to use of the central line. Similarly, placement of an arterial line may also prove necessary following initial resuscitation for more vigilant hemodynamic monitoring and for sequential blood draws that will guide further resuscitation and ventilation strategies. For small infants and neonates, a micropuncture arterial line apparatus that includes a smaller diameter wire may be helpful. Chapter 19 presents additional information about vascular access techniques.

KEY POINTS: VASCULAR ACCESS

- A minimum of two large (at least 20 gauge) intravenous catheters should be placed
- Intraosseous access should be placed if intravenous access cannot be established within three attempts or within 90 s of patient arrival
- Intraosseous access can be placed in any long bone and is a safe and effective method of emergency resuscitation

Massive transfusion and fluid resuscitation

Hemorrhage is a leading cause of death in pediatric trauma patients during the first 24–48 h after injury [38]. While damage control resuscitation has become well defined and widely implemented with solid evidence of improved outcomes in the adult population, massive transfusion guidelines have not yet been developed for the pediatric population [39,40]. Finding optimal transfusion strategies within this population poses challenges related to the differences in total blood volume and physiology among children of varying sizes and ages. Attempts to define massive transfusion in pediatric patients have led to a number of suggestions. One definition includes the transfusion of more than 50% total blood volume in 3 h, transfusion greater than 100% total blood volume in 24 h, or transfusion support to replace ongoing blood loss of greater than 10% total blood volume per minute. A commonly used and simpler definition derived from the US Department of Defense Trauma Registry defines massive trauma as 40 mL/kg of all blood products administered at any time within the first 24 h [41].

Since there are differences in adult and pediatric physiology, the strategy of permissive hypotension that has been widely accepted in injured adults without TBI cannot be simply and directly extrapolated to children [42]. As children can maintain their blood pressure in spite of significant blood loss through compensatory mechanisms, waiting for relative hypotension before resuscitation is far too late. Some authors describe the implementation of judicious "permissive tachycardia" while maintaining normal blood pressures, instead, as a mechanism of maintaining perfusion while decreasing the bleeding associated with high blood pressure in actively bleeding patients [43]. However, the goals and efficacy of "permissive tachycardia" have yet to be studied and delineated. Moreover, it is important to keep in mind that the diagnosis of TBI may not be initially revealed if other injuries require emergent surgeries.

When to initiate and how to guide transfusion of packed red blood cells requires the consideration of several factors including estimated fraction of total body blood loss, rate of active bleeding, and the determination of a transfusion threshold. Undertransfusion results in hypoxic and ischemic end-organ damage, while overtransfusion increases the length of intensive care unit (ICU) stay, ventilator dependence, and increased rates of mortality [44]. Similar to the adult Transfusion Requirements in Critical Care trials and other similar studies, transfusion studies in non-trauma critically ill pediatric patients have concluded that hemoglobin thresholds above 7 g/dL do not improve outcomes and may increase morbidity and mortality [45,46]. The support of a more restrictive transfusion threshold, e.g. at a higher hemoglobin, holds true among pediatric patients in septic shock, those with single-ventricle physiology, and those suffering from upper gastrointestinal bleed [47,48]. With the acute fluid shifts and the necessary replacement of active blood loss in trauma patients, decisions surrounding transfusion is more complex.

Advanced Trauma Life Support guidelines suggest initiation of resuscitation using 20-40 mL/kg boluses of isotonic crystalloid. The timing of transfusion needs to consider the rate of bleed, and actively hemorrhaging patients may require earlier transfusion and more crystalloid-restrictive strategies [49]. In the setting of ongoing bleed, and if initial crystalloid boluses are insufficient to cause normalization of vital signs and adequate urine output (1–2 mL/kg), blood should be administered in 30 mL/kg boluses, targeting physiological goals of normal age-appropriate heart rate, blood pressure, and urine output. Point-of-care measures, e.g. arterial blood gas, should be utilized to help guide transfusion and ensure that hemoglobin concentration is maintained within the range of target goals. Packed red blood cell freshness is an important consideration, especially in smaller infants less than 4 months of age. Young children and infants without fully matured kidneys have a decreased ability to handle the potassium load and acidemia associated with a massive transfusion of blood that has been stored for long periods of time. Transfusion with red blood cells that have been stored for over 28 days have been shown to result in longer length of ICU stay, lower discharge GCS scores, and increased mortality rates [50]. For this reason, when possible, "fresher" blood should be prioritized for critically ill younger patients and patients under 4 months should also receive cytomegalovirus negative, irradiated blood.

Once a massive transfusion threshold is triggered (>40 mL/kg), the supplementation of coagulation factors and platelets must be considered. While currently an optimal massive transfusion protocol in the pediatric population has not been established, there is general consensus that fresh frozen plasma and platelets should be administered alongside red blood cells in a 1:1:1 to 3:2:2 ratio [51]. A balanced transfusion approach is supported by overwhelming evidence that early coagulopathy occurs frequently among pediatric trauma patients [52]. Generally, platelet counts increase by 10,000/dL for every 1 mL/kg of platelets administered. Approximately 10–15 mL/kg of fresh frozen plasma will increase factor levels by 15–20%. Cryoprecipitate should be administered for fibrinogen levels less than 1 g/L and is also a source of factor VIII and factor XIII [53].

Coagulopathy in pediatric trauma patients is a result of both trauma-induced and iatrogenic coagulopathy. Iatrogenic coagulopathy describes dyscrasias due to the dilution of coagulation factors, acidosis, and hypothermia. Traumatic-induced coagulopathy describes the activation of the local coagulation system. Studies have demonstrated that children are more susceptible to coagulopathies and bleeding because of lagging coagulant maturity and an increased tendency for hyperfibrinolysis [54]. Studies of pediatric trauma patients in combat hospitals in Afghanistan and Iraq, as well as among civilian populations in the West, have demonstrated that early coagulopathy, defined as an international normalized ratio (INR) greater than 1.5, is an independent predictor for increased in-hospital mortality [55,56]. Results for early coagulopathy in the setting of TBI are more profound and suggest up to a fourfold increase in mortality [57–59]. Hence, resuscitation involving the early correction of coagulopathy using fresh frozen plasma, cryoprecipitate, and platelets is critical to increased survival in pediatric trauma patients, and particularly in those with TBI.

Challenges in optimizing blood component and coagulation factor therapy has led to a discussion of the utility of visoelastic coagulation tests as a rapid diagnostic test to identify early coagulopathy and guide treatment – i.e. thromboelastography, rotational thromboelastometry, and impedance aggregometry [60]. The point-of-care tests, which are utilized perioperatively during pediatric cardiac and liver transplant surgeries, more accurately demonstrate changes in all stages of clot formation and not just the initiation phase of blood coagulation represented by conventional tests [61]. Use of antifibrinolytic therapy, such as tranexamic acid, is also gaining attention. While it is not yet approved for use in children by the US Food and Drug Administration (FDA), trials performed in a combat setting (766 patients) demonstrated that tranexamic acid treatment is independently associated with decreased mortality in pediatric trauma patients as well as improved discharge neurological status and decreased ventilator dependence; there was no evidence of thromboembolic complications or cardiovascular events [62]. Given that tranexamic acid has been shown to reduce perioperative transfusion requirements in pediatric spine and cranial surgery, it may have an important role in pediatric hemorrhage from trauma, pending future studies [63]. Chapter 12 presents additional discussion about transfusion and coagulation monitoring.

KEY POINTS: MASSIVE TRANSFUSION AND FLUID RESUSCITATION

- Massive transfusion is approximately 40 mL/kg or more of all blood products administered within 24 h
- Prioritize fresh packed red blood cells (age <28 days) for small and critically ill infants
- Early treatment of coagulopathy decreases mortality, especially in children with TBI
- Blood transfusion should be guided by physiological goals, i.e. heart rate, blood pressure, urine output, and point-of-care hematocrit levels

Intraoperative management

Conservative management is the most commonly employed strategy for pediatric trauma, and an estimated 15% of pediatric trauma patients require surgery. Emergent surgery for pediatric trauma patients is most commonly for decompressive craniotomy and exploratory laparotomy. Hospitals receiving trauma patients should have the ability to process a patient from door to OR within 30 min, and it is important that there is a designated "crash" OR that is already set-up for trauma (Fig. 39.5). In addition to standard airway equipment such as suction, monitors, and IV access equipment, trauma rooms should have fluid warmers, forced-air warming devices, a readily available transfusion system such as a Belmont® Rapid Infuser System (Belmont Instrument Corp., Billerica, MA, USA), and equipment for ultrasound-guided placement of arterial lines and central lines. In addition, if emergent surgery is imminent, the room should be preheated, and a blood refrigerator with cross-matched products (if available) or uncrossed-matched O negative products for massive transfusion should be available.

The goal is to provide balanced general anesthesia while maintaining systemic and cerebral hemodynamic stability. Medications that decrease blood pressure should be used in reduced doses, especially in hypovolemic and hypotensive patients; efficacy of decreased dosing is generally maintained because of the lower volume of distribution in the setting of hypovolemia. Vasoactive agents should be immediately available for use to prevent induction-related hypotension. Anesthesia is often induced with a combination of medications, and most commonly includes etomidate, judicious doses of propofol, or ketamine. Etomidate causes less hemodynamic instability and should be administered in doses of 0.2–0.4 mg/kg IV. Ketamine causes less hemodynamic derangement than propofol and is administered in doses of 1–3 mg/kg. The shorter onset and duration of action of fentanyl makes it a useful analgesic in trauma, and dose ranges between 25 and 100 μg/kg are typical for the duration of a case. In very unstable patients, small doses of midazolam or scopolamine can be used for amnesia and sedation without causing hemodynamic compromise. Sevoflurane and isoflurane are generally used for maintenance of anesthesia, although doses must again be adjusted based on hemodynamic stability. Nitrous oxide should be avoided in trauma as it causes expansion of enclosed air spaces in the abdomen, thorax, and cranium

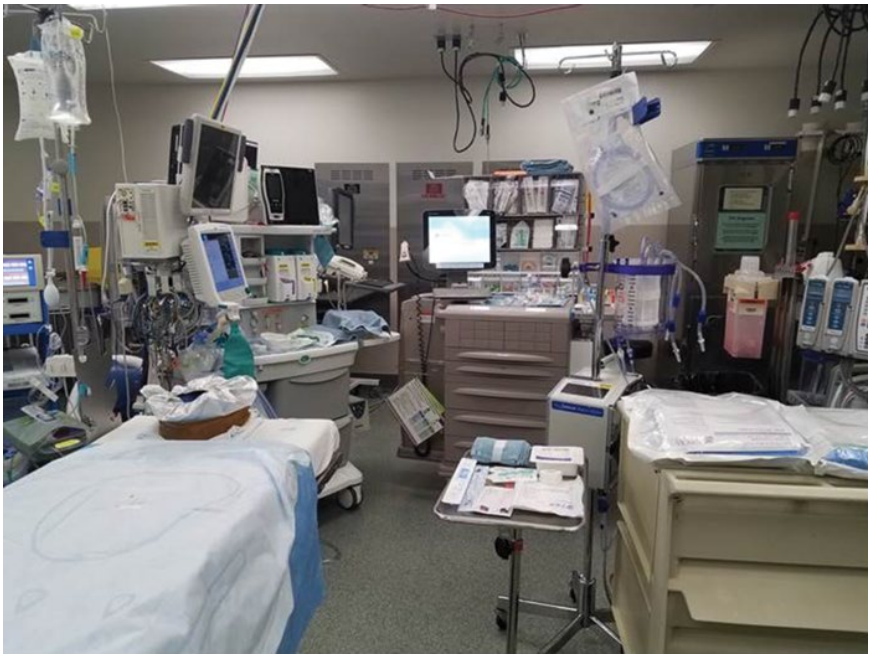

Figure 39.5 Operating room set-up for emergency trauma should include rapid infuser system, line placement equipment, fluid warmer, airway and ventilation equipment, induction and emergency drugs, and patient warming devices.

and reduces the maximum inspired oxygen concentration possible. Succinylcholine should be administered at 2 mg/kg, but should be avoided in patients with hyperkalemia, a family or personal history of malignant hyperthermia, prolonged immobility or in those with burns or denervation injuries that have been untreated for more than 24 h since the time of injury. There are variable opinions regarding pretreatment with atropine when using succinylcholine, but it should be immediately available in doses of 0.01–0.02 mg/kg in the event there is concomitant bradycardia. There exists large institutional variation regarding use of vasopressors. Phenylephrine, norepinephrine, and dopamine remain the most commonly used for blood pressure support. Recently, a study found no statistically significant difference in mean arterial pressure or cerebral perfusion pressure between vasopressor groups, although norepinephrine was associated with clinically relevant higher cerebral perfusion pressures and lower intracranial pressures compared to phenylephrine and dopamine [64].

Laboratory data that should be frequently monitored include arterial blood gases, complete blood counts, coagulation studies, and electrolytes. The stress response of trauma commonly increases glucose, and an insulin drip is often required, which is especially important in the setting of TBI. However, the greater metabolic demand of smaller infants predisposes them to hypoglycemia, particularly when they have been nil per os (NPO) for longer periods of time, so glucose monitoring is crucial and supplementation with dextrose should be administered as needed. Administration of ionized calcium is necessary when transfusing significant quantities of blood, as the citrate in stored blood components chelates calcium. Calcium chloride should be administered preferentially through a central line at boluses of 10–20 mg/kg until the ionized calcium concentration is corrected. Peripherally-administered calcium chloride should be diluted to 10 mg/mL to avoid phlebitis; an alternative is calcium gluconate at 30 mg/kg per dose via a peripheral IV line. If not already in place, a Foley catheter should be inserted to monitor urine output as an indicator of volume status and renal perfusion. It is important to be cognizant that chest tubes be placed on suction to optimize pulmonary function and reduce injury. Temperature management is of utmost important in pediatric trauma patients. Ability to maintain thermal hemostasis is inversely proportional to the patient's size, and children have a higher surface area to volume ratio and decreased ability compensate for hypothermia. Hypothermia (temperature less than 36°C) results in worsened coagulopathy, depressed cardiac output, and slow awakening. Temperature should be optimally maintained above 36°C through the use of forced-air warming, increased ambient room temperature, heat lamps, fluid warmers, and reflective head caps. Conversely, hyperthermia (temperature greater than 38°C) should also be avoided as it increases metabolic demand and undermines neurological outcomes.

KEY POINTS: INTRAOPERATIVE MANAGEMENT

- The choice of induction agent should consider hemodynamic status and goals
- Reduction of induction medication doses are used because of decreased volume of distribution in hypovolemia, and vasoactive agents should be immediately available
- Midazolam and scopolamine can be used for sedation in severely hemodynamically unstable patients
- Hypothermia results in coagulopathy, decreased cardiac output, and delayed awakening

Anesthetic considerations for specific injuries

Traumatic brain injury

Traumatic brain injury is the leading cause of death in children over the age of 1 year. TBI is more common among males (3:2 ratio), and males also have a higher risk of fatal injury [65]. The prevalent mechanism of injury varies depending on age. According to the CDC, falls are the most common mechanism of TBI, particularly in the 1–4-year age group. Bicycle-related accidents and motor vehicle crashes increase in prevalence with age, and motor vehicle collisions are the leading cause of TBI among adolescents. The CDC reports the incidence of TBI-related deaths for each age group to be: 4.3/100,000 (0–4 years), 1.9/100,000 (5–14 years), and an increased rate of 15.6/100,000 (15–24 years) [66]. Other significant mechanisms of injury include sports-related head injury, caused by sudden impact or the accumulation of more minor repetitive injury, in older children, and passenger-side airbag injury in younger children. Providers should take note of the signs and symptoms of of non-accidental TBI, particularly in children under the age of 2 years, as will be discussed later in this chapter.

Providers should have a high index of suspicion for TBI in children with multiple trauma, altered mental status, and other head and neck injuries. Infants with open frontanelles and mobile cranial sutures can accommodate intracranial bleed or swelling with a delayed presentation of symptoms. While infants may present with bulging frontanelles, the absence of a tense frontanelle on examination does not exclude the possibility of TBI. Notably, children are at greater risk for TBI because of their larger head to body ratio, thinner protective skulls, and decreased, more vulnerable myelinated tissue. Subsequently, children are more susceptible to having increased intracranial pressure (ICP). Moreoever, cerebral metabolic rate for oxygen and glucose are higher in children than adults by approximately 50% and 20%, respectively. Primary injury results from the initial impact; secondary injury may involve diffuse cerebral swelling, herniation, ischemia, or infection, as a consequence of primary injury. Primary injury includes both extra-axial injury (epidural hematoma, subdural hematoma, subarachnoid hemorrhage, and intraventricular hemorrhage) and intra-axial injury (diffuse axonal injury, contusion, and intracerebral hemorrhage) [67]. TBI is diagnosed by CT of the brain (Fig. 39.6). Diffuse axonal injury may, however, present with a normal CT scan despite increased ICP and neurological symptoms [68].

In addition to performing primary and secondary surveys, in patients suspected of having TBI, neurological assessment should be conducted using the modified GCS (Table 39.3). A GCS score of <9 necessitates tracheal intubation to ensure adequate respiration, protect the airway from aspiration, and maintain controlled ventilation for ICP management. TBI patients often have concomitant cervical spine injury. Cervical spine immobilization should be pre-emptive and requires that appropriately sized cervical spine collars be placed. In infants aged less than 6 months, a spine board should be used with tape adhered to the forehead and towels around the neck to immobilize the cervical spine. Manual inline stabilization should be performed if the c-collar or tape needs to be removed during direct laryngoscopy.

At a minimum, intravenous access adequate for expedient resuscitation and an arterial line are necessary. The addition of ICP monitoring may be used, although it is important to correct any coagulopathy prior to placing the monitor (Fig. 39.7). The degree of cerebral autoregulation impairment is related to the severity of TBI and is associated with poor outcomes; thus, it is critical that cerebral perfusion pressure (CPP) be maintained. In the setting of intracranial hypertension, CPP is measured as the difference between a patient's mean arterial pressure (MAP) and ICP. CPP should be maintained at a minimum of 40 mmHg. However, it may be wise to maintain CPP at 40–50 mmHg depending on the age of the child, with the CPP goals for older children being at the upper ranges. Maintenance of goal CPP often requires that a higher than normal MAP be maintained with the use of vasopressors. Furthermore, TBI can lead to cardiac dysfunction that may additionally require hemodynamic support using

Figure 39.7 Intracranial pressure monitor placed postoperatively in a 2-year-old patient.

vasopressors and positive inotropes [69,70]. Traditional guidelines have advocated against the use of ketamine in TBI because of the notion that it increases ICP. However, recent evidence demonstrates that ketamine may decrease ICP while maintaining CPP [71,72]. Hence, the updated Brain Trauma Foundation guidelines suggest that ketamine is a safe and effective sedative for pediatric patients with TBI [73].

An ICP above 20 mmHg is considered elevated. ICP management involves head elevation, hyperosmolar therapy, placement of an external ventricular drain (plus lumbar drain in refractory cases), high-dose barbituates, and/or decompressive craniotomy. Hyperosmolar therapy is administered in the form of hypertonic (3%) saline or mannitol; 2% hypertonic saline may be considered to avoid phlebitis if it is administered through a smaller peripheral vein. Hypertonic saline may be administered as a bolus dose of 6.5–10 mL/kg followed by a continuous infusion at 0.1–1.0 mL/kg, ensuring that serum osmolarity does not exceed 360 mOsm/L. Mannitol is less studied in the pediatric population but can be administered as a 0.25–1 g/kg bolus over 30 min, to a maximum serum osmolarity of 320 mOsm/L. A Foley catheter should be placed prior to initiation of hyperosmolar therapy, and euvolemia should be maintained by crystalloid replacement. Refractory intracranial hypertension may be treated with barbituates, such as thiopental or etomidate, if the patient has adequate blood pressure to tolerate it. The risk of adrenal suppression must be weighed when using etomidate. Propofol has not been approved by the FDA for long-term use as an infusion in infants and children, and carries the risk of propofol infusion syndrome, which results in acidosis and myocardial dysfunction. Early-onset trauma-related seizures occur with greater frequency among children, and prophylactic phenytoin is often used to reduce the risk of post-traumatic seizures. Interestingly, prevention of early-onset seizures has not been shown to decrease the incidence of late-onset post-traumatic seizures or outcomes [74]. Corticosteroids are not indicated in TBI. Table 39.4 shows the latest guidelines for the management of pediatric TBI.

Table 39.4 Guidelines for acute management of pediatric traumatic brain injury

Physiological parameter	Recommendations
Temperature	Avoid moderate hypothermia (32–33°C) early after severe TBI Hypothermia may be considered for persistent severe TBI after 8 h from injury for up to 48 h If hypothermia is induced, avoid rewarming at a rate of >0.5°C/h
Hyperventilation	Avoid prophylactic severe hyperventilation ($PaCO_2$<30 mmHg) 48 h after injury If hyperventilation is used in the management of severe refractory intracranial hypertension, consider advanced neuromonitoring for evaluation of cerebral ischemia
Cerebral perfusion pressure (CPP)	Maintain a minimum CPP of 40 mmHg Consider a CPP threshold of 40–50 mmHg depending on age, with infants at the lower end and adolescents at the upper end of this range
Hyperosmolar therapy	Consider hypertonic (3%) saline for treatment of severe TBI in boluses of 6.5–10 mL/kg and/or a continuous infusion at 0.1–1.0 mL/kg/h Do not exceed the dose necessary to maintain ICP <20 mmHg Serum osmolarity should be <360 mOsm/L. Mannitol is commonly used 0.25–1 g/kg although no studies meeting inclusion criteria were identified for use of evidence
Antiseizure prophylaxis	May consider prophylactic treatment with phenytoin to reduce early post-traumatic seizures
Sedatives	Consider etomidate or thiopental to control severe intracranial hypertension (consider risk of adrenal suppression with etomidate)
Corticosteroids	Corticosteroid use is not recommended to improve outcome or reduce ICP

ICP, intracranial pressure; TBI, traumatic brain injury.
Source: Reproduced from Bell and Kochaneck et al [77] with permission of Wolters Kluwer.

Decompressive craniotomy is indicated to relieve ICP and prevent herniation. Craniotomy should be performed to evacuate epidural hematomas in comatose patients, particularly if they are larger and likely to be caused by arterial hemorrhage. Subdural hematomas demonstrating a midline shift of >5 mm or that are thicker than 10 mm should also be evacuated. The decision to operate in intraparenchymal injury is supported by worsening of neurological exam, signs, or persistently elevated ICP. Similarly, the 2012 Brain Trauma Foundation guidelines for the mangement of pediatric severe traumatic brain injury recommend that diffuse cerebral edema, which occurs with greater frequency in the pediatric population, should be treated with craniotomy and duraplasty, especially in the setting of worsening signs and symptoms of intracranial hypertension.

Box 39.1: Predictors of poor outcomes after pediatric traumatic brain injury

- Age <4 years
- Cardiopulmonary resuscitation
- Multiple trauma
- Hypoxia (PaO_2 <60 mmHg)
- Hypoventilation ($PaCO_2$ >45 mmHg)
- Hyperventilation ($PaCO_2$ <35 mmHg)
- Hyperglycemia (glucose >250 mg/dL)
- Hyperthermia (temperature >38°C)
- Hypotension (blood pressure < 5th percentile for age)
- Intracranial hypertension (intracranial pressure >20 mmHg)

Source: Reproduced from Kanna et al [67] with permission of Wolters Kluwer.

Factors that independently affect outcomes in patients with TBI include hypoxia, hyperglycemia, fever, hypotension, and hypo- and hypercarbia (Box 39.1). Outcome studies have demonstrated that hypotension early in care results in increased in-hospital mortality (23% versus 8.6%) and decreased Glasgow outcome score upon discharge. Timely treatment of hypotension increases in-hospital survival (adjusted relative risk 0.46). Children who are hypotensive and not resuscitated in a timely manner are at 77% greater risk of in-hospital mortality compared with children who are not hypotensive in the prehospital location or emergency department [75]. Hypoxia, hypocarbia, and hypercarbia are also independently associated with poorer outcomes. Several studies have found that patients with higher PaO_2 (>100 mHg) on admission had an increased rate of survival. Survival benefit was found in patients with an admission $PaCO_2$ of 36-45 mmHg, as compared with those who were either hypo- or hypercapneic [76]. Subsequently, current guidelines recommend that hyperventilation be avoided in pediatric TBI in the initial 48 h postinjury, and should only be considered in refractory cases. If hyperventilation is performed, neuromonitoring should be conducted to prevent cerebral ischemia [77].

Abdominal trauma

Abdominal trauma accounts for the second most common pediatric traumatic injury. Abdominal trauma is present in approximately 25% pediatric trauma patients and is most commonly due to motor vehicle collisions. Children have more compliant chest walls and rib cages, both of which render their internal organs more vulnerable to external forces. Blunt trauma accounts for 85% of abdominal trauma, and 95% of blunt trauma injury is managed non-operatively. Conversely, penetrating trauma is less common in children, but usually requires damage control laparotomy. The spleen is the most commonly injured organ, followed by the liver. Unrecognized abdominal trauma can have fatal consequences. Diagnosis of intra-abdominal injury is most reliably performed through CT scan with contrast. A number of studies have assessed the utility of the focused assessment with sonography for trauma (FAST) exam in the pediatric population, since it is a primary diagnostic modality to measure intra-abdominal free fluid in adult trauma. In children, however, the FAST examination is far less sensitive, as less than half of pediatric patients have free fluid [78]. Many hospitals use a combination of FAST followed by CT, though the results of several recent studies have demonstrated that the addition of a FAST examination does not change management [79].

There are certain injury patterns that should alert the provider to mechanism-specific injury. Injury from seatbelt restraint during a motor vehicle crash is common in children. Presence of abdominal wall bruising or ecchymosis in the seatbelt distribution and abdominal pain is often predictive of underlying intra-abdominal injury [80]. Gastrointestinal mesenteric or bowel injuries represent the most common seatbelt-associated injuries, followed by splenic and hepatic injuries [81,82]. Bicycle handlebar injury represents another common cause of abdominal injury in children and typically presents with an imprint of the handlebar at the edge of the abdomen. Liver laceration is the most common intra-abdominal injury associated with handlebar injury [83,84].

Patients with abdominal trauma should have at least two large-bore intravenous lines in the upper extremity and an active type-and-screen. Non-operative management of abdominal trauma involves initial fluid resuscitation followed by monitoring for signs of hemodynamic instability, unexplained blood loss shown on serial measurements of hematocrit, and in some cases, liver and pancreatic enzymes (aspartate aminotransferase, alanine aminotransferase, and amylase). If the patient presents with penetrating intra-abdominal free air, abdominal free fluid in the presence of solid organ injury, or hemodynamic instability requiring massive transfusion, damage control laparotomy is indicated. If it remains uncertain whether there is intra-abdominal injury, such as in situations where there is intra-abdominal free fluid without solid organ injury, then a diagnostic laparoscopy may be performed [85].

If emergent laparotomy is likely, cross-matched blood products should be prepared. Intraoperative anesthetic management usually involves a rapid-sequence induction since abdominal trauma can cause severe gastric dysmotility, even if the patient is appropriately NPO. Most cases require the placement of an intra-oral or intranasal gastric tube that is connected to suction, as long as there is no concomitant esophageal injury. As in the majority of trauma cases, nitrous oxide should be avoided to prevent insufflation of the bowel or exacerbation of any undiagnosed pneumothorax. The anesthesiologist must account for the large insensible fluid losses associated with even low blood loss during open abdominal surgeries, due to the large incision, exposed bowel, and gastric tube output. Abdominal laparotomies are also associated with severe heat loss, and the anesthesiologist must be extra vigilant to ensure that the ambient room temperature is raised, fluids are warmed, and forced-air warming devices are utilized, which is particularly crucial for very small children.

Spine trauma

The incidence of spine trauma is relatively low in the pediatric population and occurs in less 2% of pediatric trauma patients. Children have more flexible interspinous ligaments and joint capsules, anteriorly wedged vertebral bodies that tend to slide forward with flexion, and flat facet joints; therefore, they tend to be at a lower risk for spinal cord fractures but are more susceptible to having associated ligementous and soft tissue injury. Spine trauma is most commonly caused by motor vehicle collisions (Fig. 39.8), although over 20% of spine trauma is

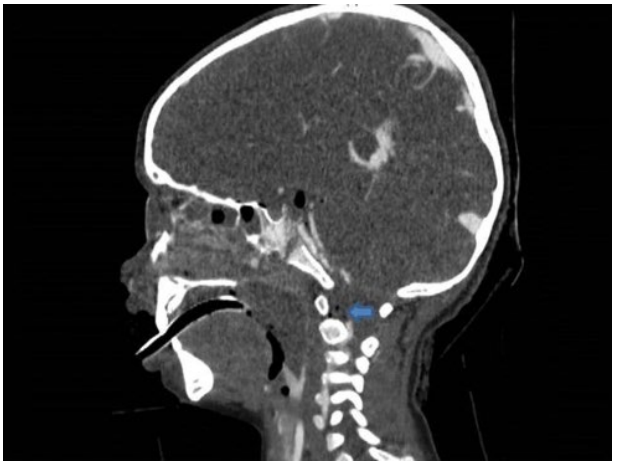

Figure 39.8 Cervical spine ligamentous injury in an 18-month infant following a high-speed motor vehicle crash. Air can be seen within the joint space of the left occipital condyle to C1 joint and C1–2 joint space. This is in association with the intracranial air, thought to represent a ligamentous disruption to the joint capsule.

sports related in older children [86]. Younger patients tend to have higher cervical spine injuries due to the more superior position of the fulcrum at C1–3 in preteens, compared to C5–6 in teenage patients. Evaluation of spine trauma involves a primary physical examination, whereby the patient's spine is immobilized, and the length of the spinal cord is palpated and grossly evaluated for pain or bony abnormalities. If injury is suspected, imaging is performed, consisting of anteroposterior, odontoid images, and lateral views of the cervicothoracic junction. Spinal cord injury without radiological abnormalities (SCIWORA) occurs when there is spinal ligamentous injury without fracture, with symptoms commonly presenting later. A recent study found that SCIWORA represents nearly 20% of spinal injuries in children aged less than 3 years, 9.4 % in children aged 3–12 years, and 5% in patients aged 13–20 years [87]. In cases where SCIWORA is suspected, magnetic resonance imaging is warranted.

Cervical spine immobilization should be pre-emptive during initial evaluation until it can be ruled out, noting that younger children are at higher risk of SCIWORA. For the anesthesiologist, this can mean increased challenges in airway management as intubation is performed with the cervical collar on or using cervical manual inline stabilization. Videolaryngoscopy can improve ease of intubation in such situations where there is limited neck extension and limited mouth opening. Similarly to the management of TBI, special attention should be paid to maintaining blood pressure at the upper ranges of normal, age-appropriate values to facilitate spinal perfusion. Patients with severe spinal injury may suffer from spinal and/or neurogenic shock, and the anesthesiologist must be prepared to support blood pressure with vasopressors and ionotropic support. The use of methylprednisolone is controversial, and studies have demonstrated no improvement in outcome with its use [88,89]. The usual dose is 30 mg/kg IV followed by 5.4 mg/kg/h for 23 h.

Cardiothoracic trauma

Thoracic injury accounts for between 5% and 12% of pediatric trauma. However, according to the 2015 Pediatric Report of the National Trauma Data Bank, thoracic trauma has the highest fatality rate of approximately 7% [90]. Patients with thoracic injury generally have higher injury scores, and the mortality rate of thoracic injury combined with abdominal or head trauma increases the mortality rate to 40% [91]. Blunt injury comprises over 90% of thoracic trauma. As a result of their increased chest wall compliance and increased mobility of mediastinal structures, children are more vulnerable to underlying soft tissue injury, and less at risk for rib fractures compared with adults. The most common pediatric thoracic injuries include pulmonary contusion, rib fractures, and hemothorax and/or pneumothorax [92].

Physical examination may reveal respiratory distress, asymmetrical or paradoxical chest movement with respiration, ecchymosis, and unilateral breath sounds on auscultation. Chest x-ray, a part of the initial ATLS diagnostic screening, can determine the presence of hemothorax, pneumothorax, and widened mediastinum. In the setting of a normal chest x-ray, studies have found that there is little utility for CT scans when looking for thoracic injury in isolation [93]. Pulmonary contusions can present 48–72 h following injury, and treatment is generally supportive. Traumatic pneumothorax requires insertion of a needle through the 5th intercostal space just anterior to the midaxillary line, followed by thoracostomy tube placement. Pneumothoraces seen on CT scan, but not on x-ray, generally do not require placement of thoracostomy tubes [94]. In the setting of persistent air leaks, thoracostomy tubes should be placed on continuous suction. Large air leaks with a persistent pneumothorax on x-ray should be treated with an additional thoracostomy tube. Hemothorax requires evacuation of blood through a thoracostomy tube connected to suction.

Anesthetic management of patients with pulmonary injury involves optimizing gas exchange, and mitigating additional lung injury. When patients with pulmonary injury undergo general anesthesia for operative procedures, nitrous oxide should be avoided to prevent the expansion of diagnosed and undiagnosed pneumothoraces. Chest tubes should be connected to suction in patients who have unresolved hemo- or pneumothoraces during intraoperative mechanical ventilation. If there is significant parenchymal lung injury, lung-protective ventilation strategies (tidal volumes of 6 mL/kg) should be considered to avoid further barotrauma. With severe rib fractures and sternal trauma, careful positioning is important, and additional support or stabilization of the thorax may be necessary, especially in prone cases. If ventilation proves challenging, arterial line placement prior to surgery is prudent to guide oxygenation and ventilation strategies. In these cases, having a size-appropriate fiberoptic bronchoscope readily available is helpful for ruling out challenges due to mucous plugging, inadvertent mainstem intubation, and tracheal tube kinking, from those due to worsening lung pathology.

Blunt cardiac trauma occurs in less than 3% of pediatric trauma patients, over 95% of which are cardiac contusions [95]. Cardiac injury is more likely in patients with anterior rib or sternal fractures, which can be accompanied by unexplained hypotension. Evaluation of patients with a high index of suspicion for having cardiac injury includes performing a 12-lead electrocardiogram (ECG) to look for arrhythmias. Cardiac enzymes can be useful to help monitor the resolution of injury. If hypotension is persistent, an echocardiogram is indicated to evaluate for functional deficits and to rule out cardiac

tamponade. Aside from pericardiocentesis for tamponade, the majority of blunt cardiac trauma is managed by supportive therapy that may include monitoring with telemetry and the use of ionotropes and vasopressors. Great vessel injury, including aortic injury, is very rare in pediatric trauma, and is diagnosed with thoracic CT with contrast.

Orthopedic trauma

Evaluation of orthopedic trauma is performed as a part of the secondary survey, and radiographical tests of the affected area are often added to the initial trauma x-ray scan. Although orthopedic injuries are less commonly life threatening, they frequently incur lifelong morbidity, and should be addressed as early as possible. Orthopedic emergencies include compartment syndrome resulting from bleeding and swelling from a crush injury, associated vascular injuries resulting in ischemic limbs, and unstable pelvic fractures resulting in uncontrolled hemorrhage. Compartment syndrome generally involves high-energy impact, which results in increased interstitial tissue pressure leading to vascular compromise. Abnormally high opioid requirements and pain disproportionate to injury should create a high index of suspicion for compartment syndrome [96]. Pelvic fractures are also a result of high-energy traumas. While the majority of pelvic fractures are stable, unstable pelvic injuries can be associated with damage to visceral structures resulting in hemorrhage and require immediate temporary stabilization while the patient is being resuscitated. Vascular injury presents as pulselessness, pallor, pain, paresthesias, and hypothermia of the affected extremity. Surgical restoration of perfusion is limb saving and should be a priority following the primary resuscitation [97].

Open fractures constitute approximately 10% of fractures in children with multiple injury, and the initial aim is to clean and cover the fracture to prevent infection [98]. Children have actively lengthening bone, and bone growth occurs by the physis near the articular surface. Injury to this area can compromise bone growth and lead to abnormal growth of the limb, with subsequent consequences to function and long-term quality of life of the patient. Hence, closed fractures should optimally be surgically corrected between 48 and 72 h after injury [99]. Intraoperative anesthetic management of patients with orthopedic trauma involves careful positioning of the affected limb, and it is important that communication and collaboration occur between the anesthesiologist and orthopedic surgeon on a plan for best positioning. Femur and pelvic fractures can result in significant blood loss, and a type-and-screen should be attained, with cross-matched blood made readily available. In older children, as with adults, bone fractures increase the risk of both fat and pulmonary emboli, and a high index of suspicion should be maintained in patients presenting with persistent tachycardia, hypoxia, and an unexplained dramatic end-tidal CO_2 to $PaCO_2$ gradient.

Facial trauma

Facial fractures account for between 1% and 14% of fractures in patients younger than 16 years of age. High-energy fractures most commonly involve the midface and mandibular regions. Frontal fractures are the most common in children due to the increased prominence of their foreheads, and time-sensitive surgeries are required in cases of traumatic optic neuropathy and retrobulbar hemorrhage [100]. Mandibular fractures are more common in children than adults and can result in challenging mask ventilation and airway management. The anesthesiologist should be prepared to deal with a difficult airway with the possibility of added challenges due to increased bloody oral secretions. If necessary, spontaneous ventilation should be maintained throughout the intubating process to avoid loss of the airway.

KEY POINTS: ANESTHETIC CONSIDERATIONS FOR SPECIFIC INJURIES

- Infants with open frontanelles and mobile cranial sutures can have intracranial bleed or swelling with delayed presentation of symptoms
- Initial hyperventilation is not recommended in pediatric TBI, and should be reserved for severe, refractory cases; neuromonitoring should be performed if hyperventilation is performed
- Abdominal trauma is most frequently managed non-operatively
- Younger children are at higher risk for spinal cord injury without radiological abnormalities, often not noticeable on CT radiography
- Compartment syndrome should be suspected in children with abnormally high narcotic requirements and pain disproportionate to injury

Child abuse and trauma

Inflicted injury, or traumatic injury resulting from child abuse, comprises approximately 8% of pediatric trauma. In 2012, in the United States alone, 2.2/100,000 children died from child abuse, 44% of whom suffered from physical injury. The 2012 rates of victimization per 1000 children were 14.2 for African-Americans, 12.4 for American Indian/Alaska Natives, 10.3 for multiracial, 8.7 for Pacific Islanders, 8.4 for Hispanics, 8.0 for non-Hispanic whites, and 1.7 for Asians [101]. A review of information from the National Trauma Data Bank found an increased prevalence of non-accidental trauma among males (58.3%). Non-accidental trauma is inversely related to age, and the majority of victims are under the age of 3 years. Children of poorer socioeconomic status are at greater risk, and 64.4% of these patients in this US data base were supported by Medicaid [102]. Non-accidental trauma patients demonstrated overall higher injury severity scores and mortality rates (8.9% versus 1.4%) [103]. Particularly concerning is the fact that up to a third of inflicted trauma cases are not recognized as being a result of abuse, with the miss rate higher at hospitals that do not have ACS verified pediatric trauma centers.

Indicators of inflicted trauma often found on patient history include prolonged interval between time of injury and presentation for medical care, history of multiple emergency room visits, and inconsistent history among parents and guardians. Physical exam indicators that raise suspicion for inflicted

Table 39.5 Association of inflicted trauma with physical exam findings

Highly associated inflicted trauma findings	Odds ratio	Confidence interval
Bruising in pre-mobile child		
Clustering of bruises	4.0	2.5–6.4
Petechiae	9.3	2.9–30.2
Chemical burns	24.6	4.94–13.5
Contact burns	5.2	1.6–22.9
Scald burns	17.4	6.4–7.2
Burns of hands	1.8	1.3–2.6
Burns of feet	6.3	4.6–8.6
Burns of buttocks	3.1	2.2–4.5
Burns of perineum	2.5	1.7–3.7
Subdural hematoma	8.2	6.1–11
Hypoxic ischemic injury	4.2	0.6–2.7
Retinal hemorrhage	14.7	6.4–33.6
Hollow viscous injury especially duodenal Injury <4 h	Unknown

Figure 39.9 CT head without contrast in 1-year-old victim of "shaken baby syndrome" showing diffuse axonal injury with diffuse effacement of the sulci and slit-like ventricles.

trauma include injury disproportionate to history, multiple injuries that appear to be at different stages of healing, and injury mechanisms that are inconsistent with the child's developmental stage [104]. There are a number of very specific findings that are highly associated with inflicted trauma (Table 39.5). Type and pattern of bruising is an important clue, and an increased risk of inflicted trauma is associated with bruising in the pre-mobile child, clustering of bruises, bruises on the cheeks, neck, back, and areas not covering bony prominences, and the presence of petechiae. A large proportion of pediatric burns are due to abuse, most commonly chemical burns, contact burns, scald burns, and burns specific to the hands, feet, buttocks, and perineum. Moreover, inflicted TBI is highly associated with subdural hematomas, hypoxic ischemic injury, and retinal hemorrhage. Hollow viscous injury, in particular duodenal injury in children under the age of 4 years, is indicative of inflicted trauma [105]. Common fractures highly specific for inflicted trauma include rib fractures, metaphyseal corner fractures, scapula fractures, sternal fractures, and spinous process fractures, as well as fractures in children who are not yet walking [106].

More specifically, inflicted TBI is a leading cause of child abuse deaths and accounts for approximately one-third of all child maltreatment deaths [107,108]. Inflicted TBI is associated with skull fractures, subdural hematomas, subarachnoid hematomas, and diffuse axonal injury. Compared with accidental TBI, the incidence of malignant cerebral edema, hypoxic ischemic injury, and retinal hemorrhage is higher in inflicted TBI. While older children who are beaten suffer from more focal lesions, neonates tend to present with diffuse axonal injury due to "shaken baby syndrome" (Fig. 39.9) [67]. A study comparing inflicted to accidental TBI found that victims of inflicted TBI are more likely to be transported from home (60% versus 33.5%, $p < 0.001$), experience apnea (34.3% versus 12.3%, $p = 0.002$), and suffer from seizures (28.6% versus 7.7%, $p < 0.001$). The demographics of inflicted versus accidental TBI is also different. Inflicted TBI victims tends to be younger than accidental TBI victims (1.7 ± 0.32 versus 92.3 ± 0.39 years, $p < 0.001$) and, contrary to accidental TBI victims, inflicted TBI occurs with greater prevalence among females compared with males (54.3% versus 34.8%, $p = 0.032$) [109]. In the United States, healthcare providers are legally required to report cases where child abuse is suspected, which in most hospitals is facilitated through their social work department. Approximately 50% of maltreated children who die are victims of previous episodes of maltreatment that were not reported [24].

KEY POINTS: CHILD ABUSE AND TRAUMA

- Inflicted trauma is most common in pre-verbal children under the age of 3 years
- "Shaken baby syndrome" often presents as diffuse axonal injury
- Approximately 50% of child abuse victims who die are victims of previous episodes of maltreatment that were not reported

Postoperative management and ICU transfer

Pediatric patients who require operative procedures have a higher mortality risk and increased need for pediatric intensive care. Tracheal extubation criteria are similar in the pediatric population to those in adults. Tracheal extubation should be considered only in patients who are hemodynamically stable, do not have significant acid–base derangements, do not have significant oxygenation or ventilation derangements, possess adequate respiratory muscle strength, and demonstrate intact airway reflexes [110]. It is important, however, to note that longer cases and younger age increase the likelihood of early tracheal extubation failure following cardiac surgery [111]. Recent studies have shown that neuromuscular weakness is the most common cause of tracheal extubation failure in critically ill children [112–114].

Postoperative transport to the pediatric ICU (PICU) or other hospital locations (e.g. CT or angiography suites) represents a very vulnerable period in the care of critically ill children, and special caution must be taken to avoid unintended life-threatening mishaps. In many hospitals, the PICU

and radiology suites are significant distances from the operating rooms, which only increases the potential for such events to occur. When feasible, intraoperative CT scanning may reduce the need for transport and transport-related complications. Spine precautions should be carefully adhered to during the transfer of the patient from one bed to another. Careful attention must be paid to avoid inadvertent loss of venous and arterial access. Constant surveillance of the patient's ABCDs should be performed, and monitoring of vital signs using a transport monitor should be continuous. Transport equipment should include an appropriately sized mask, equipment for reintubation, resuscitative medications and muscle relaxants, and an ambu bag with a positive end expiratory pressure valve, even in patients who are transferred on transport ventilators. En route end-tidal CO_2 monitoring should be standard of care. For neurotrauma patients with external ventricular drains, special attention should be paid to ensure that the drain is appropriately leveled if it is kept unclamped during transport. Both clamped and unclamped external ventricular drains should be transduced during transport, so that the ICP can be monitored frequently or continuously. There should be a readily accessible line connected to IV fluids in the event that further fluid resuscitation or medications need to be administered during transport. If the patient is dependent on large doses of vasopressors to maintain hemodynamic stability, it is recommended that a dedicated carrier line is in place to infuse cardiovascular supportive medications, as small interruptions or boluses of these medications can prove catastrophic. Warming is of utmost important as hypothermia is a common problem during ICU transport, and patients should be wrapped in warmed blankets with special attention paid to their heads. It may also help to wrap them in plastic to decrease heat loss.

Hand-off report in the ICU should be performed in the presence of the primary anesthesiology and surgical teams, the responsible PICU physicians, nurses, and respiratory care team to facilitate accuracy of information and promote continuity of care. Hand-off should include the patient's history, summary of trauma burden, and a detailed summary of intraoperative events. If the patient shows signs and symptoms of pulmonary injury, often caused by trauma-related lung injury, transfusion-related lung injury, aspiration, and infection, lung protective ventilator strategies should be employed. Lung protective ventilation involves avoiding baro- and volutrauma by maintaining tidal volumes at 6 mL/kg and using increased positive end expiratory pressure to optimize oxygenation; permissive hypercapneia may be necessary. If pulmonary injury is severe such that these strategies are not effective, extracorporeal membrane oxygenation may be necessary. Once in the PICU, monitoring for ongoing or undiscovered sources of bleeding should be continuously performed. Observation for the presence of additional fractures should also be conducted as distracting fractures or decreased communicability of children can lead to initially undiagnosed fractures. The development and implementation of PICU guidelines for trauma patients is likely to prove important for the adherence to evidence-based guidelines of care and improving outcomes. Implementation of an institutional standard pathway for PICU management of pediatric patients with TBI increases adherence to evidence-based guidelines, which has been associated with improved discharge outcomes [115].

KEY POINTS: POSTOPERATIVE MANAGEMENT AND ICU TRANSFER

- Continuous end-tidal CO_2 monitoring should be performed during the transport of mechanically ventilated patients
- Monitoring for signs and symptoms of undiscovered sources of bleeding is critical once a trauma patient is in the ICU
- Continued observation for the presence of additional, previously undetected fractures and injury is a priority in the ICU; a distracting injury or decreased communication ability of children can increase the likelihood of undiagnosed fractures and injury

Education and outcomes in pediatric trauma

Emphasis in pediatric trauma is increasingly focused on prevention, as data consistently demonstrate that a majority of fatal and non-fatal injuries in the pediatric population is preventable [116]. US government-funded programs include the National Institute of Child Health and Development Pediatric Trauma and Critical Illness Branch, which supports research and training focused on the prevention and treatment of childhood trauma, injury, and critical illness. Moreover, a section of the CDC is focused on child safety and injury prevention and contains nine funded organizations in the United States. The National Action Plan for Child Injury Prevention was created with the goals of raising awareness about child injury and highlighting prevention solutions, including the reduction of fire and burn injuries, drowning, fall-related injuries, motor vehicle-related injury, sports- and recreation-related injuries, suffocation injuries, and poisoning injuries. The center is also focused on mobilizing action on national and local levels towards the reduction of child injury [117]. While campaigns for increased awareness and safety measures regarding proper use of protective equipment such as helmets, proper seatbelt usage, and concussion awareness have been effective, resources for these campaigns are limited and are not equally distributed across all socioeconomic groups. The limitations in funding for injury prevention occur mostly in the lower income group, where disparities in pediatric trauma is very prevalent [118].

The continued development and improvement of a system-wide data collection system (i.e. registry) that aims to identify and monitor pediatric trauma care quality metrics is integral to improving quality of care and evaluating specific in-hospital care processes associated with changes in clinical outcomes [21,119]. Furthermore, TBI has been shown to have longstanding effects on behavioral, cognitive, and psychosocial outcomes of children [120,121]. Children who have experienced trauma are predisposed to suffering from post-traumatic stress disorders [122,123]. Concomitant research focusing on factors that affect post-trauma long-term outcomes, such as issues of mobility, behavior, cognition, and psychiatric well-being, is imperative to improving pediatric trauma care.

CASE STUDY

Our patient is a 1.5-year-old, previously healthy male who reportedly suffered from a ground level fall one day prior. Per reports, he was in his usual state of health until the following day when when he was found down and unresponsive. His caregiver called emergency medical services and started performing cardiopulmonary resuscitation. Upon arrival, paramedics found the patient to be posturing with a GCS score of 5, a blood pressure of 49/20, and a heart rate of 155. He was intubated in the field with a 4.0 mm cuffed tracheal tube, and a 22 gauge IV was placed into his right arm. He was placed on a backboard, and his cervical spine was stabilized with a cervical collar. During transport, he was given 120 mL of IV fluid and ephinephrine. Per his father, he had no pertinent past medical history, normal growth and development, and no known allergies.

Initial assessment in the emergency room revealed a blood pressure of 110/56, heart rate of 146, and oxygen saturation of 95% on 100% oxygen. He was estimated to be approximately 12–14 kg according to estimation using a Broselow tape. A neurological examination revealed a GCS score of 5. Physical examination revealed left flank hematoma but no other abnormalities. An additional 22 gauge IV was placed into his left arm and laboratory values including a complete blood count, emergency hemorrhagic panel, basic metabolic panel, and type-and-screen were undertaken. The on-call neurosurgery resident was called, and because of concern for intracranical hypertension, the patient was sent to the CT scanner for a head, abdomen, and pelvis scan.

A preliminary read of the CT scan reported a right occipital skull fracture and an epidural hematoma. CT also revealed fluid surrounding his left kidney and a previous non-displaced femur fracture. Imaging of his chest revealed bibasilar pleural effusions versus consolidations, possibly due to aspiration. There was no evidence of cervical, thoracic, or lumbar spine injury. Laboratory results were significant for a lactate of 3.9, increased aspartate aminotransferase and alanine aminotransferase, hematocrit of 31, and INR of 1.5. A 10 Fr Foley catheter was placed revealing non-bloody urine, and the patient was given a 65 mL bolus of mannitol before being sent to the PICU for further monitoring.

On arrival at the PICU, the patient's ICP was 18 mmHg, but over the course of the hour began to increase to the high 20s. A repeat CT scan revealed an interval increase of right subdural fluid collection measuring 11.8 cm, now associated with a 6 mm leftward midline shift with subfalcine herniation of the right frontal lobe and diffusedly effaced cortical sulci. The CT report noted concern for older blood present in addition to the acute bleed, raising concern for more than one head injury. The neurosurgery attending consulted the pediatric anesthesiology attending, and the patient was sent immediately to the OR for emergent craniotomy.

The patient arrived at the OR with a blood pressure of 79/53, heart rate of 138, and oxygen saturation of 78–95%. Of note, he had begun to have periods of rapid oxygen desaturation with decreased pulmonary compliance. In the OR, the anesthesiologists attached the patient to monitors, administered 20 mg of IV rocuronium, and connected the patient's endotracheal tube to the ventilator. His end-tidal CO_2 was 30 mmHg. He was given 20 μg of IV fentanyl and 0.5 mg of IV midazolam and 400 mg of IV cefazolin. A 20 gauge angiocath was placed into his left saphenous vein. IV fluids connected to a fluid warmer were connected to the saphenous IV line. A 22 gauge left radial arterial line was placed using ultrasound guidance. The blood bank was called, and 3 units of cross-matched packed red blood cells, 3 units of fresh frozen plasma, and 1 unit of platelets were brought to the OR. An arterial blood gas revealed a $PaCO_2$ of 45 mmHg, PaO_2 of 70 mmHg, and a hematocrit of 29%. The anesthesiologist increased the minute ventilation, and attempted gentle recruitment of the lungs, which sounded rhonchorous bilaterally. The patient was given a 100 mL bolus of plasmalyte through the fluid warmer and boluses of phenylephrine were administered to maintain mean arterial blood pressures above 70 mmHg. A third intravenous line – an 18 gauge angiocatheter – was placed in his right antecubital vein using ultrasound guidance.

Once the sterile drapes were secured, an under body and lower body air-warming blanket was turned on. The patient maintained his blood pressure with intermittent 1–2 μg/kg phenylephrine boluses during initial incision. An infusion of 1 unit of packed red blood cells and 1 unit of fresh frozen plasms was initiated. However, upon opening of the dura, his blood pressure fell precipitously to the 50s/30s. The anesthesiologist communicated with the surgeon who responded that they were noting brisk bleed. Pressure bags were used to administer fresh frozen plasma and packed red blood cells that were wide open. An epiphephrine drip was started at 0.05 μg/kg/min. The blood bank was asked to bring additional products as well as platelets to the OR. The neurosurgeon noted that the patient appeared to have a massive laceration of his transverse sinus and pulsating arterial subdural bleed. Massive transfusion of packed red blood cells, fresh frozen plasma, and platelets continued to be administered at a 1:1:1 ratio as well as boluses of epinephrine and calcium. The patient received a total of 1 L of packed red blood cells, 1 L of fresh frozen plasma, and 300 mL of platelets. Tranexamic acid was not considered because of the prolonged time since initial injury. In spite of several attempts to achieve hemostasis, the intracranial bleed could not be controlled. The decision was made to close the skull, after which the patient's blood pressure increased to 126/85 and his heartrate decreased to the 60s, consistent with Cushing's reflex. An intraoperative head CT revealed continued increasing subdural hematoma. An ICP monitor was placed revealing intracranial pressures in the 50s.

The patient was brought up the PICU using a transport ventilator, and transport monitoring including monitoring of his heart rate, blood pressure by arterial line transducer, ECG, pulse oximeter, end-tidal CO_2, and ICP. Warmed blankets were wrapped around his entire body as well as his

head. ICU hand-off included the attending and resident anesthesiologists, neurosurgery team, PICU attending and resident, PICU nurse, and respiratory therapy. In the PICU, muscle relaxation was reversed so that a neuro exam could be performed. The patient had fixed, dilated, pupils, no corneal or gag reflexes, and no notable extremity response to noxious stimuli. Medical management of his ICP was continued using hyperosmolar therapy with 3% sodium chloride. A femoral central line was placed under ultrasound guidance, and an epinephrine drip was titrated to maintain goal MAPs above 90 mmHg. EEG monitoring revealed profound generalized slowing and voltage attenuation that worsened over the course of the course of the next 2 days. Because of his refractory intracranial hypertension, cooling to 35°C was initiated. Hourly neurological examinations revealed no improvement, and on postop day 3, transcranial Doppler was performed, revealing low velocities.

The social worker, who had been consulted on admission by the emergency department team for suspicion of child abuse, discovered that the child had been dropped, and in spite of subsequent daytime sleepiness, had not been brought immediately to the hospital until he became unresponsive 1 day after the injury. A review of the patient's x-rays concluded that the non-displaced femur fracture occurred prior to this injury and was highly suspicious for prior occurrence of child abuse. The patient's half-sibling was removed from the home and placed in foster care as the investigation continued. The patient was declared brain dead and medical management was discontinued on hospital day 3.

CHAPTER 40
Anesthesia for Burns

Gennadiy Fuzaylov
Department of Anesthesia, Critical Care, and Pain Management, Massachusetts General Hospital; and Harvard Medical School, Boston, MA, USA

Introduction

Burn injuries are an important cause of morbidity and mortality in the pediatric patient and have many important implications for anesthetic care. The pediatric age group comprises 30% of all burns in the United States [1] and generates medical costs exceeding 2 billion dollars per year [2]. The most common cause is fire or flame injuries in all children, except for children under 5 years, where scald injuries are the most common cause [1]. Other types of burn include electrical burns, which usually cause tissue destruction by direct thermal damage and associated injuries, and chemical burns, whose severity depends on the chemical, its concentration, and the duration of exposure [3].

The severity of burn injury is characterized by the depth and location of the burn, the total body surface area (TBSA) involved, and the presence or absence of inhalational injury. The definitions of a major burn injury are summarized in Box 40.1. It is important to note that severe burns in infants and neonates occur with a smaller TBSA due to the immaturity of their organ systems and the subsequent difficulty maintaining homeostasis [4].

Estimation of the TBSA affected is a crucial aspect of the care of the burned child, as inaccurate estimates can lead to inappropriate resuscitation [5,6]. Because a child's head size is disproportionately larger than the body in comparison with adults, the traditional rule of nines does not accurately approximate TBSA in children. A tool for approximation of TBSA in children of various ages is shown in Figure 40.1.

Pediatric burn patients present many anesthetic challenges, such as difficult airways and vascular access, fluid and electrolyte imbalances, altered drug pharmacokinetics and requirements, and impaired thermoregulation, among others. The anesthesiologist may participate in the care of these critically ill children during initial resuscitation, operative procedures, and in the intensive care unit. The relevant pathophysiological and pharmacological changes that result from burn injuries as well as guidelines for intraoperative management and pain control are discussed in this chapter.

Pathophysiology

The skin serves as a barrier to protect the host from infection as well as heat and fluid losses, and, predictably, the destruction of this barrier by burn injury leads to infection and altered heat and fluid regulation. These changes are especially marked in children, given their high surface area to mass ratios.

A major burn injury also leads to the release of local and systemic mediators of inflammation. Local mediators, which include prostaglandins, leukotrienes, bradykinin, nitric oxide, histamine, and oxygen free radicals produce both localized and systemic capillary leak with resultant edema [7]. Systemic mediators, which include interleukin (IL)-1, IL-6, IL-8, IL-10, and tumor necrosis factor α (TNF-α), cause a systemic inflammatory response almost immediately after a burn injury [8]. This milieu of proinflammatory cytokines leads to the release of stress hormones that eventually create a hypermetabolic state, which begins 3–5 days postinjury [9] and correlates in magnitude with burn size[10].

Ultimately, a severe burn injury causes a pattern of pathological changes in all organ systems, which can be divided into the acute phase, which resolves within 24–48 h, and the hypermetabolic or late phase, which persists for much longer. These changes are discussed below and summarized in Table 40.1.

Cardiovascular

During the acute phase of burn injury, patients have a transiently decreased cardiac output due to hypovolemia and decreased venous return, depressed myocardial function, increased blood viscosity, and increased systemic vascular resistance from the release of vasoactive substances [8]. Patients with severe burns develop shock primarily due to

Gregory's Pediatric Anesthesia, Sixth Edition. Edited by Dean B. Andropoulos and George A. Gregory.

hypovolemia from the loss of intravascular volume and extravascular edema [10,11] as well as direct myocardial depression from the inflammatory response; they may also develop overt ventricular failure [12].

During the hypermetabolic phase, cardiac output increases dramatically and systemic vascular resistance decreases, and patients may develop persistent tachycardia and systemic

Box 40.1: Definitions of major burn injury

- Greater than 10% TBSA of third-degree burns
- Greater than 20–25% TBSA of second-degree burns
- Greater than 15–20% TBSA of second-degree burns in infants and neonates
- Burn injuries involving the face, hands, feet, or perineum
- Inhalational burn injuries
- Chemical or electrical burns
- Burns with associated trauma
- Circumferential burns, particularly chest
- Burns in children with significant co-morbid disease

hypertension [13]. There is some global evidence that prolonged stress responses can eventually lead to cardiomyopathy [8], although this has not been clearly demonstrated in burned children. However, there are data to suggest that children hospitalized for a burn may have an increased rate of cardiovascular disease for years after recovery and discharge, including an increased incidence of ischemic heart disease [14]. Medications such as propranolol have been studied and shown to reduce cardiac index and cardiac work in burned children during and after this hypermetabolic phase [8,13,15], which may allow for better preservation of muscle mass and strength [8]. Studies have not yet addressed whether such intervention reduces the long-term risk of cardiac events in these children.

Pulmonary

Recognizing inhalation injury in burned children is extremely important as it predicts increased resuscitation requirements as well as increased morbidity and mortality [16–18]. Pulmonary physiology is affected directly by this inhalational injury and indirectly by systemic effects of the burn, as well as independently by carbon monoxide poisoning and cyanide toxicity [19].

Direct Inhalation Injury

Pulmonary dysfunction from inhalation injury results from a variety of factors, including direct mucosal edema and sloughing, impaired mucociliary clearance, formation of endobronchial casts, inactivation of surfactant, and interstitial edema [20–22]. In general, only the upper airways (carina and above) are affected by direct thermal injury because the respiratory tract is an efficient heat exchanger; the exception to this is steam inhalation, which can cause damage more distally [23,24].

Inhalation injury should be suspected in patients with facial burns, singed nasal hairs, soot in the airway, stridor, hoarseness, dyspnea, or wheezing [25,26]. Clinically, these patients may develop stridor, laryngospasm or bronchospasm, pneumonia, tracheobronchitis, ventilation-perfusion mismatch, and increased pulmonary compliance. The diagnosis of inhalation injury is best confirmed by bronchoscopy (Fig. 40.2), with findings of mucosal erythema, edema, ulceration, and necrosis with or without carbon particles seen in the airway [27–29]. Chest radiography is often normal immediately following injury and is therefore less useful [25,26,30], but a computed tomography (CT) scan may show ground glass opacities, atelectasis, and consolidation suggestive of inhalation injury [31,32].

If inhalation injury is suspected or there are large burns to the face and neck, the most important element of treatment is early intubation, as massive edema of the tongue, uvula, epiglottis, and subglottic regions may make intubation more difficult or

Figure 40.2 Bronchoscopy image showing a burned bronchus from inhalational injury.

even impossible if delayed (Fig. 40.3) [26]. The use of a cuffed endotracheal tube is preferred as the higher pressures required to ventilate the less compliant lungs of a burn patient may lead to circuit leaks. The subsequent need to exchange the endotracheal tube in an edematous and critically ill patient can prove quite dangerous, and is ideally avoided [33].

The initial 2–5 days after inhalation injury may allow for normal ventilation prior to the development of endobronchial slough and shunting. The literature generally suggests that ventilation of the child with inhalation injury should be approached with a lung-protective strategy that aims to minimize barotrauma with low tidal volumes and peak pressures [34,35], and potentially some degree of permissive hypercapnia [36]. However, it is worth noting that these recommendations are extrapolated from acute respiratory distress syndrome (ARDS) studies in adults, and the benefits of low tidal volume strategies have not truly been demonstrated in children [34]. There may even be some data to suggest that higher tidal volume ventilation may reduce the incidence of ARDS and total ventilator days in pediatric burn patients [37]. One alternative ventilation strategy is high-frequency percussive ventilation (HFPV), which delivers high frequency (450–600/min), subtidal bursts of gas over a conventional respiratory cycle, allowing for stepwise inflation of the lung [38]. HFPV is thought to facilitate evacuation of airway debris in patients with inhalation injury [37]. HFPV has been shown to decrease peak inspiratory pressures and work of breathing while improving oxygenation in children with inhalation injury [37–39], but has not been shown to improve major outcomes

such as pneumonia, time to extubation, or mortality [38]. In addition to intubation and mechanical ventilation when needed, supportive care for the patient with inhalation injury includes aggressive pulmonary toilet, including chest physical therapy, forced coughing, therapeutic bronchoscopy when appropriate, and, if possible, early ambulation [35,40].

Pharmacological therapy for pediatric patients with inhalation injury may include aerosolized albuterol, epinephrine, nitric oxide, and a heparin–N-acetylcysteine combination. Corticosteroids do not appear to improve pulmonary function in patients with inhalation injury [41]. As patients develop bronchitis and reactive airways, nebulized albuterol is an intuitive treatment. In an animal model, it has been shown to be effective in improving compliance and decreasing peak pressures, decreasing shunt fraction, and improving the arterial–alveolar oxygen gradient [42]. While there are no prospective human data in this context, it is a reasonable intervention. Aerosolized racemic epinephrine falls into a similar category; it can help by reducing mucosal edema via a localized vasoconstrictive effect, in addition to its bronchodilatory benefits [35], though data are largely based on animal studies [43,44]. Nitric oxide has also been shown to decrease ventilation/perfusion mismatch and improve oxygenation in children with inhalation injury [45]. However, survival benefit has not been demonstrated with nitric oxide, possibly due to the key limitation of small sample sizes. A combination of nebulized N-acetylcysteine with heparin, attempting to prevent airway cast formation by antagonizing fibrin production, has been shown to reduce reintubation rates and mortality in children with inhalation injury [46]. A recent meta-analysis also found that such inhaled anticoagulant regimens improved survival and decreased morbidity without causing systemic anticoagulation [47].

Overall, evidence supporting the use of these pharmacological adjuncts generally comes from small studies or animal data, and they are therefore difficult to recommend empirically. However, they do appear to have some effectiveness with little harm, and at the very least provide useful rescue strategies for more complex children with inhalation injury. Box 40.2 shows a sample protocol used at the Shriner's Hospital in Galveston, Texas to treat inhalational injury.

Carbon monoxide poisoning

Carbon monoxide (CO) poisoning should be suspected in any child with inhalational injury or burns from open fires. Carbon monoxide impairs tissue oxygenation by displacing oxygen from hemoglobin, shifting the oxygen dissociation curve to the left and decreasing oxygen delivery, and binding to cytochromes to disrupt cellular metabolism [48,49]. Carbon monoxide poisoning is suspected clinically and confirmed by elevated carboxyhemoglobin levels on co-oximetry. The oxygen saturation will be inaccurate and typically reads 100% due to the conventional pulse oximeter interpreting carboxyhemoglobin as

Box 40.2: Inhalation injury treatment protocol

- Titrate humidified oxygen to maintain saturation >90%
- Cough and deep breath exercises every 2 h
- Turn patient side to side every 2 h
- Chest physical therapy every 4 h
- Aerosolize 3 mL of 20% N-acetylcysteine every 4 h with a bronchodilator
- Alternate aerosolizing 5000 units of heparin with 3 mL normal saline every 4 h
- Nasotracheal suctioning as needed
- Early ambulation on postoperative day 5
- Sputum cultures for intubated patients every Monday, Wednesday, and Friday
- Pulmonary function studies prior to discharge and at outpatient visits
- Patient/family education regarding inhalation injury

The protocol is continued for 7 days.

oxyhemoglobin [49–51]. However, new pulse oximeters are available that can detect carboxyhemoglobin, and these may be useful for diagnosis and monitoring treatment [52–54]. Presenting symptoms depend on the carboxyhemoglobin level: from nausea and headaches with mild CO poisoning (<20% carboxyhemoglobin) to seizures, coma, and cardiac arrest with severe poisoning (60–70% carboxyhemoglobin) [49].

The most important treatment for CO poisoning beyond supportive care is 100% oxygen, which should be initiated immediately if there is any suspicion of CO poisoning. This reduces the half-life of carboxyhemoglobin from 240–320 min at room air to 40–80 min when breathing 100% oxygen [49]. Treatment with hyperbaric oxygen is controversial and not well studied in burn patients, but hyperbaric treatment is known to further reduce the half-life of CO and may have some immunomodulatory benefits [55]. As such, after thorough consideration of the patient's other injuries and treatment needs, hyperbaric oxygen can be considered in hemodynamically stable patients with severe CO poisoning symptoms such as loss of consciousness, neurological symptoms, or ongoing acidosis.

Cyanide toxicity

Cyanide toxicity should be also be suspected in any child with inhalational injury, as cyanide can be released from the burning of plastics and glues in a fire [23,56,57]. Cyanide impairs tissue oxygenation by disrupting cellular metabolism [58–60], and will frequently present as an elevated venous oxygen level and refractory lactic acidosis. Definitive diagnosis is with a serum cyanide level, but this will likely not be determined quickly and if there is clinical suspicion, treatment decisions should not await the result. However, empirical treatment for possible cyanide exposure for burn patients without evidence of toxicity is not generally recommended in children [59].

Cyanide toxicity can be treated with sodium thiosulfate, the vitamin B12 precursor hydroxocobalamin, or nitrites such as amyl or sodium nitrite. Thiosulfate serves as a sulfate donor, which augments the intrinsic detoxification of cyanide to thiocyanate [58,59], while hydroxocobalamin binds intracellular cyanide to form the non-toxic cyanocobalamin (vitamin B12) [59,61]. Nitrites work by increasing the concentration of methemoglobin available for binding cyanide [58,61–63], but this may be dangerous in inhalation injury patients given coexisting carboxyhemoglobinemia. Moreover, young children are especially sensitive to methemoglobinemia as fetal hemoglobin converts more readily to methemoglobin and they have lower levels of methemoglobin reductase activity compared with adults [58]. As such, treatment with hydroxocobalamin may be preferred in children with smoke exposure given the absence of increased methemoglobin production and the rapid onset of action [59].

Renal

During the acute phase of burn injury, the glomerular filtration rate is decreased due to hypovolemia, decreased cardiac output, and the compensatory increased vascular tone from circulating catecholamines, vasopressin, and upregulation of the renin–angiotensin–aldosterone system [64]. As the hypermetabolic phase develops and cardiac output increases, the glomerular filtration rate also increases, but tubular dysfunction may occur in some patients and the degree of renal injury is variable from patient to patient. It is also important to note that patients with electrical or crush injuries are at increased risk of renal failure due to rhabdomyolysis and myoglobinuria [65].

Endocrine and metabolic

The hypermetabolic state that arises 24–48 h after a burn injury is the result of several mediators, including catecholamines, vasopressin, renin, angiotensin, aldosterone, glucagon, and cortisol. The magnitude of the hypermetabolic response is proportional to burn size [10,66] and is characterized by increased energy expenditure, core body temperature, muscle catabolism, lipolysis, glycolysis, futile substrate cycling, and insulin resistance [67–69]. While it was initially thought that this hypermetabolic state resolved with wound closure, there is evidence that it persists beyond this period and gradually returns to baseline during the subsequent 9–12 months postinjury [70].

One of the most important consequences of the hypermetabolic state is hyperglycemia resulting from the corticosteroid surge, reduced glucose extraction from the blood by muscle tissue, and insulin resistance [71]. Hyperglycemia in pediatric burn patients is associated with an increased rate of infections, greater catabolism, skin graft loss, and mortality [71]. Intensive insulin therapy has been shown to improve lean body mass and reduce rates of infection and multiple organ failure in burned children, but vigilance is needed to prevent hypoglycemic episodes [72,73]. Because hypoglycemia carries its own risks of morbidity and mortality [74], a blood sugar in the range of 130–150 mg/d has been suggested as a range that balances the risks of hyper- and hypoglycemia [72].

One alternative to intensive insulin therapy that is beginning to be studied is exenatide, an incretin-based drug. Because exenatide requires a hyperglycemic state in order to be effective, the risk of hypoglycemia is low, and there may be other benefits such as some protection against ischemia–reperfusion injury [75]. Studies thus far have only shown a reduction in total insulin administered when exenatide and insulin were combined, but data are not yet sufficient to determine if any outcomes are improved [75].

Other endocrine derangements include decreased levels of thyroid hormones (T3 and T4) and vitamin D [76–78], secondary to acquired hypoparathyroidism [79]. The resultant hypocalcemia and hypomagnesemia can lead to adverse cardiovascular effects and should therefore be aggressively treated in these children.

Attenuating the global hypermetabolic response is an ongoing topic of research; potential benefits of doing so include reduced cardiac work and stress, greater preservation of lean body mass and bone density, improved insulin sensitivity, and better overall growth [8]. Non-pharmacological approaches to inhibiting the hypermetabolic response include early excision and wound closure, aggressive treatment of sepsis, high protein and carbohydrate enteral feeds, environmental temperature elevation, and a resistive exercise program [9]. The best-studied pharmacological agents that may reduce hypermetabolism include insulin [80], the anabolic steroid oxandrolone [81–84], and propranolol [8,13,15,85].

Hepatic

During the acute phase of burn injury, hepatic injury and cell apoptosis result from hypoperfusion, ischemia–reperfusion

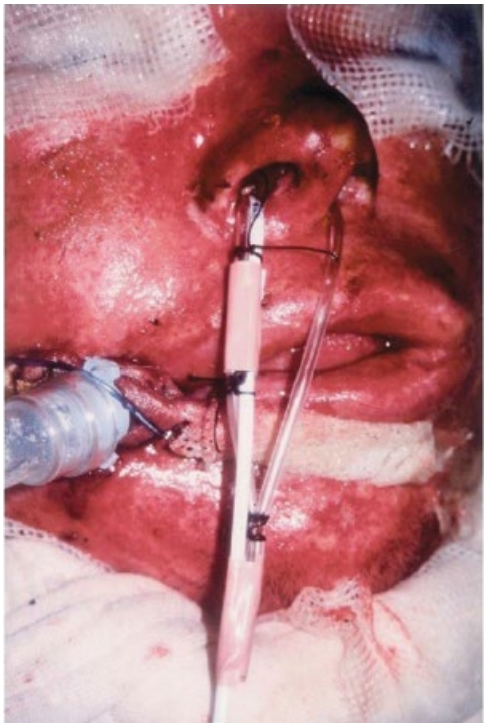

Figure 40.4 Nasojejunal tube secured with a nasal sling in a patient with facial burns. *Source*: Reproduced from Sefton et al [137] with permission of Elsevier.

injury, and circulating inflammatory cytokines [86]. Clinically, the liver enlarges and protein synthesis is impaired. This injury is reflected in elevated transaminases and bilirubin, which are typically elevated immediately postburn and return to normal over the subsequent 2–6 weeks [86]. Other pathophysiological changes include hepatic enlargement due to intrahepatic fat and edema, a decrease in the hepatic proteins albumin and transferrin, and an increase in acute phase reactants, haptoglobin, C-reactive protein, and complement. These latter changes can persist for up to 6–12 months postinjury.

Gastrointestinal

Hypoperfusion, ischemia–reperfusion injury, and circulating inflammatory mediators also damage the gut, weakening its mucosal barrier and allowing for entry of bacteria and endotoxins [87]. Additionally, patients are at high risk for ileus due to the edema from resuscitation, and for additional constipation due to opioids and sedatives [88]. However, this is not a contraindication to enteral feeding in the acute period (Fig. 40.4). On the contrary, in addition to reducing the risk of malnutrition, early enteral nutrition has been shown to reduce mucosal damage and ileus development, and to decrease endotoxinemia and TNF-α levels, thereby reducing the inflammatory and hypermetabolic responses [88]. Early enteral nutrition has also been shown to significantly reduce hospital length of stay and mortality [89]. While definitions of "early" for nutrition vary in the literature, within 6–12 h of injury is considered very early and ideal [88]. Inadequate feeding can lead to delayed wound healing and other causes of morbidity, including immunosuppression, sepsis, and loss of lean body mass [90].

Burn patients are at risk for developing gastric and duodenal stress ulcers, which may lead to gastrointestinal bleeding. Prophylactic treatment with H_2-antagonists or proton pump inhibitors may be beneficial, in addition to early feeding [88,91]. Patients can also develop acute enterocolitis, acalculous cholecystitis, or adynamic ileus requiring gastric decompression [92].

Abdominal compartment syndrome (ACS) is also an important consideration in burned children, and is routinely fatal if untreated [93]. ACS consists of elevated intra-abdominal pressures, typically a bladder pressure above 25 mmHg, with associated organ dysfunction, including reduced pulmonary compliance, oliguria, or hemodynamic instability [93,94]. The increased pressures result from decreased abdominal compliance, ascites, and bowel edema from capillary leak and ischemia–reperfusion injury. Large fluid resuscitation volumes are associated with ACS, likely by contributing to ascites and bowel edema [95,96]; in particular, resuscitation greater than 237 mL/kg over 12 h was identified as a threshold value for development of ACS [96], although this is certainly not absolute. Treatment for ACS is usually open decompression of the abdomen, which markedly reduces mortality associated with ACS [93].

Hematological

Acutely, systemic edema and intravascular volume depletion lead to hemoconcentration, which increases the hematocrit and blood viscosity. However, after initial resuscitation, anemia develops as a result of blood loss at wound sites, dilution from resuscitation, and hemolysis from heat-damaged erythrocytes [97]. In the absence of other illness, patients can likely tolerate a relatively low hematocrit in the 20–25% range, but it may be desirable to target a higher level in severely burned children to mitigate further drops from ongoing blood loss.

Thrombocytopenia can also occur due to platelet aggregation at wound sites, as well as sepsis, dilution, and medication effects[98]. Greater thrombocytopenia is associated with increased mortality in burn children [98]. A compensatory increase in clotting factor production may then occur, leading to a hypercoagulable state and possibly even disseminated intravascular coagulation [97,98].

Neurological

A number of different neurological sequelae can develop in the burned child. Elevated intracranial pressure can occur due to cerebral edema [99]. Seizures may occur, most commonly due to fever or hyponatremia [100], but other risk factors include a history of epilepsy, hypoxia, and sepsis [100,101]. Hypertensive encephalopathy can also develop, and is one of the rarer causes of seizures [102]. Electrical burn patients may additionally manifest direct spinal cord damage [103,104] or brain injury [105], depending on the entry and exit sites of the electric current.

Additionally, severely burned children can develop burn encephalopathy, a syndrome that includes personality change, delirium, hallucinations, seizures, and coma. Its incidence may be as high as one in seven severely burned children [105,106]. The most common causes of encephalopathy are hypoxia, followed by sepsis, hyponatremia, hypovolemia, and cortical vein thrombosis [106]. Although our understanding of neurological outcomes is far from complete, the majority of children who manifested burn encephalopathy made good neurological recoveries [106,107]. However, if there is a hypoxic insult associated with the burn injury, more recent data suggest that there may be up to a 33% chance of long-term cognitive deficits and emotional difficulties after recovery [107].

Immunological

Burn patients are especially vulnerable to infections for multiple reasons, including the loss of the skin barrier, the presence of multiple invasive lines for prolonged periods, hyperglycemia [108], prolonged ventilation [91], dysfunction of immune cells [92], and critical illness. Indeed, infections are the leading cause of morbidity and mortality in burn patients [109,110], and it is thought that 75% of all deaths following burn injuries are related to infection [111]. Important pathogens include gram-positive and -negative bacteria and fungi [109]. Multidrug-resistant bacteria such as *Pseudomonas aeruginosa* and *Acinetobacter baumannii* are particularly important agents in burned children, and may require special consideration in selection of antibiotics [91,109,112]. In addition, *Clostridium difficile* infection should be considered in patients with excessive diarrhea, and is associated with increased mortality in pediatric burn patients [113]. However, the use of prophylactic antibiotics is not currently recommended for pediatric burn patients [111,114]. Evidence also suggests that perioperative antibiotics do not seem to reduce the incidence of graft or donor site infection, though they remain common practice [92,111].

KEY POINTS: PATHOPHYSIOLOGY OF BURN INJURY

- Burns result in inflammation that affects every organ system, beginning with an acute 24–48 h phase that develops into a much longer lasting hypermetabolic phase
- Burn patients may initially present in severe hypovolemic and distributive shock, requiring aggressive resuscitation and/or vasopressor support
- With inhalation injury, edema may make it difficult to secure the airway; carbon monoxide poisoning or cyanide toxicity may also occur
- Early enteral feeding decreases morbidity and mortality, and should be practiced whenever possible
- Burn patients are at risk for infections from loss of the skin barrier and dysfunction of the immune system. Infection is the leading cause of mortality in burn patients

Fluid resuscitation in the acutely burned patient

Acute burn injury is accompanied by a tremendous inflammatory response that can cause significant fluid shifts [96]. Beyond this, children have even more significant evaporative and insensible loss of fluid than adults, due to their higher body surface area to mass ratios [115]. Profound hypovolemic and distributive shock can result, making appropriate resuscitation of the burned child crucial to acute management. However, there are a number of different formulae and approaches to resuscitation, with significant controversy as to which formula best approximates fluid needs and which fluid should be used, from the type of crystalloid to whether albumin or plasma should be included.

The Parkland formula remains the most widely used tool to approach the initial resuscitation of burned children [94,96,116–118], preferred by 69% of respondents surveyed at the American Burn Association meeting in 2009 [119]. The Parkland formula estimates resuscitation requirements at 4 mL/kg/%TBSA burned per 24 h; half of this is given in the first 8 h, and the remaining half in the subsequent 16 h. The fluid used is typically lactated Ringer's and, in children, is often added to the hourly maintenance requirement to account for the additional fluid losses observed in smaller patients. The modified Brooke formula is also sometimes used, albeit less frequently [119]; this predicts 2 mL/kg/%TBSA fluid volumes for resuscitation [120] given over a similar timeframe as the Parkland formula volume. Other approaches are also being developed and tried, such as nurse-driven protocols or computer-based algorithms that aim to adjust resuscitation rates based on urine output and/or hemodynamic parameters [96], but these are not in widespread use.

The choice of fluid used for resuscitation is an important one. In earlier work, colloid (particularly plasma) was considered an essential part of resuscitation using the Parkland formula. However, colloid was omitted from some recent iterations of the Parkland formula, perhaps in light of studies suggesting that it provided no outcome benefit over crystalloid, and even one review (in critically ill patients, including a small number of burn patients) that suggested that it may increase mortality [96,118]. The relative underuse of colloid is one proposed reason for the recent observation that many patients were requiring resuscitation volumes far in excess of what the Parkland formula predicted, an observation termed "fluid creep" [96,117,121–124]. This observation has led to a renewed interest in colloids and an increase in the use of albumin in resuscitation [118].

The use of colloid in burn resuscitation remains an area of controversy, including whether its use confers any benefit at all, and if so, when it is appropriate to initiate colloid therapy. Animal studies have shown that the use of colloids does not reduce the formation of burn wound edema, but does reduce edema formation in the non-burned soft tissue and reduces resuscitation fluid requirements without an increase in fluid accumulation in the lung [118]. Human data have also shown that the use of colloid reduces the overall volume of fluid needed to resuscitate burn patients [96,123]. Several studies have hinted at other benefits, including reduced edema formation, reduced mortality, reduced risk of extremity compartment syndrome, and reduced risk of renal failure [96,118,123]. However, the quality of evidence in these studies is relatively low, as many are retrospective cohort studies. Separately, several studies have documented an association between increased resuscitation volumes and complications such as ACS, extremity compartment syndrome, prolonged ventilator times, pneumonia, and sepsis [17,96,116,125–127], suggesting that there may be some benefit to reducing the overall volume of resuscitation. Overall, it is likely that there is some benefit to resuscitation with albumin, either as a rescue in case of escalating crystalloid requirements, or as a routine part of resuscitation, but studies thus far have been underpowered to find any significant benefits. Further research on this important topic is needed.

The traditional endpoint of resuscitation has been urine output of 0.5–1 mL/kg/h, up to 1.5 mL/kg/h in younger children [117]. However, in addition to standard hemodynamic variables, such as arterial blood pressure and waveform variation and central venous pressure, additional endpoints are

being used, such as cardiac output calculated by transpulmonary thermodilution (TPTD) [128]. One retrospective study of 76 children found that the cohort that had their fluid resuscitation adjusted based on cardiac output determined by TPTD was able to be resuscitated as well as the conventionally monitored group, with less overall fluid administered [126]. The benefit of TPTD is that it requires only a central line and not a pulmonary artery catheter; as these cardiac output monitors become more widely available, they will likely figure more prominently in resuscitation algorithms.

Other adjuncts to resuscitation have also been studied, such as high-dose ascorbic acid (vitamin C). As an antioxidant, it is thought that its benefit may stem from reducing the initial vascular permeability in the setting of inflammation. Despite concerns of potential renal toxicity [129], some recent data have shown vitamin C to reduce fluid requirements without significant side-effects [130]. This is not a widespread practice, though, so larger scale data are needed before vitamin C can be recommended routinely, particularly in children.

KEY POINTS: FLUID RESUSCITATION

- Aggressive fluid resuscitation remains the cornerstone of initial burn management, but there is controversy as to the best approach
- The most commonly used tool for initial fluid resuscitation is the Parkland formula: 4 mL/kg/%TBSA burned per 24 h; half of this is given in the first 8 h, and the remaining half in the subsequent 16 h
- The use of colloid is controversial, but is again gaining popularity in light of data on fluid creep and the dangers of over-resuscitation
- While urine output is commonly used as an endpoint for resuscitation, other means such as cardiac output monitoring and echocardiography are increasingly being used

Anesthetic management for acute burn procedures

Management of the pediatric burn patient presents many challenges for the anesthesiologist. Burned children may be critically ill with multiorgan dysfunction, and many aspects of their management, such as fluid resuscitation and temperature regulation, warrant even greater consideration than in the average child. However, despite how ill some of these patients may be, wound excision should not be delayed, as early excision has been shown to decrease blood loss, improve mortality, and decrease length of hospital stay [131–133]. This section discusses general considerations for the anesthetic management of pediatric burn patients in the acute perioperative setting.

Preoperative assessment and management

The preoperative assessment of the burned patient begins with an evaluation of the type of burn as well as the extent and depth, and any associated injuries. Patients with major burns or or burns of greater than 30% TBSA generally require formal fluid resuscitation and will develop some of the physiological derangements discussed earlier, while those with minor burns or or burns of less than 10% TBSA typically do not. However, in the presence of significant underlying medical illness, even patients with minor burns may require more aggressive treatment and resuscitation. As such, it is important to have a global understanding of the patient's overall physiological state, which can be understood by assessing parameters such as the patient's current hemodynamics and/or pressor requirements, pulmonary compliance and ventilator settings, volume status, and urine output.

The physical exam should include a thorough airway evaluation in order to identify patients with distorted airway anatomy who might be difficult to ventilate or intubate. Even if the patient is already intubated, the airway should still be evaluated as reintubation may occasionally be required due to a leak around the endotracheal tube or an unintended extubation. It is also important to note the locations of existing intravenous access and invasive monitors, and to identify potential sites for additional lines if needed.

Review of the burn patient's laboratory studies for electrolytes, complete blood count, coagulation studies, and metabolic and acid–base status is crucial. The patient should also have an active blood type and screen. In patients with inhalation injury, a chest x-ray may also be helpful. If there is suspicion of carbon monoxide poisoning or other inhalation-associated pathology, co-oximetry results should be evaluated.

Fasting guidelines and nil per os (NPO) guidelines warrant special consideration in burn patients, given their high metabolic needs. In general, enteral nutrition should be continued for as long as possible preoperatively. There are some data to suggest that a fasting period of 2 h for nasogastric tube feeds is adequate [134], but the data are limited [135] and there is some evidence that burn patients can develop gastric stasis [136,137]. As such, transpyloric feeds are preferred, as continuing them throughout the perioperative period does not appear to increase aspiration risk [136]. As a general rule, nasogastric feeding tubes should be placed to suction preoperatively, and then left to drain to gravity intraoperatively. Enteral nutrition is strongly preferred over parenteral nutrition because the latter is associated with altered gut physiology and increased permeability, a greater risk of sepsis, and increased mortality [138,139].

Transport to the operating room should be carried out with precautions appropriate to critically ill patients, including (as needed) a transport monitor and ventilator or bag–mask, and easy access to resuscitation medications and airway equipment. The decision to premedicate a child will depend on their mental status and degree of anxiety, as well as their hemodynamic and respiratory status.

Monitoring

The general principles of perioperative monitoring are no different for pediatric burn patients than for other pediatric patients, including standard American Society of Anesthesiologists (ASA) monitors and further invasive monitors as indicated by the patient's status. However, the logistics and details are frequently more complicated in burn patients.

Large areas of burn injury may make standard monitor placement difficult, and may necessitate creative electrocardiogram (ECG) lead placement or use of alternatives such as esophageal ECG monitoring [140]. Pulse oximetry on a finger or toe may be less reliable with extensive burn injury, hypothermia, or high-dose vasopressor use; alternative sites include the ear, buccal mucosa, tongue, and esophagus [141–143]. Temperature monitoring is especially important, as burn patients can lose heat quickly. An arterial line may be of benefit if large fluid shifts or blood loss are expected, or if extremity injuries preclude use of a blood pressure cuff. Central venous pressure and urine output may be used along with blood pressure to assess the patient's volume status and resuscitation needs, but may be less useful if there is intra-abdominal hypertension or ACS [93].

Intravenous access

The large fluid shifts and potential blood loss that accompany excision and grafting surgeries necessitate good intravenous access for fluid resuscitation. However, obtaining intravenous access in burn patients can be difficult if there is insufficient surface area left for the placement of lines. Central venous catheters are commonly used, but the catheter length and resistance limit the speed of fluid replacement when compared to shorter, larger bore peripheral catheters. In cases where intravenous access cannot be obtained but access is urgently needed, temporary intraosseous lines can be placed fairly rapidly and are an acceptable back-up [144].

Pharmacokinetics of induction and maintenance drugs

Burn injury results in altered pharmacokinetics of many anesthetic drugs due to changes in the volume of distribution, protein binding, and metabolism [145]. The volume of distribution increases because of the large extracellular volume resulting from capillary leak and fluid resuscitation. Protein binding is also altered as there may be increased α_1-acid glycoprotein and decreased albumin concentrations [9]. Drug metabolism is initially reduced due to renal and hepatic hypoperfusion, but during the hypermetabolic phase drug clearance is often greater than baseline.

In general, most conventionally used induction and maintenance agents are safe to use in pediatric burn patients, including propofol, thiopental, ketamine, potent inhalational agents, nitrous oxide, and opioids. Induction can be inhalational or intravenous, and if the patient's airway and clinical status are favorable this can even be done prior to moving the child to the operating table in order to reduce painful movement. If patients are too hemodynamically unstable to tolerate a potent inhalational anesthetic, a nitrous/narcotic technique with or without ketamine supplementation is often better tolerated.

The pharmacology of neuromuscular blocking agents is markedly altered in burn patients. Burn injury causes a significant upregulation of extrajunctional nicotinic acetylcholine receptors, which leads to a greater efflux of potassium when the depolarizing muscle relaxant succinylcholine is administered. Additionally, these extrajunctional receptors are more immature and therefore stay open longer, which leads to even greater potassium efflux and the potential for lethal hyperkalemia [146,147]. This receptor upregulation generally occurs at the 48–72 h mark [147]; as such, succinylcholine is generally considered safe to use up to 24 h after burn injury, with the 24–48 h range being a slightly more gray area. In general, succinylcholine should also be avoided for 1–2 years after major burn injury, as the pharmacodynamics may not return to normal until the patient's wounds are healed and functional mobility is regained [147].

Non-depolarizing muscle relaxants do not carry the same risk as depolarizing muscle relaxants. However, the same upregulation of acetylcholine receptors also leads to slower onset times and larger total dose requirements for non-depolarizing agents [146]. Data from one study demonstrating the difference in rocuronium onset and recovery between burn patients and controls are shown in Table 40.2. When muscle relaxation is necessary, the patient's train of four should be monitored carefully and muscle relaxants titrated to effect.

Table 40.2 Rocuronium onset, twitch recovery, and quality of intubating conditions in burn patients and controls

	Controls	Burns	Controls	Burns
Dose of rocuronium (mg/kg)	0.9	0.9	1.2	1.2
Onset to 95% paralysis, mean ± SD (s)	68 ± 16	115 ± 58*	57 ± 11*	86 ±20
Recovery to TOF ≥0.8, mean ± SD (min)	132 ± 23	103 ± 25*	162 ± 28*	126 ± 14*
Excellent intubating conditions (%)	65	38*	79	67*

* $p < 0.05$ compared with controls with same dose.
TOF, train of four.

Airway management

Airway management in the pediatric burn patient can be extremely challenging (Fig. 40.5). Facial and airway edema can significantly distort normal airway anatomy, and limited neck mobility and mouth opening may compound this. As such, any child with face, neck, or upper chest burns should be approached as a potentially difficult airway. The airway should be assessed carefully and a clear management plan developed, including the availability of a surgeon capable of performing a surgical airway should it become necessary.

Perhaps the most important element of the plan to secure the difficult airway is deciding whether the patient should be awake, sedated, or under general anesthesia, and if the latter, whether the patient should be paralyzed or breathing spontaneously. While awake intubation may be favored in the presence of craniofacial abnormalities or facial burns that suggest difficult mask ventilation, doing so may only be practical in older, cooperative patients. Spontaneous ventilation can still be maintained in younger children; although they may not be awake and cooperative, deep sedation or general anesthesia can be induced using a combination of agents that do not significantly reduce respiratory drive, including ketamine, dexmedetomidine, and volatile agents. This provides an

Figure 40.5 A burn patient with an anticipated difficult airway. Note the neck contractures and hence inability to extend the neck, contractures and tightness of perioral tissue that limit mouth opening, and singed nares with minimal opening.

additional margin of safety in the burned child who may prove difficult to intubate or ventilate. If a paralytic is to be used, the time since burn injury must be considered when selecting a paralytic and dosage (discussed elsewhere in this chapter).

Endotracheal tubes can be placed orally or nasally, and in some patients there may be only one option. When possible, oral intubation is generally preferred given the potential for sinus infection with prolonged nasal intubation. Practice has generally moved away from uncuffed endotracheal tubes to low-pressure, high-volume cuffed endotracheal tubes, as leaks may develop around uncuffed tubes at the higher ventilatory pressures that may be required to ventilate the noncompliant lungs in the patient with inhalational injury [33].

Fluid management

Excision and grafting procedures in the operating room (Fig. 40.6) can cause significant blood loss, but the exact amount can be difficult to quantify. Estimates in the literature vary widely; an average across several estimates was 5.48% of total blood volume lost per 1% TBSA excised [148], although the same authors found their own estimate with the use of the aforementioned blood conservation techniques to be 0.84% of total blood volume lost per 1% TBSA excised. Blood loss in the head and face may be higher still [149]. Formulae are useful in general but limited in their ability to accurately estimate blood loss for a specific patient; as such, measurement of laboratory values remains crucial in the setting of ongoing bleeding. Intraoperative blood loss can be replaced with crystalloid, colloid, or blood products, as determined by the patient's lab values and estimated blood loss. There is some evidence to suggest that when transfusing blood products in the setting of pediatric burn excision, a ratio of 1:1 PRBC:FFP results in less immediate postoperative coagulopathy and acidosis when compared to a 4:1 ratio, as well as an overall reduction in amount of blood product transfused [149].

A number of techniques can be employed to reduce the amount of intraoperative blood loss, including the use of electrocautery, topical or infiltrated epinephrine, compressive dressings, and extremity tourniquets [131,132]. Earlier excision also significantly reduces blood loss, as the wound becomes progressively more hyperemic with time [131,132]. Staged high-dose epinephrine clysis, or subcutaneous injection, with an average dose of 24.6 μg/kg of epinephrine has been shown to be safe and effective in reducing blood loss in children [150], and a meta-analysis recently showed reduced blood transfusion with the use of clysis [151]. As with any use of tumescent solution, the patient's volume status should be carefully monitored, as excessive fluid uptake and associated complications have been reported [152,153].

Temperature regulation

The loss of an intact skin layer significantly increases the burn patient's intraoperative heat loss, and children are especially

vulnerable given their larger surface area to volume ratios. In addition to the usual dangers of hypothermia, the metabolic energy that is used to increase heat production is diverted from other areas, such as wound healing [154]. Strategies that may be useful for minimizing heat loss in burn patients include warming the operating room, using heat lamps or reflective barriers (e.g. a plastic sheet) over the patient, using forced-air warming blankets, administering warmed IV fluids and blood products, and humidifying anesthetic gases.

KEY POINTS: ANESTHETIC MANAGEMENT

- Preoperative airway examination, a global sense of fluid balance, NPO status, and continuation of nutrition when possible are important considerations
- Most anesthetic agents are safe to use in burn patients, including propofol, thiopental, ketamine, potent inhalational agents, nitrous oxide, and opioids
- Succinylcholine is contraindicated after 24 h due to the risk for lethal hyperkalemia from upregulated, extrajunctional acetylcholine receptors
- Non-depolarizing muscle relaxants are safe, and dose requirements for these drugs will generally be significantly increased
- A difficult airway in burn patients can be from edema, limited neck mobility and mouth opening, and scarring
- Intraoperative blood loss during excision and grafting procedures can be significant and requires vigilance on the part of the anesthesiologist

Pain control

Unlike acute postsurgical patients, children with second- and third-degree burns experience chronic pain with superimposed acute pain during a prolonged course of treatment. Burn pain is frequently undertreated [155,156] and burned children continue to report extremes of pain, especially with dressing changes and wound care [157]. Additionally, it has become clear that undertreatment of childhood burns has long-standing negative consequences on children's physical and psychological well-being. Physical consequences include a neurohormonal stress response that is associated with slower wound healing [158], as well as long-term alterations in somatosensory and pain processing [159] that may prime children for more intense future pain responses [160]. From a psychological standpoint, in-hospital pain in burn patients has been directly correlated to post-traumatic stress disorder symptoms in children of all ages [161], and better pain control may in fact reduce many of these symptoms [162,163]. As such, improving pain control in pediatric burn patients is imperative. One approach to optimizing pain management for burned children is to consider the different sources of pain in their hospitalization – including background pain, procedural pain (e.g. dressing changes), and perioperative pain – and develop a plan for each. Figure 40.7 summarizes recommended interventions as well as those needing further investigation for each of these phases of care.

Background pain and sedation

One of the most commonly used medication regimens for background pain and sedation in burned children is acetaminophen along with a combination of an opioid such as morphine and a benzodiazepine such as midazolam [164–167]. However, there are few data evaluating this regimen in comparison to others, and no data to suggest that one opioid or benzodiazepine is superior to another in this context. The addition of dexmedetomidine to a morphine/midazolam combination has been shown to improve sedation in burned children [166], but it should be started as an infusion (without a bolus) or doses of other agents should be reduced to avoid hypotension with dexmedetomidine initiation [164]. The use of non-steroidal anti-inflammatory drugs as co-analgesics is not well studied in pediatric burn patients due to concerns for potential side-effects, especially bleeding risk, gastrointestinal complications, and renal toxicity [167,168].

Gabapentin, an anticonvulsant that has increasingly been used for chronic and neuropathic pain, has been studied as an adjuvant background pain medication in adult burn patients, but not in children. The adult studies have had mixed results; two smaller studies reported reduction in pain [169] and opioid consumption [170] with scheduled gabapentin use after admission, but a larger controlled trial did not find any benefit [171]. As such, it is unclear if patients benefit from the routine addition of gabapentin.

Procedural pain

Approaches to analgesia and sedation for burned children undergoing dressing changes have generally focused on varying combinations of propofol, ketamine, dexmedetomidine, and remifentanil to provide deep sedation. Because several different combinations of drugs were compared to each other in a number of small studies, it is difficult to evaluate each regimen on its own merits or find one to be unequivocally superior to the others based on current data.

Doses that have been suggested in the literature for sedation in this context include propofol 1–2 mg/kg, ketamine 1–2 mg/kg, and dexmedetomidine 0.5–1 μg/kg, with infusions of these agents as indicated by the duration of the procedure, and remifentanil 0.1 μg/kg bolus followed by 0.05 μg/kg/min infusion [172–175]. Ketamine and dexmedetomidine have the benefit of being agents that do not cause significant respiratory depression.

Non-pharmacological approaches to procedural pain are also valuable adjuncts. Child life therapy, for example, can significantly reduce pain and anxiety scores during dressing changes [176]. New technologies such as virtual reality are also rapidly advancing and growing in their medical applications. By replacing the sensory experience of the hospital and immersing patients in a computer-generated world, virtual reality can distract patients from pain and significantly improve their experience [177]. A number of small studies have shown significant reductions in pain scores during dressing changes for both adults and children when using virtual reality compared with control distraction techniques [178–181]. As such, as these technologies become more widely available, they may become more regularly used elements of treatment in burn patients.

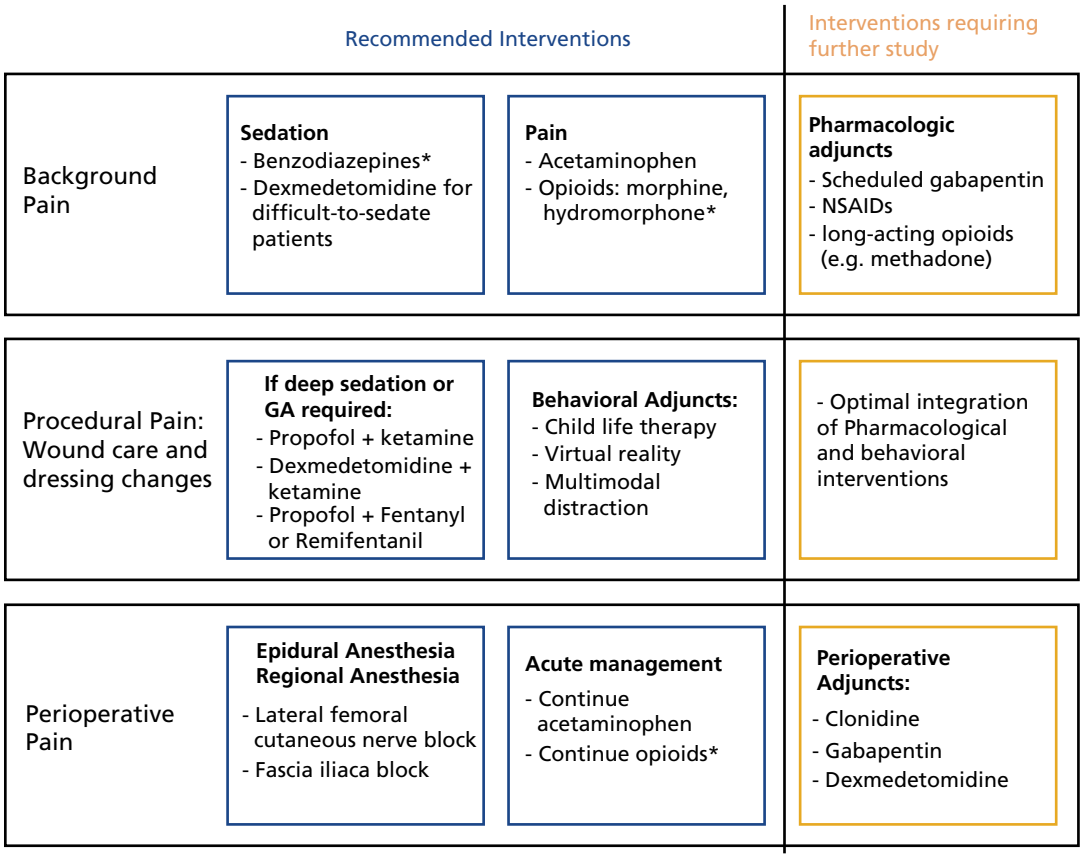

Figure 40.7 Approaches to pediatric burn pain management in different phases of care. This figure provides a summary of evidence-supported interventions for pediatric burn pain, as well as areas requiring further study before recommendations can be made. Given the overall paucity of data, some of the recommended interventions are based on incomplete data and still need to be evaluated further, but have a promising literature base. Medications noted with an asterisk (*) are considered by authors in the literature to represent widespread current practice, and their inclusion as recommended interventions is based on this status quo and opinion rather than clear data. *Source*: Reproduced from Pardesi and Fuzaylov [191] with permission of Wolters Kluwer.

Perioperative pain

There is considerable overlap between the management of background pain and perioperative pain in burn patients. Background medications such as acetaminophen and opioids are generally continued in the perioperative period and make up the mainstay of acute postoperative pain management. However, while studies on perioperative adjuncts are growing in the general pediatrics literature, such research is almost non-existent in burned children. This may be due to the fact that the optimal timing and use of a perioperative adjunct is unclear for a burn patient already in baseline pain. Agents that have been studied as general perioperative adjuncts include clonidine, gabapentin, dexmedetomidine, and ketamine.

Preoperative oral clonidine 4 μg/kg has been shown to significantly reduce postoperative analgesic requirements and pain scores in children [182], but its utility for burn patients is unknown. Gabapentin (15 mg/kg) has some encouraging data on its use as a premedication when studied in pediatric scoliosis patients [183], but these data are far from conclusive and burn patients have not been studied. Similarly, dexmedetomidine premedication (1 μg/kg) [184–187] has been shown to reduce postoperative pain [187,188], but the only study in burn patients was equivocal, likely due to its small sample size [189]. The intraoperative use of ketamine has also been evaluated in the general pediatrics literature, where it was found to decrease postoperative pain for only the first 6 h, without an opioid-sparing effect [190]. As such, while there are some data to support the preoperative administration of clonidine, gabapentin, and dexmedetomidine for reduction of postoperative pain in pediatric surgical patients, these agents have not been evaluated in burn patients as to ideal frequency and timing.

Therapeutics studied in the perioperative management of pediatric burn patients are summarized in Table 40.3 [191].

Regional anesthesia

Regional anesthesia has been evaluated primarily in the context of control of pain at donor sites for graft harvesting – which are frequently noted to be more painful than recipient sites – but has also been studied for dressing changes. The nerve blocks studied include primarily the lateral femoral cutaneous nerve (LFCN) and fascia iliaca blocks. The LFCN innervates the lateral thigh, covering one of the most common sites for donor harvest [192,193], while the fascia iliaca block covers the LFCN as well as the femoral nerve, which allows the block to cover the anterior thigh for larger graft harvests [192].

A handful of studies have evaluated the use of regional anesthesia in burn patients. In the only prospective trial to date of nerve blocks for pediatric skin graft harvests, 19

Table 40.3 Therapeutics studied in perioperative pain management of pediatric burn patients

Phase of care	Medication/procedure	Notes
Preoperative (premedications)	Clonidine: 4 μg/kg	Strong evidence to suggest reduced postoperative pain in non-burn literature
	Gabapentin: 15 mg/kg	Moderate evidence to suggest reduced postoperative pain in non-burn literature
	Dexmedetomidine: 1 μg/kg	Strong evidence to suggest reduced postoperative pain in non-burn literature; one negative trial in burn patients
Intraoperative	Ketamine	No evidence to support use for postoperative pain improvement
	Dexmedetomidine: 1 μg/kg	Strong evidence to suggest reduced postoperative pain in non-burn literature; unstudied in burn population
Postoperative	Acetaminophen	Effective; continue as background medication
	Opioids: morphine and hydromorphone	Mainstay of acute postoperative management; no evidence to favor one opioid over another
	Peripheral nerve blocks: LFCN and fascia iliaca	Likely performed pre- or intraoperatively
		Good evidence for improved postoperative pain control (pediatric and adult data)

LFCN, lateral femoral cutaneous nerve.

children were randomized to surgical infiltration of local anesthetic (control group), an ultrasound-guided single-shot LFCN block, or a fascia iliaca block with catheter. Children who received either nerve block had less postoperative pain than those who received the surgical infiltration of local anesthetic. LFCN block patients were more comfortable in the immediate postoperative period, while patients with a fascia iliaca catheter were more comfortable in the subsequent 48 h [192]. Studies in adult burn patients have also shown reduced postoperative pain, opioid consumption, and nausea and vomiting in burn patients receiving nerve blocks [194]. Additionally, dressing changes can also be comfortably performed in patients with nerve blocks, as has been shown in some adult patients [195]. There were no significant complications associated with regional anesthesia in any of these studies.

Taken together, these data suggest that there is a significant role for regional anesthesia in pain control for burn patients, both for graft harvests as well as for dressing changes, and regional techniques should be employed whenever possible and appropriate.

KEY POINTS: PAIN CONTROL

- Pain is often undertreated in burn patients; this can have physiological and psychological consequences, from potentially delayed wound healing to post-traumatic stress disorder
- Background pain is commonly treated with benzodiazepines and opioids, but dexmedetomidine has been shown to be a good adjunct
- Sedation for dressing changes often includes combinations of propofol, ketamine, dexmedetomidine, and/or remifentanil. Non-pharmacological treatments are useful, including child life support and distraction technologies such as virtual reality
- Regional anesthesia, such as lateral femoral cutaneous nerve or fascia iliaca blocks, should be considered for treatment of graft donor sites

Anesthetic management for reconstructive procedures

After the primary burn wound is healed, burn patients often return to the operating room multiple times for reconstructive procedures, such as scar revisions, re-excisions, and grafting. At this stage, remote from the initial burn, patients will generally no longer display extreme physiological disturbances, and pharmacokinetics gradually return to normal.

Anesthesia for reconstructive surgery is generally similar to that of other plastic surgical operations. Previous anesthetic records are generally an important source of information regarding airway management and pain medication requirements. Because reconstructive procedures do not typically result in large amounts of blood loss or extensive fluid shifts, a single peripheral intravenous line and standard monitors are often sufficient, although each case should be assessed individually. It is important to bear in mind that these children will often be returning for repeat procedures, so careful attention should be paid to anxiolysis and tailoring the type of induction to the child's comfort and preferences so as to minimize potential fear, anxiety, and unpleasantness. With appropriate attention to these aspects of the patient's experience, adverse psychological outcomes can be avoided in patients undergoing frequent general anesthetics [196].

One area that warrants special consideration in the recovered burn patient is airway management. Patients with head and neck burns can develop severe contractures that can distort the airway, limit mouth opening and neck flexion, and obstruct the nares [197], all of which can lead to a difficult airway. Mask ventilation can be difficult in these patients because the jaw thrust and chin lift maneuvers may be precluded by scarring and contractures, and insertion of oral or nasal airways may be precluded by microstomia or scarring of the nares [197]. As such, if difficulty with mask ventilation is anticipated, it is advisable to maintain spontaneous ventilation either throughout the induction and intubation, or at least until confirmation of the ability to mask ventilate. The airway can then be approached using difficult airway adjuncts, including the laryngeal mask airway (LMA), videolaryngoscopy, or a fiberoptic scope. In severe cases, the patient may require surgical release of contractures in order to

Figure 40.8 A difficult airway in a burned child, requiring neck dissection with local anesthetic and deep sedation with spontaneous ventilation in order to facilitate endotracheal intubation.

facilitate intubation (Fig. 40.8); this can be done with the patient anesthetized and spontaneously breathing volatile agents via a facemask or LMA, supplemented with local anesthesia [198,199]. If a difficult airway is anticipated in the recovered pediatric burn patient, it is also critically important to have available a surgeon who could perform a potentially challenging tracheostomy as a rescue option.

KEY POINTS: ANESTHETIC MANAGEMENT FOR RECONSTRUCTIVE PROCEDURES

- Burn patients may return to the operating room many times for reconstructive procedures, often long after the initial burn, and will generally no longer display extreme physiological disturbances
- Airway evaluation is crucial, as poorly treated burns can develop scars and contractures that may profoundly limit head and neck mobility or mouth opening
- With a difficult airway, securing the airway, spontaneous ventilation, and using medications such as ketamine and potent inhalational agents may allow a more controlled situation for airway management

CASE STUDY

An 18-month-old girl was transferred to a burn hospital from a rural village. She had suffered severe head and chest burns from hot oil at 1 year of age, but had been otherwise healthy prior to this injury. On initial presentation, she had required a tracheostomy for airway control due to widespread burns to the mouth and face that precluded safe oral intubation. When the neck swelling had decreased and the burn wounds completely healed, the tracheostomy was decannulated prior to discharge from hospital. The patient now presented for treatment of her profound neck and mouth contractures and facial deformity, as shown in Figure 40.9A.

Although the burn wounds had healed, the progressive severe contractures of the face, anterior neck, and shoulders led to increasing respiratory compromise, including obstructive sleep apnea with bradycardia and desaturation to 70–80%. The airway was more prone to obstruction in the supine position. Hence, the child most often slept prone on her mother's shoulder and chest. Because of the contracture-related microstomia, she was only able to swallow liquid food. The chin and the sides of the face were pulled down and tethered to her upper sternum and upper chest wall. The anterior neck structures (larynx, trachea, carotids) were not palpable. Her nares were completely occluded such that no nasal discharge was noted even during her crying spells. The skin of her face and facial contour were markedly irregular. Neither flexion nor extension of her head was possible.

Direct visual examination of the oral cavity and pharynx was impossible due to the extreme microstomia and lack of cooperation of the patient. Attempts by the ear, nose, and throat (ENT) surgeon to examine the air passages by fiberoptic endoscopy were futile in view of the closed nares. CT scan of the head and neck confirmed the obstruction of the external nares, and showed relatively normal oropharyngeal, glottic, and laryngeal structures.

After extensive discussions between pediatric, burn, cardiothoracic, and ENT surgeons and anesthesiologists, a plan was formalized. The first step was the establishment of a safe method for gas exchange as a precautionary measure. This was achieved by extracorporeal membrane oxygenation (ECMO) via cannulation of the femoral vein during ketamine sedation and analgesia. The second step was induction of general anesthesia while the child was on ECMO. The third step was the release of the neck contractures to provide anterior access to the trachea for an emergency tracheostomy, if necessary, and to facilitate endotracheal intubation. Oral commissurotomy was deliberately avoided as the child was heparinized for the ECMO. Any bleeding from the commissurotomy into the oral cavity had the potential to impair visibility during intubation and lead to aspiration and/or laryngospasm. The final step was direct laryngoscopy and intubation.

The day before surgery, a peripheral intravenous line was placed. Antacid prophylaxis was initiated with pantoprazole and ranitidine 2 h before surgery. The child was reassessed in the induction room with her mother. Scopolamine (0.1 mg) and atropine (0.2 mg) IV were administered for sedation and to reduce oral secretions that may occur with the subsequent planned use of ketamine. After placement of a pulse oximeter, incremental doses of ketamine (0.25 mg/kg per dose up to 3.5 mg/kg) were titrated over 30 min to sedate the child and separate her from her mother. The patient was positioned supine on the operating room table, and other standard monitors were attached. Surprisingly, the patient did not manifest any serious airway obstruction in the supine position when asleep with ketamine.

Additional doses of ketamine (total dose 5.5 mg/kg) were administered to provide analgesia and sedation. Local anesthetic was administered in the groin by the surgeons. Intravenous heparin was administered for anticoagulation. Femoral vein cut-down and ECMO cannulation were expeditiously completed. At this point, general anesthesia was slowly induced with sevoflurane through an anesthesia facemask. With general anesthesia maintained via facemask and successful assisted mask ventilation, the surgeons performed a limited neck release, which now provided a potential access to the trachea anteriorly if necessary. Having confirmed the ability to ventilate, muscle relaxant was administered (rocuronium 1 mg/kg) and the patient was successfully intubated with a styletted 3.5 mm cuffed endotracheal tube with extreme anterior pressure on the larynx. Anesthesia was maintained with sevoflurane and nitrous oxide, with additional muscle relaxation and opioids. Tracheostomy was considered as an option to secure the airway, but was decided against because of the potential for intratracheal bleeding due to the anticoagulation.

With the endotracheal tube in place, further neck release and dissection were performed. The ECMO circuit was then gradually weaned, and vital signs indicated that ventilation and gas exchange were adequate, allowing discontinuation of ECMO. Over the course of the operation, she received 500 mL lactated Ringer's solution. About 100 mL of blood was transfused from the ECMO reservoir. After grafting of the neck was completed, she was transferred to the pediatric intensive care unit, intubated and in a stable condition. She was extubated uneventfully in the ICU 2 days later.

The patient subsequently underwent multiple additional surgeries for revisions. For these procedures, endotracheal intubation was achieved by direct laryngoscopy, after induction of anesthesia with ketamine, sevoflurane, and muscle relaxant. Figure 40.9B shows the improvement in the patient's scarring partway through her process of reconstructive surgery.

This case study demonstrates just how difficult the airway of the recovered pediatric burn patient can be. In this case, many factors suggested a difficult airway: severe contractures, difficulty identifying anatomical structures, inability to move the head and neck, microstomia, and obstructed nares. An additional factor worth noting is the presence of obstructive sleep apnea, suggesting the need for additional caution when inducing the patient. One of the most instructive elements of this case is the importance of multidisciplinary collaboration in care of the complex patient, and using that expertise in order to develop a clear plan for management of the patient. With appropriate preparation and careful planning, even extremely challenging airways can be managed when approached systematically.

Introduction

Improved anesthetic techniques and advanced technology in the last two decades [1] have led to an increase in invasive and non-invasive pediatric procedures performed outside the operating room in most institutions. In the past years, as operating room cases increased by 250% at Boston Children's Hospital, anesthesia services outside the operating room increased by almost 350% (Table 41.1). In 2016, 10,200 out of 32,476 (31%) anesthetics were administered to patients outside the operating at Cincinnati Children's Hospital Medical Center. Although the majority of procedures are accomplished in the radiology suite, they are now complemented by anesthesiology support in gastroenterology, pulmonology, radiotherapy, and the dental and oncology clinics (Table 41.2). Anesthesiologists have been leaders in establishing guidelines and recommendations for sedation and anesthesia services provided by both anesthesiologists and non-anesthesiologists [2–7]. In this chapter we will explore the special considerations for providing anesthesia and sedation services in various clinical areas outside the operating room and will review common organizational, equipment, and personnel considerations and strategies. We conclude with the roles of quality improvement and simulation in non-operating room anesthesia (NORA) locations and speculation about the future of pediatric sedation outside the operating room.

Specific NORA sites

Diagnostic radiology

Computed tomography scans

Computed tomography (CT) was introduced into clinical practice in the late 1970s. CT differentiates between high-density (calcium, iron, bone, contrast-enhanced vascular and cerebrospinal fluid (CSF) spaces) and low-density (oxygen, nitrogen, carbon in air, fat, CSF, muscle, white matter, gray matter, and water-containing lesions) structures. Because the scan time is quick, CT may be preferable for patients who are medically unstable and in need of rapid diagnosis. Understanding the goal of each imaging study allows the sedation/anesthesia provider to choose the safest and most effective regimen to allow a meaningful study. As an example, in order to obtain the high-quality "high-resolution" CT required to evaluate lung parenchymal detail, motion-free images at inspiration and expiration are required. Significant atelectasis may lead to difficulty with interpretation and diagnosis. A consistent anesthetic approach will often optimize interpretive results among radiologists [8]. Atelectasis in the dependent regions of the lung appears within 5 min of anesthesia induction [9], regardless of anesthetic choice or respiratory management [10]. In "healthy" lungs, collapsed areas are re-expanded, and a normal functional residual capacity restored if airway pressures are raised beyond the alveolar opening

Table 41.2 Multidisciplinary programs involving the department of anesthesiology: Boston Children's Hospital

Program	Departments
Advanced Fetal Care Center	Anesthesia, cardiology, general surgery, genetics, medicine, neurology, neurosurgery, newborn medicine, ORL, plastic surgery, radiology, urology
Brain Injury Program	Anesthesia, general surgery, neurology, neurosurgery, orthopedics, psychiatry/psychology, sports medicine
Center for AeroDigestive Disorders (CADD)	Anesthesia, GI, ORL, pulmonary program
Cleft Lip and Palate Program	Anesthesia, audiology, dentistry, general surgery, genetics, nursing, oral and maxillofacial surgery, ORL, pathology, plastic surgery, psychiatry/psychology, social work
Craniofacial Anomalies Program	Anesthesia, audiology, dentistry, genetics, neurosurery, nursing, oral and maxillofacial surgery, ORL, pathology, plastic surgery, psychiatry/psychology, social work
Heart Transplant Program	Anesthesia, cardiac surgery, cardiology, cardiovascular program, general surgery, nutrition, physical therapy, pathology, radiology
Intestine and Multivisceral Transplant Program	Anesthesia, general surgery, GI, nutrition
Liver Transplantation	General surgery, gastroenterology, nutrition center, psychiatry
Lung Transplant Program	Anesthesia, cardiac surgery, cardiology, general surgery, psychiatry/psychology, respiratory diseases
Pain Treatment Service	Anesthesia, physical and occupational therapy, psychiatry, rheumatology
Trauma Program	Anesthesia, critical care medicine, emergency medicine, general surgery, neurosurgery, orthopedics, psychiatry/psychology, radiology
Vascular Anomalies Center	Anesthesia, cardiology, cardiovascular program, dermatology, endocrinology, general surgery, hematology, medicine, neurology, neurosurgery, nursing, oncology, oral and maxillofacial surgery, ORL, orthopedics, pathology

GI, gastrointestinal; ORL, otorhinolaryngology.

pressure. The recruitment maneuver has been shown to improve arterial oxygenation and lung compliance. It is important to note that while using high inflating pressures is benign in most cases, high-pressure ventilatory strategies can lead to hemodynamic compromise and possibly cause lung injury from overdistension of non-collapsed lung areas [11,12].

CT scans for visualizing the sinuses, ears, inner auditory canal, and temporomandibular bones (e.g. for choanal atresia or craniofacial abnormalities) may require direct coronal imaging with extreme head extension or absolute immobility for 3D reconstruction. The more common studies involving 3D reconstruction are cardiac, craniofacial, and pulmonary (larynx, trachea, bronchi, and pulmonary parenchyma) imaging [13]. The cardiac studies are often done in collaboration with cardiologists and radiologists who are able to make structural and functional assessments of the heart. These scans can also be challenging because adenosine is often requested in order to briefly pause heart function so that image quality is optimized [14].

Any patient who is at risk for cervical instability should be properly screened prior to neck extension, such as children with Down syndrome, whose incidence of instability varies from 12% to 32% [15]. Many children with Down syndrome require cervical spine radiographs prior to participating in advance sports events. Usually, the parents are well aware of the radiological findings. The cervical spine films, however, do not predict at the risk of dislocation [16]. Rather, neurological signs or symptoms such as abnormal gait, increased clumsiness, fatigue with ambulation, or a new preference for sitting games are predictors of risk. The asymptomatic Down syndrome child with radiological evidence of instability may be approved for procedural sedation, however unnecessary neck movement should be avoided. Any child who displays neurological signs or symptoms should not be sedated by either a nurse or an anesthesiologist until neurosurgical or orthopedic consultation is obtained.

Radiologists employ gastrografin (diatrizoate meglumine and diatrizoate sodium) when evaluating abdominal masses. Gastrografin diluted to 1.5% is usually considered a clear liquid, however the volume administered orally is not insignificant. Newborns less than 1 month of age receive 60–90 mL, infants between 1 month and 1 year of age may receive up to 240 mL, and children between the ages of 1 and 5 years receive between 240 and 360 mL. In order to opacify the bowel optimally for abdominal examination with CT the contrast is best administered 1 h prior to imaging [17]. Waiting several hours after the administration of contrast will often result in inadequate opacification of the small bowel [17]. Because sedation or anesthesia should usually be accomplished within a window of 1–2 h after ingestion of the contrast, most "elective" nil per os (NPO) guidelines would be violated, yet the scan must be completed while the gastrografin is still in the gastrointestinal tract. There are no published data to guide optimal induction or sedation techniques as they relate to aspiration risk in these circumstances. Some providers may choose to perform rapid-sequence induction of general anesthesia with tracheal intubation while others may choose deep sedation without airway protection [18,19]. Full-strength (3%) gastrografin is hyperosmolar and hypertonic. All gastrografin should be diluted to an isosmolar and isotonic 1.5% concentration of neutral pH. There is one case report of 1.5% gastrografin aspiration in a child with no adverse sequelae [20]; therefore, the risk of using a 1.5% concentration of gastrografin seems low [21].

The radiation dose for children undergoing CT scanning has long been a concern, and the recent Image Gently campaign has been effective in dramatically reducing the

radiation exposure for CT scans in children by standardizing approaches to the technical aspects of scanning, as well as indications for the scan itself [22,23]. In addition, modern multislice CT scanners can obtain detailed images quickly and with significant reduction in radiation exposure, often with minimal or no sedation. With the great increase in magnetic resonance imaging (MRI), CT scan imaging decreased, but in the modern era with the concern over prolonged sedation and anesthesia in young children [24] (see Chapter 46), CT scanning once again has become the modality of choice in some indications, including some congenital heart disease studies [25].

Magnetic resonance imaging

The first commercial MRI scanner was introduced in 1990. Over the past three decades MRI has evolved beyond a diagnostic tool to encompass a broader role in diagnosing and evaluating obstructive sleep apnea, developmental delay, behavioral disorders, seizures, failure to thrive, apnea/cyanosis, hypotonia, and mitochondrial/metabolic disorders. Magnetic resonance angiography and venography evaluate vascular flow and can sometimes replace invasive catheterization studies for follow-up or initial evaluations of vascular malformations, interventional treatment, or radiotherapy [26].

Functional MRI (fMRI) is an evolving technology which measures the hemodynamic or metabolic response related to neural activity in the brain or spinal cord. The hemodynamic response (increase in cerebral blood flow, cerebral blood volume, and cerebral capillary and venous oxygen saturation) is the basis of image contrast in fMRI. fMRI is often able to localize sites of brain activation and is now dominating brain mapping techniques due to its low invasiveness and lack of radiation exposure [27–29]. Some fMRI studies require cognitive facility and are typically interactive with a conscious and responsive patient. The current use of fMRI in children is primarily focused on presurgical evaluation of language and memory function for intractable epilepsy, and preoperative assessment of eloquent cortex in patients with brain lesions (tumors, cavernous malformations). Currently it is an established tool for pain research and recently has been applied to the understanding of anesthetic mechanisms, brain injury, and respiratory control [29]. fMRI that requires patient responsiveness is generally performed in unsedated children with the aid of distraction techniques and most recently with the use of video goggles (Resonance Technology, Northridge, California, USA) (Fig. 41.1). These goggles are designed specifically for fMRI and are approved for the 1.5 and 3T environment. They are able to deliver audio and visual stimulation, measure patient response through the use of patient input devices, and are able to track eye movement. In addition, they can be used for children as young as 4–5 years of age to avoid sedation for MRI studies. fMRI studies on sedated children is a relatively new field and those who provide sedation describe propofol and dexmedetomidine infusions as agents that can maintain spontaneous ventilation and immobility while also enabling the child to respond to verbal, tactile, or auditory stimulation. fMRI studies on children who require sedation to maintain immobility will be a challenge facing anesthesiologists as we move through the next decade.

Anesthesiologists need to adapt to these evolving technologies. Magnetic resonance enterography, for example, is a method of examining the bowel without the use of ionizing radiation and has recently emerged as highly effective method of assessing inflammatory bowel disease in children. This technique requires the administration of oral contrast. Appropriate timing of imaging after oral contrast agent administration is crucial in order to opacify the bowel and optimize the images. These authors administer enteric contrast through an oral gastric tube after placement of an endotracheal tube and extubate these patients awake after suctioning the stomach at the conclusion of the study [30].

Figure 41.1 Virtual reality system for functional MRI, and avoidance of sedation in young children. See text for details. *Source:* Courtesy of Cincinnati Children's Medical Center.

Three-dimensional studies utilizing MRI have evolved in concert with CT studies. Airway studies, in particular, provide a means of diagnosing areas of airway compromise and collapse that were not identified on bronchoscopy and fluoroscopy. These studies have specific anesthetic management implications as they require that the trachea remains unintubated and the patient breathes spontaneously in order to be able to visualize areas of collapse. The use of intravenous dexmedetomidine, among other techniques, will allow immobility, simulation of natural sleep, and maintenance of spontaneous ventilation. As these children present with obstructive sleep apnea, however, the anesthesiologist must anticipate that airway obstruction can occur under sedation as it does during natural sleep [31–34].

MRI-guided surgical procedures, commonly referred to as magnetic resonance therapy, have evolved over the past decades, enabling surgeons to benefit from MRI in real or near-real time intraoperatively. The logistical challenges in creating a surgical suite that is equipped with an MRI scanner are considerable. In addition to the routine precautions that must be taken in a typical diagnostic MRI suite, all surgical supplies and equipment must be magnetic resonance safe or conditional. In general, access to this surgical suite is restricted to personnel fluent in MRI safety procedures and guidelines. Magnetic resonance therapy is currently being used for neurosurgery to guide the resection of tumors, seizure foci, and vascular malformations [35]. Additional applications have extended its use to otolaryngological, general surgery, and orthopedic procedures [36].

The MRI environment is unique because of its strong static magnetic field, high-frequency electromagnetic (radiofrequency or RF) waves, and a pulsed magnetic field. Magnetic field strengths are measured in units of Gauss (G) and Tesla

(T): 1 T is equal to 10,000 G. The main magnetic field of a 1.5 T magnet is about 30,000 times the strength of the earth's magnetic field. The main magnetic field of a 3 T system is 60,000 times the earth's magnet field. To put this into context, the strength of electromagnets used to pick up cars in salvage yards is equivalent to the field strength of a 1.5–2.0 T magnet. This field strength is able to transform static oxygen cylinders into flying projectiles which can travel at speeds approaching 40 miles per hour. The American College of Radiology established guidelines to minimize the risk of MRI-related mishaps [37], but did not directly address anesthesiologists' unique needs. In 2008 the American Society of Anesthesiologists (ASA) assembled a task force composed of anesthesiologists, a radiologist with MRI expertise, and two methodologists; a practice advisory on anesthetic care for magnetic resonance imaging followed [38]. This document establishes important recommendations for safe practice as well as consistency of anesthesia care in the MRI environment. In 2008, the Joint Commission on Accreditation of Healthcare Organizations, USA (the Joint Commission) recognized the existing and potential hazards of the MRI environment when they published a sentinel event alert [39] specifically identifying eight types of possible injury.

As technology has advanced, 1.5 T magnets have been supplanted by 3 T magnets. The field strength and magnetic force generated by a 3 T MRI scanner is unforgiving to the careless or accidental introduction of a ferrous object into the environment. Placing a magnet outside the MRI scanner is a crude and sometimes inaccurate way to test objects. If the object is not attracted to the magnet, this is not an absolute indication that there is no ferrous material present; a positive attraction, however, will provide critical information to the anesthesiologist. Some unusual objects that have found their way into the MRI suite in order to become projectiles include a metal fan, pulse oximeter, shrapnel, wheelchair, cigarette lighter, stethoscope, pager, hearing aid, vacuum cleaner, calculator, hair pin, oxygen tank, prosthetic limb, pencil, insulin infusion pump, keys, watches, and steel-tipped/heeled shoes [40]. Small objects can usually be easily removed from the magnet; large objects may have so much attractive force with the MRI scanner that they are impossible to remove by manual force. In these circumstances, quenching the magnet may be the only way to release the object. This process is not without substantial risk: as helium gas is vented, condensation and considerable noise fills the suite. All personnel are required to vacate the suite during a quench as there is a risk of hypoxic conditions should helium accidentally enter the room.

It is important to remember that the magnet is always on, and the dangers of the electromagnetic field are always present. The American College of Radiologist recommends that the MRI suite be divided into four zones with increasing safety and access requirements as patients, staff, and equipment move closer to the scanner. The establishment of safety zones in the MRI environment addresses restrictions to access of the MRI environment (Table 41.3) [37]. This safety approach was acknowledged by the MRI Task Force of the ASA in its updated practice advisory in 2015 [41]. Because the 1.5 and 3 T scanners have different magnetic field strengths, an object which is MRI safe in a 1.5 T magnet is not necessarily safe in a 3 T magnet. MRI safety labeling is specific for magnetic field strength.

As advances have been made in the technology of MRI as well as in clinical experience, there has been a parallel evolution in labeling practices from the initial standards established by the US Food and Drug Administration (FDA) in 1997 to the current standard for labeling equipment established by the American Society for Testing and Materials International in 2005 (Table 41.4) [42]. For example, the magnetic resonance (MR) compatible terminology has been deleted because it became apparent that the terms "MR safe"

Table 41.3 MRI safety zones

Zone	Definition	Access
Zone I	This region includes all areas that are freely accessible to the general public. This area is typically outside the MR environment itself and is the area through which patients, healthcare personnel, and other employees of the MR site access the MR environment	General public
Zone II	This area is the interface between the publicly accessible uncontrolled zone I and the strictly controlled zone III. Typically, the patients are greeted in zone II and are not free to move throughout zone II at will, but rather are under the supervision of MR personnel. It is in zone II that patient histories, answers to medical insurance questions, and answers to MRI screening questions are typically obtained	Unscreened MRI patients
Zone III	This area is the region in which free access by unscreened non-MR personnel or ferromagnetic objects or equipment can result in serious injury or death as a result of interactions between the individuals or equipment and the MR scanner's particular environment. These interactions include, but are not limited to, those with the MR scanner's static and time-varying magnetic fields. All access to zone III is strictly restricted, with access to regions within it (including zone IV) controlled by, and entirely under the supervision of, MR personnel	Screened MRI patients and personnel
Zone IV	This area is the MR scanner magnet room. Zone IV, by definition, will always be located within zone III because it is the MR magnet and its associated magnetic field that generates the existence of zone III.	Screened MRI patients under constant direct supervision of trained MR personnel

MR, magnetic resonance; MRI, magnetic resonance imaging.

Table 41.4 Current terminology used to label implants and devices [42]

Definition	US Food and Drug Administration	American Society for Testing and Materials (ASTM) International	Icon label
MR safe	The device, when used in the MRI environment, has been demonstrated to present no additional risk to the patient or other individual, but may affect the quality of the diagnostic information. The MRI conditions in which the device was tested should be specified in conjunction with the term MR safe since a device which is safe under one set of conditions may not be found to be so under more extreme MRI conditions	An item that poses no known hazards in all MRI environments. Using the new terminology, MR safe items include non-conducting, non-metallic, non-magnetic items such as a plastic Petri dish. An item may be determined to be MR safe by providing a scientifically based rationale rather than test data	"MR" in green in a white square with a green border, or the letters "MR" in white within a green square
MR conditional		An item that has been demonstrated to pose no known hazards in a specified MRI environment with specified conditions of use. Field conditions that define the MRI environment include static magnetic field strength, spatial gradient, dB/dt (time-varying magnetic fields), radio frequency (RF) fields, and specific absorption rate (SAR). Additional conditions, including specific configurations of the item (e.g. the routing of leads used for a neurostimulation system), may be required. In particular, testing for items that may be placed in the MRI environment should address magnetically induced displacement force and torque, and RF heating. Other possible safety issues include, but are not limited to, thermal injury, induced currents/voltages, electromagnetic compatibility, neurostimulation, acoustic noise, interaction among devices, and the safe functioning of the item and the safe operation of the MR system	"MR" in black inside a yellow triangle with a black border. Item labeling must include results of testing sufficient to characterize the behavior of the item in the MRI environment
MR unsafe		An item that is known to pose hazards in all MRI environments. MR unsafe items include magnetic items such as a pair of ferromagnetic scissors	"MR" in black on a white field inside a red circle with a diagonal red band

MR, magnetic resonance; MRI, magnetic resonance imaging.

and "MR compatible" were confusing and were often used interchangeably or incorrectly [43]. Portable equipment to be brought into the magnet room (zone IV) should be identified with a green square "MRI safe" label. A yellow triangle "MRI safe" label should be affixed to equipment that requires strict precautions to be observed when used inside the magnet room. For example, the anesthesia machine is an MRI conditional device, and needs to be placed a minimum distance from the magnet to remain safe and functional. Portable equipment that is required for use in the controlled zones but has ferrous components will have a red circle "MRI unsafe" label and must not be brought into zone IV. The safety of any unlabeled devices to be brought in the controlled area should be discussed with MRI staff and an MRI safety officer.

Personal risks in the MRI environment apply to anesthesiologists and patients. Anesthesiologists must be aware of many personal items taken for granted – clipboards, pens, watches, scissors, clamps, credit cards, eyeglasses, paper clips, etc. [44–46]. MRI safety issues include implanted objects (e.g. cardiac pacemakers), ferromagnetic attraction creating "missiles," noise, biological effects of the magnetic field, thermal effects, equipment issues, and claustrophobia. Some stainless steel may contain ferritic, austenitic, and martensitic components [47–49]. Martensitic alloys contain fractions of a crystal phase known as martensite, which has a body-centered cubic structure, is prone to stress corrosion failure, and is ferromagnetic. Austenite is formed in the hardening process of low carbon and alloyed steels, and has ferromagnetic properties. Iron, nickel, and cobalt are also ferromagnetic. For this reason, the components of *any* implanted device should be carefully researched prior to entering the magnet. Stainless steel or surgical stainless objects interacting with an external magnetic field may produce translational (attractive) and rotational (torque) forces. Intracranial aneurysm clips, cochlear and stapedial implants, shrapnel, intraorbital metallic bodies, and prosthetic limbs may move and potentially dislodge. Special precautions should be taken with cochlear implants in the 3 T environment as those non-removable magnets may suffer demagnetization in the scanner [50]. Some eye make-up and tattoos may contain metallic dyes and therefore cause ocular, periorbital, and skin irritation [51,52]. Some tissue expanders employed in reconstructive surgery have a magnetic port to help identify the location for intermittent injections of saline [53]. Bivona® tracheostomy tubes (Smiths Medical, Kent, UK) usually contain ferrous material (although not specified in the package insert) and should be replaced with a Shiley®

tracheostomy tube (Covidien-Nellcor, Boulder Colorado, USA) prior to entering the MRI environment. Recognizing the unique hazard posed by the MRI environment, in 2008 the Joint Commission issued a sentinel event alert [39].

Cardiac pacemakers present a special hazard in and around the MRI scanner, especially in patients who are pacemaker dependent. Most pacemakers have a reed relay switch that can be activated when exposed to a magnet of sufficient strength [54]. This activation could convert the pacemaker to the asynchronous mode. There are at least two known cases of patients with pacemakers who died from cardiac arrest while in an MRI scanner. The autopsy of one patient determined that the death was the result of an interruption of the pacemaker in the magnetic environment [55]. In addition to the risk of pacemaker malfunction, there is also the chance that torque on the pacer or pacing leads may create a disconnect or microshock [56]. Recent studies demonstrate that with careful preparation, selected patients with permanent pacemakers and implantable cardioverter defibrillators may safely undergo imaging in the 1.5 T environment without any inhibition or activation of their device [57]. Patients with implanted cardiac pacemakers or cardioverter defibrillators should only be scanned in locations staffed with radiologists and cardiologists of appropriate expertise [37]. In general, MRI should not be performed on patients with implanted electronic devices. When MRI is considered essential by the referring physician and consulting radiologist, a plan for managing these patients during the scan should be developed in collaboration with the ordering/referring physician, medical director, or on-site radiologist and other appropriate consultants (e.g. the patient's pacemaker specialist or cardiologist, or device manufacturer). For implanted pacemakers and implantable cardioverter defibrillators, it is anticipated that the cardiologist will be physically available during the scan should the device malfunction [38]. Following the MRI, a cardiologist should confirm function of the device and recheck it within 1–6 weeks. MRI-compatible pacemakers have been available since 2011 [58]. These devices are specifically designed to retain normal function during and after the MRI process and are now available from several manufacturers. Despite the availability of these devices, the same precautions noted above, including cardiologist availability, should be followed.

The biological effect of MRI should be considered when offering parent-present induction if the parent is pregnant. To date, there is no evidence to support the risk of MRI-caused chromosomal aberrations in humans. Studies in amphibians demonstrate that exposure to a 4 T magnetic field does not cause any defects in embryological development [52]. Most institutions do not routinely allow pregnant family members to accompany their children into the MRI scanner. MRI scans during pregnancy are discouraged by the American College of Radiology during the first and second trimester, unless fetal imaging is required or the MRI is necessary for emergent medical care [14].

Some patients experience claustrophobia and have difficulty cooperating during the study. Anxiety reactions [59] are estimated to occur in 4–30% of patients [60]. Patients with extreme skeletal abnormalities such as advanced scoliosis or flexion contractures, although motivated, may be unable to lie motionless or supine on the solid, uncushioned MRI table for the extended duration of a spine MRI. These patients may require general anesthesia for positioning and comfort or may need adjunctive pain medication.

Current advances in physiological monitors and anesthesia machines for the MRI environment have optimized the ability of the anesthesia care provider to provide safe care in the MRI suite. Remote monitor displays make it unnecessary for the anesthesiologist to remain in the scan room during most of the procedure; only during breath-holding procedures or contrast injection is it necessary for the anesthesiologist to enter the scanner room during the imaging procedure. The Dräger Fabius® MRI (Dräger Medical AG, Lubeck, Germany) was designed for MRI and approved by the FDA in 2008 for use within both a 1.5 and 3 T magnetic field up to field strength of 400 G (Fig. 41.2). The Fabius, equipped with two vaporizers, has an electronically controlled ventilator capable of

(A)

(B)

Figure 41.2 (A) Modern MRI-compatible anesthesia machine, with two vaporizers and a ventilator capable of multiple ventilation modes. This system is certified for function in 1.5 and 3 T MRI systems. The machine must be situated outside the 400 G magnetic field radius for proper functioning. delivering multiple modes of ventilation in the MRI suite. Advances in physiological monitoring now offer the ability to monitor electrocardiogram (ECG) and pulse oximetry in a 1.5 and 3T MRI scanner via wireless, fiberoptic communication (Invivo Precess®, Invivo, Orlando, FL, USA and Medrad Veris® Monitor, Bayer, Indianola, PA, USA) (Fig. 41.3). Conventional ECG monitoring is not possible because as the lead wires traverse the magnetic fields, image degradation occurs and, most importantly, the ECG leads will heat and cause patient burns. Fiberoptic ECG monitoring is necessary to minimize the risk of patient burn. Even with fiberoptic cables, it is important to recognize that the connections between the ECG pads and the telemetry box are still hardwired, and careful attention must be paid to prevent frays, overlap, exposed wires, and knots in the cables [61]. It is advisable to provide an interface between the patient's skin and the ECG leads (e.g. a facecloth). There have been reports of burns from the ECG leads as a result of a current generated between the leads and the patient's sweat. Pulse oximeters are also fiberoptic. Failure to remove the conventional pulse oximeter probe/adhesive has resulted in second- and third-degree burns [61,62]. Respiratory and anesthetic gas monitoring has advanced to the point that complete monitoring, as would occur in the operating room, is now routine with MRI-compatible equipment. For patients with a natural airway, a divided nasal cannula both to administer

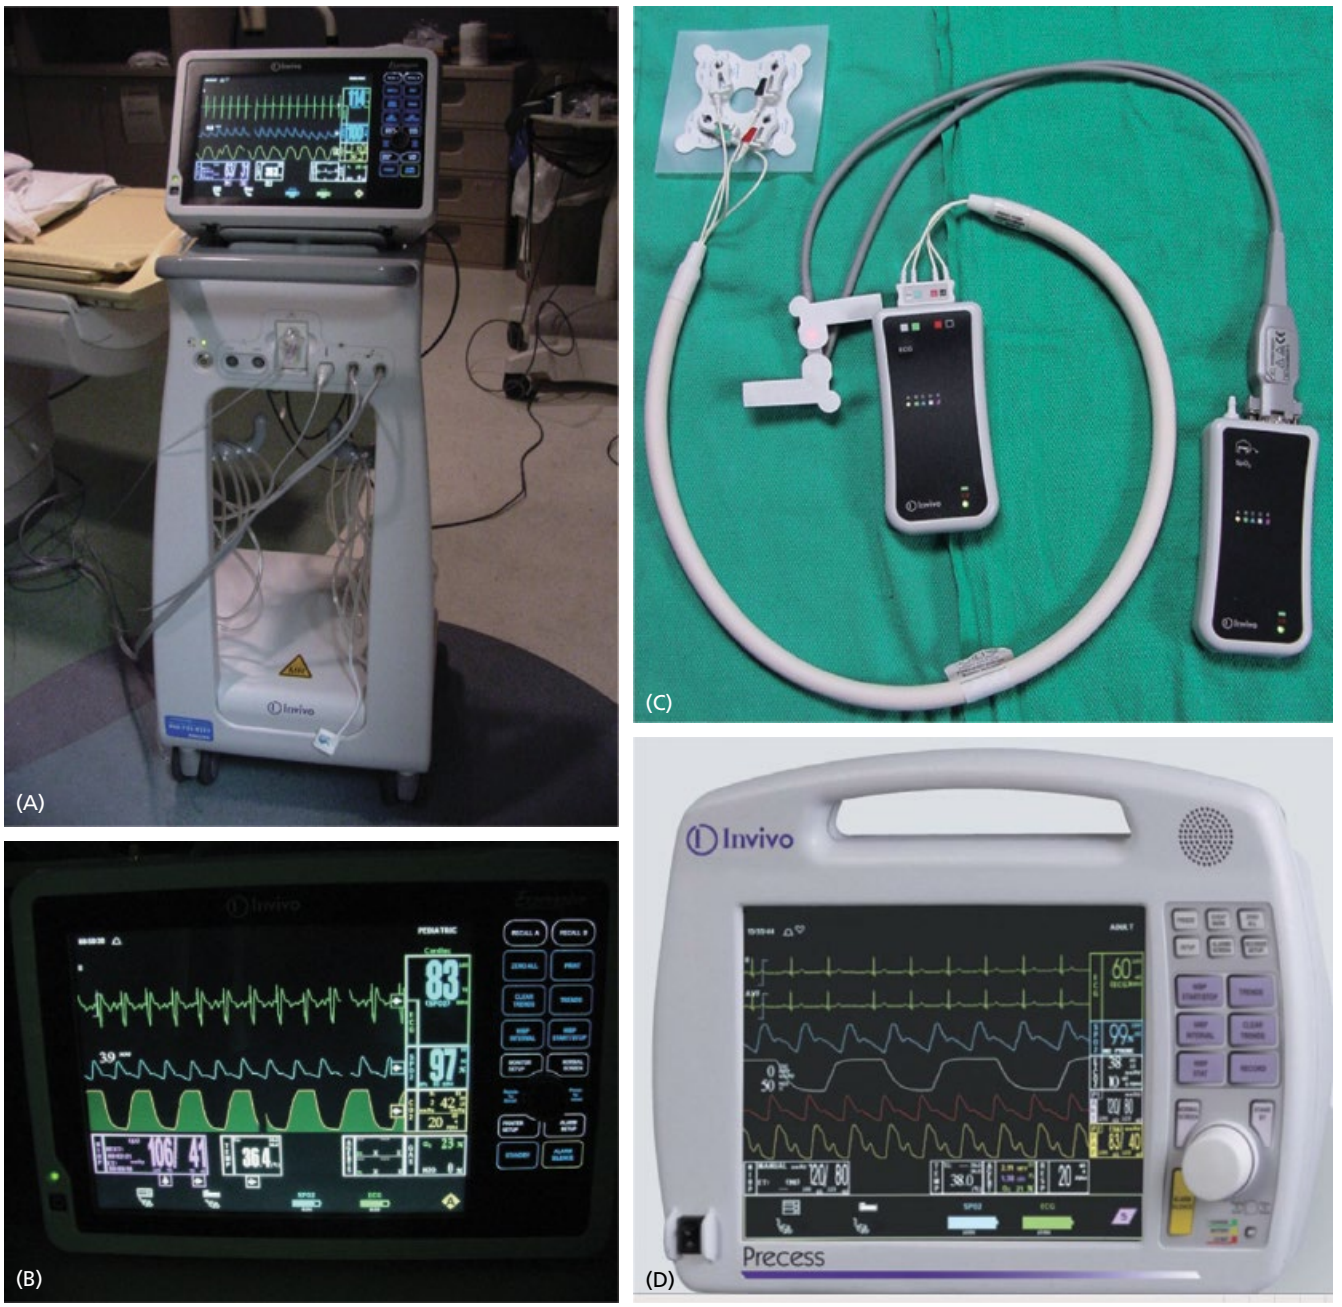

Figure 41.3 (A) Modern MRI-compatible monitor situated in a MRI scanner room. These monitors are capable of monitoring ECG, SpO_2, oscillometric blood pressure, end-tidal CO_2 via a nasal cannula, endotracheal tube, or laryngeal mask airway, anesthetic gases, temperature, and two invasive blood pressures. supplemental oxygen and to monitor end-tidal CO_2 to detect airway obstruction and to ensure optimal ventilation, is important.

Despite the advancing technology in physiological monitors and anesthesia equipment, the MRI environment continues to pose some limitations for anesthesia care. Surface (skin) temperature monitoring cables are available, but axillary temperature may not be an adequate substitute for rectal or esophageal temperatures. Core temperature monitoring can be accomplished with a FDA-approved physiological device and disposable temperature probes that are MRI conditional and manufactured by Invivo (Orlando, FL, USA) and Philips Healthcare (Andover, MA, USA).

The advent of special MRI-compatible infusion pumps for agents such as propofol allow the pump to be deployed in the scan room itself, with short tubing lengths to allow accurate delivery of the intended drug or fluid dose. These pumps include the MRIdium® (iRadimed Corp., Winter Park, FL, USA) and Medrad Continuum Infusion System® (Warrendale, PA, USA) (Fig. 41.4). These pumps have remote consoles so that the infusion rates can be changed from the MRI control room via wireless communication algorithms. Although some conventional infusion pumps (e.g. Medfusion® 3500 syringe pump, Smiths Medical, Kent, UK) claim safety in an MRI environment beyond specified distances from the magnet, depending on magnet strength, it is not recommended that these devices be used in the scanner room. Besides the MRI safety aspect, the magnetic and radiofrequency fields can cause pump malfunction in standard systems. An alternative is to utilize standard infusion pumps just outside the door of the scanner room, with multiple lengths of infusion tubing threaded under the door, reaching inside the bore of the scanner to the patient. This is commonly used for patients receiving vasoactive infusions requiring very accurate microinfusion pumps. Problems with this approach include increased resistance through the long tubing causing pump malfunction.

The magnetic field may also affect the ECG. The changes in the T wave are not due to biological effects of the magnetic field but rather to superimposed induced voltages. This effect of the magnetic field on the T wave is not related to cardiac depolarization, since no changes to the P, Q, R, or S wave have ever been observed in patients exposed to fields up to 2 T. There are no reports of MRI affecting heart rate [63], ECG recording [64], cardiac contractility [65], or blood pressure [66]. One study, however, found that humans exposed to a 2 T magnet for 10 min developed a 17% increase in cardiac cycle length (CCL, the duration of the R-R interval). The CCL reverted to pre-exposure length within 10 min of removing the patient from the magnetic field [67]. The implications of this finding are unclear. While this change in patients with normal hearts may be of no consequence, the implications of this finding in patients with fragile dysrhythmias or sick sinus syndrome have yet to be determined.

Average noise levels of 95 decibels (dB) have been measured in a 1.5 T MRI scanner, comparable to noise levels of very heavy traffic (92 dB) or light road work (90–110 dB). Exposure to this level of noise has not been considered hazardous if limited to less than 2 h per day [68]. There are case reports, however, of both temporary [69] and permanent [70] hearing loss after an MRI scan. Magnets of 3 T offer the advantage of less image degradation and improved neuro- and musculoskeletal imaging. However, as the field strength increases, so does the noise [71]. In fact, the peak sound pressure level of a 3 T magnet exceeds 99 dB, the level approved by the International Electrotechnical Commission. Ear protection is required of all

Figure 41.4 (A) MRI-compatible infusion pump in the scan room, with propofol infusing in a 7 kg infant. (B) Remote wireless display and controller.

patients undergoing MRI studies for research purposes [37]. Earplugs or MRI-compatible headphones are strongly encouraged for all patients and personnel (family members included) who remain in the 3 T magnet during imaging. fMRI provides additional challenges in the 3 T environment: the noise of the 3 T magnet can interfere with the acoustic stimulation generated for purposes of obtaining the fMRI [72,73].

Although studies in mice [74] and dogs [75] suggest that exposure to magnetic fields may increase body temperature, it is unlikely that static magnetic fields up to 1.5 T have any effect on core body temperature in adult humans [76]. This may be of greater concern in infants and small children, for example in cardiac MRI studies, which require a long time for the procedure [77]. The specific absorption rate (SAR) is measured in watts per kilogram and is used to follow the effects of RF heating. The FDA allows a SAR of 0.4 W/kg averaged over the whole body [78]. *Ex vivo* exposure of large metal prostheses to fields over six times that experienced in MRI have not revealed any appreciable heating [79]. So far, there has been no conclusive evidence that RF is a significant clinical issue in magnets up to 3 T. Conversely, the need for a cool room to ensure functioning of the MRI scanner, and the lack of MRI-compatible forced-air warming systems, combined with the frequent need for small infants to undergo MRI scanning, often results in hypothermia. Usually, the best prevention is to swaddle the infant in warmed blankets before the procedure to minimize heat loss, and utilize a condenser humidifier if an endotracheal tube or laryngeal mask airway (LMA_ is used to manage the airway.

Intravenous gadopentetate dimeglumine (gadolinium (e.g. Magnevist®)) is used to enhance MRI images. With an elimination half-life of 1.3–1.6 h, gadolinium is excreted via the kidneys after forming a complex with chelating agents [80]. Adults and children have similar elimination half-lives, with 95% excreted within 72 h [81]. Because gadolinium does not contain iodine, it does not produce an osmotic load [82]. Important warnings from the FDA suggest that patients with advanced kidney failure are at risk of developing nephrogenic systemic fibrosis or nephrogenic fibrosing dermopathy after gadolinium-based MR contrast agents. The FDA first notified healthcare professionals and the public about this risk in June 2006. The ASA MRI Advisory Panel concluded that anesthesiologists should not administer gadolinium to patients with acute or severe renal insufficiency because of the elevated risk of nephrogenic systemic fibrosis. Rather, the need for and actual administration of gadolinium contrast in this patient group should be the responsibility of the radiologist, nephrologist, and other appropriate consultants [37]. Newer forms of gadolinium-based contrast agents (gadoteridol (e.g. ProHance®), gadobutrol (e.g. Gadavist®), gadoterate meglumine (e.g. Dotarem®)), have chemical structures (macrocylic versus open chain) that minimize the likelihood of dissociation of the gadolinium from its chelate to become toxic-free gadolinium, the cause of the nephrogenic systemic fibrosis [83].

KEY POINTS: DIAGNOSTIC RADIOLOGY

- It is important to remember that the magnet is always on and the dangers of the electromagnetic field are always present
- Portable equipment to be brought into the magnet room (zone IV) should be identified with a green square "MRI safe" or yellow triangle "MRI conditional" label
- The American College of Radiology recommends that the MRI suite be divided into four zones with increasing safety and access requirements as patients, staff, and equipment move closer to the scanner
- Core temperature monitoring can be accomplished with a FDA-approved physiological device and disposable temperature probes that are MRI conditional
- Cardiac pacemakers present a special hazard in and around the MRI scanner, especially in patients who are pacemaker dependent

Interventional radiology and angiography

Interventional techniques include non-vascular and vascular intervention [78]. Embolization and sclerotherapy are utilized for treating vascular malformations, aneurysms, fistulas, and hemorrhage as well as accomplishing renal ablation and presurgical embolization of hypervascular masses. Percutaneous transluminal angioplasty and fibrinolytic therapy are emerging techniques in pediatric institutions. Even in the smallest babies, great success is being reported, and the important contribution that adequate sedation and analgesia can make to ultimate outcome has been recognized [84,85]

Vascular malformations are congenital aberrant connections between blood vessels and may be composed of lymphatic, arterial, and venous connections. These lesions, present at birth, are often discrete and not clearly visible, although they may expand rapidly, growing with the child (Fig. 41.5). This rapid proliferative phase may occur in response to hormonal changes (pregnancy, puberty), trauma, or other stimuli [86]. Moreover, they may be high-flow or low-flow lesions, depending on which vessels are involved. High-flow lesions include arteriovenous fistulas, some large hemangiomas, and arteriovenous malformations. High-output cardiac failure and congestive heart failure with possible pulmonary edema should be anticipated especially with high-flow lesions. Low-flow lesions consist of venous, intramuscular venous, and lymphatic malformations. Careful planning is essential in the management of these patients as well as for unanticipated emergencies. Vein of Galen aneurysmal malformations (VGAMs) constitute 1% of all intracranial vascular malformations [87]. This lesion is actually a cerebral arteriovenous fistula of the median prosencephalic vein that fails to regress during fetal life. It usually has multiple arterial feeder vessels, and drains via the straight sinus or persistant falcine sinus (Fig. 41.6) [88,89]. Anesthetic management of this challenging congenital anomaly requires familiarity with the nature and technical demands of the interventional radiology procedure, along with the underlying anatomical and physiological challenges and associated risks. Cardiac failure occurs in these patients as the large flow volume of the VGAM shunt is returned to the right atrium and pulmonary circulation with pulmonary vasoconstriction and pulmonary hypertension resulting in right ventricle failure. Early identification and staged embolization of the feeding arteries and draining veins may reduce blood flow and lead to a greater survival

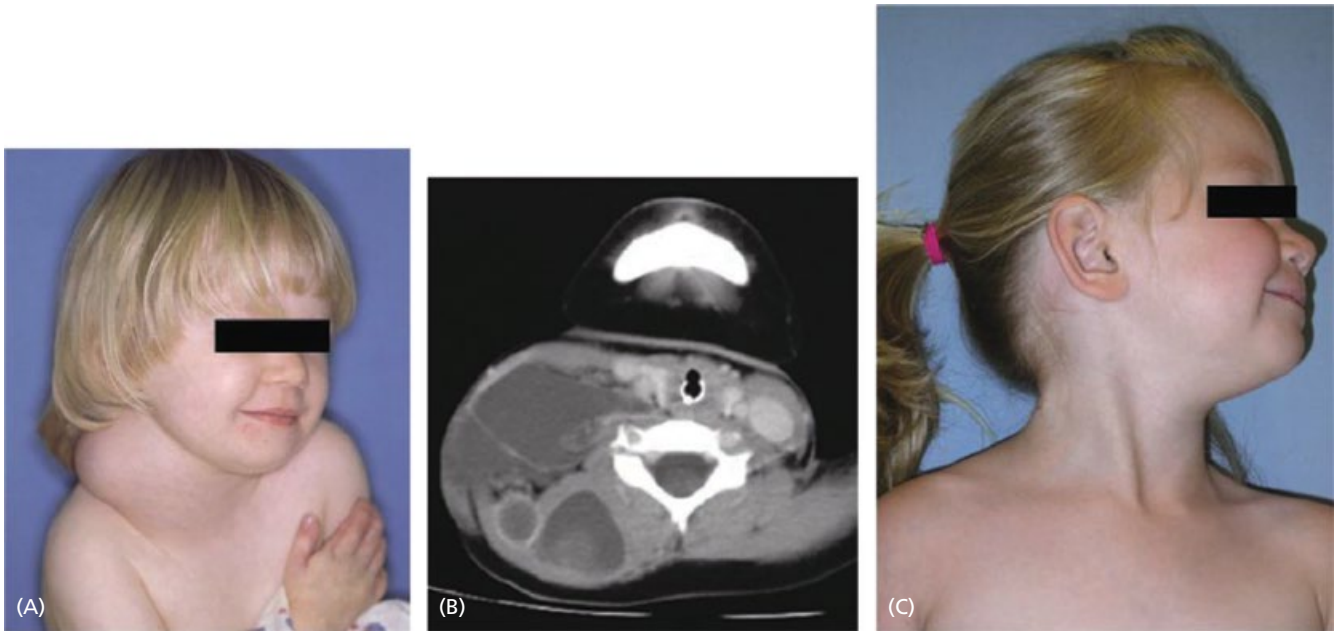

Figure 41.5 Macrocystic lymphatic malformation of the neck and right upper extremity, treated with direct injection of ethanol and then four sessions of OK-432 injection. The ethanol injections were ineffective, but the OK-432 injections resulted in complete regression of the mass. (A) Clinical photograph before OK-432 sclerotherapy showing a large focal right neck mass. (B) Axial CT scan after intravenous contrast medium injection showing macrocysts in the right neck. The thick-walled cyst was previously injected with ethanol. (C) Clinical photograph taken 1 year after four injections of OK-432 showing complete regression of the right neck mass. *Source:* Reproduced from Burrows and Mason [309] with permission of Elsevier.

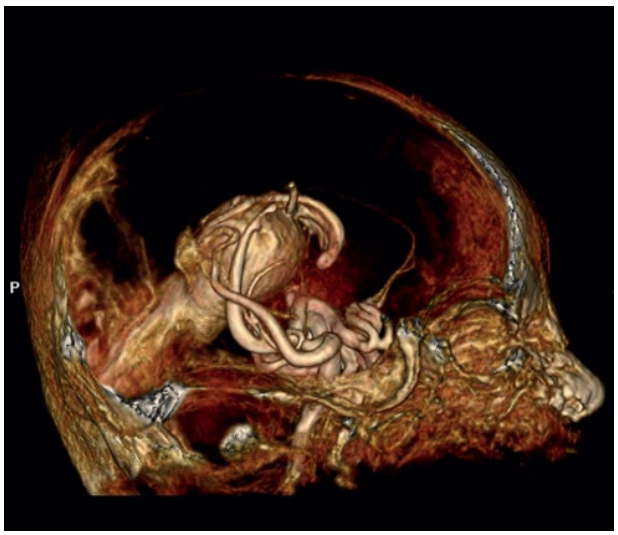

Figure 41.6 MRI angiography 3D reconstruction of a very large Vein of Galen aneurysmal malformation located in the pineal region with aneurysmal dilation. It receives blood predominantly from the vertebral arteries although some anterior supply is also suspected. Drainage is via the straight sinus to the torcula and bilaterally to the internal jugular veins. *Source:* Courtesy of A. Prof Frank Gaillard, Radiopaedia.org, rID: 22778.

rate in these patients [90]. Anesthetic management must address this complex pathophysiology and be tailored to the severity of heart failure and pulmonary hypertension [91]. The most critically ill of these patients are neonates receiving substantial ventilatory support, in addition to inotropic support and inhaled nitric oxide. Right-to-left shunting via a patent ductus arteriosus and patent foramen ovale is common, patients are often cyanotic, and injection of embolic material may traverse the malformation and reach the right ventricle, worsening the pathophysiology. Often several staged embolization procedures are needed to reduce the level of shunting and stabilize the patient. A recent systematic review and meta-analysis of VGAM endovascular embolization documented 34 published studies involving 667 patients [92]. Forty-four percent of the patients were neonates, and 41% were infants 1 month to 2 years of age. Complete occlusion was obtained in 57%, partial occlusion in 43%, and mortality rate was 12%; causes included intractable heart failure, neurological complications, and technical problems. The overall complication rate for cerebral hemorrhage and venous thrombosis was lowest with three or more staged embolizations (42% versus 59% with a single embolization). This review underscores the complex nature of the VGAM treatment paradigm and the need for thorough multidisciplinary planning in the approach to these challenging patients.

Because vascular malformations enlarge over time, even asymptomatic lesions may require intervention. Symptomatic patients may suffer from pain, tissue ulceration, disfigurement, airway or cardiovascular compromise, impairment of limb function, coagulopathy, claudication, hemorrhage, and progressive nerve degeneration or palsy. Because large vascular lesions require multiple embolizations, parents and patients are often comforted by seeing familiar faces, another benefit of having a team of anesthesiologists staffing the radiology suites. Sequential vascular embolization can be used as a bridge to surgical resection.

Large hemangiomas may be associated with the coagulopathy of the Kasabach–Merritt syndrome. In this condition, the hemangioma traps and destroys platelets and other coagulation factors, resulting in thrombocytopenia and an increased risk of bleeding. As the hemangioma involutes, the coagulation status improves [93]. A condition described as systemic intravascular coagulation can occur after the embolization of extensive vascular malformations. This condition is marked

by an elevated prothrombin time with a decrease in coagulation factors and platelets.

When embolizing vascular malformations, radiologists often aim to cut off not only the feeding vessels but also the central confluence (nidus) where much of the arterial shunting occurs. Embolic agents include stainless steel mini-coils, absorbable gelatin pledgets and powder, detachable silicone balloons, polyvinyl alcohol foam, cyanoacrylate glue, and ethanol. The choice of agent depends on the clinical situation and the size of the blood vessel. When permanent occlusion is the goal, polyvinyl alcohol foam and ethanol are often employed. Both occlude at the level of the arterioles and capillaries. Medium to small-sized arteries may be occluded with coils, which are the equivalent of surgical ligation. Particularly in trauma situations, when only temporary (days) occlusion is the goal, absorbable gelatin pledgets or powder are used [94].

Absolute ethanol is injected in vascular malformations to promote sclerosis. Sclerotherapy or embolization with absolute (99.9%) ethanol increases the risk of developing a post-procedure coagulopathy [95] marked by positive d-dimers, elevated prothrombin time, and decreased platelets. Ethanol causes thrombosis because it injures the vascular endothelium [96]; it also denatures blood proteins. Extensive ethanol injections can cause hematuria and urinary catheters should be inserted to monitor urine output, diuresis, and hematuria. Liberal intravenous fluid replacement will ensure that the hematuria clears prior to discharge. Ethanol can cause neuropathy and tissue necrosis if not injected selectively. Finally, ethanol can also produce significant serum alcohol levels (Fig. 41.7). Up to 1 mL/kg of ethanol can be administered; blood ethanol levels have been greater than the intoxication level of 0.008 mg/dL [97]. Patients with high serum ethanol levels are either sedated or extremely agitated, depending on their individual response to intoxication.

Embolization or balloon occlusion of arteriovenous malformations (AVMs), vascular tumors, intracranial aneurysms, and fistulas carries considerable risk of catastrophic results. Such risks include a sudden intracranial hemorrhage, acute cerebral ischemia, or catheter or balloon migration. If sedated, the patient may require urgent airway management. Very long cases require a urinary catheter, especially if contrast material is utilized. AVMs involving the head and neck frequently require cannulation of the external carotid artery branches and the thyrocervical trunk. All patients scheduled for embolization should be typed and cross-matched for blood. Those patients who undergo embolization of AVMs of the head and neck are at risk for stroke, cranial nerve palsies, skin necrosis, blindness, infection, and pulmonary embolism [98]. It is important to assess and document the full return of baseline neurological status after the patient is extubated.

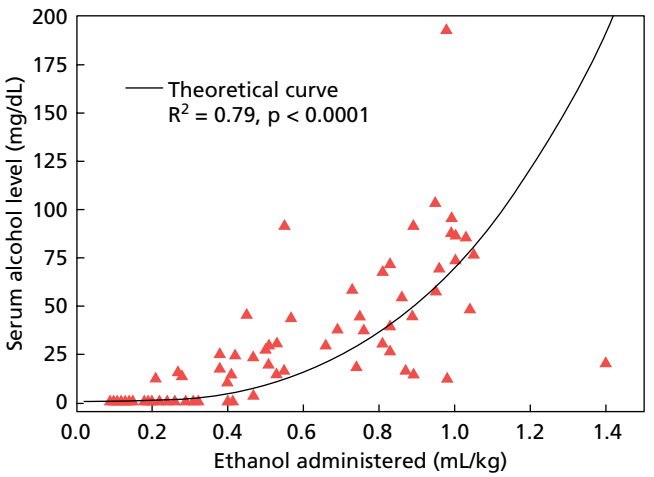

Figure 41.7 Graph showing the positive relationship between serum ethanol level and amount of ethanol administered. Solid line indicates the theoretical curve, where *x* is the amount of ethanol administered, and *y* is the predicted serum ethanol level. Triangles represent empirical values. *Source:* Reproduced from Mason et al [97] with permission of RSNA.

Recent advances have involved the use of provocative testing during cerebral imaging in order to identify and protect targeted areas of the brain prior to embolization. Provocative or superselective Wada testing (intracarotid sodium amobarbital procedure) has become an important part of endovascular management of numerous extracranial and intracranial vascular conditions. It can be used with neurophysiological monitoring in cases in which patient cooperation and steadiness are important [99]. Nevertheless, the value of awake neurological assessment (wake-up test) cannot be underestimated when neurophysiological monitoring responses are equivocal. Barbiturates, etomidate, propofol, and, most recently, dexmedetomidine have been described as agents able to maintain sedation while still preserving the patient's ability to respond [100–105].

Anesthesiologists need to have in-depth understanding of the physiology of the cerebral lesions to be treated, the requirements for successful treatment, and the potential effects of the proposed treatment. Cerebral angiography requires motionlessness as well as exquisite control of ventilation. Anesthetic technique, in choice of agent as well as in control of arterial CO_2 tension, may affect cerebral blood flow and volume and hence the quality of the scan. Cerebral angiography in children may be performed for the diagnosis or follow-up of Moya Moya disease and the anesthetic technique should minimize the risk of transient ischemic attacks and stroke during the procedure [106]. An arterial line for this short procedure is generally not required. Normocapnia is desirable in the vast majority of cases, and any proposed acute hypocapnia should be discussed with the proceduralist. The risk of significant bleeding is rare but adequate intravenous access is prudent. Other considerations include controlled ventilation to facilitate access to and visualization of the vasculature for the radiologist. In the event of vasospasm or difficult access, the radiologist's direct administration of nitroglycerin in small doses (25–50 μg) may facilitate visualization and access. Occlusion of the venous portion of the AVM without complete occlusion of the arterial inflow vessels could result in acute swelling and bleeding. Vascularity reduction through occlusion of major feeder vessels is the goal of embolizing large AVMs prior to planned surgical excision. This may be accomplished as a staged procedure over several days, involving repeat anesthetics.

Angiographic imaging may be enhanced through the use of glucagon. Glucagon is effective for digital subtraction angiography, visceral angiography, and selective arterial injection in the viscera. When needed, glucagon is administered in divided doses of 0.25 mg to a maximum of 1.0 mg intravenously. Risks include glucagon-induced hyperglycemia, vomiting (particularly when given rapidly), gastric hypotonia,

and provocation signs of pheochromocytoma [107–109]. Children who receive glucagon should routinely receive prophylactic antiemetics.

Ultrasound-directed procedures

Needle biopsies and drainage procedures (kidney, liver, lung, muscle, unknown mass, unknown fluid) are directed with ultrasound guidance. Ultrasound is useful for placement of difficult central catheters and peripherally inserted central catheters. The requirement for general anesthesia versus sedation for ultrasound-guided procedures depends in part on the duration of the procedure, the location involved, the risks associated with the procedure, and any procedural requirements. The need for controlled ventilation with breath holding may require an endotracheal tube and general anesthesia. Associated secondary effects of the end-organ disease must be kept in mind in the overall anesthetic care plan.

Biopsies of anterior mediastinal masses pose serious challenges because of the risk of cardiopulmonary catastrophes [110]. Maintenance of spontaneous breathing is generally recommended because positive pressure ventilation can compromise blood flow in the pulmonary vessels which are already narrowed by the tumor mass. The supine position can exacerbate the changes in hemodynamic and respiratory physiology. Turning the patient prone or lateral may alleviate the obstructive symptoms or cardiac compromise. An otolaryngologist with a rigid bronchoscope or, in some cases, the ability to initiate cardiopulmonary bypass, should confirm ability to maintain spontaneous breathing before the procedure. Many anesthetic strategies can facilitate this goal, including inhalation techniques with potent volatile agents or intravenous anesthetic techniques such as use of ketamine/dexmedetomidine [111]. Regardless of the choice, an inadequate anesthetic with subsequent patient movement risks accidental puncture of the internal mammary vessels that can result in a life-threatening hemorrhage [112,113]. See Chapter 26 for further discussion about anterior mediastinal masses.

KEY POINTS: INTERVENTIONAL RADIOLOGY AND ANGIOGRAPHY

- Anesthetic management of challenging vascular malformations requires familiarity with the nature and technical demands of the interventional radiology procedure, along with the challenges and associated unique risks of the underlying disorder
- VGAM may result in severe heart failure and pulmonary hypertension in the neonate, and requires significant resources and multidisciplinary planning for staged procedures that can optimize outcomes
- Large hemangiomas may be associated with the coagulopathy of the Kasabach–Merritt syndrome
- Anesthesia for ultrasound-guided biopsies of anterior mediastinal masses is usually designed to preserve spontaneous breathing and may be accomplished with volatile or intravenous anesthetics including combining the analgesic effect of ketamine with the sedative effect of dexmedetomidine

Nuclear medicine

Nuclear medicine is one of the oldest functional imaging disciplines. These scans are useful for identification of epileptic foci in refractory epilepsy, evaluation of cerebrovascular (Moya Moya) disease, and the evaluation of cognitive and behavior disorders [114]. Anesthesiologists become involved when the child's medical history suggests that procedural sedation would not be appropriate. In order to complete these scans, the child must remain motionless for at least 1 h.

The two most common nuclear medicine studies that require the administration of an anesthetic are single photon emission computed tomography (SPECT) scans and positron emission tomography (PET) scans. SPECT scans use single-photon γ-emitting radioisotopes and rotating gamma cameras to produce 3D brain images. SPECT scans involve the use of radiolabeled technetium-99 (half-life 6 h), which has a high rate of first-pass extraction as well as intracellular trapping in proportion to regional cerebral blood flow [115]. This scan is ideal when seeking seizure foci, and often precedes surgical resection of the identified focus. The technetium radionuclide is ideal because it remains intracellular and can be visualized on the scan hours after a seizure has occurred. Ideally, the child should be scanned within 1–6 h of the seizure. The radionuclides are physiologically harmless and non-allergenic. Caretakers should, however, wear gloves to minimize contact with radiation-containing secretions.

PET scans use PET and radionuclide tracers of metabolic activity such as oxygen or glucose metabolism [116,117]. Unlike SPECT scans, PET scans should be performed during the seizure itself. Because of the short half-life of the glucose tracer (110 min), the scan is best completed during the seizure or within 1 h thereafter.

In addition to using PET scans for diagnostic purposes, nuclear imaging is also being used as an intraoperative adjunct to identify neoplasms, in much the same way that MRI has been incorporated into the surgical suite. Surgical suites are currently being built that are equipped with PET scanners [118]. The anesthetic implications of the nuclear medicine environment involve largely the safety precautions that must be implemented with respect to the radioactive nucleide. All bodily fluids (includes saliva, sweat, and urine) must be handled with radiation safety precautions.

Metaiodobenzyl guanidine (MIBG) is a compound that can be combined with radioactive iodine (^{131}I) to deliver targeted radiotherapy to treat high-risk neuroblastoma. MIBG is a compound that is absorbed by neuroblastoma cells; when combined with ^{131}I it provides targeted radiation to neuroblastoma cells with much less risk to normal, adjacent tissue.

Magnetoencephalography

Magnetoencephalography (MEG) is a neuroimaging modality that uses extremely sensitive magnetometers to record and localize electrical activity of the brain [119,120]. The signals are produced by superconducting quantum interference devices and amplified, and are used most often in children to localize seizure foci in preparation for epilepsy surgery. MEG is a functional modality utilized in the awake patient whenever possible, but some younger children will require sedation to hold still and tolerate positioning in the head coil for the procedure. There is a paucity of published reports about sedation techniques for MEG in children; but a regimen that

has been effective at Texas Children's Hospital is dexmedetomidine 1 μg/kg load over 10 min, and infusion of 0.5–2 μg/kg/h for the scan, which preserves the MEG signals and allows successful completion of a diagnostic-quality study in young children in most all cases. Opioid supplementation with fentanyl or remifentanil is frequently utilized; propofol is to be avoided. The scans require 1.5–2 h, and the patients are prone to seizures; if seizures are brief they may occur without airway compromise, but can be treated with midazolam if necessary.

Radiation oncology

Radiation oncologists use ionizing photons to destroy lymphomas, acute leukemias, Wilms tumor, retinoblastomas, and tumors of the central nervous system in children. Repeat sessions are typical, requiring reliable motionlessness in order to precisely aim the beam at malignant cells while sparing healthy cells. A planning session in a simulator is often scheduled prior to the initiation of radiotherapy so that fields to be irradiated can be plotted and marked.

Radiotherapy

Radiotherapy is usually very brief and non-painful. The key issue is the anesthesiologist's limited access to the patient. Remote video monitoring as well as ECG and pulse oximeter use is crucial. Two, or in some locations, three video cameras are used to look at the monitors, the chest, and the face of the patient. Central access in young children helps immensely. It is important to remember that babies undergoing radiotherapy following a prolonged fast are at risk for hypoglycemia; delayed awakening or tremulousness should prompt a glucose determination.

Fractionated radiotherapy divides the total radiotherapy course into discrete daily sessions, allowing normal tissue repair between sessions while the tumor burden is lessened or destroyed. *Hyperfractionated* or multiple session daily radiotherapy is a modality reported primarily in adults for head and neck cancer. The rationale for twice-daily fractionation in children is that fractionation to growing bone in rats reduces the growth deficit by 25–30%; the hope is that other normal tissues may be similarly spared during growth [121,122]. While one successful approach has been to give infants an initial formula feeding 6 h before their first treatment and keep them NPO until recovery from their second anesthetic 6 h after the first [123], with the current liberalization of NPO guidelines we prefer to give children clear liquids during their recovery from the first anesthetic and keep them NPO thereafter for 4 h prior to the second anesthetic.

Stereotactic radiosurgery

Stereotactic radiosurgery (gamma knife) is a major advance in the treatment of selected intracranial arteriovenous malformations and tumors in children [124]. A focused, single, large fraction of radiation is used instead of smaller, daily fractions. Stereotactic radiosurgery uses relatively weak-intensity γ-rays produced by 201 cobalt-60 (^{60}Co) sources which intersect at a single point where all 201 beams converge to destroy tumors, vascular malformations, or abnormal tissue sites within the brain. Normal brain tissue surrounding the abnormality is therefore relatively protected from radiation effects. For optimal results, tumor volume ideally has to be small (≤14 cm^3) [125].

The stereotactic procedure begins with a CT scan or MRI, followed by computer calculations for dose and the 3D coordinates for the beam. The child is placed in a stereotactic headframe which is screwed into the cranium. Most adults are able to tolerate the entire procedure with local anesthesia or sedation. Adults and older children who tolerate this procedure with sedation alone may vomit as a result of the anxiety, the headache, or the location of the tumor itself. Once the calculations are complete, the patient is transferred to the radiosurgery suite. Following the irradiation, the patient is allowed to emerge from the anesthetic [124]. The most common perioperative problem is nausea and vomiting, probably due to radiation sensitivity of the chemoreceptor trigger zone. Because the headframe is heavy and cumbersome, it is difficult for the vomiting patient to turn their head in order to protect their airway. Children (including most adolescents) typically require a general anesthetic. General anesthesia with tracheal intubation is induced prior to placement of the headframe. The key for removal of the headframe is taped to the frame itself. A nasogastric tube is placed for the day's anesthetic.

Stereotactic radiotherapy

Stereotactic radiotherapy is more precise localization of the fractionated radiation dose over the same duration of time as conventional radiotherapy, with the adjunctive use of a headframe. Considerations for the headframe include ease of application, reliability, ability to deliver supplemental oxygen and support the airway with a facemask if needed, and rapid removal of the facial restraint should it become necessary.

Total body irradiation

Total body irradiation (TBI) is generally performed twice a day over a 6-week period, usually in preparation for a bone marrow transplant. As these patients progress with their TBI treatment and become more immunocompromised, there is an increased risk of acquiring an illness during the course of treatment. Vomiting, respiratory illness, poor nutrition, or hypovolemia are all possible. Cancellation of a TBI treatment because of an associated illness is discouraged because it disrupts the course of treatment and could compromise their overall prognosis. Ondansetron in combination with dexamethasone or propofol has been found to be beneficial as a prophylactic for nausea and vomiting in children undergoing TBI and should be considered for first-line antiemetic therapy [126]. Although anesthesiologists are wary of the risks of aspiration, both sedation and general endotracheal anesthesia have been found to decrease the incidence of vomiting with TBI [127,128].

Proton radiotherapy is a newer modality thath can limit irradiation of normal tissues, because the proton is a charged particle and the radiation dose can be directed to a smaller area and there is a minimal exit radiation dose. As of 2017, there are approximately 60 of these centers in operation worldwide, including 20 in the USA [129]. Pediatric cancers amenable to treatment with this modality include intracranial tumors, sarcomas, ependymoma, neuroblastoma, and retinoblastoma [130]. Treatments commonly require 30–90 min, and children age 4 years and under usually require anesthesia or sedation. A survey of 17 centers documented that total IV

anesthesia with propofol, with nasal cannula, or facemask was utilized for 57% of anesthetics, general anesthesia with sevoflurane and LMA in 36%, and intubated general anesthesia in 7%. Of note, 43% of proton therapy centers had no anesthesia waste gas evacuation capability [131]. Complicating delivery of anesthesia care in this population is that many proton radiation centers are freestanding facilities, often at some distance from the hospital or surgery centers.

Dental and oral surgery

The high prevalence of pediatric dental disease, breadth of options available for difficult child behavior, and parental expectations will generate and maintain the need for sedation/anesthesia services in children who presented for dental procedures [132,133]. Oral sedation ± nitrous oxide inhalation have been the mainstays of pediatric dental sedation for many years; however, recently parents and practitioners have become accustomed to outpatient general anesthesia for children [134]. Moderate or deep sedation or general anesthesia are required for patients who have special needs, or when the dental or surgical requirements become more complex [135].

Midazolam alone may not provide sufficient sedation and the addition of an opioid can increase the risk of respiratory depression or vomiting. Dexmedetomidine appears to provide a good alternative for successful dental sedation due its analgesic effects, antisialogog properties, anxiolytic and sympatholytic effects, and lack of respiratory depression [136].

Recent reports have pointed to the highest adverse event risk group as being children less than 6 years of age and being cared for by a general dentist [137,138]. No single sedative was implicated in these reports. These findings have led to increased scrutiny of pediatric dental sedation by the public and the medical community. Each US state has unique requirements for a dentist to perform procedural sedation, with considerable variations among states regarding training standards, education, and credentials.

The equipment requirements for dental surgery in NORA locations are identical to those for the operating room. Supplies, drugs, and equipment necessary for the administration of anesthesia and emergency management should be immediately available in a designated cart in these locations. The ASA issued a statement on NORA locations in October 2003, which was last amended in October 2013 [139]. If a central fresh gas supply is not available, portable cylinders can be used. Additional considerations for the medically complex patient undergoing dental rehabilitation are necessary, e.g. congenital heart disease patients before surgery or transplant, patients with craniofacial anomalies and difficult airways, or patients with complex genetic or metabolic syndromes. Adequate preoperative planning, equipment and drugs for emergencies, and plans for postoperative admission are often necessary in NORA locations.

Clinic and office procedures

Endoscopy

Gastrointestinal endoscopy constitutes the bulk of procedures performed by a pediatric gastroenterologist [140]. Depending upon the patient and the type of procedure contemplated (therapeutic versus diagnostic), children may require no sedation, minimal to moderately deep sedation, or general anesthesia. Over the past 20 years, the volume of endoscopic procedures has increased by 2–4-fold in the adult community, and has most likely increased at a similar rate in children [141].

Although some recommend that deep sedation be limited to anesthesiologist delivery only [142–148], gastroenterologists have reported that they too are able to safely administer and/or supervise sedation [149]. The ASA's statement on the safe use of propofol makes the point that when it is not possible to have an anesthesiologist involved in the care of a patient then "non-anesthesia personnel who administer propofol should be qualified to rescue patients whose level of sedation becomes deeper than initially intended and who enter, if briefly, a state of general anesthesia" [150]. It is estimated that one-quarter of all adult endoscopies are performed with propofol sedation [141], although there is a wide variation in pediatric practice [151]. Children with more complex medical problems, anticipated airway difficulties, morbid obesity, or behavioral problems can undergo their procedure in the operating room. Regardless of the site of the procedure, all patients scheduled for sedation for endoscopy should be evaluated beforehand to confirm that they are appropriate candidates. In addition, the anesthetic technique depends on the procedure, the patient, and the skill of the endoscopist as well as the limitations and capabilities of the endoscopy suite.

Esophagogastroduodenoscopy

Access to the airway is limited once a transoral endoscope is in place. It is important to maintain spontaneous ventilation during deep sedation because any airway intervention needed typically requires the removal of the endoscope. The two most stimulating portions of esophagogastroduodenoscopy (EGD) are transoral and transpyloric passage of the endoscope. A smooth endoscope insertion can be aided by topical spray of local anesthesia to the oropharynx to help eliminate coughing and gagging.

Currently there is no standard airway technique that can offer the best balance of minimizing respiratory complications and maximizing efficiency during EGD. Insufflation of sevoflurane through a nasopharyngeal airway has been associated with an increase in airway complications without benefitting efficiency [152]. Maintenance of anesthesia with propofol using the native airway was associated with a higher incidence of respiratory complications compared with techniques including endotracheal intubation, without any improvement in efficiency [153]. Recent studies have shown that using propofol without airway intervention during EGD is feasible, without increasing the risk of respiratory complications [154]. LMAs also appear to be an acceptable and safe airway technique for otherwise healthy children undergoing routine EGD [155].

Most endoscopy-related respiratory complications occur during EGD, especially in infants and younger children, when compared with colonoscopy. A combination of factors, including the large size of the endoscope, partial airway obstruction, and abdominal distension due to air introduced into the stomach as well as sedation, may contribute, leading to hypoventilation. This has led several groups to select 6 months of age as the time prior to which general anesthesia with endotracheal

intubation is required for the procedure, due to the higher respiratory complication rate in this age group [145,147]. Targeted controlled intravenous infusions of propofol, with or without dexmedetomidine, have been used effectively in children (3–10 years) who underwent EGD with spontaneous ventilation without endotracheal intubation. In the presence of dexmedetomidine, the dose–response curve of propofol appeared unaffected [156].

Colonoscopy

Access to the airway is unimpeded during a colonoscopy. Deep sedation can be achieved more readily, and if respiratory problems occur, airway interventions are straightforward to manage. Patients undergoing colonoscopy will experience increased stimulation during certain parts of the procedure such as traversing the colon to the splenic flexure and the ileocecal valve. At times, abdominal pressure is applied to help advance the colonoscope. The depth of the anesthetic should be adjusted accordingly.

Endoscopic retrograde cannulation of the pancreas

Many institutions report success of procedural sedation in pediatric patients undergoing endoscopic retrograde cannulation of the pancreas [157,158]. However, general anesthesia with endotracheal intubation may make the procedure easier to perform, especially if it is of long duration, the patient has significant co-morbid diseases, or the procedure is performed with the patient in the prone position.

KEY POINTS: CLINIC AND OFFICE PROCEDURES

- Currently, there is no standard airway technique that can offer the best balance of minimizing respiratory complications and maximizing efficiency during EGD
- Most endoscopy-related respiratory complications occur during EGD when compared with colonoscopy, especially in infants and younger children
- The laryngeal mask airway appears to be an acceptable and safe airway technique for otherwise healthy children undergoing routine EGD

Anesthetic management of NORA procedures

In the several decades since the initial guidelines for pediatric sedation outside the operating room [159], not only have numerous organizations taken it upon themselves to fashion standards of practice, they have variously acknowledged and in many cases overtly approved the practice of non-anesthesiologist-administered sedation and analgesia medications, creating their own standards, guidelines, and policy statements, sometimes reinforced by citing relevant peer-reviewed literature. Furthermore, the regulatory environment is different for every state in the USA (Table 41.5). As experts in the continuum of sedation and anesthesiology, we sometimes find ourselves in a cognitively, clinically, and diplomatically tense and uncertain situation, which ultimately can only be answered through education, collaboration, and consistency of policy at least at the institutional level. The breadth of these regulations, nevertheless, is staggering.

Standards

Until the 1990s, sedation in the USA was limited predominantly to delivery by anesthesiologists, radiologists, dental medicine, and emergency medicine physicians. It now encompasses other specialties which include gastroenterology, intensive care medicine, hospital medicine, pediatric medicine, and nursing [160–162]. Worldwide, however, the majority of pediatric sedation is still administered by anesthesiologists. The challenge facing sedation care providers is the lack of consensus on sedation standards with respect to skills, training, qualifications, sedatives, physiological monitoring, NPO guidelines, routes of delivery, and emergency preparedness. A global look at sedation guidelines reveals that there is lack of consistency not only between the specialties within a single continent, but also between the continents. Different specialty societies as well as institutions in the USA and worldwide have published guidelines, policies, and recommendations, many of which do not agree [163]. In the USA, in response to the deaths of dental patients after sedation with midazolam, the National Institutes of Health and the American Academy of Pediatrics published two nearly identical consensus documents on sedation in 1985 [164–167]. Depth of sedation was introduced as a continuum, consisting of three levels: conscious sedation, deep sedation, and general anesthesia. Recently, the terminology has evolved to include four depths (minimal, moderate, deep sedation, and general anesthesia) and to eliminate the term "conscious sedation" [4,168,169]. This terminology has been adopted by the Joint Commission and specialty societies worldwide. Limitations of the sedation continuum have been recognized, particularly the subjective determinants of using patient response to verbal and tactile stimulation in order to determine the sedation depth. Future efforts should be made to identify objective criteria in order to determine depth of sedation and, more importantly, the risk of adverse events [170].

Organization

At a minimum, safe patient care requires appropriate anesthesia equipment and monitors and adequate space and experienced ancillary providers who are knowledgeable and facile in providing assistance if needed. Each off-site area has its own needs, goals, and guidelines. It is ideal to designate a team of anesthesiologists committed to providing NORA anesthesia care and troubleshooting the logistical challenges in the various locations. Each member should rotate regularly through the different NORA sites in order to maintain familiarity with the procedures, to foster a relationship with the physicians and ancillary personnel, and to understand the anesthesia demands unique to each site including ongoing advances. Technological advances are expanding in the field of radiology, and complicated imaging studies challenge the anesthesiologist to have an understanding of the unique conditions which the study requires.

GI, gastrointestinal.

In the past, NORA locations were not designed with the anesthesiologist in mind. The need for anesthesia had not been anticipated when off-site locations were planned. It is only within the past few decades that the demand for anesthesia services in these sites has substantially expanded. Thus, most NORA locations have not been configured to support an anesthetic. Ideally, anesthesiologists should be involved in the early stages of site design to ensure that minimum standards for anesthesia delivery are met and to troubleshoot engineering issues and advocate for adequate space for anesthetic induction and emergence [159,171]. Physical plant considerations for MRI site planning have been previously described [160]. When anesthesia services are requested, these sites may not meet minimum standards [161] and will require reengineering to meet minimum requirements of the ASA. The anesthesia machine should be equipped with back-up supplies of E cylinders filled with oxygen and nitrous oxide. If pipeline oxygen is not available, then oxygen should be supplied from H cylinders (6600 L) rather than the smaller E tanks (659 L). For MRI locations in particular, induction of anesthesia or sedation is often best accomplished in an induction area, outside the scanner room, to allow full access to the patient and the use of non-MRI-compatible equipment such as laryngoscopes. Issues such as airway obstruction, emergence, or need for resuscitation are best addressed in such a location.

Scavenging systems should be carefully evaluated in the NORA location. Unlike the operating room, passive scavenging systems may not always be possible. A safe means of active scavenging may be provided by the vacuum at the wall or wall suction canisters. A scavenging system should be dedicated solely to waste gases. Many MRI scanners do not have wall suction because MRI-compatible wall suction is not widely available. If the suction is located outside the MRI suite, then a mouse-sized hole may be created in the suite's wall to allow suction tubing to be passed inside [172]. A standard anesthesia cart at each anesthetizing location should be fully stocked with essential medications, necessary additional equipment, a spare self-inflating (Ambu®) bag, endotracheal tubes, LMAs, suction catheters, intravenous supplies, laryngoscope handles and blades, and a variety of oral and nasopharyngeal airways (Fig. 41.8).

Electrical circuitry and lighting in NORA locations may not be up to operating room standards even if the outlets are grounded and up to hospital grade. Although some NORA locations carry minimal risk of electrical shock or electrocution, these sites do not have line-isolation monitors and will not warn of excess leakage of current. Supplemental lighting for recordkeeping, label verification, establishment of IV access, and visualization of the patient is critical. Even under the best circumstances, for example, lighting is dim in the MRI scanner and monitoring by simple clinical observation can be limited. Video monitoring or hardwiring through reinforced walls can allow remote video display of the patient and physiological monitors within.

A storage area large enough to stock anesthesia equipment and supplies must be easily and quickly accessible. This area

Figure 41.8 MRI-safe anesthesia cart. The contents include nasal airways, oropharyngeal airways, laryngeal mask airways, oxygen nasal cannulas, facemasks, and suction catheters.

should be routinely checked, restocked, and kept locked when anesthesia services are not required. The need for redundancy of non-disposable supplies is a matter of philosophy. Are two laryngoscopes enough, or should there be a third? Is one ECG monitor enough, or should there be a battery-operated monitor for back-up and transport? Drugs should be checked per the usual operating room routine and expired medications replaced. Gas cylinder supplies must be reliable, especially in areas without piped oxygen. A code cart should be conveniently located in an area known to all physicians and ancillary personnel. This cart should be routinely checked and restocked. With ever-larger volumes of patients using these sites, strong consideration should be given to having a difficult airway cart available close by.

Finally, NORA locations are often distant from the operating room. Patients may need to remain anesthetized during transport to or from the NORA location. For these circumstances, assured elevator access with key-controlled emergency over-rides is a must. All anesthesiologists who deliver NORA services should be familiar with their surroundings. Checklists are invaluable to guarantee consistent patient care, anesthesia monitoring, equipment, documentation, and back-up assistance.

Practitioners

Interdisciplinary skepticism is abundant and the need for leadership remains crucial; a director of anesthesia and sedation at a NORA location can orchestrate, facilitate, and coordinate these services as well as educate all clinical stakeholders and the public. Specific guidance is provided in several standards from the ASA, especially the "Statement on Granting Privileges for Administration of Moderate Sedation to Practitioners Who Are Not Anesthesia Professionals" and further in "Continuum of Depth of Sedation: definition of general anesthesia and levels of sedation/analgesia." By being available to answer questions, provide on-site consultation, examine patients, and provide support or emergency airway expertise, the anesthesiologist can also guide a nurse-administered sedation program. Nurses who provide sedation under the supervision of the ordering physician should be Pediatric Advanced Life Support and Basic Life Support

certified. In October 2012, the ASA passed an amendment to the advisory on deep sedation by non-anesthesiologists: "because of the significant risk that patients who receive deep sedation may enter a state of general anesthesia, privileges for deep sedation should be granted only to non-anesthesiologist physicians who are qualified and trained in the medical practice of deep sedation and the recognition of and rescue from general anesthesia." The Joint Commission advocates that anesthesiology departments play a role in the development of training and privileging programs for sedation but they no longer hold the role of being "in charge" of sedation services. The Joint Commission also requires that individuals who administer sedation are able to rescue patients from whatever level of sedation or anesthesia is achieved, *whether intentional or unintentional* [39]. This is the context within which the ASA documents were created. Attention to the sedation continuum and a paean for translating subjective assessments to more consistently measureable physiological endpoints has recently been published [173]. Regardless of the intended level of sedation or route of drug administration, the sedation of a pediatric patient may result in respiratory depression, laryngospasm, impaired airway patency, apnea, and cardiovascular instability (Table 41.6). Sedation-related safety and effectiveness are determined by the circumstances and professional skills rather than by the chosen sedative-specific pharmacological characteristics. Consequently, it is wise to formulate separate recommendations regarding professional skills and competence for different levels of sedation (mild sedation on one hand and moderate to deep sedation on the other hand) [174].

As recommended by the Joint Commission, sedation-related policies and procedures should be part of a quality assurance initiative that should accompany all sedation programs. Ideally, adverse events such as failed or prolonged sedations, paradoxical reactions, hypoxia, emesis, unscheduled admission, and cardiac or respiratory events should be identified and entered into a computerized database. In addition, the NORA nurse should call all patients and families within 24 h in order to follow-up on patient outcome and identify any delayed adverse events.

Scheduling and preparation of patients

Appropriate planning for an anesthetic begins with familiarity with the procedure. The requesting service (e.g. neurology, surgery) orders the procedure and then leaves the logistics of scheduling to the NORA service (e.g. radiology, anesthesiology). Radiologists recognize that the administration of an anesthetic will lengthen their total time commitment to a patient and potentially limit the number of procedures accomplished in a day [175,176]. A well-coordinated system to screen patients on the day of the procedure is important. Experienced personnel, ideally a certified pediatric nurse practitioner, should be designated to take initial vital signs, review recent medical history, begin IV lines if necessary, and familiarize the family with the upcoming procedure including anesthesia.

Screening patients for NORA procedures may be challenging and time consuming. Many children are chronically ill, nutritionally impaired, and medically complicated. These issues must be carefully addressed through attention to the patient's history, physical examination, old medical records, outside consultations, and close communication with other medical colleagues. Several consultants may need to confer in

Table 41.6 Continuum of depth of sedation: definition of general anesthesia and levels of sedation/analgesia*

	Minimal sedation anxiolysis	Moderate sedation/analgesia ("conscious sedation")	Deep sedation/analgesia	General anesthesia
Responsiveness	Normal response to verbal stimulation	Purposeful† response to verbal or tactile stimulation	Purposeful† response following repeated or painful stimulation	Unarousable even with painful stimulus
Airway	Unaffected	No intervention required	Intervention may be required	Intervention often required
Spontaneous ventilation	Unaffected	Adequate	May be inadequate	Frequently inadequate
Cardiovascular function	Unaffected	Usually maintained	Usually maintained	May be impaired

* Monitored anesthesia care does not describe the continuum of depth of sedation, rather it describes "a specific anesthesia service in which an anesthesiologist has been requested to participate in the care of a patient undergoing a diagnostic or therapeutic procedure." Because sedation is a continuum, it is not always possible to predict how an individual patient will respond. Hence, practitioners intending to produce a given level of sedation should be able to rescue patients whose level of sedation becomes deeper than initially intended. Individuals administering moderate sedation/analgesia ("conscious sedation") should be able to rescue patients who enter a state of deep sedation/analgesia, while those administering deep sedation/analgesia should be able to rescue patients who enter a state of general anesthesia.

† Reflex withdrawal from a painful stimulus is NOT considered a purposeful response.

Minimal sedation (anxiolysis) is a drug-induced state during which patients respond normally to verbal commands. Although cognitive function and physical coordination may be impaired, airway reflexes and ventilatory and cardiovascular functions are unaffected.

Moderate sedation/analgesia ("conscious sedation") is a drug-induced depression of consciousness during which patients respond purposefully to verbal commands, either alone or accompanied by light tactile stimulation. No interventions are required to maintain a patent airway, and spontaneous ventilation is adequate. Cardiovascular function is usually maintained.

Deep sedation/analgesia is a drug-induced depression of consciousness during which patients cannot be easily aroused but respond purposefully† following repeated or painful stimulation. The ability to independently maintain ventilatory function may be impaired. Patients may require assistance in maintaining a patent airway, and spontaneous ventilation may be inadequate. Cardiovascular function is usually maintained.

General anesthesia is a drug-induced loss of consciousness during which patients are not arousable, even by painful stimulation. The ability to independently maintain ventilatory function is often impaired. Patients often require assistance in maintaining a patent airway, and positive pressure ventilation may be required because of depressed spontaneous ventilation or drug-induced depression of neuromuscular function. Cardiovascular function may be impaired.

order to fully understand the patient's current state of health. Not every procedure is elective. Urgent procedures may be required *despite* an upper respiratory tract infection, ongoing pneumonia, deteriorating physical status, untreated gastroesophageal reflux, sepsis, or hemodynamic instability. In these situations, consultation between the anesthesiologist, the requesting physician, and the radiologist should confirm urgency. Anesthesia plans should be adjusted to accommodate the requirements of the procedure (e.g. breath holding for chest CT scan) and the patient's medical condition.

It is not always possible for an anesthesiologist to provide sedation and anesthesia for all children when there is a large volume of cases. A structured nursing sedation program can provide safe and effective sedation. In many hospitals, the requesting department "outsources" responsibility for sedation to another department which could include pediatrics, hospital medicine, anesthesiology, intensive care, or emergency medicine. After patient screening, an appropriate referral for either general anesthesia or procedural sedation is the usual result. Because MRI is performed in a unique environment, it is more efficient to have the MRI nurses screen the patient prior to and on the day of the procedure. To ensure consistent decision making, the departments of anesthesiology and radiology should develop a set of guidelines and easily identifiable "red flags" (Table 41.7) to help in this triaging process. If there are any questions or need for additional medical history or studies, the nurse and anesthesiologist must confer before making the final decision regarding general anesthesia or procedural sedation. In addition, chronically ill children often have electrolyte disturbances, coagulation and hematological abnormalities, and hemodynamic instability. A consent for the administration of general anesthesia or procedural sedation must be obtained, in parity with policies established for anesthesia in the operating room.

Because gastroesophageal regurgitation is common in infants, a detailed clinical history should be taken with regard to the incidence and timing of the regurgitation. If the reflux is predictable (e.g. only associated with mealtimes or soon thereafter) children are usually approved for procedural sedation. NPO guidelines are adjusted to minimize the risk of reflux. For example, if the baby refluxes within 2 h of solid feeds, but never after 3 h, then the NPO guidelines for this infant may be extended to 6 h for solids.

Postanesthesia care

Recovery criteria and the postanesthesia care unit (PACU) environment in NORA locations must be no different than the postanesthesia care delivered to children following an operative procedure. Each site must have sources of supplemental oxygen, the ability to deliver positive pressure ventilation, the availability of suction and monitoring equipment, and a nursing staff trained in postanesthesia care. Specific antagonists of opioids and benzodiazepines should be available. If the administration of an antagonist is necessary, continuous and prolonged monitoring is needed. Discharge criteria should be established by an anesthesiologist in conjunction with the NORA service and its nursing staff. The American Society of Anesthesiologists issued a statement on NORA locations in an October 2013 update, recognizing the importance of the recovery period – with the expectation that there will be a designated postanesthetic recovery area with qualified personnel for the transport and recovery of these patients [139].

Analgesic requirements postprocedure are extremely variable. While groin puncture may be only mildly annoying for adults, the inability to move about and the ache of blood dissecting subcutaneously causes considerable discomfort in children. Following angiography, all children require a minimum PACU stay of 4 h to ensure that the puncture site does not bleed or develop a hematoma. Ideally, the patient should be pain-free and resting supine and motionless in order to minimize the risk of a groin-puncture bleed or hematoma. Experienced nursing staff will be able to recognize, manage, and call for extra help when they encounter unexpected

Table 41.7 "Red flags" for sedation

1	Apnea	If documented by sleep study, strong clinical history, or routine use of an apnea monitor, with significant likelihood of respiratory risk – availability of ICU must be considered
2	Unstable cardiac disease	If cyanotic, depressed myocardial function, or significant stenotic or regurgitant lesions – will likely require substantial planning, often in coordination with a cardiologist or cardiac anesthesiologist, and availability of ICU
3	Respiratory compromise	Recent (<8 weeks) pneumonia, bronchitis, asthma, or respiratory infection – if necessary to proceed, may require general endotracheal anesthesia to control coughing, and availability of ICU
4	Craniofacial defect	Potential for airway difficulty – availability of difficulty airway equipment or airway procedures (intubation and extubation) in the OR
5	History of a difficult airway	Potential for airway difficulty – availability of difficulty airway equipment or airway procedures (intubation and extubation) in the OR
6	Active gastroesophageal reflux or vomiting	If in poor control, with or without medical or surgical treatment – may require general endotracheal anesthesia with a rapid-sequence induction
7	Hypotonia and lack of head control	If patient is unable to maintain their own airway without assistance – appropriate perioperative planning must include airway support and ICU. Patients with underlying muscular or mitochondrial disorders may have specific anesthetic risks
8	Allergies to barbiturates	Usually the mainstay of a sedation protocol – cross-allergies must be considered
9	Prior failed sedation	Previously unable to be sedated or unsuccessful imaging study because of excessive movement – may require general anesthesia for an optimal study
10	Tremors	Unlikely to be ablated with sedation – may require general anesthesia for an optimal study

ICU, intensive care unit; OR, operating room.

agitation, delirium, or an unanticipated/undesired change in mental status.

Following embolization procedures, patients frequently experience pain or swelling, the severity depending upon the extent of embolization, the agent used for embolization, postembolic swelling and amount of tissue necrosis. A variety of analgesic techniques are available, and the use of steroids perioperatively, while not directly decreasing pain, may be of benefit in reducing edema and postembolic neuritis. Postembolic swelling will influence perioperative airway management for procedures in the head and neck. Pediatric patients may need to remain intubated following such procedures, particularly when edema in the floor of the mouth, tongue, hypo- or oropharynx, or anterior neck could compromise the airway.

Nausea or vomiting may increase venous blood pressure because of the Valsalva maneuver, which can aggravate bleeding and swelling in puncture sites or following head and neck procedures. Hypothermia is a risk at some NORA locations because the MRI, CT, and interventional radiology equipment requires a cool environment. Heating lamps and forced-air heaters may be utilized when safe and appropriate. Finally, with the use of iodine-containing radiocontrast media and sclerosing and embolizing agents, consideration must be given to adequate volume resuscitation, the risk of a contrast reaction, as well as bladder catheterization for the detection of oliguria, polyuria, or hematuria.

KEY POINTS: ANESTHETIC MANAGEMENT OF NORA PROCEDURES

- Sedation-related policies and procedures should be part of a quality assurance initiative which should accompany all sedation programs
- Sedation-related safety and effectiveness are determined by circumstances and professional skills rather than by the chosen sedative agent's pharmacological characteristics.
- There is still need for evidence-based guidelines that address current discrepancies in fasting guidelines, measurement of sedation depth, and standardization of definitions of adverse events among specialty groups
- Recovery criteria in NORA locations must be no different to those of the surgical postanesthesia care unit

Resuscitation

Each NORA location is unique with regard to conducting resuscitation. Redundancy of monitoring devices and equipment is important; one should not be limited to a single item that could malfunction at the time of resuscitation. Patients with multiple allergies, shellfish allergies, or atopic disease are at increased risk of exhibiting anaphylaxis to iodine-containing contrast. These patients may benefit from pretreatment with steroids and antihistamines. Areas with restricted access, MRI areas in particular, should have designated adjacent locations to perform full resuscitation. These areas should be equipped with wall oxygen, suction, and full monitoring and resuscitation capability. A self-inflating silicone bag (no ferromagnetic working parts) or non-ferrous Jackson Rees circuit should always be kept inside the MRI suite.

The physicians, nurses, anesthesiologists, technologists, and support personnel must know the location of a readily accessible code cart. In addition, a hard board to be placed under the patient during resuscitation should be available. Mock codes should be performed regularly to ensure adequate flow, teamwork, and delineation of responsibilities in the event of an emergency. The MRI scanner poses a special problem in the event of cardiorespiratory arrest. To date, there is no defibrillator that has met FDA approval for entering the MRI environment. Rather, the ASA Task Force on Anesthetic Care for MRI Practice advises that resuscitation be initiated in the MRI scanner as the patient is being removed from the MRI environment to an adjacent area equipped with a defibrillator, physiological monitor, and code cart [38]. Protracted resuscitation should never be conducted in the scanner because as support personnel rush inside to assist, unremoved ferrous materials will become projectiles and create an even more hazardous situation. Quenching a magnet should not be an alternative, because it requires a minimum of 3 min to eliminate the magnetic field. In addition, inadequate exhaust during a quench has been known to produce hypoxic conditions in the scanner and has resulted in a patient death. A "black quench" (loss of liquid coolant with resulting coil meltdown) could require replacement of the scanner, a costly and time-consuming undertaking.

Difficult airway management in NORA sites

If a child with a known difficult airway requires endotracheal intubation in order to complete the scheduled procedure, then it is wise to perform the anesthetic induction in the operating room, an area where access to difficult airway equipment and extra help is readily available. Regardless of an anesthesiologist's comfort level and familiarity with NORA environments, the same depth of back-up coverage is simply not available. It is also important to jointly discuss the plan for airway management in patients with a difficult airway and have a clear plan before anesthesia induction. The availability of a fiberoptic bronchoscope, video laryngoscope, and the difficult airway cart should be confirmed.

The unanticipated difficult airway is problematic in a remote location. Therefore, it is important to confirm that appropriate airway management instruments including different sizes of facemasks, oral and nasopharyngeal airways, endotracheal tubes, laryngoscope blades and handles, and appropriately sized LMAs are stocked in all NORA anesthesia carts. If the trachea cannot be intubated and the lungs cannot be ventilated with a mask, LMAs can provide a successful alternative. Many case reports describe the successful use of LMAs in children with difficult craniofacial anomalies such as Goldenhar syndrome [177,178] and even Pierre Robin sequence [179]. Similarly, a lightwand may facilitate endotracheal intubation in the child with a difficult airway [180]. Recently introduced video laryngoscopes (e.g. Glidescope®), in infant through pediatric sizes, should be strongly considered for availability in NORA locations.

It is important to recognize that the airway that had not been difficult on induction may become difficult on emergence following sclerotherapy with alcohol and subsequent tissue edema, particularly at the base of the tongue, the neck, or the mediastinum [181–183]. These patients will often require several days of airway support and ongoing evaluation in the intensive care unit until tissue swelling and airway compromise is no longer a concern.

Blood loss management outside the operating room

Transfusion requirements are rare in NORA locations, yet preprocedural anemia, accidental perforation of vascular structures, or medical transfusion requirements such as sickle cell disease or prematurity may require transfusion therapy. Equipment familiar to the anesthesiologist and identical to that available in the operating room is a welcome sight in a life-threatening emergency. Calling for additional help, establishing additional vascular access, and coordinating with the blood bank is crucial. Having a runner available may be critical when there is no equivalent to a circulating nurse. It may become necessary to involve a surgeon urgently and transport the patient to the operating room, in which case another anesthesia team setting up the operating room while the patient is being prepared for transport would be optimal.

Selection of anesthetic technique and agents

The selection of an anesthetic technique, as in any circumstance, depends on the patient's underlying medical condition, age, drug tolerance, and anticipated procedure. The assistance of the anesthesiology department is often sought when prior sedation has failed [184] and an anesthetic or deep sedation is needed to provide ideal conditions and allow successful completion of the procedure. The anesthetic care plan will ultimately be a product of institutional expectations, the patient's co-morbidities, and the anesthesiologist's preference.

Preparation of the stomach and aspiration prophylaxis are of particular concern for urgently scheduled cases (outside of NPO guidelines) or when the medical history suggests aspiration risk. If using H2 receptor antagonists, bronchospasm may occur in asthmatic patients because of the relative increased availability of H1 receptors. H2 blockers may also inhibit the metabolism of other concurrently administered medications. Metoclopramide accelerates gastric emptying and increases tone in the lower esophageal sphincter, but is associated with a significant incidence of extrapyramidal side-effects in children. Ondansetron works synergistically with other agents through its vagal blocking actions in the gastrointestinal tract as well as through its inhibition of the chemoreceptor trigger zone via serotonin receptor antagonism, particularly for patients undergoing radiotherapy with pulses of chemotherapy. [185,186].

The airway management may be influenced by the procedure itself as well as anticipated postprocedure requirements. Access to the patient's airway in locations outside the operating room is often limited – MRI scanners have a long bore with the patient out of the line of sight of the anesthesiologist. Radiotherapy accelerators and TBI machines are sited within a locked room. Interventional procedures are often performed so that the patient can be imaged with biplane fluoroscopy and therefore the physical plant is designed to accommodate the imaging equipment and not the needs of the anesthesiologist. Airway obstruction, laryngospasm, and the presence of secretions may all be difficult to determine. Hypoventilation and apnea are difficult or impossible to determine by direct observation. As long as an appropriate plan is chosen and appropriate monitoring is used, there is no evidence to support a specific standard for airway management.

Appropriate drug selection for the intended procedure includes a clear understanding of the pharmacokinetics and pharmacodynamics of the chosen sedative/anesthetic agent and drug interactions and is imperative for safe pediatric procedural sedation practice. We will focus below on the current sedation/anesthetic agents currently used by sedationists.

Barbiturates may be useful as a sole method of providing sedation. Pentobarbital (Nembutal), for example, has the advantage of providing sedation, minimal respiratory and circulatory depression, and is rarely associated with adverse events [187]. Barbiturates have no analgesic properties, and can produce paradoxical reactions, especially in children. Furthermore, no antagonist to barbiturates is available, thus dosing should be carefully titrated. Intravenous pentobarbital by titration has been used successfully by radiologists while monitoring oral and nasal air flow, oxygen saturation with a pulse oximeter (SpO_2), end-tidal carbon dioxide, and cardiac rate and rhythm. Transient decreases in SpO_{2in} up to 7.5% of patients have been reported; interventions have included stimulation and head repositioning [188,189]. Other studies have described the use of pentobarbital both in the oral and intravenous form [104,190]. For infants less than 1 year of age, oral pentobarbital is more successful and carries a lower rate of adverse events compared with chloral hydrate [190]. The long half-life of pentobarbital (approximately 24 h) requires careful and conservative recovery and discharge guidelines. The dosage of pentobarbital is 2–6 mg/kg PO, up to 9 mg/kg in patients who are receiving barbiturate therapy.

Propofol (2,6-diisopropylphenol) is an intravenous hypnotic agent approved by the FDA in the United States for the induction and maintenance of anesthesia. Its package insert specifies that it "be administered only by persons trained in the administration of general anesthesia" [191]. Although propofol does not have a labeled indication for children less than 3 years of age, it has been used extensively in this age group as a means of providing sedation or anesthesia. Propofol sedation by bolus or continuous infusion for brain MRI can provide successful imaging conditions but with the risk of need for airway intervention and respiratory compromise [192]. A recent comparison of dexmedetomidine with propofol in children with and without obstructive sleep apnea suggests that dexmedetomidine offers the benefit of preserved respiratory drive, less need for artificial airway support, and fewer incidences of airway compromise [31,193].

There is a rare, often fatal complication known as propofol infusion syndrome (PRIS) most often seen with prolonged propofol administration (>48 h) at high doses (>4 mg/kg/h). PRIS is characterized by metabolic acidosis, rhabdomyolysis of skeletal and cardiac muscle, arrhythmias (bradycardia, atrial fibrillation, ventricular and supraventricular tachycardia,

bundle branch block, and asystole), myocardial failure, renal failure, hepatomegaly, and death [194–198]. In 1992 the deaths of five children who had received long-term, high-dose propofol infusions were reported. These children died from myocardial-related causes, presumed to be related to propofol, in conjunction with lipemic plasma, metabolic acidosis, and an enlarged or fatty liver [199]. This syndrome arises from interference with the electron transport chain and derangement of mitochondrial metabolism. Propofol should be used with caution for sedation in critically ill children and adults, as well as for long-term anesthesia in otherwise healthy patients, and doses exceeding 4–5 mg/kg/h for long periods (>48 h) should be avoided [200–202]. There are now over 150 published case reports of PRIS, with 36% of cases in children [203]. PRIS can occur during anesthesia, and more recently, cases have been seen with lower doses, and with shorter duration of infusion; 20% of cases had propofol infusions of less than 20 h. Metabolic acidosis was observed in 77% of patients, and ischemic changes on ECG and arrhythmias in two-thirds of patients. Rhabdomyolysis is observed in 56%. The mortality rate has decreased in recent years and was 51% for the entire series [203]. Vigilance for this rare but devastating complication is necessary with prolonged propofol infusions of >6–8 h.

Propofol administration by non-anesthesiologists has generated tremendous controversy. The ASA guidelines specifically state that only personnel qualified to provide general anesthesia should administer this medication. Sedation providers administering propofol must be able to recognize respiratory depression and be skilled in advanced airway management. Recent large, prospective, observational studies in nearly 100,000 children showed that administration of propofol was safe in a variety of settings by sedation providers well versed in sedation management and airway rescue [204–206]. Another recent multicenter study examined the safety and efficacy of pediatrician-administered propofol in 36,516 procedural sedations, showing that pediatricians can administer propofol safely. The study also highlighted the importance of appropriate training to increase the safety of procedural sedation in children [207].

Opiates reduce anesthetic and pre- and postprocedure analgesic requirements. They are reversible with naloxone. While opioids may be unnecessary for non-painful diagnostic procedures, they may be very useful for therapeutic interventions, especially for those patients with postprocedural pain. They are also useful following anthracycline chemotherapy, when patients have documented impaired myocardial function [208]. Because opioids depress the ventilatory response to CO_2, this respiratory depression may be of particular concern for children with increased intracranial pressure. Opioids may also worsen pre-existing nausea and vomiting, particularly common for children undergoing cancer treatment. Caution should be exercised when opiates are combined with other sedatives as the risk of respiratory depression is substantial.

Benzodiazepines have the advantage of anxiolysis with minimal vomiting and cardiorespiratory depression. Diazepam (Valium®) is painful during intravenous injection and may lead to thrombophlebitis; midazolam (Versed®) is water soluble, and therefore may be more suitable intravenously or intramuscularly. The elimination half-life of midazolam averages 2.5 h compared to 20–70 h for diazepam [209,210]. Young patients or patients with significant liver disease may have prolonged duration and exaggerated effect of the benzodiazepines.

Ketamine has enjoyed great popularity during the past 30 years or more for sedation, analgesia, or anesthesia outside the operating room due to its support of the cardiovascular and respiratory systems. Ketamine-induced nightmares, hallucinations, delusions, and agitation are rare in children [211,212]. The combination of ketamine and propofol ("ketofol") is being administered with increasing frequency. Ketamine with propofol blunts the emetogenic and psychocognitive effects of ketamine, while the synergistic effect of ketamine tends to decrease the risk of propofol-associated respiratory depression and hypotension [213]. Ketamine sedation programs, administered by registered nurses and supervised by interventional radiologists, have been developed by anesthesiologists for selective patients and procedures [187,214]. This protocol has allowed painful procedures, and even organ biopsies, to be tolerated by patients who previously would have required general anesthesia [187,215].

Dexmedetomidine (DEX), a highly selective α2-adrenergic agonist, offers some unique and unmatched qualities. DEX is approved for adult sedation via intravenous infusion or bolus (labeling only in the USA) and infusion (labeling in USA and European Union) [216,217]. Despite the lack of pediatric labeling, DEX administration has been described via a variety of routes for sedation, anxiolysis, analgesia, and as an anesthetic adjunct. An extremely important advantage of this novel sedative agent is its potential for neuroprotection particularly in children [218]. DEX is unique in that it produces a state that resembles natural sleep [219,220]. Animal model studies demonstrated that this sedation mimics the endogenous sleep pathway, stimulating the locus coeruleus [221]. Studies in children suggest that the endogenous sleep pathway may be similarly stimulated. The electroencephalograms of children sedated with DEX have been shown to resemble those of natural non-rapid eye movement sleep [222]. Particularly for pediatric sedation for radiological imaging studies, DEX alone can, in high doses, achieve immobility for MRI and CT examinations [223–225]. While it appears to have minimal effects on respiratory drive and the CO_2 response curve, DEX administration may be accompanied by bradycardia, hypotension, and hypertension [223,224,226].

With DEX administered at induction doses of 2–3 mg/kg/min over 10 min followed by an infusion of 1.5–2 mg/kg/min, success rates have been reported of up to 97.6% for MRI scans. In this dose range, the incidence of bradycardia was 16%, with a mean arterial pressure within 20% of age-adjusted normal ranges [226]. Extreme bradycardia can occur if administered to a patient receiving digoxin and syncope, likely from a vasovagal response, which has been reported in the literature as well as in the package insert [227–229]. Moreover, the use of glycopyrrolate to treat the bradycardia is discouraged, as it may result in extreme hypertension [230]. A recent retrospective study showed that the administration of a prophylactic anticholinergic prior to DEX in pediatric imaging studies did not show any advantage other than a transient clinically insignificant increase in heart rate and systolic blood pressure [231]. Combining DEX with IV ketamine has been successfully described for invasive procedures, with fast onset and amnesia, sedation, analgesia, and hemodynamic stability

[232,233]. This combination has been described in adults and children for extracorporeal shock wave lithotripsy [234], lumbar puncture [235], bone marrow biopsy, burn dressing changes [236,237], chest tube insertion, and femoral cut-down for tunneled central venous catheter placement.

Currently, all standard anesthetic and sedative agents used for pediatric sedation including propofol, etomidate, sevoflurane, desflurane, isoflurane, and ketamine produce profound neurotoxic effects in laboratory animals [238]. DEX has not been shown to be neurotoxic in animal studies [239]. Future studies are still required to examine the effect of DEX on neurodevelopmental outcome. Another important question that remains to be answered is the use of combinations of sedatives and neurocognitive outcome.

Transmucosal sedative agents and new methods of drug delivery

The rapid delivery of drug to the bloodstream and the central nervous system after intranasal (IN) administration offers unique advantages that may allow a rapid onset of sedation and greater patient and provider satisfaction [240]. Currently IN midazolam is the most commonly studied medication by this route, although recent data on fentanyl, ketamine, sufentanil, DEX, and combinations of these drugs are available [241]. Reports show that IN midazolam produces nasal burning and irritation in up to 66% of patients. Intranasal DEX seems to be devoid of this discomfort, rendering it a very attractive alternative. The use of non-traditional routes (nasal and buccal) of DEX has been described in recent years. Intranasal DEX bioavailability approximates 65% (35–93%) while buccal DEX approximates 81.8% (72.6–92.1%) [242,243]. In children, IN DEX has been utilized for sedation in doses ranging from 1 to 4 μg/kg [244,245]. A nebulized combination of low-dose ketamine and DEX (1 mg/kg + 1 μg/kg) has been shown to provide more satisfactory sedation and smoother induction of general anesthesia than nebulized ketamine (2 mg/kg) or DEX (2 μg/kg) alone in children [246]. There is wide dose range of IN ketamine used in clinical practice. More research is required to determine the optimal dosing range and to identify patient populations who might require high ketamine doses in order to produce adequate sedation or amnesia [247].

Target-controlled infusion (TCI) systems are intended to more precisely deliver sedation using pharmacokinetic models specific for a particular medication such as propofol or remifentanil. TCI devices administer a bolus followed by a decline in infusion rate to rapidly achieve and maintain a steady-state drug concentration in the plasma or at the site of drug effect [248]. This method of drug delivery contrasts with non-modeled infusion schemes where constant rates result in a rise in blood concentration rather than a steady-state plasma concentration. TCI delivery systems are currently used worldwide but are not widely available for pediatric use. TCI is currently not approved or available in the USA. It is important to recognize that no new technology can replace the role of a capable and vigilant sedation provider monitoring a sedated patient.

Some patients will require general anesthesia because of previous sedation failures, the need for a secure airway, or procedural logistics. Newer, less soluble anesthetic agents such as sevoflurane and desflurane have pharmacokinetic profiles that compare favorably with propofol in adults [249]; there seems little reason to think that would not be the case with children, although pediatric anesthesiologists often avoid using desflurane because of its pungency and associated airway irritability. Since its introduction to clinical practice is the mid-1990s, sevoflurane has become the volatile anesthetic of choice in children. Its lack of airway irritability and its ability to provide children with stable hemodynamic function coupled with its rapid onset and offset make sevoflurane a useful agent [187].

Volatile agent vaporizer performance in the MRI suite has been studied. The output of a Fortec II® vaporizer (Fraser Harlake, Orchard Park, NY, USA) was variable according to the vaporizer's location and the orientation of the bimetallic strip within the magnetic field [250]. The movements of the bimetallic ferromagnetic temperature compensator within the MRI magnetic field altered vaporizer output by as much as 91% of the dialed output concentration. Several other vaporizers examined (Ohio Forane®, Ohio Medical Products, Madison, WI, USA; Ohmeda Isotec IV® vaporizer, Ohmeda, Steeton, UK; and the Forane Vapor 19.1®, Dragerwerk AG, Lubeck, Germany) were incompatible with the MRI environment because of stronger ferromagnetic internal component content or the location of a ferromagnetic spring within the temperature compensator. Measuring inspired and end-tidal levels of volatile agents when delivering a general anesthetic in the MRI environment may provide reassurance. Modern MRI-compatible anesthesia systems have magnetic field detector systems that inform the anesthesiologist when the machine is within a magnetic field strong enough to affect vaporizer and machine performance. In general, situating the machine and vaporizers as far from the magnet as practically possible within the scan room, and following the manufacturer's instructions as to machine operation, will optimize conditions and ensure accurate volatile anesthetic delivery.

Regional anesthesia, rarely administered outside the pediatric operating room, nevertheless remains a valid choice in some circumstances. Intercostal nerve blocks may be very useful for lung or rib biopsies, chest tubes, biliary or subphrenic drainage procedures, and insertion of biliary stents. Nerve block of the brachial plexus by the axillary, interscalene, or supraclavicular route has been reported for the brachial approach to catheterization [251,252] and neuraxial block of the lower extremities for femoral catheterizations and percutaneous approaches to the kidney [253]. Spinal anesthesia has been successfully used for repeat painful radiotherapy on lower extremities, in conjunction with regional hyperthermia and limb exsanguination [254].

Indwelling central catheters are implanted in the majority of radiotherapy patients and can be utilized for induction and maintenance of anesthesia, blood draws, intravenous fluid administration, and chemotherapy. Dressing changes are often accomplished in conjunction with the sedation or anesthesia. Antiseptic preparation of all injection sites is critical. At the end of the session the catheter should be carefully flushed with heparinized saline. An alternative to central lines is the use of a heparin lock peripheral IV line, changed weekly, with careful parental instruction. Smoothness of emergence is particularly important following angiographic procedures because of the risk of dislodging a clot or bleeding at the

puncture site. Some of these patients have been heparinized without protamine reversal. Unlike adults, sandbags and weights are not routinely applied to angiographic cannulation sites of children.

Finally, on occasion, the loss of self-control with sedation results in dysphoria, and some patients fare better when completely awake. Minimal medication may be preferable in patients with complicated and unstable medical conditions who may not tolerate the anesthesia or sedation. Some procedures (unilateral carotid barbiturate injection or Wada test) may require conversation, interaction, and responsiveness of the patient. Cooperation required during these procedures can be challenging especially with traditional sedatives such as fentanyl, midazolam, and/or propofol. In addition, these agents have well-known respiratory depressant effects. Dexmedetomidine provides sedation that parallels natural sleep, sympatholysis, and an anesthetic-sparing effect without relevant respiratory depression [216,217].

KEY POINTS: SELECTION OF ANESTHETIC TECHNIQUE AND AGENTS

- The ASA guidelines specifically state that only personnel qualified to provide general anesthesia should administer sedating medications
- Combining dexmedetomidine with ketamine can be an attractive sedation choice
- Intranasal dexmedetomidine seems to be devoid of the discomfort frequently associated with nasal midazolam, rendering it a very attractive alternative for non-invasive pediatric procedural sedation
- Dexmedetomidine is an emerging alternative for sedation in variety of pediatric procedural settings

Safety issues

As anesthesiologists find themselves participating in the care of patients requiring increasingly sophisticated imaging technology, it is appropriate to examine the risks for patients and staff exposed to the types of high energies and contrast agents used.

Ionizing radiation

Radiation exposure is directly proportional to the duration of the procedure and inversely proportional to the square of the distance from the source. Henderson et al monitored the radiation exposure of 16 pediatric anesthesia fellows during a 2-month period [255]. Fellows assigned to the cardiac catheterization lab had fluoroscopy exposure time of 14–85 min per case, typically for 2–3 cases per day. For these anesthesiologists, badge readings ranged from 20 to 180 mrem/month. All non-cardiac anesthesia fellows had undetectable (<10 mrem/month) levels. All fellows wore lead aprons, 50% wore a thyroid shield, and one stepped at least 3 m away from the source during every exposure; this latter fellow had a reading of 30 mrem, despite having spent 26 h in the catheterization lab. The annual maximum permissible dose (MPD) for non-radiation workers (including anesthesiologists) is 100 mrem or 1 mSv. For comparison, the MPD for radiation workers is 50 mSv annually, and 10 mSv times age cumulatively. MPD during pregnancy for radiation workers (per gestation) is 5 mSv. Safety precautions for all anesthesia practitioners include strict requirements to wear lead aprons and thyroid shields in fluoroscopy areas, to wear radiation detection badges and have them measured at regular intervals, step as far away as possible and out of the direct line of radiation, and use mobile, transparent, lead-impregnated plastic "walls" as an extra source of protection (Fig. 41.9).

The American College of Radiology has raised public and professional awareness about the risks of ionizing radiation and the importance of tailoring the dosing to the needs of the child. The Society of Pediatric Radiology established the Image Gently campaign to seek alternative methods of lowering radiation exposure to children during imaging studies (www.imagegently.org). This has expanded from radiation during CT imaging to include procedures in interventional radiology [256–258]. Web-based training and education has been developed to offer a quality improvement module for CT safety in children [259].

High-intensity magnetic fields

Magnetic resonance imaging exposes the patient (and the healthcare workers surrounding the patient) to a static magnetic field, a rapid switched spatial gradient magnetic field,

Figure 41.9 Anesthesiologist with proper ionized radiation shielding and safety precautions in a cardiac catheterization laboratory. Note the full lead apron with thyroid shield, radiation detection badge, and lead-impregnated plastic wall. He is also standing at some distance away from the cameras, and not in the direct line of radiation emission.

and radiofrequency magnetic fields. The static magnetic field, which causes alignment of unpaired tissue protons, may cause movement of ferromagnetic devices such as vascular clips, ventricular shunt connectors, casings for pacemakers, and control devices for pacemakers. Metallic devices in other areas, particularly when invested with fibrous tissue are less problematic [61,260]. As mentioned previously, tissue expanders may have magnetic ports to facilitate identification of the injection site. Despite their low mass, such ports have a potential for torque and movement in the presence of a strong magnetic field, therefore the specific type of tissue expander should be identified prior to patient evaluation in an MRI scanner [53]. Assessment of risk in patients with implants or other possibly ferromagnetic devices or objects consists of a careful history including penetrating wounds, physical examination to look for scars, and possibly a plain radiograph of the region in question [261]. Other concerns have been increased blood pressure, cardiac arrhythmias, and impaired mental function. While described or theorized on an experimental basis, little clinical documentation is available.

The magnetic field generates an electric current 2–3 orders of magnitude less than a defibrillator (10 mA/m^2, compared to 1,000–10,000 mA/m^2). This current strength may nevertheless reprogram a programmable pacemaker and interfere with its function [56]. Exposure to a strong external magnetic or electromagnetic field can lead to conversion of a demand pulse generator from synchronous to asynchronous mode, damage to the reed switch (which activates the fixed rate pulse generator), reprogramming of pacemaker parameters, induction of currents in the electrode wires, or to displacement of the generator itself. Indeed, it is the sensitivity of some reed switches that has determined the "safety boundary" of magnetic resonance devices as being 5 G (5×10^{-4} T). Patients with implantable defibrillators/cardioverters, implantable infusion (e.g. insulin) pumps, cochlear implants and neurostimulators, are all at risk for having the implant device reprogrammed upon exposure to the magnetic field. Defibrillator failure has been reported in the MRI environment [262]. As noted earlier, MRI-compatible, conditionally safe pacemakers are now available [58].

Radiofrequency pulses cause heat production in metallic implants and coiled wires such as ECG cables or pulse oximeter cables if looped and laying on the patient's skin. Patients with compromised thermoregulatory abilities, such as those with cardiac problems, fever, or taking certain drugs, may be at particular risk. Included in this group are infants, whose SAR is greater than that of adults because of the greater ratio of body surface area to body mass, and whose thermoregulatory abilities may be interfered with during a general anesthetic [76]. SAR refers to the energy absorption (e.g. increasing body temperature) with an increase in the total amount of RF energy absorbed [263].

Increased reports of vertigo, nausea, and a metallic taste have been found in a study on human exposure to a 4 T magnetic field (whole-body scanner) [264]. Fertilized frog embryos exposed to a 4 T magnetic field did not demonstrate any adverse effects on early development [52]. An increase in cardiac cycle length of 17% was found in healthy volunteers in a 2 T environment after 10 min of exposure, causing speculation about the effect of the 2 T environment on the sinus node [67] This may be of particular concern in patients with a pre-existing arrhythmia history. Of more significant concern in pediatric patients is the potential for hypothermia because of the air flow directed through the scanner cavity and the inability to control room temperature or use radiant warmers. The use of warm IV fluid bags, thermal packs, and blankets can decrease heat loss. Excellent reviews of monitoring considerations and equipment choices in the MRI environment as well as patient safety principles are available [46,70,261,263,265,266] and the American College of Radiology (with a representative from the ASA) has published a white paper on magnetic resonance safety [37].

Magnetic resonance imaging and spectroscopy do not employ ionizing radiation. However, secondary harmful effects, such as magnetic objects becoming projectiles within the magnetic field as they approach the bore of the magnet and potentially causing injury, are a consideration [267,268]. Patients (and anesthesiologists) with metallic implants such as vascular clamps, hemostatic clips, dental devices, heart valve prostheses, intravascular coils, filters and stents, ocular implants, orthopedic implants, otological implants, shrapnel, penile implants, and vascular access ports must be individually evaluated for their risk in the MRI environment [269,270].

Use of intravascular contrast media

In a comprehensive review, Goldberg noted approximately 5% of radiological exams with radiocontrast media (RCM) are complicated by adverse reactions, with one-third of these being severe and requiring immediate treatment [271]. Anaphylaxis during anesthesia has recently been the subject of several consensus conferences [272–274]. Reactions occur most commonly in patients between 20 and 50 years of age, and are relatively rare in children. The male : female ratio is about 1:2.5, not dissimilar to the gender distribution of other allergies such as to latex, aspirin, and neuromuscular blocking agents. With a history of atopy or allergy, the risk of a reaction is increased from 1.5- to 10-fold. Reactions vary from mild, subjective sensations of restlessness, nausea, and vomiting to a rapidly evolving, angioedema-like picture accompanied by respiratory distress, bronchospasm, arrhythmias, and cardiac arrest. Because of the high molar concentration of contrast media (often >1000 mOsm, and sometimes >2000 mOsm), caution should be exercised with patients who have a limited cardiovascular reserve such as patients in congestive heart failure or those with cardiomyopathy. In addition, volume-depleted young children (NPO for prolonged intervals, bowel preps) should be pre-hydrated prior to RCM administration. Because contrast agents are hypertonic, the initial hypertensive response is usually followed by equilibration with the extracellular fluid compartment within 10 min, heralded by the onset of diuresis. Special attention should be paid when administering iodine RCM to any child with a history of congestive heart failure. Patients with hepatic or renal dysfunction should be observed closely for signs of impaired excretion of the RCM. In sickle cell disease, the increase in blood osmolarity may precipitate shrinkage, clumping, and, ultimately, sickling of erythrocytes and vascular occlusion. Sickled cells are known to align with external magnetic fields to which they are exposed; it is unknown how this theoretical concern compares, for example, with the normal forces of deformation imposed on red cells of patients

with sickle cell disease in their normal course through the vascular tree [70]. Those patients dependent on a full intravascular volume status (patients with sickle cell disease, cyanotic congenital heart disease with a restricted pulmonary circuit volume, patients with arteriovenous shunts, etc.) should be monitored carefully for an initial rise in filling pressures and intravascular volume and subsequent diuresis following an osmolar load. Patients with impaired excretory mechanisms, such as those in renal failure, must be monitored closely following high osmolar loads. Low osmolar RCM are relatively safe with regard to life-threatening reactions, but moderate non-life-threatening reactions requiring some treatment occur 0.2–0.4% of the time, and a severe life-threatening reaction can occur in 0.04% of patients [275]. The risk of contrast reaction to non-ionic contrast media is rare. A recent review of 12,494 patients reported overall a 0.46% incidence of contrast reaction, all being mild or moderate and none classified as severe [276].

Gadolinium dithylenetriaminepenta-acetic acid is a low osmolar ionic contrast medium used for MRI, with a slower clearance in neonates and young infants than in adults, yielding longer windows for imaging [277]. Free gadolinium has a biological half-life of several weeks with uptake and excretion taking place in the kidneys and liver. Unfortunately, free gadolinium is quite toxic and is therefore chelated to another structure that restricts the ion and decreases its toxicity. The most common adverse reactions are nausea, vomiting, hives, and headache. Local injection site symptoms include irritation, focal burning, or a cool sensation. Transient elevations in serum bilirubin (3–4% of patients) have been reported and a transient elevation in iron for Magnevist® and Omniscan® (15–30% of patients) occurs, which tends to reverse spontaneously within 24–48 h [278]. Anaphylactoid reactions occur in the order of 1:100,000 to 1:500,000 and are more rare (<1:100,000 doses) in children.

The older literature states that patients who have had anaphylactic reactions to shellfish are at increased risk of anaphylactoid reaction to RCM. The irony of the statement is that it may be correct, but for non-obvious reasons. The original rationale was that shellfish contain high quantities of iodine and therefore it was assumed that there would be a risk of cross-reactivity. However, neither shellfish allergy nor RCM reactions are due to iodine. Atopy per se is a risk factor; therefore, the association between atopy and anaphylactic reactions to shellfish and a possible predisposition to a RCM reaction may indeed be valid.

The treatment of severe allergic reactions, whether anaphylactoid or anaphylactic, is no different than for any other allergic reaction. Epinephrine, aminophylline, atropine, diphenhydramine, and steroids have all been employed in order to control varying degrees of adverse reactions. A patient who requires RCM administration and who has had a previous reaction to RCM has an increased (35–60%) risk for a reaction on re-exposure. Pretreatment of these high-risk patients with prednisone and diphenhydramine 1 h before RCM administration reduces the risk of reactions to 9%; the addition of ephedrine 1 h before RCM administration further reduces the rate to 3.1% [279–281].

Allergic reactions rarely occur with oral agents. The incidence of severe anaphylactoid reactions to gastrointestinally administered agents is approximately 0.004:10,000 and the causes remain unknown. Gastrointestinal complications include nausea, vomiting, and diarrhea. One of the factors that may protect against having an allergic reaction is the poor absorption of oral iodinated contrast agents. Indeed, disruption of the gastrointestinal mucosa is recognized as causing an increase in absorption of oral contrast and the urinary excretion of contrast in a gastrointestinal study is a well-recognized sign. Yet rarely will they be associated with bronchospasm, flushing, periorbital edema, pruritis, rash, rhinitis, and urticaria.

Potential anesthetic and sedative neurotoxicity

Animal models of anesthetic and sedative exposure in the neonatal and early infancy age periods consistently demonstrate increased neuroapoptosis and other types of neurodegeneration, and long-term neurobehavioral effects of exposure to all common anesthetics and sedative agents that bind to γ-aminobutyric acid and N-methyl-D-aspartate receptors to produce their effects. This includes all volatile anesthetic agents, propofol, barbiturates, ketamine, benzodiazepines, and etomidate [282]. The human data are less convincing, and a short single exposure to anesthetics does not appear to have an effect on longer term neurodevelopmental outcomes [283,284]. However, some retrospective cohort studies demonstrate an association with repeated or prolonged anesthetics and higher incidence of learning disability, cognition and language problems, and other neurodevelopmental outcome problems [285,286].

In 2016 the US FDA issued a drug safety communication, warning that "repeated or lengthy use of general anesthetic and sedation drugs during surgeries or procedures in children younger than 3 years or in pregnant women during their third trimester may affect the development of children's brains" [287]. The FDA has directed physicians to communicate with parents about this potential problem, and to discuss whether a procedure with sedation or anesthesia should be done now or can be postponed until after age 3 years. In addition, the duration of the anesthetic, and the potential need for repeat anesthetics, should be discussed, according to the FDA. This warning has generated considerable controversy [288], and also has led to evaluation of some procedures for medical necessity, including brain MRI for developmental delay in an otherwise asymptomatic patient [24]. A recent systematic review of 29 studies in 2299 children with developmental delay who had brain MRI found that only 7.9% of MRI scans led to an etiological diagnosis of the developmental delay [289]. More data are needed in this area before changing practice since recommendations for diagnostic testing for developmental delay emphasize brain MRI as a primary modality [290]. Chapter 46 has an extensive discussion of anesthetic neurotoxicity.

A strategy to avoid sedation in young infants up to the age of about 3 months is the "feed and swaddle" technique, which involves coordinating the scan time after a feed, and wrapping the infant in a blanket, using noise attenuation, and gentle restraint with a vacuum bean bag (Fig. 41.10) [291]. Shorter scans in younger infants are most amenable to

Figure 41.10 Feed and swaddle technique for non-sedated MRI in young infants. The neonate is wrapped in blankets and a vacuum bean bag, with noise attenuators in place, ready for transport to the MRI scanner suite. *Source:* Reproduced from Barkovich et al [291] with permission of Springer Nature.

this technique, which requires coordination and cooperation among MRI technologists, parents, and nursing staff. Noise reduction is crucial for this approach. Other measures increasing success are reducing scan time by focusing on the clinical question and tailoring sequences to reduce time, and using motion correction software. This approach has become more common in order avoid the risks of sedation and anesthesia, including respiratory and cardiovascular risk, and the potential but as yet unproven risk of neurotoxicity in young infants.

Quality improvement and simulation in NORA locations

With increasing economic pressure for cost containment and efficiency in the context of quality care, sedation/anesthesia providers should not only focus on medical knowledge but also on the application of quality improvement principles in NORA locations. Improvement requires leadership support and a team approach embracing transparency and open communication. In several pediatric centers, applied quality improvement methodology in NORA locations has been recently reported to improve work flow and safety for patients requiring anesthesia for radiological procedures. In the first quality improvement project, the percentage of successful start on time for the first patient scheduled with general anesthesia in MRI was 36% prior to starting the improvement project. At the conclusion of the project the on time start had improved to 84%. The key interventions of this project primarily focused on standardizing the processes for completing the preimaging evaluation and for anesthesia induction [292].

Many of the infusion medications used in radiology (propofol, dexmedetomidine, etc.) are used for sedation/anesthesia and the errors related to programming and operation can be catastrophic [293]. The common reasons for intravenous medication infusion errors are incorrect programming of weight or dose, programming a wrong medication, and over-ride of alerts by providers without recognizing an error. By using plan–do–study–act cycles, the second quality improvement project showed that utilizing a brief two-person verification approach in the radiology department can reduce medication errors due to wrong infusion pump programming [294].

The willingness of personnel to speak up about a patient safety concern is an important part of safety and is equally important in the operating room and outside the operating room. The third project examined the concept of doing a challenge and response checklist to prevent errors in pediatric freestanding ambulatory surgery centers for patients undergoing MRI. The authors concluded that this approach can dramatically improve teamwork and patient safety in the operating room and in the radiology suite [295].

Finally, a recent quality improvement project examined the variables associated with postscan hypothermia in neonatal intensive care unit infants undergoing MRI and concluded that applying quality improvement principles minimizes hypothermia in this challenging patient population [296].

Medical simulation is emerging as a powerful educational tool capable of exploring technical, behavioral, and systems issues within healthcare [297,298]. Simulation enacts a participative clinical event for the purpose of learning, practicing, evaluating, testing, and understanding human actions [297]. Practitioners can learn in simulation without putting patients at risk and can also incorporate a review of educational content and debriefing by an expert facilitator to drive learning [297]. Recent studies have explored how simulation enhances pediatric sedation practice. A recent study supported the notion that patient safety was enhanced when simulation was incorporated into training for pediatrician-administered sedation [299]. Simulation can also address "latent error" identification such as patient vulnerabilities in complex healthcare environments [300]. Studies evaluating performance among pediatric trainees demonstrated clear deficiencies in life-saving skills such as resuscitation and airway management [301,302].

KEY POINTS: QUALITY IMPROVEMENT AND SIMULATION IN NORA LOCATIONS

- Improvement requires tremendous leadership support and a team approach, which embraces transparency and open communication
- The use of quality improvement methodology in NORA locations can improve work flow and safety
- Simulation can address systemic failures that undermine patient safety and may provide a unique tool capable of exploring patient vulnerabilities in complex healthcare environments

Future directions of pediatric sedation

The provision of pediatric sedation will likely change qualitatively as well as quantitatively in the future in response to changes in imaging technology and non-invasive or minimally invasive procedures outside the operating room. This will occur within the environment of a growing emphasis on

cost, efficiency, safety, and patient satisfaction. New and safer sedative agents, innovative delivery systems, broadening of non-anesthesiologist practitioners and their training, increased deployment of high-quality databases informing quality improvement methodology, standardized definitions of adverse events amongst multiple practitioners in multiple sites, and evolving requirements for credentialing are expected changes in the future practice of pediatric sedation.

The last decade has seen a significant growth of interventional procedures that are replacing many surgical procedures. More and more care in NORA locations is expected and some of this care will be provided by non-anesthesia providers in the future. Pediatric anesthesiologists should play a critical role in collaborating with non-anesthesiologists in examining practice and outcomes. The results will inform and advance sedation practices. For example, a successful collaboration among anesthesiologists, intensivists, emergency physicians, and hospitalists working with over 130,000 patients showed no difference in complications between specialists [303,304].

Previously, depth of sedation was defined based on a patient's response to verbal or tactile stimuli. Recently, the International Sedation Task Force (World Society of Intravenous Anaesthesia) created a sedation reporting tool that is open access, on-line, free of Health Insurance Portability and Accountability Act identifiers, and a means of collecting and sharing data worldwide among all specialists (www.AESedationReporting.com) [305]. This AE Sedation Reporting Tool has already been adopted and promoted by specialists in multiple disciplines worldwide for sedation studies of both adults and children [306–308].

KEY POINTS: FUTURE DIRECTIONS OF PEDIATRIC SEDATION

- Large, prospective outcome studies are necessary to determine optimal sedation practices
- As the demand for procedural sedation continues to expand, sedation providers must continue to be creative in their search for novel, safe, effective, and efficient methods to deliver care
- There is a need for multispecialty groups to share results and devise evidence-based guidelines that address current discrepancies in training, equipment, techniques, and outcomes

Summary

The demand for anesthesia and sedation services in sites distant to the operating room is continuing to increase. Providing patient services in NORA locations can be challenging and can pose risks that may not exist in the operating room. As technology advances, the anesthesia/sedation providers must maintain an understanding of the procedures in order to tailor the anesthetic/sedative appropriately. Versatility must be maintained to adapt to the different clinical situations required for delivering anesthesia/sedation in NORA locations. All stakeholders in the provision of NORA sedation and anesthesia services must recognize that as the demand for these services grows, so also should their ability to understand the specific environment and to do careful risk analysis when selecting patients and formulating an individual as well as an institutional plan of care.

CASE STUDY

An 18-month-old, 18 kg boy is scheduled for an MRI of the brain to evaluate new onset of grand mal seizures, photophobia, and increasing irritability. He has been well previously. He is currently taking phenobarbital and phenytoin.

The evaluation of children presenting for imaging studies is very similar to the evaluation of children requiring surgery. This rather large toddler's preanesthetic evaluation has to consider the efficacy of his anticonvulsant therapy because he is on two medications. Grand mal seizures of the tonic-clonic variety are usually the easiest to control, particularly if they originate from a single seizure focus, but generalized tonic-clonic seizures associated with a progressive metabolic disease, or complex partial seizures, are more difficult to control. Multimodal therapy is often required in these circumstances. The history is important here because seizure thresholds may be affected by the administration of or the withdrawal from a general anesthetic, in the first case raising the threshold and in the second case lowering it. Therefore, during emergence, the patient may be at increased risk for a seizure.

Many induction plans are acceptable. Intravenous access may be more difficult prior to induction due to the size of the patient (18 kg at 18 months of age, approximately the size of an average 4 year old), multiple attempts, and the increased stress. Crying and aerophagia would be expected. If a general anesthetic were required we would be inclined to proceed with a parent-present mask induction. Most imaging studies only require immobilization and are not stimulating. The sedation level can change rapidly from minimal sedation to general anesthesia; therefore, the expectation of the Joint Commission is that a deeply sedated patient should be able to be rescued from a depth of general anesthesia. If it seemed like deep sedation would be a good strategy and easy intravenous access is likely, we would probably plan on using pentobarbital sedation rather than dexmedetomidine, the other alternative we commonly use. The effect of dexmedetomidine on seizure threshold is controversial; some (early) studies indicated that it may lower the seizure threshold, although in these studies enflurane and sevoflurane were used as part of the anesthetic technique. Pentobarbital, on the other hand, would raise the seizure threshold and perhaps provide a greater margin of safety for this poorly controlled toddler. With this plan, airway management would likely consist of a natural airway with supplemental oxygen, without any adjunctive devices. Use of a divided nasal cannula capable of end-tidal CO_2

monitoring is an important monitoring technique in these patients for early detection of airway obstruction. Video camera monitoring of the patient in the bore of the scanner is useful to detect inadequate sedation with patient movement, or airway obstruction. Minimal obstruction of the natural airway with preservation of pharyngeal muscle tone will allow the procedure to continue with an adequate level of sedation. If significant upper airway obstruction occurs, the rocking motion of the head, neck, and chest may interfere with the quality of the scan, and therefore the anesthetic plan would need to be modified because the study requires a motionless patient.

A total intravenous anesthetic (TIVA) technique with propofol may also be chosen. Supplemental oxygen is provided with a nasal cannula. Placement of a shoulder roll and/or an oral airway is helpful in maintaining patency of the airway. If the airway remains obstructed, then a general anesthetic (intravenous or inhalational) can be employed with a laryngeal mask airway or endotracheal tube.

Safety concerns in the environment of the magnet are critical. It is important to remember that the magnet is always on, and the dangers of the electromagnetic field are ever present. Ferrous-containing elements of the anesthetic equipment have to be eliminated for the sake of patient safety as well as the test results. Iron-containing materials become missiles in the MRI scanner, depending on iron content and mass, but magnetic attraction obeys the inverse square law such that the closer it gets to the bore of the magnet the greater the attraction becomes. Oxygen tanks, tables, and anesthesia machines have been "sucked into" the bore of the magnet. For the anesthesiologist and other medical personnel, anything containing iron in their pockets can become projectiles as well, such as stethoscopes or scissors. In addition, personal identification cards such as hospital ID cards and credit cards can have their information rendered useless; beepers and telephones will also have their radiofrequency chips scrambled to the point of uselessness. In the event of an emergency, removing the patient from the magnet room to a less hostile environment is the preferred initial course of action.

The duration of PACU stay will depend on how many seizures the patient ordinarily has per day, the competence of the parents in dealing with these seizures, and to some extent the risks of driving home (e.g. distance to home, distance to closest hospital). We would probably keep the patient for 4–6 seizure-free hours in the PACU, with the resumption of his previous oral medications, consultation with his neurologist, and postoperative blood levels, which should be easy to obtain. We would restart his anticonvulsants following the scan. The half-lives are drawn out enough and the onset is long enough that his level will neither decline nor be increased drastically if he resumes his usual oral schedule a few hours later. It will probably be unnecessary to give him any intravenous equivalent doses of his phenobarbital or phenytoin.

CHAPTER 42
Pediatric Intensive Care

Rajeev Wadia, Becky J. Riggs, Dheeraj Goswami, Jamie McElrath Schwartz, and Melania M. Bembea
Department of Anesthesiology and Critical Care Medicine, Johns Hopkins University School of Medicine, Baltimore, MD, USA

Pediatric intensive care unit team

The pediatric intensive care unit (PICU) is a complex system of multidisciplinary care delivery for many different medical and surgical diagnoses. The care team is large and diverse, including but not limited to physicians, nurses, respiratory therapists, social workers, discharge planners, nutritionists, child life specialists, and family members. Subspecialization of pediatric critical care is increasing, including cardiac and neurological critical care. The number of pediatric critical care beds is increasing while numbers of general inpatient care beds are decreasing, reflecting the rising inpatient complexity and illness. The majority of patients in the PICU are straightforward medical and surgical patients with single-system organ dysfunction, although children who are chronically critically ill with long-term organ system failure are present as well. Because of the paucity of rehabilitation, chronic care, and hospice options for children in the community, the PICU often serves these purposes as well. This chapter provides an overview of disease processes and therapies provided in the PICU that are pertinent to perioperative care of children.

Relationship between the PICU and operating room

The PICU is part of the operative complex that provides perioperative care for children. There is high utilization of anesthesia services by PICU patients, and anesthesiologists and intensivists must work closely together to provide optimum care for critically ill children. Critically ill patients have increased perioperative anesthetic risk by virtue of organ system dysfunction and, in some cases, emergency designation [1,2]. Communication and collaboration between the pediatric intensivist and anesthesiologist is key to patient optimization and surgical and anesthetic decision making. Ideally, anesthesiologists have a working knowledge of issues faced by intensivists and vice versa – thus improving perioperative care.

Patient hand-offs between the anesthesiologist and PICU are common and should be a quality care focus. Standardized pediatric operating room (OR) to PICU hand-offs have been shown to improve quality of information provided, timeliness of antibiotic and analgesic dosing, and to decrease errors and omissions during hand-over [3,4].

Gregory's Pediatric Anesthesia, Sixth Edition. Edited by Dean B. Andropoulos and George A. Gregory.

Family-centered care in the PICU

The Institute for Patient- and Family-Centered Care defines family-centered care as encompassing four core concepts: respect and dignity, information sharing, participation in care and decision making, and collaboration between patients, families, and the healthcare team [5]. In the PICU, these concepts are realized through structural design and systems that prioritize families' needs. Physical plant features such as waiting rooms, bathrooms, kitchen areas, and patient rooms that recognize parent and family function in the PICU are critical [6]. Rounds participation is important to families as a place for information sharing and participation in decision making [7–9]. Particularly for the patient with developmental disability, parental presence, knowledge of baseline or communication strategies, and interpretation of symptoms are important. Recognition and support of the key role that families play in patient care and recovery is central to family-centered care in the PICU.

PICU family-centered care impacts the anesthesiologist's practice as it demands demonstration to the family and patient the collaboration and communication between the OR and the PICU. Anesthesiologists can support PICU family-centered care by allowing the family to participate in perioperative discussion and decision making, demonstrating communication and effective hand-off between environments, and respecting the role that families and patients play in the healing process.

Continuous quality improvement in the PICU

Quality care delivery in the PICU a universal goal, but "quality" is neither well defined nor easily measured. When pediatric critical care was in its infancy, measures of outcome were limited to mortality. As mortality in the PICU has remained low at 2–3.3% for the general PICU population, measurements of quality have turned to morbidities and complications of care [10,11]. Common quality metrics in critical care include hospital-acquired conditions such as central line-associated bloodstream infection (CLABSI), catheter-associated urinary tract infection, ventilator associated events, and pressure ulcers. For each of these morbidities, PICU practice prevention bundles and education strategies have been developed and implemented with varying effectiveness in reduction [12–14]. Electronic medical record triggers have provided another method to monitor and improve quality via dashboards [15,16].

CLABSI is the metric with the highest cost to the patient and healthcare system and the best-studied quality metric; it has significant attributable financial costs and affects length of stay [17]. Risk factors for CLABSI include multilumen central lines and line location; femoral lines have the greatest risk and subclavian lines the least risk [18,19]. Bundling of CLABSI prevention, insertion, and maintenance practices has been shown to decrease CLABSI rates in a large multicenter database review and single-center reports [20]. As anesthesiologists frequently insert and manage invasive devices, awareness and adherence to current practices is critical to the prevention of these costly complications.

Other emerging PICU quality metrics focus on the prevention of delirium and efforts at early mobility and rehabilitation. There is increasing recognition that previous practices of sedation and immobility may have a negative impact on physical and psychological healing and increase the risks for complications, including sleep deprivation and delirium [21,22]. In addition to the classic care bundles for CLABSI and ventilator-associated pneumonia, there are care bundles to reduce delirium and encourage early mobility and rehabilitation [23,24]. Knowledge of these efforts in the PICU impacts anesthesia care by informing choices in anesthetic technique and pain and sedation management.

KEY POINTS: PICU TEAM, OR, FAMILY-CENTERED CARE, AND QUALITY IMPROVEMENT

- The PICU team is diverse and includes physicians, nurses, respiratory therapists, nutritionists, and many other disciplines
- There is high utilization of anesthesia and perioperative services by PICU patients, and excellent communication and collaboration for care and hand-offs is essential
- Family-centered care encompasses respect and dignity, information sharing, participation in care, and collaboration
- Mortality in the PICU has remained low and measurements of quality have turned to morbidities and complications of care, including CLABSI, ventilator-associated pneumonia, and pressure ulcers

Organ system function and failure

Pediatric multiple organ dysfunction syndrome (MODS) represents a continuum of physiological disturbances that are potentially reversible in early stages and appear to become irreversible after a certain tipping point [25]. MODS occurs in more than 25% of PICU patients [26–28] and is more common in neonates and infants compared with older children [29,30]. It represents the leading final pathway to death in children who suffer critical illness triggered by acute insults as diverse as sepsis, trauma, burns, acute respiratory distress syndrome, congenital heart disease, inborn errors of metabolism, transplantation, and others [31,32]. Regardless of the inciting event, children with MODS have mortality rates ranging between 10% to as high as 57% [26,27,29,31,33–35].

First defined in 1986 as the simultaneous presence of two or more organ dysfunctions using the criteria proposed by Wilkinson et al [36,37], the definition criteria and monitoring of pediatric MODS have undergone several transformations over the years [38–41]. A recently published study comparing the two most recent criteria for pediatric MODS, Goldstein et al [41] and Proulx et al [40,42–44], conducted in a cohort of 842 consecutive PICU patients admitted at a single institution between 2009 and 2010, showed that the application of the two definitions in the same population yielded different rates of MODS: 21.4% versus 37.3%, respectively [26]. Applying the two definitions yielded different 90-day mortality rates for patients with MODS at PICU admission (11.5% versus 17.8%,

p = 0.038), but similar 90-day survival of patients without MODS at PICU admission (98.9% versus 98.6%, p = 0.73), using the Goldstein versus Proulx criteria, respectively [26].

While not yet universally incorporated into routine clinical care, serial assessments of pediatric MODS scores have become an integral part of clinical studies in pediatric critical care. New and progressive MODS (NPMODS) has been proposed as the primary outcome in a number of completed and ongoing major clinical studies in pediatric critical care, replacing mortality [45–47], because NPMODS develops in most patients who die and is significantly associated with worse functional outcomes in survivors [31,45,46,48,49]. NPMODS is defined as the development of dysfunction of two or more organ systems after hospital admission, or progression of MODS as evidenced by the worsening of one or more organ dysfunctions [45].

There are three published pediatric MODS scores: the PEdiatric Logistic Organ Dysfunction (PELOD, with the recently updated PELOD-2) score [40,44,50,51], the Pediatric-Multiple Organ Dysfunction Score (P-MODS) [52], and the modified Sequential Organ Failure Assessment (SOFA) scores for children [53,54]. PELOD-2 is comprised of 10 measures within five organ systems, including neurological (Glasgow coma scale (GCS) score, pupillary reactions), cardiovascular (lactatemia, mean arterial pressure), respiratory (PaO_2/FiO_2, $PaCO_2$, mechanical ventilation), renal (creatinine), and hematological (white blood cell count, platelet count) [44]. The score ranges from 0 to 33, measured in integers [44]. P-MODS is comprised of measures from five organ systems, including cardiovascular (lactatemia), respiratory (PaO_2/FiO_2 ratio), renal (blood urea nitrogen (BUN)), hematological (fibrinogen), and hepatic (bilirubin) [52]. Each variable is rated from 0 to 4, and P-MODS is the sum of the five variables [52]. P-MODS was developed and validated using data over the entire PICU course [52]. Lastly, modified SOFA scores for children have been proposed but only evaluated in the postoperative cardiac pediatric population in a small sample size study (n = 142), at admission (initial), 12 and 36 h postoperatively [53], and in the general PICU population at a single time-point at PICU admission as a severity of illness score [54]. Of these scores, PELOD and its updated version, PELOD-2 (Table 42.1), are the only scores validated in prospective multicenter cohorts that can be calculated serially during the PICU stay.

Table 42.1 PEdiatric Logistic Organ Dysfunction 2 (PELOD-2) score elements

System	Score element
Neurological	Glascow coma scale
	Pupillary reaction (both)
Cardiovascular	Lactatemia (mmol/L)
	Mean arterial pressure (mmHg)
Renal	Creatinine (μmol/L)
Respiratory	PaO_2 (mmHg)/FiO_2
	$PaCO_2$ (mmHg)
	Invasive ventilation
Hematological	White blood cell count (× 10^9/L)
	Platelet count (× 10^9/L)

Cardiovascular disease

Assessment of cardiovascular function

Evaluation of a patient's cardiovascular state in the intensive care unit (ICU) involves performing a physical examination and evaluating physiological monitors and laboratory values. Evaluation of the electrocardiogram (ECG) for rate, rhythm, morphology, and presence of dysrhythmias can provide clues about myocardial well-being, while tachycardia, frequent premature ventricular contractions, and ST segment depression or elevation depict a more ominous sign of oxygen supply–demand mismatch. Abnormalities in end-tidal CO_2 ($ETCO_2$), pulse oximetry waveform and saturation, blood pressure, pulse pressure, central venous pressure (CVP), and cerebral and somatic oximetry can help elucidate underlying cardiovascular pathology. Signs and symptoms that may suggest poor cardiac output may also be appreciated on physical exam – dyspnea, crackles, depressed liver edge, peripheral edema, weak central and peripheral pulses, delayed capillary refill time, cool and mottled skin, abdominal pain, and abnormal third and fourth heart sounds. Laboratory studies to assess end-organ function can validate the degree of poor perfusion states – international normalized ratio (INR), liver enzymes, BUN, creatinine, lactate, B-type natriuretic peptide, and troponin.

When the underlying etiology is not clearly evident, or further characterization of the mechanism for cardiovascular demise is necessary, echocardiography is needed to gain detailed information about cardiac anatomy and function. Transthoracic echocardiography is non-invasive, does not often require sedation, and may quickly be performed at the bedside. Recent development of point of care ultrasound approaches utilizing portable ultrasound equipment stored in the PICU used by trained intensivists has greatly expanded the availability of this technique [55]. In children, 2D views allow for determination of left ventricule (LV) function – normal shortening fraction of 28–44% and ejection fraction of 55–65%. M-mode echocardiography is more commonly used to assess global right ventricule (RV) function by the tricuspid annular plane systolic excursion, which is the distance of downward movement of the lateral tricuspid valve annulus toward the apex during systole (Fig. 42.1). This has good correlation with isotopic-derived RV ejection fractions [56]. Growth-related changes have been published for children [57]. The pressure gradients across valves and RV pressure may be calculated using Doppler flow analysis. The velocity of blood moving across a valve or chamber can also be determined using Doppler. This velocity (V) in cm/s can then be used to determine the pressure difference (ΔP) in mmHg across the valve or chamber using the simplified Bernoulli equation:

$$\Delta P = 4 \times V^2$$

As an example, if the flow across the aortic valve using Doppler echocardiography is 3 cm/s, then the ΔP across the aortic valve is $4 \times 3^2 = 36$ mmHg. Similarly, the RV pressure can be determined if there is enough tricuspid jet to determine a velocity of blood flow. However, the estimation of RV pressure must take into account the opposing CVP that flows into the ventricle (the tricuspid jet travels from the RV to the

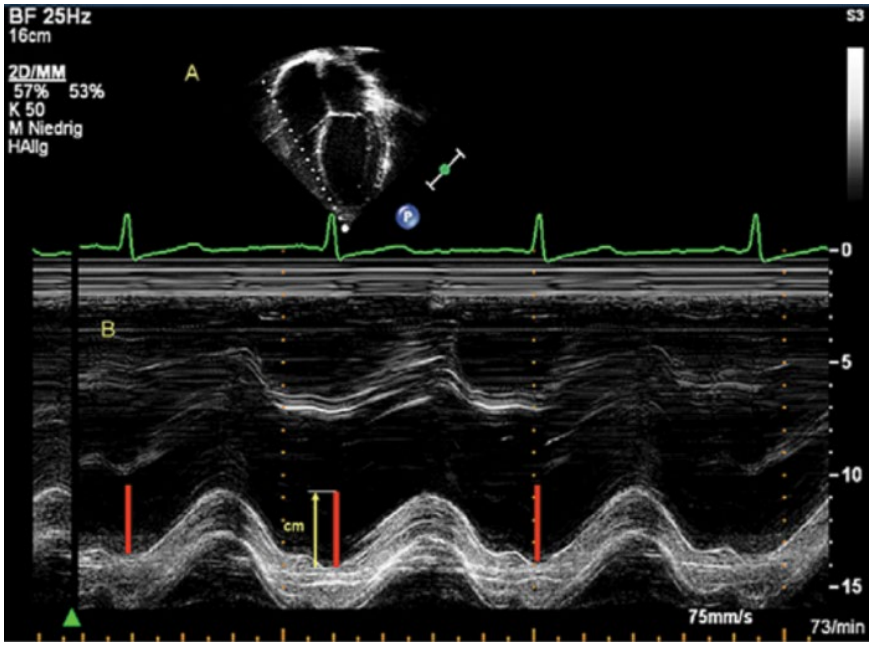

Figure 42.1 Apical four-chamber view of a transthoracic echocardiogram evaluating the right ventricle. (A) The white broken line indicates M-mode cursor placement at the tricuspid lateral annulus. (B) Representative M-mode imaging of the Tricuspid annular plane systolic excursion (TAPSE) in a patient with normal right and left ventricular function. The yellow arrow marks the upper and lower measure points. *Source:* Reproduced from Koestenberger et al [57] with permission of Elsevier.

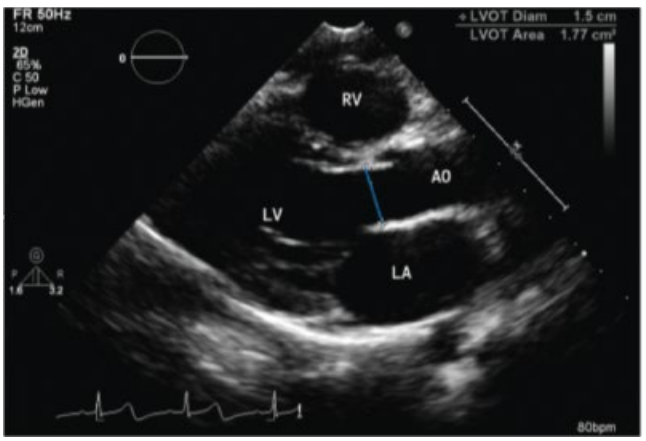
atrium). Thus, the RV pressure is the pressure difference across the tricuspid valve plus the CVP (or right atrial v-wave). For simplicity, if there is no direct catheter measurement of the CVP, it is assumed the CVP in most conditions is approximately 5–7 mmHg. Therefore, if the tricuspid jet velocity is 2.4 cm/s, the RV pressure is $4 \times (2.4)^2 + 5$ mmHg = 28 mmHg.

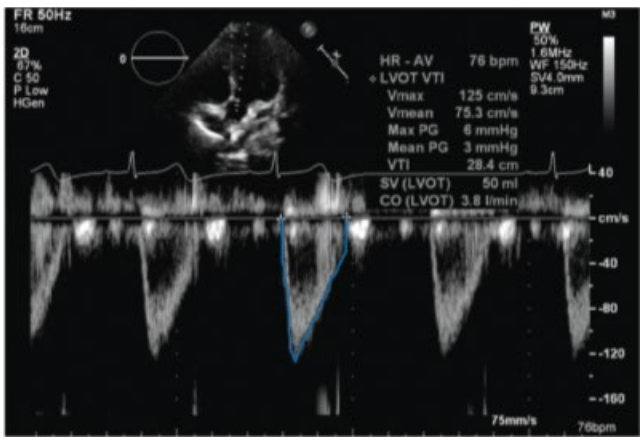
It is often important to estimate cardiac output, which can be measured by a variety of modalities. Non-invasive techniques are most commonly used and include echocardiography, magnetic resonance imaging (MRI), and non-invasive Doppler devices; however, invasive thermodilution and Fick methods may still be used in many PICUs. Echocardiography determination of cardiac output requires measuring the LV outflow tract (LVOT) diameter and the velocity time integral of the Doppler signal across the LVOT (Fig. 42.2). When the LVOT velocity time integral (LVOT VTi) is multiplied by the area of the outflow tract, a good estimation of stroke volume is obtained, using the following equation:

$$\text{Stroke volume} = \text{LVOT VTi} \times \text{LVOT cross} - \text{sectional area}$$

The cross-sectional area is calculated from the measured LVOT diameter, since area = $\pi \times (\text{diameter}/2)^2$. Cardiac output then simply becomes the calculated stroke volume multiplied by the heart rate. This Doppler-derived method assumes laminar flow across the LVOT and has been shown to be reproducible even in the context of severe heart disease [58]. LVOT



(A)



(B)

Figure 42.2 The left ventricular outflow tract (LVOT) diameter is measured in the parasternal long axis view (A) and the use of pulsed Doppler for the measurement of the velocity–time integer (VTi) is obtained in the five-chamber apical view (B). Cardiac output (CO) = SV × HR and SV = VTi × LVOT cross-sectional area. The LVOT cross-sectional area = $\pi/(\text{diameter}/2)^2$. *Source:* Reproduced from Gaspar and Morhy [334]. Gaspar, https://www.hindawi.com/journals/bmri/2015/596451/abs/. Licensed under CC BY 3.0.

VTi alone has been suggested to outperform both ejection fraction and Doppler-derived cardiac output [59]. Cardiac output by MRI can also be determined and is typically the modality of choice for measuring RV function. However, the disadvantages include transportation away from the PICU and the need for sedation in young children who cannot remain still for the time required to obtain adequate images. In 2001, the non-invasive, transcutaneous Doppler ultrasound device was introduced, and appears to be a promising adjunct in the assessment of the cardiovascular state in a variety of patients. For example, the ultrasonic cardiac output monitor (USCOM, Sydney, Australia) uses high-fidelity continuous wave Doppler to measure cardiac blood flow by placing a transducer in the left parasternal position or suprasternal notch to measure transaortic blood flow. Using a nomogram for aortic valve cross-sectional area, the cardiac output can then be continuously measured using the same principles used with Doppler echocardiography as described above. Given the continuous information this device can provide, the operator can measure response and effectiveness to medical therapy. The accuracy of such devices depends on obtaining accurate LVOT VTi, therefore continuous monitoring assumes that the ultrasound beam from the transducer remains in the same plane as the blood flow and does not move. As with Doppler echocardiography to measure cardiac output, the presence of aortic regurgitation, ascending aortic aneurysm, and arrhythmias may be sources of error. Further validation of such devices is ongoing, with recent studies showing some promise [60–62].

Cardiac output at the bedside can also be measured by the Fick method, where oxygen consumption (VO_2) is estimated, or with thermodilution using a pulmonary artery (PA) catheter. Both methods require invasive monitoring with central venous access. Furthermore, placement of a PA catheter requires a sheath to access the vein, which may present undue harm. As a result, such methods are infrequently used in children. The Fick method states that the amount of a substance taken up by the body per unit of time is equal to the arterial amount of oxygen minus the venous amount of oxygen multiplied by the cardiac output. Thus, cardiac output can then be calculated by the following formula:

$$\text{Cardiac output} = VO_2 / (C_aO_2 - C_VO_2)$$

where C_aO_2 is the arterial oxygen content and C_VO_2 is the mixed venous oxygen content (mL of O_2/dL). Oxygen consumption is difficult to measure and is therefore estimated, hence the accuracy of the Fick method relies on the correct estimation of oxygen consumption (VO_2), making it prone to error. Normal resting VO_2 is 125 mL O_2/min per m^2 body surface area (BSA). For the average adult whose BSA is 2 m^2 this is 250 mL O_2/min. Ideally with the patient breathing air, C_aO_2 and C_VO_2 can then be measured from arterial and mixed venous blood samples, respectively. Oxygen content of blood is the amount of oxygen bound to hemoglobin plus the amount of oxygen dissolved in blood, as shown by the equation:

$$O_2 \text{ content}\,(\text{mL } O_2 / \text{L}) = (1.34 \times \text{Hb} \times O_2 \text{ saturation} \times 10) + (0.003 \times PO_2)$$

where Hb is the hemoglobin (g/dL), PO_2 is the partial pressure of oxygen in blood (mmHg), 1.34 represents the amount of oxygen bound per gram of hemoglobin (mL O_2/g of Hb), and 10 represents the conversion for dL to liter. As an example, for a child with a BSA of 1.5 m^2 and Hb concentration of 14 g/dL, a blood gas drawn from a peripheral arterial line (P_aO_2 of 90 mmHg and S_aO_2 of 100%) and a blood gas drawn from a central line in the internal jugular vein ($P_{mv}O_2$ 35 mmHg and $S_{mv}O_2$ 70%), using the equation above the C_aO_2 is 187.87 mL O_2/L and the C_VO_2 is 131.43 mL O_2/L. Assuming a VO_2 of 125 mL/min/m^2, the cardiac output = (125 mL O_2/min × 1.5 m^2)/(187.87 mL O_2/L – 131.43 mL O_2/L) = 187.5/56.44 = 3.32 L/min.

The thermodilution method to calculate cardiac output uses a PA catheter and involves injecting a known quantity of an indicator (room temperature or iced sterile crystalloid) into the right atrium and then measuring the change in temperature downstream at the PA. Using software, this change in temperature measured at the thermistor of the PA catheter is graphed over time (Fig. 42.3). A curve is generated, with the area under the curve (AUC) representing the cardiac output. Cardiac output is inversely proportional to the AUC, thus the smaller the AUC the higher the cardiac output because there is less time for the thermistor to record a temperature change due to the higher cardiac output. Conversely, when blood flows slowly across the thermistor (low cardiac output), there is a greater change in temperature and the AUC is higher. Accuracy of thermodilution relies on proper temperature and volume of injectate, absence of concomitant intravenous solutions that can interfere with accurate temperature measurement, absence of respiratory cycle interference (injection is best when done at the end of expiration), proper PA catheter position, and the absence of an intracardiac shunt and right heart valvular regurgitation. With the inherent risk of

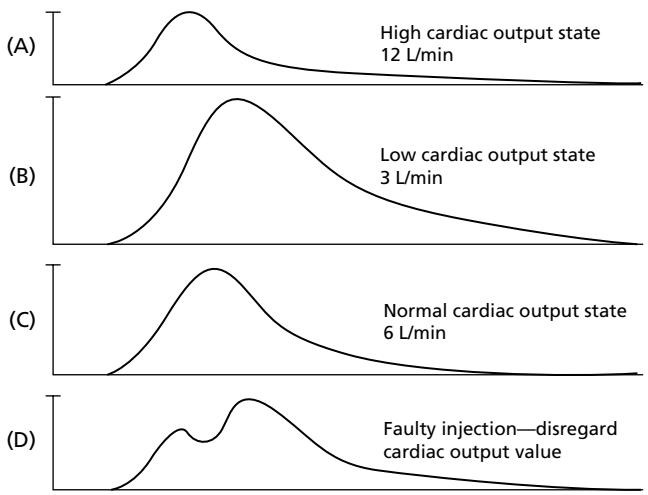


Figure 42.3 Various cardiac output thermodilution curves. The amount of temperature change is plotted along the *y*-axis and time is plotted along the *x*-axis. Administration of the cold injectate occurs just before the slope of the line starts to rise. Normal cardiac output (curve C) shows a smooth upstroke with a gradual downslope back to the baseline. When CO is high (curve A) the rise will be less than normal because the blood flow is higher past the thermistor tip of the pulmonary artery catheter, subsequently causing a smaller change in temperature. Conversely, with low CO (curve B) the rise will be greater because the blood flow past the thermistor will be slower, allowing a greater change in temperature to occur. Faulty injections (curve D) will often have uneven upstrokes on the curve, mandating a repeat injection. *Source:* Reproduced from Cruz and Franklin [335] with permission of Elsevier.

insertion and maintenance of PA catheters, and the emergence of newer non-invasive modalities, the use of PA catheters has decreased in PICUs over time. See Chapter 19 for further discussion of cardiovascular monitoring.

KEY POINTS: ASSESSMENT OF CARDIOVASCULAR FUNCTION

- Physical exam, ECG, arterial and central venous pressure; and peripheral, mixed venous, cerebral, and somatic oximetry, are all used to assess cardiac and circulatory function
- Echocardiography, including point of care bedside echo, can be extremely useful in assessment of cardiac function, filling, abnormal anatomy, and pericardial effusion
- Pulmonary artery catheterization and cardiac output measurement, pulmonary capillary wedge pressure, and oxygen delivery measurement and calculations are possible in selected PICU patients but are infrequently used

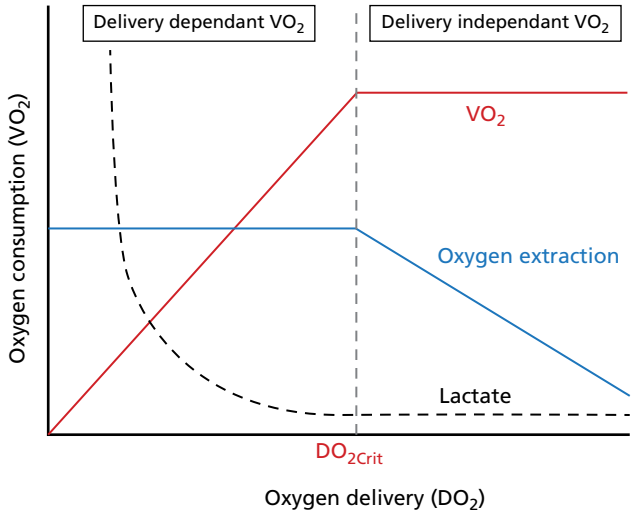

Figure 42.4 Oxygen delivery (DO_2) and consumption (VO_2) curves. As DO_2 decreases, VO_2 remains constant due to increasing oxygen extraction – during this time DO_2 is independent of VO_2. Once a critical point of DO_2 is reached, oxygen extraction cannot increase any further. Thus any further decrease in DO_2 will result in decreased VO_2. This leads to a shift to anaerobic metabolism with lactate production. Eventual circulatory collapse occurs if interventions fail to raise DO_2 back to, or above, the critical point.

Definition of shock

Shock is an unstable condition characterized by the inability to deliver adequate tissue perfusion to meet cellular needs, which can result in abnormal tissue function. Cellular hypoperfusion results in tissue hypoxia, disruption of intracellular milieu, intracellular acidosis, and abnormal cellular function. Although the initial effects can be reversed, prolonged deficiency can lead to irreversible organ injury and death. It must be recognized that shock can also occur in situations where adequate tissue perfusion exists, but there is still abnormal cellular function. In such conditions, the problem is impaired cellular uptake and/or utilization of oxygen, resulting in end-organ failure and death if not reversed. Therefore, early recognition and intervention has been the staple for the treatment of shock.

Effective management of shock requires an understanding of oxygen delivery (DO_2) and VO_2. Oxygen delivery includes the oxygen content of arterial blood (C_aO_2) and cardiac output (CO), as seen by the following equation:

$$DO_2\,(\text{mL of } O_2/\text{min}) = CO \times C_aO_2 \times 10\,\text{dL/L}$$

where cardiac output (L/min) is dependent on heart rate and stroke volume, and C_aO_2 (mL O_2/dL) encompasses the oxygen saturation and hemoglobin level, as described earlier. Tissue oxygen demand dictates VO_2. VO_2 is equal to DO_2 multiplied by oxygen extraction: $VO_2 = DO_2 \times$ oxygen extraction. As seen from the equation, when tissues are initially deprived of DO_2 in early shock, oxygen extraction increases to maintain VO_2 in an attempt to maintain aerobic metabolism. This increase in oxygen extraction is effective in most situations to maintain aerobic metabolism. Furthermore, redistribution of blood to organs that have little oxygen reserve, such as the brain and heart, occurs by sympathetic stimulation. But as shock continues, there comes a critical point (DO_{2crit}) where the ability to further increase oxygen extraction stops (Fig. 42.4). Beyond this, any further decrease in DO_2 results in a decrease in VO_2, exhausting the body's oxygen reserve and shifting to anaerobic metabolism, causing a rise in serum lactate. If interventions are not successful in raising DO_2 to at least the critical point, circulatory collapse ensues.

The effective management of shock requires interventions to improve DO_2 and reduce VO_2. VO_2 can be reduced by sedation and paralysis. DO_2 can be increased by interventions to improve both CO and C_aO_2. It is most easily done by increasing inspired oxygen concentration, maintaining appropriate hemoglobin level, and ensuring adequate heart rate and preload. The initial stage of resuscitation includes achieving adequate circulating intravascular volume by rapid intravenous fluid administration. Although crystalloids have no oxygen-carrying capacity, with intact cardiac function they can improve CO and microcirculatory perfusion, and subsequent DO_2. Improvement in CO from fluid resuscitation occurs because of an increase in fluid in the central venous system that allows more blood to flow down the pressure gradient between the central veins and the right atrium (RA). As a result, the RA pressure rises and improves both ventricular filling (preload) and myocardial stretch, leading to optimal contractility according to the Frank–Starling principle. Eventually there comes a point where further increases in RA pressure with fluid administration does not lead to improved CO, indicating the patient is no longer "fluid responsive." Thus, interventions to improve CO with the administration of adrenergic drugs may be necessary. Adrenergic agonists affect inotropy (force of contraction), chronotropy (heart rate), and systemic vascular resistance via stimulation of α- and β-adrenergic receptors (Table 42.2).

Several different classifications of shock exist. One of the most recognized classifications includes hypovolemic, distributive, cardiogenic, and obstructive shock. Each category is not mutually exclusive; a disease state can include more than one shock state.

Hypovolemic shock occurs due to loss of intravascular blood volume from either hemorrhage (e.g. trauma, surgical, or

Table 42.2 Continuous vasoactive medications

Drug	Dose	α-receptor	β1-receptor	β2-receptor	Effect	Comment(s)
Dopamine (DA)	1–10 μg/kg/min	0	++	++	Primary β effect at lower doses will increase HR, improve inotropy, and decrease systemic vascular resistance (SVR)	Because it improves CO and decreases SVR it is useful in cold shock, where the CO is low and SVR is high
	10–20 μg/kg/min	+++	++	0	Better vasoconstrictor (α > β) effect at higher doses	Greater potential of arrhythmias with higher doses. Inhalational agents may enhance arrythmogenic effects of DA
Dobutamine	1–20 μg/kg/min	+	+++	++	Primary β effects increases HR and cardiac contractility, while decreasing SVR	Useful for cardiogenic shock (low CO with preseved BP due to normal or high SVR). It can also be used with NE to improve inotropy and counteract the intense vasoconstriction of NE
Epinephrine	0.05–0.1 μg/kg/min	++	++	++	Has some β_2 effect at lower doses	First-line choice for cold hypodynamic shock. Lower doses may decrease SVR and redirect blood flow away from the splanchnic circulation, even though BP and CO increase
	0.1–0.3 μg/kg/min	++++	++++	++	More vasoconstriction (α) and inotropic (β_1) effects at higher doses	Epinephrine can cause an increase in lactate that is independent of lactate changes due to organ hypoperfusion
Norepinephrine	0.05–0.5 μg/kg/min	++++	++	0	Increases SVR (α) far more than it increases HR and contractility (β)	Some advocate its use as a first-line agent in fluid refactory, hypotensive, hyperdynamic shock (i.e. low SVR states characterized by wide pulse pressure with a DBP that is less than half the SBP)
Phenylephrine	0.1–2 μg/kg/min	++++	0	0	Direct α agonism produces intense venous and arterial vasoconstriction, with a reflexive decrease in HR	Especially useful in neurotrauma to improve MAP (and hence cerebral perfusion) without increasing cerebral metabolism and blood glucose
Milrinone	0.25–1 μg/kg/min	N/A	N/A	N/A	Selective phosphodiesterase III inhibitor that blocks cAMP hydrolysis	Altrenative to dobutamine in cardiogenic shock. Has synergistic effects with β-adrenergic agonists (which increase cAMP production) to improve inotropy. Should be used with caution as it can reduce SVR, which then leads to hypotension
Vasopressin	0.1–2 mU/kg/min	N/A	N/A	N/A	Its actions are independent of catecholamine receptor stimulation	Increases MAP by increasing SVR, without any significant increase in PVR. Can be considered in catecholamine-resistant vasodilatory shock

BP, blood pressure; cAMP, cyclic adenosine monophosphate; CO, cardiac output; DBP, diastolic blood pressure; HR, heart rate; MAP, mean arterial pressure; NE, norepinephrine; PVR, pulmonary vascular resistance; SBP, systolic blood pressure; SVR, systemic vascular resistance.

gastrointestinal blood loss) or non-hemorrhagic causes. Non-hemorrhagic causes include intravascular volume loss (e.g. from gastroenteritis, diabetes insipidus, diabetes mellitus, heat stroke, burns, or decreased fluid intake) or fluid redistribution to the interstitial space (e.g. from sepsis, surgery, burns, intestinal obstruction, nephrotic syndrome, anaphylaxis, or trauma).

Distributive shock occurs as a result of inappropriate loss of peripheral vascular tone, leading to vasodilation and low systemic vascular resistance (SVR). This results in a relative hypovolemia due to an inadequate effective blood volume with a maldistribution of blood flow to organs. Blood pressure is low and CO can either be increased, unchanged, or decreased. Common causes include sepsis, anaphylaxis, neurological injury, and drug-related causes. Sepsis is perhaps the best studied and occurs from a dysregulated systemic inflammatory state in response to an infection.

Cardiogenic shock is characterized by impairment in myocardial contraction. In children without congenital heart disease (CHD), shock is most often secondary to myocarditis or cardiomyopathy, whereas shock from dysrhythmias and myocardial infarction are less common than in adults. Children with CHD who undergo repair on cardiopulmonary bypass can have postoperative low cardiac output syndrome. Some children with CHD, especially those who undergo palliative surgical procedures (e.g. Fontan), can develop ventricular failure from chronic valvular insufficiency or obstruction, as well as chronic volume overload from residual or unrepaired shunts.

Obstructive shock occurs when forward flow of blood through the heart is impaired, either from a congenital or acquired lesion. Common causes include cardiac tamponade, increased intrathoracic pressure from a tension pneumothorax, massive pulmonary embolism, pulmonary hypertension, hypertrophic obstructive cardiomyopathy, aortic valve stenosis, aortic dissection, and mediastinal masses.

The presentation of shock in children differs with age. Adults and older adolescents typically exhibit a warm shock state – decreased perfusion with brisk capillary refill and bounding peripheral pulses secondary to low SVR and normal to increased CO. Infants and young children more commonly have a cold shock state – decreased perfusion with delayed capillary refill, diminished peripheral pulses, and cool or mottled extremities secondary to increased SVR and low CO. This difference reflects the inability of infants and young children to significantly increase heart rate and SVR to the same extent as adults [63]. Consequently, vasoconstriction resulting in cold shock is the predominant response to a decrease in CO in pediatric septic shock, with hypotension manifesting as a relatively late finding in young children [64].

Treatment of shock

Guidelines for treatment of pediatric shock include treating the underlying cause, restoration of appropriate DO_2 to all tissues of the body, and removal of metabolic products produced during anaerobic metabolism. In general, established resuscitation guidelines for pediatric septic shock serve as the best example for other types of shock. The management of pediatric sepsis has been addressed at length in the Surviving Sepsis Campaign Guidelines (SSCG) in 2008 and 2012, but the most recent guidelines in 2016 did not include any additional specific recommendations in the management of pediatric sepsis. Much of what has been suggested, however, is based on expert consensus and adult evidence.

For a patient with suspected sepsis, the SSCG in 2012 suggested a protocolized approach [65]. Many recommendations were made, but emphasis was clearly on early initial resuscitation, obtaining blood cultures prior to antibiotic initiation, prompt imaging to identify potential sources for infection, early administration of empirical broad-spectrum antibiotics within 1 h of recognition of severe sepsis, and early and aggressive source control. The initial evaluation of a child begins with assessment of the state of perfusion and, if impaired, rapid intravenous access and administration of parenteral fluids should begin, with the goal to restore tissue DO_2 within the first 6 h. At the same time, laboratory tests should be obtained, and include: complete blood count, C-reactive protein, comprehensive metabolic chemistry panel (including liver and renal function tests), coagulation panel, fibrinogen, lactate, and blood or other fluid bacterial and fungal cultures. The implementation of a bundled approach to resuscitation can improve adherence to guidelines, decrease time to therapy, and improve outcomes in septic shock [66,67]. For example, implementation of a sepsis resuscitation protocol improved the median time to antibiotic administration from 130 to 30 min ($p < 0.001$) in children with severe sepsis or septic shock when they arrived at the emergency department [66].

Initial resuscitation of pediatric sepsis begins with infusion of up to 20 mL/kg of isotonic crystalloids over 5–10 min, titrated to reversal of hypotension, increased urine output, and achievement of normal capillary refill, peripheral pulses, and improved level of consciousness without inducting hepatomegaly or rales. If intravenous access cannot be obtained quickly within 5 min, it is recommended to place an intraosseous (IO) needle to prevent further delays in resuscitative measures, as it is considered to be as good as a peripheral IV for administration of fluid and medications. This is important since a higher mortality rate in children can occur when administration of 40 mL/kg is not achieved within the first hour or treatment is not initiated within the first 30 min after diagnosis (Fig. 42.5) [68].

The choice of initial fluid for resuscitation has been the subject of much recent debate. Crystalloids are typically the preferred initial choice for volume resuscitation in children because of their near-universal availability, low cost, and perceived safety. However, it must be recognized that crystalloids can quickly redistribute between the plasma and the extracellular fluid within 30 min of administration and have little oncotic properties, requiring ongoing administration. Recent concern about the use of 0.9% saline (a non-buffered/non-balanced salt solution) has emerged due to supraphysiological chloride content promoting renal injury and exacerbating systemic inflammation when compared with balanced solutions (lactated Ringer's or Plasma-Lyte®) in adults [69,70]. Although no large, randomized prospective study exists, the clinical relevance of this should be recognized and the use of a balanced salt solution should receive consideration. Nonetheless, using a large pediatric administrative database, Weiss et al showed that resuscitation in pediatric sepsis with lactated Ringer's was not associated with improved outcomes compared with 0.9% saline [71]. More studies on 0.9% saline are needed before its use is discouraged, therefore any readily available crystalloid for initial resuscitation should suffice, but consideration to switch to a balanced salt solution should occur if arterial pH falls below 7.20 or serum chloride rises to more than 110 mEq/L [63]. The use of colloids is an appealing alternative to crystalloid fluid – on the one hand they can improve plasma oncotic pressure and better restore intravascular volume, but in the presence of capillary leak they may exacerbate interstitial edema. The literature on colloid versus crystalloid for initial resuscitation is mixed, and until definitive data exist guidelines continue to recommend crystalloid for initial resuscitation but acknowledge that the addition of colloids such as 5% albumin represent a reasonable option for children with persistent shock and hypoalbuminemia (serum albumin <3 g/dL) despite 60 mL/kg of 0.9% saline or lactated Ringer's [65].

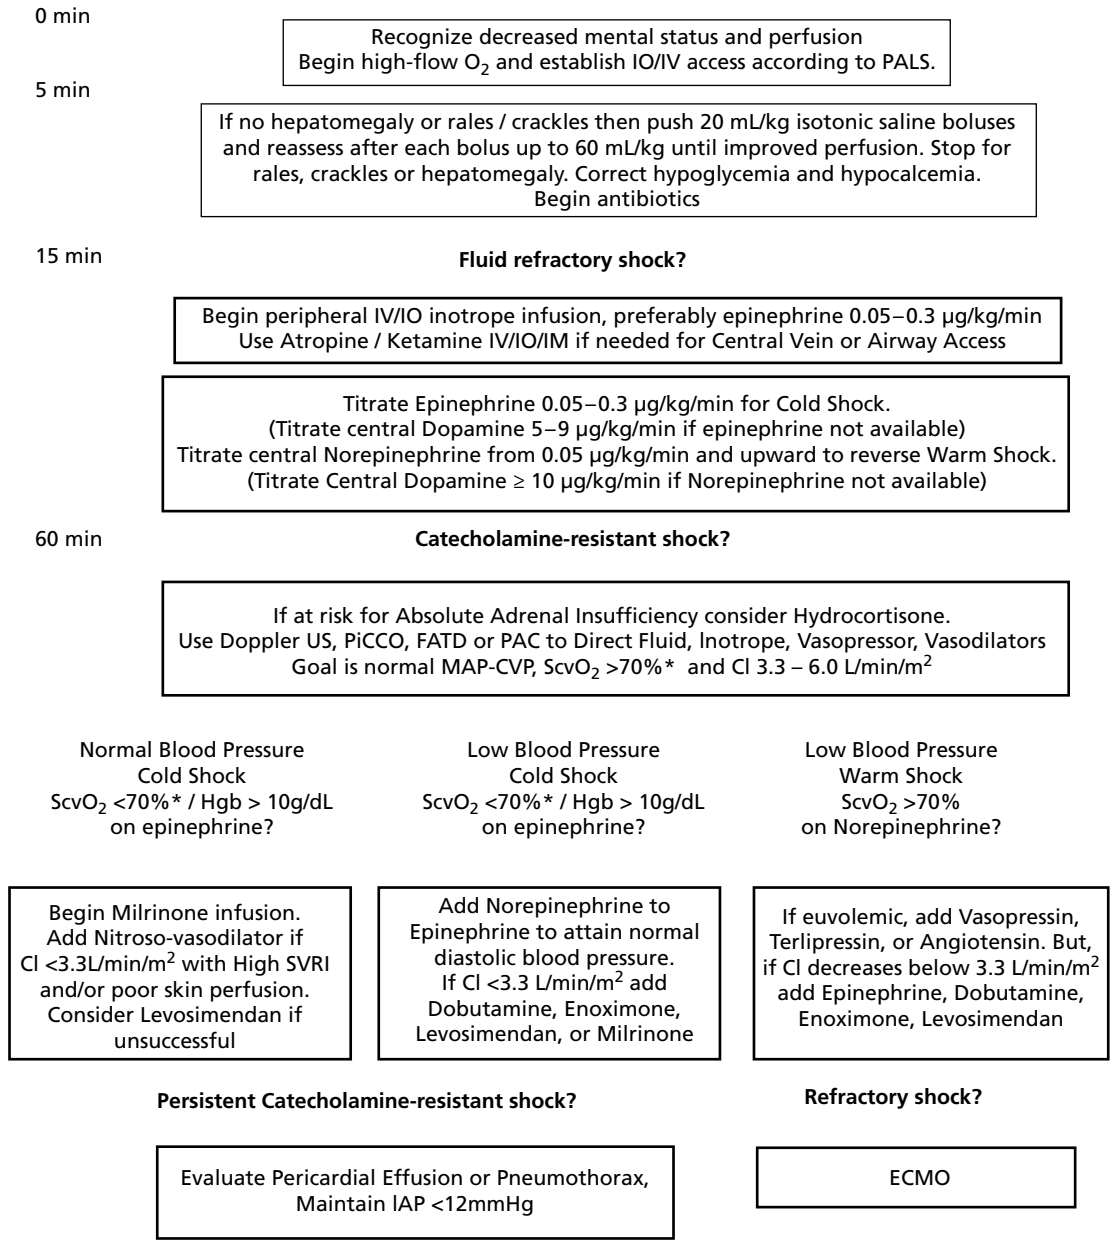

Figure 42.5 The American College of Critical Care Medicine algorithm for time-sensitive, goal-directed management of hemodynamic support in infants and children. Proceed to the next step if shock persists. (1) First-hour goals – restore and maintain heart rate thresholds, capillary refill ≤2 s, and normal blood pressure in the first hour or in the emergency department. (2) Subsequent intensive care unit (ICU) goals – if shock is not reversed proceed to restore and maintain normal perfusion pressure (MAP – CVP) for age, $ScvO_2$ >70% (* except congenital heart patients with mixing lesions), and cardiac index (CI) >3.3 to <6.0 L/min/m^2 in the PICU. CVP, central venous pressure; ECMO, extracorporeal membrane oxygenation; FATD, femoral arterial thermodilution; Hgb, hemoglobin; IAP, intra-abdominal pressure; IM, intramuscular; IO, intraosseous; IV, intravenous; MAP, mean arterial pressure; PAC, pulmonary artery catheter; PALS, pediatric advanced life support; PiCCO, pulse contour cardiac output; SVRI, systemic vascular resistance index; US, ultrasound. *Source:* Reproduced from Davis et al [82] with permission of Wolters Kluwer.

Early goal-directed therapy (EGDT) in adults was first shown to significantly reduce mortality in adults with septic shock (30.5% versus 46.5%, p = 0.009) in 2001 [72]; since that time, aggressive fluid resuscitation followed by initiation of inotropic and/or vasoactive medications for pediatric patients with fluid-refractory shock has been advocated. EGDT helps guide resuscitative efforts toward improvement in physiological parameters. A variety of clinical parameters, hemodynamic monitoring, and laboratory data can be used to asses a patient's response to fluid therapy, including heart rate, blood pressure, capillary refill time, quality of central/peripheral pulses, mental status, urine output (goal ≥0.5 mL/kg/h), CVP, central venous oxygen saturation ($S_{CV}O_2$), and serum lactate [63]. In the landmark adult study of EGDT, a continuous target $S_{CV}O_2$ >70% with red blood cell (RBC) transfusion was implemented [72]. A reduction in mortality was also seen in pediatric sepsis when continuous $S_{CV}O_2$ monitoring (39.2% versus 11.8%, p = 0.002) [73] or intermittent $S_{CV}O_2$ monitoring (33% versus 55%, p = 0.02) [74] was performed. Implementing EGDT in children therefore requires invasive central venous access, which may not be easy to obtain and may potentially distract providers from resuscitative efforts. Moreover, recent

larger studies in adults that compared EGDT with continuous $S_{CV}O_2$ monitoring with usual care showed them to be equally effective [75–78]. This change likely exists because the early sepsis trials that demonstrated significant mortality benefit with EGDT were limited by small sample size, non-randomization, and incomplete adherence to protocols [79]. Patients enrolled in more recent studies may have benefited from improved identification of sepsis, early antibiotic administration, and aggressive fluid resuscitation which have been established as standards of care since the original EGDT articles were published. Monitoring of $S_{CV}O_2$ is therefore recommended only if central venous access is established for other reasons.

An alternative to $S_{CV}O_2$ is monitoring blood lactate levels, as it is a surrogate for tissue hypoxia and anaerobic metabolism. In adults, initial level correlates with increased mortality [80], and in children whose serum lactate normalized to <2 mmol/L within 4 h of the onset of management had decreased organ dysfunction at 48 h [81]. It should be noted that the absence of elevated serum lactate does not equate to absence of severe sepsis, as not all septic patients have an elevated serum lactate. Therefore, resuscitation should not be delayed in the absence of elevated lactate.

Inotropic and vasoactive agents are frequently necessary to restore tissue perfusion in septic shock. They should be instituted if shock persists after 60 mL/kg of isotonic fluid have been administered in 15 min (fluid-refractory shock). Ideally, with each 20 mL/kg administration the patient should be evaluated for changes in clinical parameters, and if signs of fluid overload (i.e. hepatomegaly, rales, hypoxemia, tachypnea) are present, resuscitation should continue with the administration of inotropic agents. Furthermore, in patients with suspected or known components of cardiogenic shock, volume resuscitation should proceed judiciously with fluid boluses (5–10 mL/kg at a time), and, if necessary, should proceed with inotropic support using dopamine or norepinephrine.

Choosing the appropriate vasoactive mediation in children depends on the underlying clinical features. Either dopamine or epinephrine should be used if low CO and high SVR are present (cold shock) [82], but norepinephrine used if high CO and low SVR are present (warm shock) [65]. Children may have shifts between shock states, and therefore changes in vasoactive medications may be needed.

Alternative vasoactive agents in pediatric septic shock include milrinone and vasopressin. Milrinone is a phosphodiesterase-3 inhibitor most commonly used in cardiogenic shock because it improves inotropy and lusitropy (myocardial relaxation), and decreases SVR. In one randomized control trial in pediatric septic shock, when milrinone was administered together with catecholamines to volume-resuscitated patients, it improved cardiovascular function (cardiac index, stroke volume index, and DO_2) while significantly decreasing the SVR index [83]. In adults with catecholamine-resistant vasodilatory (warm) shock, vasopressin is suggested as an alternative to restore optimal tissue perfusion [65]. However, in a 2017 systematic review of children receiving vasopressin or terlipressin, there was no observed benefit on mortality and length of PICU stay, only a trend towards increased risk for tissue ischemia [84]. This difference in efficacy has been suggested to be due to variable levels of vasopressin and its precursor copeptin in children with septic shock, compared to the relative deficiency among adults [85].

The use of corticosteroids in shock is controversial. In the 2012 SSCG the use of steroids was only recommended for children with (1) fluid-refractory, catecholamine-resistant shock, and (2) suspected or proven adrenal insufficiency [65]. A single stress dose of hydrocortisone (50–100 mg/m^2/day) should be given as early as possible. A serum cortisol level should be drawn prior to administration of the first dose, because if it is low it suggests that ongoing replacement may be beneficial. It is reasonable to continue replacement steroids until the patient becomes hemodynamically stable and no longer requires vasoactive infusions; however, there is insufficient evidence to support a particular duration of time over which to wean the steroids. On the other hand, there is no proven benefit of steroids in patients with a relative adrenal insufficiency from a critical illness [86,87].

The administration of RBCs is recommended to maintain a hemoglobin goal of 10 g/dL during the initial management of septic shock, however lower hemoglobin levels could be tolerated if there is no cardiovascular instability or decreased DO_2. In one study, critically ill children who were randomized to a restrictive strategy group (Hb <7 g/dL) received 44% fewer transfusions and had no significant difference in new or progressive multiple organ dysfunction, compared with the liberal strategy group (Hb <9.5 g/dL) [45].

Intravenous immunoglobulin is an adjuvant that has been suggested for certain patients with sepsis, but pediatric studies are mixed regarding its benefit, unless there is concern for toxic shock syndrome [88,89]. Other therapies such as plasma exchange and immunomodulation therapies exist for certain subsets of shock, but general use is discouraged.

KEY POINTS: DEFINITION AND TREATMENT OF SHOCK

- Shock is characterized by the inability to deliver adequate tissue perfusion and oxygenation to meet cellular needs, which can result in abnormal tissue function
- Shock may be hypovolemic, distributive, cardiogenic, or obstructive
- Treatment of shock depends on the cause but involves increasing oxygen delivery and maintaining or decreasing oxygen consumption

Disorders of cardiac rhythm

Arrhythmias in children occur more frequently in children with underlying CHD than in those with a structurally normal heart [90]. Children with CHD have a lifelong risk for the development of arrhythmias. Arrhythmias can occur secondary to electrolyte abnormalities, myocardial hypoxemia, elevated catecholamine states (e.g. pain, anxiety, fever), or due to iatrogenic causes (e.g. central venous catheters, drug-induced). Arrhythmias most commonly affect hemodynamics when ventricular function is compromised. Thankfully emergencies due to unstable arrhythmias are rare in children [90].

Arrhythmias originate above the ventricles (atrial or supraventricular) or from the ventricles. Premature atrial

contractions are usually benign, even if they occur frequently. Premature ventricular contractions have a wider QRS complex followed by a pause, and if frequent require investigation because they may contribute to LV dysfunction. Correction of electrolyte abnormalities and screening for underlying cardiac disease is necessary.

Arrhythmias can also be classified as either tachyarrhythmias or bradyarrhythmias. Tachyarrhythmias decrease diastolic time, which can result in myocardial ischemia from increased demand and decreased supply. This is most problematic in children with underlying heart disease. Bradyarrhythmias, however, are more concerning in young infants and children because the stroke volume does not increase with lower heart rates to maintain CO [91].

Supraventricular tachycardia (SVT) describes any narrow complex (QRS <120 ms) tachyarrhythmias that originate above the bundle of His. SVT is due to re-entry pathways or increased automaticity. Tachycardia from re-entry originates from circuits within an accessory pathway (atrioventricular (AV) re-entry tachycardia), within the AV node (AV nodal re-entry tachycardia), or within the atrium (atrial flutter or fibrillation). Tachyarrhythmias from increased automaticity occur from foci within the atrium (ectopic atrial tachycardia, multifocal atrial tachycardia) or from ectopic junctional foci.

Atrioventricular re-entry tachycardia is the most common type of SVT in children, and more commonly occurs in infants [90]. It classically involves antegrade conduction down the AV node with retrograde conduction back up to the atrium through the accessory pathway which lies outside the AV node. However, during sinus rhythm antegrade conduction across both the AV node and accessory pathway results in the characteristic pre-excitation of the QRS wave ("delta wave"). This ECG finding is known as the Wolf–Parkinson–White pattern, and for those who develop SVT it is known as the Wolf–Parkinson–White syndrome. AV nodal re-entry tachycardia is the most common SVT in older children and adolescents [90]. It occurs when there are two pathways within the AV node itself, each having different conduction and refractory periods. Management of both AV re-entry tachycardia and AV nodal re-entry tachycardia is similar. If hemodynamically stable, termination of the rhythm can be attempted with vagal maneuvers (bag of ice to the face) or pharmacological block of AV node conduction with adenosine (initial dose of 100 μg/kg with subsequent increases of 100 μg/kg to a maximum of 400 μg/kg/dose). If adenosine is unsuccessful or the child is hemodynamically unstable, synchronized direct current (DC) cardioversion (0.5 J/kg) should be administered. If re-entry recurs, sotalol, flecainide, or amiodarone may be necessary [90]. Verapamil is a calcium channel blocker that blocks the AV node for a longer period of time than adenosine, but due to its risk of hemodynamic collapse in infants <6 weeks of age its use is contraindicated in infants less than 2 years old [92].

Atrial flutter and atrial fibrillation are tachyarrhythmias that are rarely seen in children. Atrial flutter usually occurs in the newborn period, except in patients who have had CHD surgery (tetralogy of Fallot, atrial septal defect, or Fontan operations). It is due to a re-entry circuit around the tricuspid valve. Adenosine does not convert atrial flutter or fibrillation to a sinus rhythm and can lead to serious rhythm degeneration and even death. Acute atrial flutter or fibrillation can be terminated with pharmacological (IV amiodarone) or electrical DC cardioversion. Evaluation of an atrial thrombus should be considered prior to cardioversion if long-standing. Alternatively, rate control without conversion can be achieved with β-blockers or calcium channel blockers.

Ectopic atrial tachycardia (EAT) and multifocal atrial tachycardia (MAT) occur from increased automaticity. When present, EAT can be difficult to control with medication and cardioversion. Treatment requires amiodarone, sotalol, flecainide, digoxin, or catheter ablation [90]. Early recognition and treatment are important since long-standing EAT can lead to tachycardia-induced cardiomyopathy. MAT is usually due to underlying CHD or metabolic abnormality [91]. Treatment of MAT involves treating the underlying condition, or achieving rate control with β-blockers and calcium channel blockers. Cardioversion of MAT can also occur with amiodarone or flecainide administration [90].

Junctional arrhythmias are supraventricular rhythms that originate above the bundle of His near the AV junction. They are characterized by a narrow QRS complex with a regular R-R interval, with absent or non-conducted P waves, unlike when the rhythm originates from the sinus node. Junctional rhythms can be slow (junctional bradycardia) or fast (junctional tachycardia). In children, the most common junctional rhythm is junctional ectopic tachycardia. It is seen following repair of CHD (e.g. ventricular septal defect, tetralogy of Fallot, AV canal) and can result in hemodynamic compromise. It occurs from AV dissociation with a ventricular rate that exceeds the atrial rate (e.g. if QRS rate >170 bpm, then the P wave rate <170 bpm). Treatment involves decreasing the ventricular rate by correcting fever and cooling to 32–34°C, correcting electrolytes, treating hypovolemia and anemia, discontinuing or reducing inotropes, optimizing sedation (i.e. dexmedetomidine) and neuromuscular blockade, IV amiodarone, and/or over-ride pacing.

Ventricular tachyarrhythmias have a widened QRS (≥120 ms) and can originate above the ventricles (i.e. SVT with aberrant conduction across an accessory pathway or associated bundle branch block) or from the ventricles (i.e. ventricular tachycardia). Regardless, it is important to initially evaluate and treat all ventricular tachyarrhythmias as if they are ventricular tachycardia (VT), which could be potentially life threatening [91]. Ventricular tachycardia (≥3 consecutive beats) originates below the bundle of His. If it lasts longer than 30 s, it is considered sustained VT. Monomorphic VT has the same QRS morphology whereas polymorphic VT has changing QRS complexes. The mechanisms by which VT occurs is similar to SVT, either by re-entry pathways or increased automaticity [90]. It can be seen in structural heart disease, myocardial ischemia, cardiomyopathy, myocarditis, drug toxicity, electrolyte derangements, and genetic channelopathies [90]. If the patient is hemodynamically stable, IV amiodarone (5 mg/kg over 30–60 min, maximum 300 mg/dose) or procainamide (15 mg/kg over 30–60 min) should be administered, with close hemodynamic monitoring [90]. Synchronized cardioversion (0.5-1 J/kg) is necessary if hemodynamic instability occurs at any point in time, and immediate defibrillation (2–4 J/kg) if the patient is pulseless. In torsades de pointes (wide QRS complexes "twisting" around the ECG axis) treatment is with IV magnesium sulfate (25–50 mg/kg).

Conditions that increase the risk of sudden cardiac death include structural abnormalities such as hypertrophic cardiomyopathy and arrhythmogenic right ventricular cardiomyopathy, as well as diseases without structural heart disease that include inherited channelopathies (Brugada syndrome, Lev–Lenègre syndrome, long QT syndrome, short QT syndrome, and catecholaminergic polymorphic VT) [93,94]. Such patients should have close cardiology care and those at high risk for degeneration to ventricular tachyarrhythmias may benefit from ICU placement.

Bradyarrhythmias can occur from a reduction in impulse generation at the sinus node or disruption of its propagation across the AV node. They are usually benign and rarely need acute treatment; however, they can represent life-threatening conditions that need prompt intervention, such as increased intracranial pressure (ICP), medication effects/overdose, myocardial ischemia, severe hypothermia, and acute systemic hypoxemia [90]. They can also occur in children following cardiac surgery due to injury to the sinus node, necessitating temporary pacing. Second- and third-degree heart block occurs due to intermittent failure or complete absence of conduction across the AV node, respectively. In infants, symptomatic patients may appear severely ill at presentation. Furthermore, in sick sinus syndrome an alternation between bradycardia and tachycardia can occur, known as tachy-brady syndrome. In such conditions, temporary or permanent pacemaker implantation may be necessary [90].

KEY POINTS: DISORDERS OF CARDIAC RHYTHM

- Arrythmias are more common in children with CHD and most commonly affect hemodynamics when underlying ventricular function is compromised
- Arrhythmias can be supraventricular or ventricular, or tachy- or bradyarrythmias
- Early rapid treatment of hemodynamically unstable tachydysrhythmias with drugs or cardioversion, and bradydysrhythmias with drugs or pacing, is essential to prevent further deterioration

Congenital heart disease

Care of the child with CHD begins at birth when the transition from fetal circulation occurs. If the underlying diagnosis was diagnosed prenatally, pre-emptive preparations and plans are typically in place prior to delivery of the infant. However, if there was no prenatal diagnosis, prompt recognition followed by stabilization and transport to an appropriate monitored location is needed. Children with CHD require a collaborative effort from many different subspecialties, which can be best accomplished in a children's hospital. Extracardiac malformations are also best addressed in such facilities.

Care for the newborn with suspected CHD is initially performed in a neonatal ICU or PICU. Recognition of newborns with CHD first begins by determining if the disease is ductal dependent. Ductal-dependent lesions require a patent ductus arteriosus to either provide adequate pulmonary blood flow or adequate systemic blood flow (Fig. 42.6). When the ductus arteriosus begins to close, newborns with ductal-dependent pulmonary blood flow will become profoundly cyanotic, whereas those with ductal-dependent systemic blood flow develop systemic hypoperfusion with shock. Quickly re-establishing ductal patency can restore stable physiology. A continuous infusion of prostaglandin E1 is started, and is best administered through reliable intravenous access, such as a central umbilical venous catheter. In extremis, IV or IO placement should not be delayed by attempts to place a central catheter.

Delineation of the underlying cardiac anatomy often only requires a transthoracic echocardiogram. Then, depending on the underlying lesion, a surgical or interventional procedure is necessary. Newborn surgical or interventional procedures (definitive or palliative) are performed to provide a more reliable source of blood flow. While awaiting intervention, frequent monitoring of oxygenation and systemic perfusion is required. In mixing lesions, where shunting can occur, an equal balance of pulmonary and systemic blood flow is targeted. Not infrequently this requires controlled ventilation with intubation and mechanical ventilator support or inotropic support with vasoactive medications. In cases of life-threatening cyanosis or pulmonary hypertension, a bedside balloon atrial septostomy under ultrasound guidance is performed. This allows increased amount of mixing at the atrial level (i.e. for transposition of great arteries) or relief of elevated right heart pressure in newborns with pulmonary hypertension. When such interventions fail, mechanical circulatory support (i.e. extracorporeal membrane oxygenation (ECMO)) may be necessary. Until a surgical or interventional procedure can be performed, the goal is to provide adequate end-organ perfusion. This is best monitored by observing the level of alertness/consciousness, myocardial function (i.e. correlate of adequate coronary perfusion), urine output, cerebral and somatic oximetry using near-infrared spectroscopy, capillary refill time, and serum laboratory values (lactate, renal, and liver function tests).

Postoperative surgical care almost exclusively occurs in specialized PICUs. Care has dramatically improved over the years and is thought to be attributable, at least in part, to improvements in diagnostic modalities, surgical techniques, cardiopulmonary bypass support, anesthetic management, postoperative care, and the use of ECMO to manage postoperative cardiac dysfunction [95]. A systematic and comprehensive hand-off between surgeon and anesthesiologist and the ICU team is mandatory when transitioning care. Standard of care universally involves continuous intra-arterial and CVP monitoring for children undergoing repair on cardiopulmonary bypass. While early extubation is safe in many cases, many children still require postoperative mechanical ventilation. The influence of cardiopulmonary interactions help dictate ventilator strategies and settings. Frequent assessment for postoperative bleeding is required, and in small children blood product replenishment is often necessary. Finally, postoperative cardiac function is of utmost importance. Low cardiac output syndrome is commonly observed 6–12 h after bypass, with an incidence of 25%, and requires inotropic support [95]. In addition, temporary cardiac pacing can be used to augment cardiac output or when conduction abnormalities occur (e.g. junctional rhythms, AV conduction block). As myocardial function improves, inotropic support and temporary

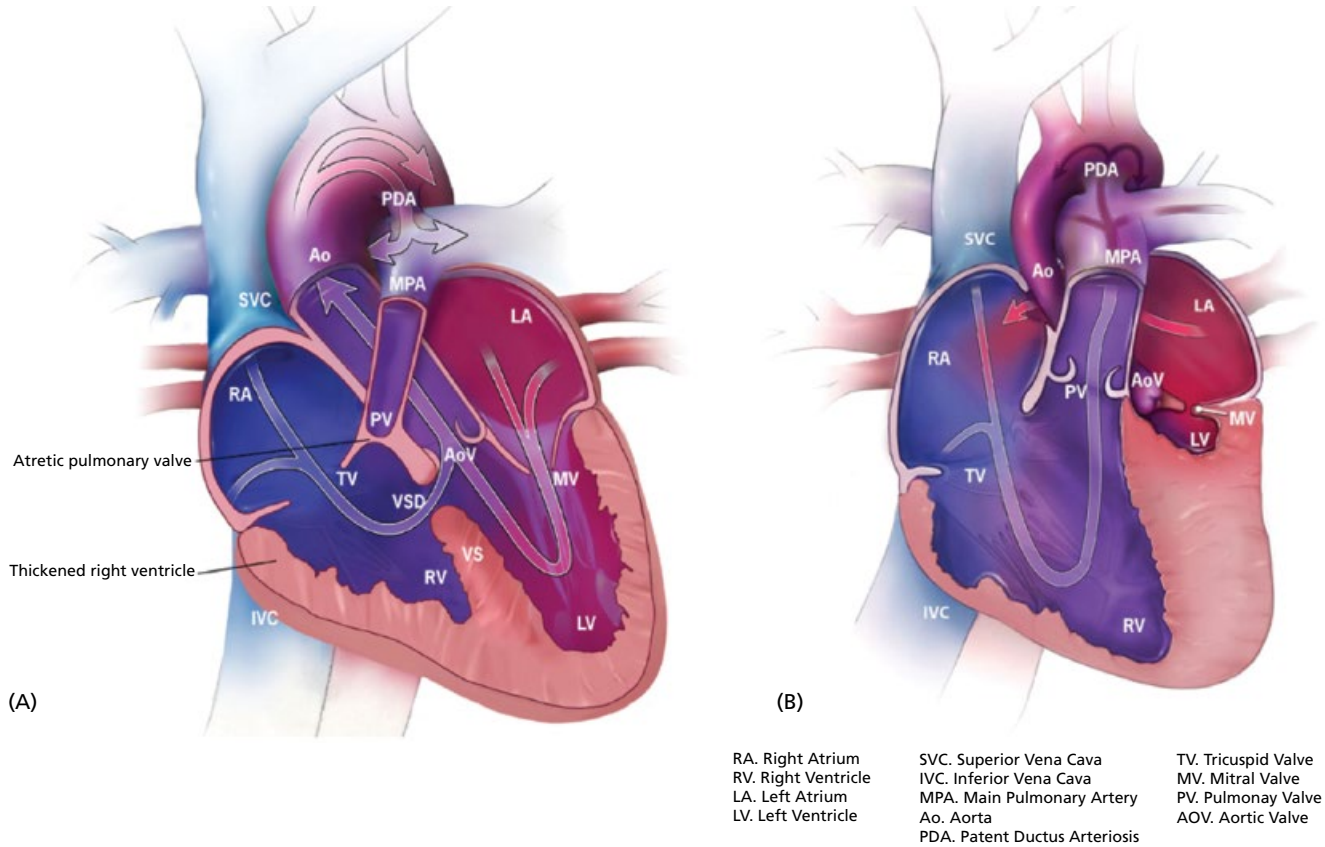

Figure 42.6 Many congenital heart disease lesions are ductal dependent with varying direction of blood flow across the ductus arteriosis. (A) Severe tetralogy of Fallot/pulmonary atresia: left-to-right flow, from the aorta to the pulmonary arteries (ductal-dependent pulmonary blood flow). (B) Hypoplastic left heart syndrome: right-to-left flow, from the pulmonary artery to the aorta (ductal-dependent systemic blood flow). Examples of ductal-dependent pulmonary blood flow include pulmonary atresia, critical pulmonary stenosis, tricuspid atresia, severe tetralogy of Fallot, and severe Ebstein anomaly. Examples of ductal-dependent systemic blood flow include critical aortic stenosis, interruption of the aortic arch, and hypoplastic left heart syndrome. *Source:* Courtesy of the Centers for Disease Control and Prevention, Division of Birth Defects and Developmental Disabilities.

pacing can be discontinued. If conduction abnormalities remain, permanent pacemaker implantation may be needed.

Although most surgical patients recover adequate ventricular function to separate from cardiopulmonary bypass, some do not. In such situations mechanical circulatory support with ECMO is needed. ECMO can also be initiated in the ICU should patients fail to recover adequate cardiac function. Should this situation arise, prompt evaluation of cardiac function and laboratory markers is needed. When cardiac function improves, ECMO can be discontinued. If it does not, further investigation with cardiac catheterization or surgical reintervention is indicated. However, despite all efforts, if recovery does not occur, either bridge to transplant or terminal discontinuation support may be necessary.

Medical cardiac disease

Heart failure in children can occur in both those with structurally normal hearts and in children with CHD. Cardiac dysfunction in non-surgical, structurally normal hearts can occur from a variety of factors: infection, autoimmune disease, chromosomal abnormalities, chronic arrhythmias, pulmonary hypertension, metabolic diseases, and toxin exposure, to name a few. This section will focus on two of the more common medical causes of heart failure resulting in admission to the PICU: myocarditis and cardiomyopathy.

Myocarditis

Myocarditis is an inflammatory disease that results in myocardial injury. It can present with a broad spectrum of clinical manifestations, ranging from generalized malaise to non-specific symptoms that rapidly progress to cardiac arrest. In the developed world, viruses are the most common etiology (adenovirus, coxsackie virus, parvovirus B19, Ebstein–Barr virus, human herpesvirus 6, cytomegalovirus, influenza virus) [96]. Myocardial injury is thought to be from both direct viral invasion and the host immune system response [96,97]. Delayed gadolinium enhancement of the myocardium on MRI is increasingly being used to evaluate children with suspected myocarditis, but endomyocardial biopsy or serum viral polymerase chain reaction studies are needed to identify the causative organism [96]. Outcomes for children are substantially better than in adults, with an overall mortality of 7.2% in one multi-institutional pediatric database [98]. Treatment depends on the severity of dysfunction. Acute management may include intravenous immunoglobulin, corticosteroids, inotropic agents, and even mechanical circulatory support as a bridge to recovery or transplantation (i.e. ECMO or ventricular assist device) [96]. Subacute and chronic management may also include diuretics, vasodilators, angiotensin-converting enzyme inhibitors, β-blockers, aldosterone antagonists, and aspirin. Functional echocardiographic recovery in children with myocarditis has been reported to be as high as 70%, with a cardiac transplantation requirement as high as 23% [99].

Cardiomyopathy

Pediatric cardiomyopathies are a group of diseases that affect the ventricular myocardium and is not due to abnormal loading conditions or CHD [100]. According to the International Society for Heart and Lung Transplant, cardiomyopathy is the most common cause of heart transplantation in children older than 1 year, with nearly 40% of children with a symptomatic cardiomyopathy either undergoing heart transplant or dying within 2 years [101]. The major cardiomyopathies encountered in childhood are dilated cardiomyopathy, hypertrophic cardiomyopathy, restrictive cardiomyopathy (RCM), LV noncompaction cardiomyopathy, and one with a mixed phenotype (Fig. 42.7). Pediatric cardiomyopathies are genetically heterogeneous with many different causative genes and multiple mutations in each gene [100]. Furthermore, environmental and infectious factors either causing or contributing to cardiomyopathy may be present, particularly in children with dilated cardiomyopathy where evidence of viral myocarditis is common [100].

The evaluation of a child with suspected cardiomyopathy may require an extensive work-up, including genetic and metabolic testing, due to the multifactorial etiology. Echocardiography and cardiac MRI can establish the diagnosis and provide risk stratification. Although treatment is disease specific based on the underlying pathophysiology, goals of therapy are the same: improving symptoms and reversing the ventricular remodeling process that is linked to the progressive heart failure that occurs [102]. These children can go on to require implantable cardioverter defibrillator, mechanical circulatory support, or cardiac transplantation.

Ventricular assist devices

The emergence of mechanical circulatory support (MCS) of the failing heart has helped advance the treatment of heart failure. MCS can be used in the short term (e.g. acute postsurgical cardiac failure or acute graft rejection) when the expected recovery is within days or weeks, or in the long term when the underlying disease state is unlikely to recover.

Options for MCS include ECMO, intra-aortic balloon pumps, and left ventricular assist devices (LVADs). ECMO provides short term cardiopulmonary support and can be emergently initiated via percutaneous insertion; however, the lack of mobility, higher risk of complications, and inability to provide prolonged support are limitations. Similar to ECMO, intra-aortic balloon pumps can quickly be inserted percutaneously, but are unable to provide long-term support. Furthermore, decreased familiarity among pediatric providers and the higher heart rates and incidence of arrhythmias interfering with coordinated inflation and deflation of the balloon frequently preclude the use of intra-aortic balloon pumps in children [103]. LVADs can be used both for short- and

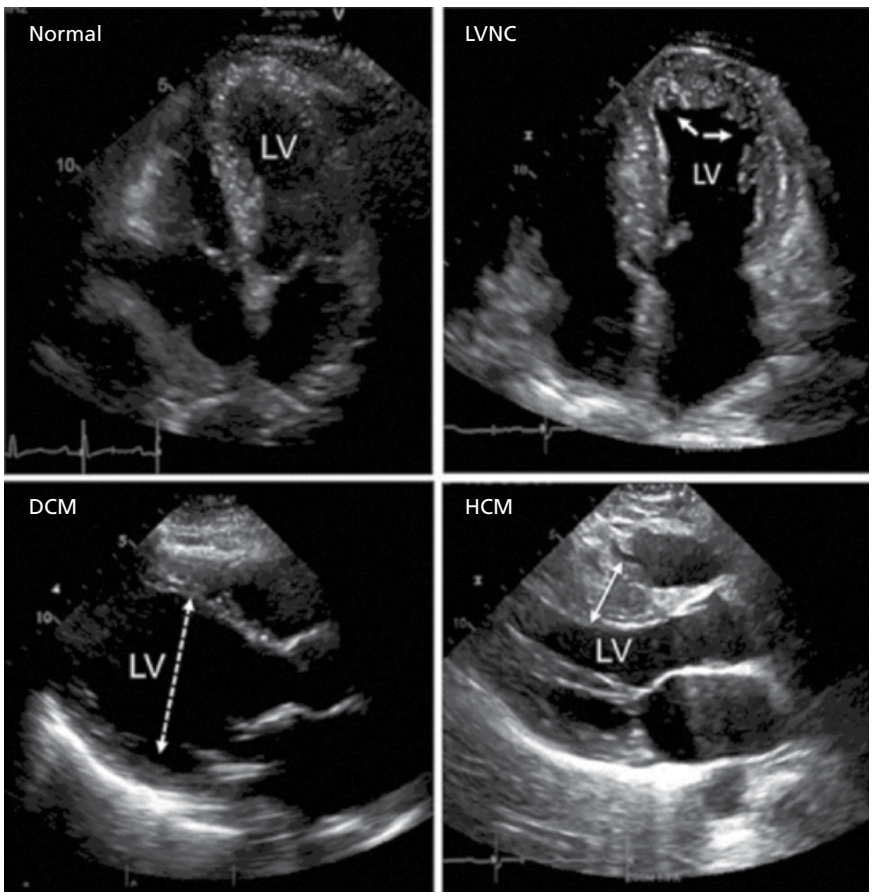

Figure 42.7 Echocardiography of the three more common forms of cardiomyopathy. Left ventricular non-compaction (LVNC) is shown in the upper right (arrows indicate deep trabeculations in the left ventricle (LV)). Dilated cardiomyopathy (DCM) is defined by enlarged LV diameters (dashed double-sided arrow). Hypertrophic cardiomyopathy (HCM) is defined with a thickened LV, including the septum (marked with double-sided arrow). *Source:* Reproduced from McNally and Mestroni [336] with permission of Wolters Kluwer.

long-term therapy, have a lower risk of infection and inflammatory response, allow for early extubation, facilitate mobility and rehabilitation, and allow for hospital discharge [104]. Subsequently, the use of LVADs has become common in bridging to cardiac transplant for patients with advanced heart failure not responding to medical therapy.

LVADs work by decompressing the failing LV and pumping blood into the systemic circulation to restore end-organ function. The first LVADs developed mimicked the pulsatile flow of the native heart; however, they have been largely replaced by continuous flow devices that are smaller, more durable, and almost completely internalized [104]. Infants and children with BSA <0.7 m^2 are still supported with pulsatile ventricular assist devices. Pulsatile LVADs preserve arterial pulses because a predetermined volume is ejected into the arterial circulation with each discharge. The Berlin Heart EXCOR® (Berlin Heart AG) ventricular assist device consists of a pneumatically operated diaphragm using a large external compressor (Fig. 42.8). The large external system precludes discharge from the hospital, and its higher incidence of side-effects have given way to the use of continuous flow devices when able.

The most common continuous flow LVADs available in the United States are the HeartMate II™ axial flow LVAD (Abbott Laboratories) and the HeartWare™ centrifugal flow HVAD (Medtronic). The new HeartMate 3™ centrifugal flow LVAD (Abbott Laboratories) is currently available only to adults participating in clinical trials (Fig. 42.9) [105]. The HeartMate II

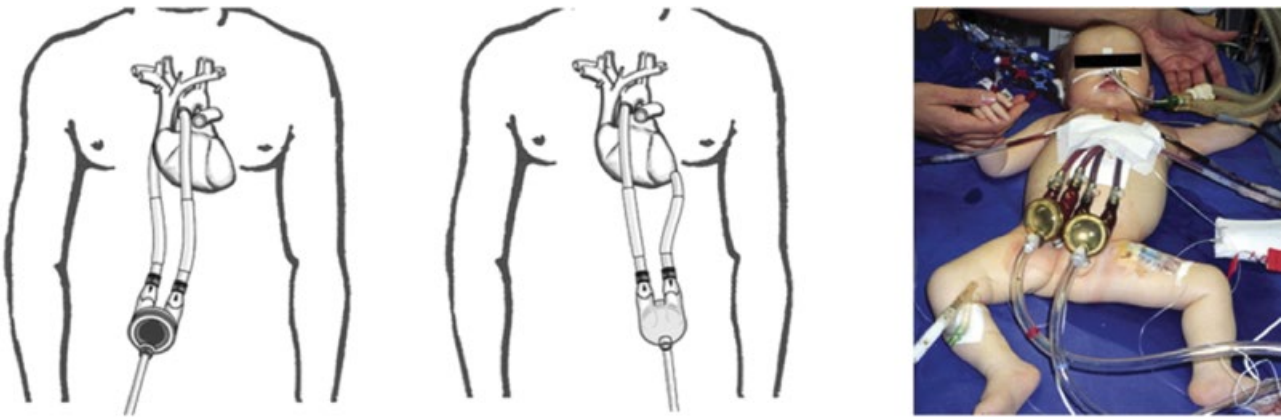

Figure 42.8 Implantation of a Berlin Heart EXCOR® Pediatric ventricular assist device in left (A, B) and biventricular (C) modes. This device is a paracorporeal, pneumatic, compressor-operated diaphragm pump. It can provide cardiac outputs of 0.4 to >5 L/min, depending on pump chamber size and pump rates. Pump chamber sizes are available in stroke volumes of 10–80 mL. The inflow cannula to the device is implanted either in the left atrium (A) or the apex of the left ventricle (B). Left apical implantation is preferred because it provides better unloading of the left ventricle. (C) Implantation is also possible for biventricular support. *Source:* Reproduced from Hetzer et al [337] with permission of Elsevier.

(B, C) The HeartWare™ and HeartMate 3™ systems have a centrifugal pump design with the pump residing within the pericardial space. All devices can provide up to 10 L/min of flow. *Source:* Courtesy of Thoratec and Medtronic websites.

can be used in children >45 kg or with a BSA >1.3 m^2; its use has been supplanted by the smaller HeartWare HVAD system which can be used for patients with BSA >0.7 m^2. Constant drainage of the LV by continuous flow LVADs can result in a dampened arterial pulse or eliminate it altogether. Contractility of the LV with aortic valve opening are required to generate a palpable pulse. To measure blood pressure, a Doppler ultrasound is placed over the brachial artery and an upper extremity blood pressure cuff is slowly deflated. The first audible sound heard is the mean arterial pressure (MAP). Alternatively, an intra-arterial catheter can be used to continuously monitor the MAP, and it is preferred when major intravascular fluid shifts or volume loss are anticipated (e.g. major surgical cases). Effective blood pressure control and intravascular volume allows for optimal LVAD performance. LVADs, especially continuous flow LVADs, are "preload dependent" and "afterload sensitive." Unobstructed flow into the LVAD inflow cannula within the LV is dependent on adequate ventricular filling (preload). LVAD outflow into the aorta is affected by afterload. In situations with high afterload (high blood pressure), the LVAD will perform a greater amount of work to meet systemic needs. This higher work may require higher LVAD speed and produces higher power (watts), which can lead to greater fluid requirements and increased RBC hemolysis. This in turn can increase strain on the right heart.

Patients with LVADs require anticoagulation and antiplatelet therapy to prevent thrombosis within the device and decreased risk for arterial embolic stroke. As a result, bleeding is the most frequent adverse event in adults with LVADs and accounts for 9% of the total mortality associated with LVADs [106]. It is not uncommon to have gastrointestinal bleeding from the development of AV malformations with friable vessels that are prone to bleeding [107]. Therefore, management requires a thoughtful approach to making adjustments to anticoagulation and antiplatelet therapy. The right balance between the risk of bleeding and thrombosis needs to be found for each individual, especially if invasive procedures are required. Chapters 27 and 28 present additional information about congenital and acquired heart disease.

KEY POINTS: CONGENITAL HEART DISEASE, MEDICAL CARDIAC DISEASE, AND VENTRICULAR ASSIST DEVICES

- Routine early surgery on neonates with CHD and an understanding of the effects of cardiopulmonary bypass on cardiac, respiratory, and neurological systems are cornerstones of cardiac surgery care in the ICU
- Heart failure from myocarditis and cardiomyopathy are common; aggressive treatment to provide diuresis, hemodynamic and respiratory support, and increase oxygen delivery are essential to prevent multiorgan failure and cardiac arrest
- ECMO and ventricular assist device support are increasingly used in heart failure and should be applied early before cardiac arrest or severe deterioration

Respiratory disease

Respiratory monitoring

Clinical examination of the critically ill child remains the cornerstone of respiratory assessment and monitoring, and should include visual inspection (e.g. skin color and perfusion, respiratory rate and pattern, nasal flaring, retractions, use of accessory muscles) and auscultation to evaluate the presence of abnormal respiratory sounds (e.g. stridor wheezing, rales, rhonchi). A child in impending respiratory arrest may display respiratory pauses, cyanosis or pallor, bradycardia, and a decreased level of consciousness associated with severe hypoxemia and/or hypercarbia.

The respiratory rate of PICU patients is continuously monitored using impedance pneumography. The percent oxygen saturation of arterial hemoglobin (SpO_2) is also continuously monitored using pulse oximetry. Modern pulse oximetry has become more reliable than in the past with devices that protect against artifacts due to external light sources (e.g. surgical lights) or motion. Pulse oximetry provides inaccurate readings in states of low cardiac output, increased venous pulsations, presence of fetal hemoglobin, carboxyhemoglobin (e.g. smoke inhalation), methemoglobin (e.g. during therapy with inhaled nitric oxide), or during treatment with methylene blue. Pulse oximetry also loses accuracy once saturations drop below 60%. Pulse oximetry is primarily utilized for the detection of hypoxemia, which is generally defined as SpO_2 <90% or a decline of >10% below baseline SpO_2. Pulse oximetry is also used to help guide FiO_2 delivery and thus minimize blood draws for repeated blood gases. The FiO_2 delivered varies by type of non-invasive delivery method (Table 42.3).

Non-invasive monitoring of ventilation in the critically ill child is conducted with capnography and transcutaneous CO_2 monitoring devices. Capnography has become routine in the modern PICU. It measures and graphically displays changes in CO_2 concentrations during the respiratory cycle as a function of time. Practitioners are familiar primarily with $ETCO_2$ monitoring or time-based capnography. In addition to $ETCO_2$ monitoring, volume-based capnography can be used to measure anatomic dead space and pulmonary capillary perfusion. $ETCO_2$ represents the partial pressure of CO_2 at the end of expiration and is normally <5 mmHg lower than $PaCO_2$ in healthy children. This difference increases in states of decreased cardiac output, right-to-left intracardiac shunting, pulmonary vascular abnormalities, and pulmonary overdistention leading to increased dead space. Volume-based capnography allows for measurement of alveolar minute ventilation and the

Table 42.3 Oxygen delivery by non-invasive means

Device	FiO_2	Flow
Nasal cannula	Up to 40%	<5 L/min
Simple facemask	Up to 60%	6–10 L/min
High-flow humidified nasal cannula	Close to 100%	1–30 L/min
Non-rebreather mask with reservoir	Close to 100%	6–15 L/min
CPAP or BiPAP therapy	100%	As needed to deliver pressure

BiPAP, bilevel positive airway pressure; CPAP, continuous positive airway pressure.

ratio of relative dead space (Vd) to tidal volume (Vt): Vd/Vt = ($PaCO_2$ – ECO_2)/$PaCO_2$; where ECO_2 is the mean expired CO_2.

Capnography can be initiated in the non-intubated, spontaneously breathing child, using sidestream monitoring devices via a nasal cannula. In mechanically ventilated patients, $ETCO_2$ monitoring is conducted with sidestream, or, more commonly, low-volume mainstream monitoring devices. The capnography waveform presence and shape, and $ETCO_2$ value, provide valuable information in a variety of clinical scenarios: confirmation of endotracheal tube placement, prompt alert for ventilator malfunction or disconnected circuits, information on respiratory rate and pattern, dead space estimates, variations in cardiac output, and presence of obstructive airway disease.

Mechanical causes for a sudden drop or absent $ETCO_2$ include a displaced or obstructed endotracheal tube, or a dysfunctional ventilator or ventilator circuit that is disconnected or defective (e.g. leaking). Pathological causes for decreasing $ETCO_2$ include hyperventilation, decreased cardiac output, or decreased pulmonary capillary blood flow due to pulmonary artery embolism or pulmonary hypertension. A high $ETCO_2$ indicates hypoventilation, improved cardiac output, or increased pulmonary capillary blood flow.

Transcutaneous CO_2 monitoring is used primarily in neonatal ages in an effort to decrease repeated blood sampling [108], and tends to lose accuracy at older ages. In the PICU, transcutaneous CO_2 monitoring is used to observe trends in patients where capnography cannot be used (e.g. high-frequency oscillatory ventilation, non-invasive positive pressure ventilation without ability to use sidestream $ETCO_2$).

Esophageal manometry is used to measure changes in pleural or transpulmonary pressures during the respiratory cycle. Esophageal pressure monitoring can complement extubation readiness tests, but has limitations related to its invasive nature (i.e. placement of a balloon catheter into the lower third of the esophagus) and artifacts, as well as inadequate accuracy of measurements in the pediatric age [109,110].

Continuous monitoring and display of airway graphics is a routine feature of modern mechanical ventilators. Besides measures of Vt, gas flow, and airway pressures, displays of flow–volume, pressure–volume, flow–time, pressure–time and volume–time loops guide clinicians in selecting the optimal amount of support for each individual patient, with the goal of minimizing the work of breathing and optimizing patient–ventilator synchrony. Normal values for measurements of respiratory mechanics are presented in Table 42.4. See Chapter 19 for additional discussion of respiratory monitoring.

Finally, imaging is an important component of respiratory monitoring, with the chest radiograph the mainstay of assessment, often performed daily for intubated PICU patients, or whenever a major change or event occurs. Recently, point of care ultrasound (POCUS) of the lungs and airway has been increasingly used at the bedside, and can be used to quickly determine causes of respiratory deterioration, including lung consolidation, pneumonia, pneumothorax, pleural effusion, pulmonary edema, and endotracheal tube position [111]. As more intensivists are trained in POCUS techniques they are likely to see more daily use, and may even potentially replace the chest radiograph in some settings [112,113]. See Chapter 19 for further discussion of POCUS.

Table 42.4 Respiratory mechanics

	Infant	Adult
Respiratory frequency (breaths/min)	30–40	12–16
Inspiratory time (s)	0.4–0.5	1.2–1.4
I:E ratio	1:1.5–1:2	1:2–1:3
Inspiratory flow (L/min)	2–3	24
Tidal volume		
mL	18–24	500
mL/kg	6–8	6–8
Functional residual capacity (FRC)		
mL	100	2200
mL/kg	30	34
Vital capacity		
mL	120	3500
mL/kg	33–40	52
Total lung capacity		
mL	200	6000
mL/kg	63	86
Total respiratory compliance		
mL/cmH_2O	2.6–4.9	100
mL/cmH_2O/mL FRC	0.04–0.06	0.04–0.07
Lung compliance		
mL/cmH_2O	4.8–6.2	170–200
mL/cmH_2O/mL FRC	0.04–0.07	0.04–0.07
Specific airway conductance (mL/s/cmH_2O/mL FRC)	0.24	0.28
Respiratory insensible water loss (mL/24 h)	45–55	300

Status asthmaticus

Epidemiology

Asthma is an important public health problem around the world. In the USA, the prevalence of asthma has been estimated at 8.4% in children aged 0–17 years, and this has increased over time [114,115]. Asthma is the leading cause of chronic illness in children, with exacerbations resulting in emergency department asthma visit rates of 10.7 and asthma hospitalization rates of 2.1 per 100 children with asthma [115]. Asthma death rates are estimated at 0.03 per 1000 children with asthma [115]. Risk factors for mortality include a history of prior PICU admission or respiratory arrest requiring intubation.

Pathophysiology

Asthma is a multifactorial disease with polygenetic and environmental influences. It is a chronic inflammatory disorder characterized by bronchoconstriction, airway hyper-responsiveness, and airway edema, with hypersecretion of mucus and mucus plugging [116]. In time, patients with asthma develop remodeling of the airways, with sub-basement fibrosis, injury to epithelial cells, smooth muscle hypertrophy, and angiogenesis [116]. Typical asthma symptoms include cough, wheezing, chest tightness, and breathlessness [116]. Status asthmaticus presents with exacerbation of these symptoms and respiratory distress that can vary in intensity. Common triggers for status asthmaticus are exposure to allergens and viral infections. Severe airway obstruction leads to air trapping with increased dead space, reflected in flattening of the diaphragm on chest imaging. A prolonged expiratory phase ensues, due to active, rather than passive, expiration against increased airway resistance.

Hypoxia develops early during status asthmaticus due to ventilation/perfusion mismatch. The initial compensatory tachypnea is manifested by hypocarbia on blood gases. In time, patients develop respiratory muscle fatigue leading to hypercarbia and respiratory failure if unaddressed.

Hemodynamics can be affected during status asthmaticus by several factors. Lung hyperinflation leads to stretching of the pulmonary vasculature, increased pulmonary vascular resistance, and subsequent right ventricular strain. In addition, large fluctuations in intrathoracic pressure lead to increased left ventricular afterload and decreased venous return to the right atrium, with development of pulsus paradoxus, an exaggerated decline in systolic blood pressure during inspiration that can be diagnosed by pulse palpation or examination of pulse oximetry or arterial waveform tracings.

Therapy

Children presenting with status asthmaticus require immediate medical attention to avoid respiratory failure and arrest. Hypoxia is addressed with supplemental oxygen via a nasal cannula or facemask. Inhaled bronchodilators and systemic corticosteroids should be initiated early. Patients who do not show signs of improvement should be considered candidates for transfer to the PICU for advanced therapies, including additional inhalational bronchodilators, systemic bronchodilators, heliox, non-invasive and invasive ventilation, inhaled anesthetics, and ECMO. Table 42.5 summarizes the dose, physiological action, potential benefits, and adverse events and risks for therapies used for status asthmaticus [117].

Presentation of a child with wheezing, cough, and respiratory distress does not equate to asthma exacerbation. The differential diagnosis of a first time episode of wheezing includes new-onset asthma, as well as foreign body aspiration, congestive heart failure, and pneumonia. However, in severe status asthmaticus, diagnostic testing should not delay initiation of therapy and/or transfer to the PICU. When time allows, an arterial or venous blood gas to determine the degree of gas exchange abnormalities, complete cell blood count to evaluate for infection, basic metabolic panel and lactate to evaluate for electrolyte abnormalities, degree of dehydration, and anaerobic metabolism, and a chest radiograph should be obtained. In most instances, chest radiographs in children with status asthmaticus will reveal hyperinflation. A chest radiograph should be obtained in all severe cases to rule out other diagnoses as noted above and diagnose complications related to status asthmaticus (e.g. pneumothorax). See Chapter 7 for further discussion of the etiology, pathophysiology, and treatment of asthma.

Pediatric acute respiratory distress syndrome

Consensus definition

Differences in pathophysiology, co-morbidities, clinical practice, and outcomes of acute respiratory distress syndrome (ARDS) in children compared with adults [118,119] have motivated the development of a pediatric-specific ARDS definition, published in 2015 following the conclusion of the Pediatric Acute Lung Injury Consensus Conference (PALICC) (Table 42.6) [120]. A definition for children at risk for pediatric ARDS was also developed to raise the alert for patients at risk for respiratory deterioration (Table 42.7) [121]. The PALICC definition of ARDS accounts for the increasing utilization of non-invasive mechanical ventilation in children, for the decrease in invasive monitoring (including arterial catheters) in children, and for special pediatric populations cared for in the ICU (i.e. cyanotic heart disease, chronic lung disease, left ventricular dysfunction) [121]. Pediatric ARDS is the development of respiratory failure not fully explained by cardiac failure or fluid overload, within 7 days of a known clinical insult, associated with chest imaging findings of new infiltrate(s) consistent with acute pulmonary parenchymal disease, and hypoxia requiring non-invasive or invasive mechanical ventilation [121]. Hypoxia is defined using the oxygenation index for ventilated patients (OI = mean airway pressure divided by the PaO_2/FiO_2 ratio) as mild (OI 4 to <8), moderate (OI 8 to <16), and severe (OI ≥16), and as PaO_2/FiO_2 ≤300 or SpO_2/FiO_2 ≤264 while on full facemask bi-level ventilation or continuous positive airway pressure (CPAP) ≥5 cmH_2O [121]. While pediatric ARDS does not have age limits, it excludes patients with perinatal-related lung disease [121].

Pathophysiology

ARDS is characterized by the loss of the epithelial and endothelial permeability barrier integrity and the presence of protein-rich edema fluid in the alveoli, immune activation and severe inflammation, activation of coagulation with suppression of fibrinolysis, and surfactant depletion and degradation – a combination of pathophysiological processes that lead to injury of the lung epithelium and vascular endothelium [119]. The clinical consequences of these pathophysiological changes are hypoxemia, decreased functional residual capacity, increased physiological deadspace, decreased lung compliance, and radiographic opacities [119]. Resolution of ARDS starts early in the ARDS course, and entails resolution of the inflammatory process, repair of the lung epithelium and endothelium, and fluid removal [119].

Therapy

Treatment recommendations for pediatric ARDS were published by PALICC in 2015 [120], along with supporting arguments [122–126]. The goals of pediatric ARDS management in the PICU are to support oxygenation, ventilation, and work of breathing while minimizing barotrauma, atelectrauma, and volutrauma, to treat the underlying cause, and to provide general ICU supportive care while minimizing complications. Pediatric ARDS is treated with multimodal therapies including non-invasive support and ventilation using high-flow nasal cannula, CPAP, or bi-level positive airway pressure (BiPAP), and mechanical ventilatory support. Pulmonary pharmacological therapies such as inhaled nitric oxide (iNO), exogenous surfactant, or anti-inflamatory agents (e.g. corticosteroids) are not recommended for routine use in pediatric ARDS [120]. iNO use may be considered in cases of severe pediatric ARDS or documented pulmonary hypertension or severe right heart dysfunction [120]. Other pulmonary ancillary therapies include cautious suctioning to minimize the risk of derecruitment, and prone positioning attempting to improve oxygenation in severe pediatric ARDS [120]. Non-pulmonary therapies include: (1) provision of minimal yet effective sedation to facilitate tolerance of mechanical ventilation, to optimize oxygen delivery and

Table 42.5 Adjunct therapies for status asthmaticus

Therapy	Suggested dose	Physiological action	Potential benefits	Adverse effects and risks	Risk potential (frequency)
Ipratropium	250 μg every 6 h	Bronchodilation and decreased mucous production	Prevents hospital admissions when given early in emergency department setting; no clear benefit to continuing after admission to hospital	No reported adverse events	Mild (rare)
B-agonists (intravenous)	Terbutaline intravenously: 10 μg/kg bolus, then 0.2 μg/kg/min; may titrate 0.2–1 μg/kg/min	Bronchodilation/smooth muscle relaxation via β-receptors	Intravenous route may improve delivery to distal airways; no clear additive benefit to inhaled β-agonists	Tachycardia, dysrhythmias, diastolic hypotension	Moderate (common)
Methylxanthines	Aminophylline intravenously: 6 mg/kg bolus, then 1 mg/kg/h; titrate to goal serum level 5–15 μg/mL	Bronchodilation/smooth muscle relaxation; phosphodiesterase inhibitor	Similar effectiveness of intravenous β-agonists; no reduction in ICU or hospital length of stay	Tachycardia, nausea	Moderate (common)
Magnesium (intravenous)	25–75 mg/kg intravenous bolus (maximum 2.5 mg)	Bronchodilation/smooth muscle relaxation by altering calcium flow into sarcoplasmic reticulum	Prevents hospital admissions when given early in emergency department setting	Malaise, nausea	Mild (rare)
Magnesium (nebulized)	150 mg of inhaled insulin (2.5 mL of 250 mmol/L solution)		May improve lung function in patients with severe asthma when added to inhaled β-agonist; probably not additive or superior to intravenous magnesium	No reported adverse events	Mild (rare)
Antibiotics	Azithromycin 10 mg/kg every 24 h per oral or intravenously	Treatment of concomitant bacterial infections; anti-inflammatory effect of macrolides	Potential improvements in lung function with chronic use of macrolides but no clear benefit to routine antibiotic administration during asthma exacerbations	No reported adverse events	Mild (rare)
Ketamine	1 mg/kg bolus followed by 0.75 mg/kg/h intravenous infusion	Bronchodilation through catecholamine release in peripheral nervous system	Immediate decrease in airway resistance and improved lung function; no data on patient outcomes	Tachycardia, bronchorrhea, hallucinations, laryngospasm	Moderate (common) to severe (rare)
Heliox	Goal ≥50% inhaled helium (i.e. FiO_2 <50%)	Promotes laminar flow by reducing gas density	Immediate decreases in work of breathing and $PaCO_2$	No reported adverse events	Mild (rare)
Non-invasive ventilation (NIV)	N/A	Positive pressure supports respiratory muscles and may stent open small airways; HFNC may assist with CO_2 wash-out	NIV leads to decreases in work of breathing and improvements in oxygenation; no data regarding other outcomes or benefits with HFNC	Intolerance of mask interface, air leak syndrome	Mild (rare)
Inhaled anesthetics	Sevoflurane: 0.5–3% concentration in inhaled gas	Bronchodilation/smooth muscle relaxation	Immediate decreases in $PaCO_2$ and airway resistance	Hypotension, apnea, malignant hyperthermia	Moderate (common) to severe (rare)
Extracorporeal membrane oxygenation	N/A	Gas exchange through artificial membrane	Allows surrogate oxygenation and ventilation while reducing mechanical ventilatory support	Bleeding, stroke, vessel injury, mechanical failure	Moderate (common) to severe (rare)

ICU, intensive care unit; HFNC, high-flow nasal cannula.

Table 42.6 Pediatric acute respiratory distress syndrome (PARDS) definition

Age	Exclude patients with perinatal related lung disease			
Timing	Within 7 days of known clinical insult			
Origin of Edema	Respiratory failure not fully explained by cardiac failure or fluid overload			
Chest Imaging	Chest imaging findings of new infiltrate(s) consistent with acute pulmonary parenchymal disease			
Oxygenation	**Non-invasive mechanical ventilation**	**Invasive mechanical ventilation**		
	PARDS (No severity stratification)	Mild	Moderate	Severe
	Full facemask bi-level ventilation or CPAP ≥5 cm H_2O†	4 ≤ OI < 8	8 ≤ OI < 16	OI ≥ 16
	PF ratio ≤ 300	5 ≤ OSI < 7.5*	7.5 ≤ OSI < 12.3*	OSI ≥ 12.3*
	SF ration ≤ 264*			
	Special Populations			
Cyanotic Heart Disease	Standard Criteria above for age, timing, origin of edema and chest imaging with an acute deterioration in oxygenation not explained by underlying cardiac disease.‡			
Chronic Lung Disease	Standard Criteria above for age, timing, and origin of edema with chest imaging consistent with new infiltrate and acute deterioration in oxygenation from baseline which meet oxygenation criteria above.‡			
Left Ventricular dysfunction	Standard Criteria for age, timing and origin of edema with chest imaging changes consistent with new infiltrate and acute deterioration in oxygenation which meet criteria above not explained by left ventricular dysfunction.			

* Use PaO_2-based metric when available. If PaO_2 is not available, wean FiO_2 to maintain SpO_2 (2 × [mean airway pressure × 100]/SpO_2) or SpO_2:FiO_2 (SF) ratio.
† For non-intubated patients treated with supplemental oxygen or nasal modes of non-invasive ventilation, see Table 41.7 for "at-risk" criteria.
‡ ARDS severity groups stratified by OI (FiO_2 × mean airway pressure × 100]/PaO_2) or OSI should not be applied to children with chronic lung disease who normally receive invasive mechanical ventilation or children with cyanotic congenital heart disease.
CPAP, continuous positive airway pressure; OI, oxygenation index; OSI, oxygen saturation index.

consumption, and work of breathing; (2) addition of neuromuscular blockade when sedation is not adequate to achieve effective mechanical ventilation; (3) nutrition aimed at meeting metabolic needs, and to maintain growth and facilitate recovery; (4) goal-directed fluid management aimed at maintaining adequate intravascular volume while preventing positive fluid balance, end-organ perfusion, and optimal delivery of oxygen; and (5) transfusion at a threshold hemoglobin of 7 g/dL in clinically stable children with adequate oxygen delivery, excluding cyanotic heart disease, bleeding, and severe hypoxemia [120].

Outcomes

Mortality following pediatric ARDS has decreased over time, with current rates estimated between 21% and 45% [127,128]. Children requiring ICU-level care for ARDS are at risk for pulmonary function abnormalities after hospital discharge, representing both obstructive and restrictive disease [128]. Current recommendations include screening with respiratory symptom questionnaires and pulse oximetry, spirometry when developmentally appropriate, and referral to a pediatric pulmonologist for any patients with identified deficits in pulmonary function [120]. Pediatric ARDS follow-up should also include physical, neurocognitive, emotional, family, and social function evaluation within 3 months of hospital discharge, as well as prior to entering school, for young patients [128,129], with mounting evidence indicating long-term deficits in functional status, health-related quality of life, and risk for post-traumatic stress disorder in mechanically ventilated pediatric patients [130].

KEY POINTS: RESPIRATORY DISEASE

- Monitoring, including physical exam, capnography, flow–volume and pressure loops, chest radiography, and lung ultrasound are important assessment tools
- Severe status asthmaticus requires immediate transfer to the PICU for advanced therapy including inhaled and IV bronchodilators, non-invasive and invasive ventilation, heliox, inhaled anesthetics, and ECMO
- ARDS is the development of respiratory failure not fully explained by cardiac failure or fluid overload, and treatment is supportive with non-invasive and invasive ventilation, iNO, pulmonary toilet, nutrition, and hemodynamic support to maximize oxygen delivery

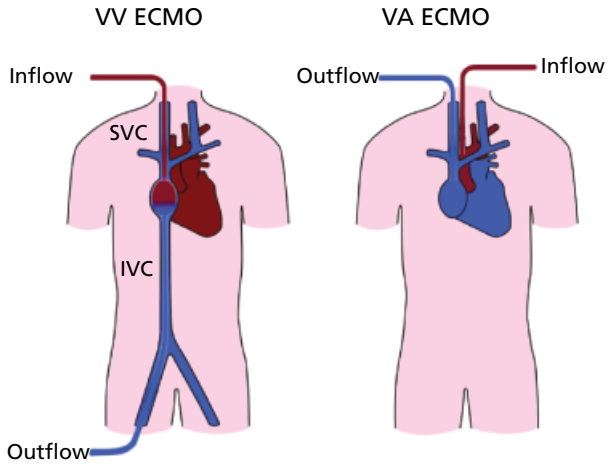

Figure 42.10 Venovenous (VV) and venoarterial (VA) extracorporeal membrane oxygenation (ECMO). IVC, inferior vena cava; SVC, superior vena cava. *Source:* Reproduced from Thiagarajan [338] with permission of Wolters Kluwer.

Extracorporeal life support

Modes of support and circuit configurations

Extracorporeal life support (ECLS) in children is primarily provided in the form of ECMO. ECMO is deployed in children with severe refractory cardiopulmonary failure or cardiac arrest who do not respond to conventional modes of therapy and support. It entails cannulation of one or more large vessels. The two most common circuit configurations are venovenous, with blood draining from and returning to the venous system, and venoarterial, with blood draining from the venous system and returning directly into the systemic arterial system. Venovenous ECMO is used primarily for respiratory failure, while venoarterial ECMO is used primarily for cardiac failure and extracorporeal cardiopulmonary resuscitation (ECPR). Venovenous ECMO operates in series with the heart and lungs, while venoarterial ECMO operates in parallel with the heart and lung, thus providing partial bypass of the two organs.

In infants, the vessels used for ECMO cannulation are the right internal jugular vein for venovenous ECMO support using a double-lumen cannula, or the right internal jugular vein and right common carotid artery for venoarterial ECMO support using two single-lumen cannulas. Older children and adolescents can be cannulated through the femoral vessels for both venovenous as well as venoarterial ECMO support. Children of all ages can be cannulated through a central approach (i.e. direct cannulation of the heart or major vessels) through a thoracic incision, typically a median sternotomy. Deoxygenated blood drains from the patient through a drainage cannula, to a plastic circuit, a pump, a membrane lung, and heat exchanger. Oxygenated blood is then returned to the patient, directly in the arterial circulation via the aorta or to the venous circulation where it is circulated through the lungs prior to reaching the systemic circulation (Fig. 42.10). An optional venous reservoir can be inserted between the drainage cannula and the pump to serve as a compliance chamber and to allow non-invasive pressure measurements.

Two types of pumps are used for ECLS: roller and centrifugal pumps (Fig. 42.11). Roller pumps are occlusive pumps that function by positively displacing blood as a function of

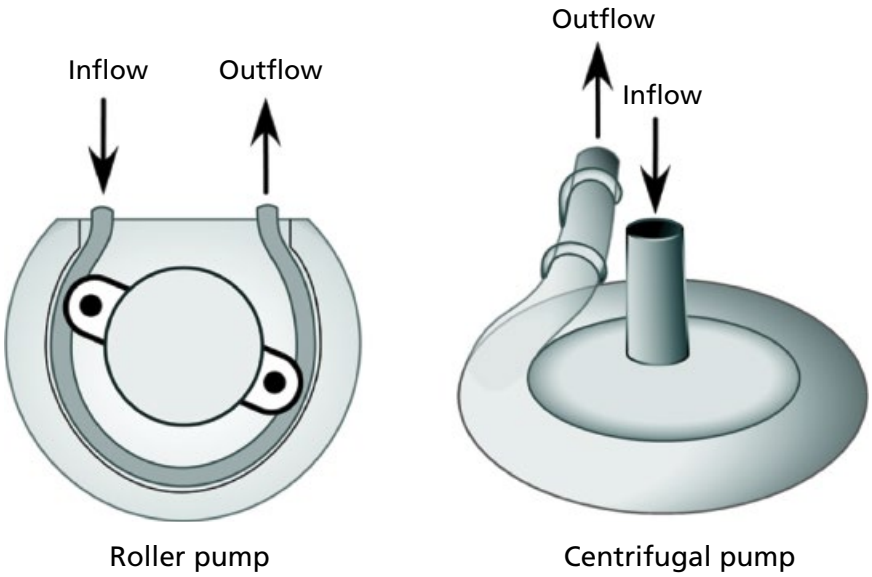

Figure 42.11 Roller and centrifugal pumps. *Source:* Reproduced from Thiagarajan [338] with permission of Wolters Kluwer.

pump speed. Centrifugal pumps are non-occlusive pumps that use an impeller assembly to produce a hydrodynamic gradient through rotational kinetic energy. Both types of pumps have been successfully used in children, although in recent years centrifugal pumps have been increasingly replacing roller pumps [131]. The Extracorporeal Life Support Organization reported that, from 2009 to 2015, centrifugal pumps were used in 55–60% of pediatric ECLS and neonatal cardiac and ECPR cases reported to the registry, while roller pumps were used in 54% of neonatal respiratory cases [131].

The membrane lung transfers O_2 and CO_2 by diffusion across a membrane between a blood phase and a gas phase. Most contemporary membrane lungs use hollow fibers, with extracapillary blood flow and intracapillary gas flow. The two most common membrane materials are polymethylpentene and polypropylene. The sweep gas is the gas applied to the gas phase of the membrane lung, typically a blend of O_2 and nitrogen, occasionally with added CO_2 or nitric oxide. The sweep gas inlet O_2 fraction (FsO_2) is controlled by a gas blender and ranges from 0.21 to 1.0.

The heat exchanger transfers heat between the blood phase and a water phase, separated fully by a heat exchanging material. The temperature of the blood returning to the patient can be fully controlled at a preset level. Modern membrane lungs may have integrated heat exchangers. A bridge is an optional tubing connection between the drainage and the reinfusion lines of the circuit, close to the patient. For venoarterial ECMO, clamping of the drainage and infusion limbs with opening of the bridge allows blood to circulate in the circuit while the patient undergoes a weaning trial. Access ports for medication and blood product administration, blood draws, and connections to renal replacement therapy (RRT) or plasmapheresis devices, can be added to ECMO circuits, and may be essential in small infants and children with inadequate vascular access. ECMO circuits are also equipped with safety devices, including bubble sensors placed on the reinfusion limb of the circuit to detect and avoid air embolization, and alarms for pressure changes. Pressure is usually monitored at the pump inlet and preoxygenator, and postoxygenator sites. An increasing pressure gradient between pre- versus postoxygenator sites usually indicates clot formation in the oxygenator. Lastly, contemporary ECMO circuits contain non-invasive devices for monitoring and display of blood flow rate, hemoglobin, hematocrit, PO_2, PCO_2, mixed venous saturation, etc., as well as surface coating or modification with materials that improve biocompatibility and reduce thrombogenesis [132].

General indications and contraindications

Indications for ECMO have evolved since the technique was first used in an intensive care unit in 1972 [133]. While initially ECMO was primarily used in the neonatal age primarily for respiratory indications, the last years have seen a plateau in neonatal ECMO utilization, accompanied by an increase in pediatric ECMO for primary respiratory, cardiac, and ECPR indications [131].

Respiratory indications for neonatal ECMO support include primary pulmonary hypertension of the newborn, meconium aspiration syndrome, congenital diaphragmatic hernia, and other, more rare, pulmonary diseases. Of these, congenital diaphragmatic hernia has the lowest survival to hospital discharge (50%), while meconium aspiration syndrome has the highest survival (93%) [131]. Respiratory indications for pediatric ECMO support are diverse and include ARDS, infections (e.g. bronchiolitis, pertussis, bacterial, viral, or fungal pneumonia), foreign body aspiration, and asthma. Venovenous ECMO as a bridge to lung transplantation has also been increasingly reported in the literature [134]. Overall survival in children with respiratory failure requiring ECMO support is 60% [131].

Cardiac indications for ECMO support include perioperative support and support for non-surgical conditions. Perioperative pediatric cardiac support may be required for preoperative stabilization (e.g. profound cyanosis, cardiogenic shock, or severe pulmonary hypertension), inability to wean patients from cardiopulmonary bypass, postoperative low cardiac output syndrome, and postoperative cardiac arrest. Non-surgical cardiac conditions that may require ECMO support include myocarditis and cardiomyopathy, pulmonary hypertension, arrhythmias with hemodynamic compromise (including from toxic ingestion), septic shock, cardiac trauma, and rejection of transplanted heart. Overall survival to hospital discharge is 45% following neonatal cardiac ECMO and 57% following pediatric cardiac ECMO [131].

ECPR represents rapid deployment of ECMO to support children with cardiac arrest failing to respond to conventional cardiopulmonary resuscitation. Specialized multidisciplinary teams and hospital-wide systems are required for the development and sustainability of an ECPR program. The overall survival following ECPR in neonates and children is 43% [131].

Contraindications for ECMO support have also evolved over time. General relative contraindications include prematurity <34 weeks' gestation, small size (<2 kg), poor prognosis of primary diagnosis, severe brain injury, uncontrolled hemorrhage, irreversible organ failure, and limitations in care [135]. Risks and benefits of ECMO support should be discussed with the patient's family in the context of each individual patient's disease and wishes.

Management of the neonatal and pediatric ECMO patient

The vascular site of cannulation and appropriate cannula selection based on expected size of the vessels and amount of flow needed are typically discussed by a multidisciplinary team prior to deployment of the ECMO team. In the pediatric age group, cannulation is typically performed by a general pediatric surgeon or a cardiac surgeon. A dose of 75–100 units/kg of unfractionated heparin is administered prior to cannula insertion. Correct cannula placement can be confirmed by x-ray, fluoroscopy, and/or echocardiography. The ECMO circuit can be primed with crystalloid (typically for children >20 kg) or blood, especially in infants and young children at risk for hemodilution. Adequate critical care personnel, equipment, and medications should be available at the bedside for ongoing support of the critically ill child undergoing ECMO cannulation, including the ability to perform exquisite cardiopulmonary resuscitation should the need arise.

Neurological monitoring. Neurological injury is frequent in children supported on ECMO due to risk factors associated with their critical illness as well as ECMO-related risk factors. Neurological injury in the form of intracranial hemorrhage, thromboembolic stroke, or anoxic brain injury has been described in up to one-third of pediatric ECMO patients [131,136,137]. Ideally, sedation and the use of neuromuscular blockade should be minimized in ECMO patients. When unsafe to do so (e.g. in severe pulmonary hypertensive crises), neurological monitoring is typically conducted using modalities such as cerebral oximetry, electroencephalography, and serial transfontanellar cranial ultrasounds [138].

Respiratory support. The goals of respiratory support during ECMO are to avoid atelectasis while limiting ventilator-induced lung injury, to mobilize secretions, and the resolution of pulmonary edema. When possible, sedation is decreased or interrupted to allow for spontaneous ventilation with pressure support, or extubation. Otherwise, mechanical ventilation is usually via pressure control ventilation with a positive end-expiratory pressure of ~10 cmH_2O, a rate of 10 breaths/min, and a peak inspiratory pressure of 18–20 cmH_2O [135].

Cardiovascular support. Cardiovascular support during venovenous ECMO is provided according to standard ICU practice, as the patient's cardiac output is fully dependent on native cardiac function. Following venovenous ECMO support, improved oxygenation through the circuit's membrane lung, decreased right ventricular strain, and decreased intrathoracic pressure due to ability to decrease ventilatory support and thus mean airway pressure all have a favorable impact on the patient's hemodynamics. If needed, vasoactive infusions can and should be used during venovenous ECMO. In patients on venoarterial ECMO support, total cardiac output is the sum of the native cardiac output and the extracorporeal flow [135]. Usually, vasoactive infusions required immediately prior to venoarterial ECMO initiation can be quickly decreased and/or discontinued once ECMO flow is established. Vasopressors may need to be maintained during the ECMO course in patients with vasoplegia (e.g. septic shock, toxic ingestions).

Renal supportive therapy. Sixty to 74% of children on ECMO meet criteria for acute kidney injury (AKI) at the time of ECMO initiation, with 86–93% of patients meeting the criteria for AKI by 48 h on ECMO [139]. Diuretics and RRT in the form of continuous venovenous hemofiltration or hemodialysis are frequently used in ECMO patients. While fluid overload has been shown to be associated with unfavorable outcomes in ECMO patients [140] and should be avoided, controversy remains regarding the optimal timing of RRT initiation and rate of fluid removal during ECMO.

Nutrition. Children on ECMO are usually managed following nutrition recommendations for other critically ill children. Early introduction of enteral nutrition can be beneficial, with no evidence that it is associated with adverse events [141,142].

Infection surveillance. The prevalence of hospital-acquired infections in ECMO patients is 10–12% [143,144]. Temperature is controlled through the circuit's heat exchanger, therefore the ECMO team relies on other signs and symptoms of infection and laboratory data suggesting a new infection. There are no data to support routine blood prelevation for culture or the use of prophylactic antibiotics during the ECMO course, although both have been reported as relatively common practices [145].

Anticoagulation and blood product administration. Exposure of blood to the artificial ECMO circuit is accompanied by a systemic inflammatory response with capillary leak, multiple organ dysfunction, and activation of the coagulation pathway and cellular blood elements (leukocytes, platelets) [132]. The result is a hypercoagulable state in the circuit that requires initiation of anticoagulation therapy, with a precarious balance of maintaining circuit patency, avoiding thrombus formation in the circuit and thus risk for embolization, while at the same time avoiding hemorrhage in the anticoagulated patient [132]. Although newer generations of ECMO circuits, pumps, and oxygenators are more biocompatible and less thrombogenic, thrombosis and bleeding remain important complications during ECMO [131,146] and require close monitoring and management of anticoagulation. Typically, unfractionated heparin infusion is initiated upon ECMO cannulation, at rates ranging from 10 to 40 units/kg/h. Activated clotting time remains the main point-of-care test for anticoagulation monitoring during pediatric ECMO, with general goals of 180 to 220 s. Other tests of coagulation, including antifactor Xa, activated partial thromboplastin time, prothrombin time, INR, antithrombin III, thromboelastography, or rotational thromboelastometry are used at different frequencies and combinations by most ECMO programs [147]. Antithrombin administration in the form of pooled plasma antithrombin or recombinant antithrombin has become common practice in many ECMO centers, but data on pharmacokinetics, pharmacodynamics, and safety are still subject to controversy and will require further study [148–151].

ECMO patients receive large amounts of blood products required in face of bleeding, disseminated intravascular coagulation, or hemolytic anemia and thrombocytopenia secondary to shear injury. It is estimated that children on ECMO receive as much as 40–105 mL RBCs/kg/day [152,153]. Generally, ECMO centers use a hemoglobin goal of 10 g/dL in an effort to optimize oxygen delivery. Platelet count goals vary based on risk of bleeding and underlying pathology, but generally range between 50,000 and 100,000 cells/mm^3 [147]. Plasma and cryoprecipitate are administered for goal fibrinogen concentrations of 100 or 150 mg/dL prior to surgical procedures. Administration of activated factor VII may be required in cases of severe intractable hemorrhage [154,155].

Procedures on ECMO

The heparin infusion rate is usually decreased in anticipation of on-ECMO procedures such as chest tube placement, vascular catheter placement, or complex surgery (e.g. congenital diaphragmatic hernia repair). If the patient is supported on a circuit with antithrombotic surface modification, the heparin infusion can also be discontinued temporarily, with close and frequent inspection to monitor for clot formation and/or coagulopathy. Antifibrinolytic agents (e.g. Ɛ-aminocaproic acid, tranexamic acid) may be required, as well as administration of platelets, plasma, or cryoprecipitate to optimize platelet count and fibrinogen prior to the procedure.

Weaning from ECMO

Signs of improvement in respiratory and cardiac function should be assessed daily during the ECMO course. Improved oxygenation and ventilation and indicators of improved

cardiac function (e.g. increasing pulse pressure, $ETCO_2$, mixed venous saturations) are indicators for respiratory and cardiac recovery. Weaning from venovenous ECMO entails decreasing FsO_2 (sweep gas inlet oxygen fraction) and eventually interrupting gas flow through the oxygenator. Weaning from venoarterial ECMO in neonates and children usually entails gradual decrease in extracorporeal flow, along with optimization of ventilatory support, and the addition of inodilators, inotropes, or pulmonary vasodilators, as needed. A weaning trial is then performed by discontinuing flow from and to the patient by clamping the drainage and return limbs of the circuit close to the cannulas and opening the bridge to maintain flow through the circuit. The amount of hemodynamic support that the patient may still require off ECMO is assessed clinically and using echocardiography data. After a period of ~30 min, a decision can be made on whether the patient can be safely decannulated or if continued extracorporeal support is needed.

KEY POINTS: EXTRACORPOREAL LIFE SUPPORT

- ECMO can be venoarterial for severe cardiac with or without respiratory failure, or venovenous for primary respiratory failure without severe cardiac failure
- Respiratory indications for ECMO include ARDS, infections, sepsis, asthma, and as a bridge to lung transplant
- Cardiac indications for ECMO include postcardiac surgery, myocarditis, cardiomyopathy, pulmonary hypertension, and arrhythmias

Neurological diseases

Neurological examination

The purpose of the neurological examination is to assess and monitor the integrity of the central and peripheral nervous systems. This can be challenging in an infant who, developmentally, may not be able to speak or follow basic commands at baseline. A thorough history that chronologically identifies the onset and setting of symptoms including frequency, duration, and effects on the child is essential to an accurate diagnosis. Typically, the history is given by a parent, guardian, or caretaker who has the child's best interests in mind, but in the case of abusive head trauma, the individual may also be the child's assailant. It is essential to determine if a child is developmentally appropriate by asking about prematurity, prior illnesses, accidents, surgeries, hospitalizations, medications, parental consanguinity, and how their performance is in daycare or school when compared to their peers as part of the neurological exam [156]. Most developmentally normal children 4 years and older can accurately contribute to their medical history [157].

It is important to ask questions about whether, and to what extent, the neurological disorder has impacted cognition, behavior, and language, and the degree to which daily living activities have been compromised. A skilled clinician develops a focused differential diagnosis during history taking and uses the physical examination to further narrow and confirm the exact diagnosis and determine the extent of impairment. Given the critical instability of children in the PICU, the neurological exam is often limited by sedative agents, neuromuscular blockade, severity of illness, or recent trauma. Upon admission to the PICU, all children will have a neurological exam, and those with new neurological deficits or altered mental status will most likely have the neurological exam repeated every 1–3 h. At minimum, all children should be evaluated for their level of consciousness, comfort, cranial nerve function including pupillary light reflex, respiratory effort, motor function, sensory function, tone, and reflexes.

Assessing consciousness

When infants and children have severely altered level of consciousness, the GCS is used to establish and trend their level of consciousness. Developed over 40 years ago, the GCS is an easily reproducible scale that allows multiple caregivers to consistently assess and monitor the level of consciousness over a period of time [158]. The GCS, now a core part of most traumatic brain injury (TBI) clinical guidelines, influences initial decision making, surgical management, and alerts intensivists to the neurologically deteriorating patient in their unit. New research from the large multicenter Approaches and Decisions in Acute Pediatric TBI (ADAPT) trial suggests that early GCS scores are strongly associated with mortality in pediatric TBI patients [159,160]. The same GCS developed for adults is used for children; however, a modified scale is used for infants who are developmentally unable to speak (Table 42.8). Both the adult and pediatric GCS overall scores range from 3 to 15 and are calculated from the patient's motor, verbal, and eye-opening response to audible and physical stimulation. Many neurointensivists have opined that inclusion of pupil reactivity would improve the performance of the GCS at lower total scores in both adults and children [161].

Assessing comfort

Often, critically ill babies and children cannot self-report their level of pain because of their baseline inability, changes in cognition, the use of sedatives, or the presence of an endotracheal tube. As a result, the PICU utilizes many validated, standardized pain assessment tools. For example, the Wong–Baker FACES® pain rating scale is a visual scale for interactive patients, aged 3 years and older, that uses a series of cartoon faces ranging from happy at 0 to a devastated, crying face at 10. The patient chooses the face that best describes their current pain level (Fig. 42.12) [162]. The face, legs, activity, cry, and consolability scale (FLACC scale) is a validated measurement used to assess pain in infants and children 2 months to 7 years or in any non-verbal, developmentally delayed patient. The FLACC scale is based on five criteria, each assigned a score between 0 and 2, with an overall score range of 0–10 [163]. The state behavioral scale (SBS) is a validated, sedation assessment instrument that provides a systematic description of the sedation–agitation continuum for infants and young children supported on mechanical ventilation. The SBS is a 6-point scale ranging from –3 to +2 that is typically monitored at the same frequency as vital signs (Fig. 42.13) [164]. The neonatal infant pain scale (NIPS) is a validated, standard pain assessment tool for neonates that contains five behavioral measurement and one physiological measurement with an overall score range of 0–7 (Table 42.9) [165]. The routine use of simple, yet valid and reliable, observational tools to assess

Table 42.8 Adult and pediatric Glasgow coma scales

Activity	Adult/child response	Infant response	Score
Eye opening (E)	Spontaneous	Spontaneous	4
	To verbal stimuli	To verbal stimuli	3
	To pain	To pain	2
	None	None	1
Best verbal response (V)	Oriented, appropriate	Coos and babbles	5
	Confused conversation	Irritable cries	4
	Inappropriate words	Cries to pain	3
	Incomprehensible sounds	Moans to pain	2
	No response	None	1
Best motor response (M)	Obeys verbal command	Normal spontaneous movement	6
	Localizes stimulus	Withdraws to touch	5
	Withdraws from noxious stimulus	Withdraws to pain	4
	Decorticate flexion	Decorticate flexion	3
	Decerebrate extension	Decerebrate extension	2
	No response (flaccid)	No response (flaccid)	1

Total score is sum of E + V + M
Minimum score is 1E + 1V + 1M = 3
Maximum score is 4E + 5V + 6M = 15

pain in the PICU is necessary to ensure adequate pain management in critically ill patients.

Cranial nerves

A basic cranial nerve exam should be performed upon admission to the PICU and followed daily to hourly if any deficits are identified. If deficits are identified or the patient is at high risk for developing deficits, the pediatric neurology team is often consulted for a more complete cranial nerve examination. *Cranial nerve I* is rarely evaluated by intensivists. In the awake and cooperative patient, *cranial nerve II*, the optic nerve, is evaluated by testing visual acuity with a Snellen chart. In patients with depressed mental status, funduscopic examination with an ophthalmoscope looking for papilledema or optic disk pallor can quickly assess for intracranial hypertension or optic neuritis. It is essential to evaluate for retinal hemorrhages with an ophthalmoscope in babies less than 3 years of age presenting with head trauma, looking for retinal pathology associated with abusive head trauma [152]. If retinal pathology is identified, consultation to pediatric ophthalmology for further investigation, documentation, and monitoring is needed [152]. Determining and monitoring the optic nerve sheath diameter with bedside ultrasound has a good level of diagnostic accuracy for detecting intracranial hypertension in children [166].

Cranial nerves III, IV, and VI. The extraocular muscles are controlled by cranial nerves III, IV, and VI. Extraocular movements can be quickly evaluated by having the child visually follow the movement of your finger in six cardinal directions without moving their head. Paralysis of cranial nerve III will lead to ptosis, dilation of the pupil, and displacement of the eye downward and outward. Dysfunction of cranial nerve IV will cause the eye to deviate up and outwards, often causing a compensatory head tilt by the child to correct diplopia. Injury to the cranial nerve VI causes medial deviation of the eye and inability to abduct the eye beyond the midline. Nystagmus is involuntary and unsurpassable eye movements that may be vertical, horizontal, rotatory, or mixed. Horizontal nystagmus is often a side-effect of drugs like phenytoin or can be due to injury to the cerebellum or vestibular system in the brainstem. Structural abnormalities or brainstem dysfunction cause vertical nystagmus. The pupils should be examined for size, equality, and response to light. Unreactive pupils are an ominous sign, while small reactive pupils may indicate the presence of opioids or barbiturates but may also be caused by damage to the pons. Large reactive pupils may be caused by atropine, tricyclic antidepressants, or pharmacological withdrawal. In a comatose child where evaluation of extraocular eye movements is impossible, the pupillary exam can and should be performed frequently.

Cranial nerves V, VII, VIII, IV, X, and XII. The sensory component of cranial nerve V innervates the ophthalmic, maxillary, and mandibular regions of the face, which can be stimulated by either light touch or pain. In an unconscious

Dimensions	Levels
Respiratory drive	1. No spontaneous respiratory effort 2. Spontaneous but ineffective exhaled tidal volume (Patient specific: <4mL/kg) 3. Spontaneous and effective exhaled tidal volume (Patient specific: > 4mL/kg)
Response to ventilation	1. No spontaneous breathing 2. Easy spontaneous breathing (fully synchronized with mechanical ventilation) 3. Having difficulty synchronizing with ventilator 4. Unsynchronized with mechanical ventilation, compromising oxygenation/ventilation
Coughing	1. No cough with suction 2. Coughs only when suctioned 3. Coughs when repositioned 4. Occasional spontaneous cough 5. Frequent spontaneous coughing that does not resolve with suctioning 6. Bronchospastic or choking
Best response to stimulaiton	1. No resonse to noxious stimuli 2. Responds to noxious stimulis 3. Responds to touch 4. Responds to voice 5. No external stimulus is required to elicit response
Attentiveness to care provider	1. Unable to pay attention to care provider 2. Able to pay attention to care provider but drifts off after stimulation 3. Spontaneously pays attention to care provider (Infant – fixes and follows) 4. Vigilant of care provider/Eyes follow care provider – watchful 5. Hyper-vigilant to care provider/Panicky when care providers approch patient
Tolerance to care	1. Does not distress with any procedure including noxious 2. Will distress with noxious procedures 3. Distresses with procedures (i.e., repositioning) 4. Distressed (e.g., picking at tubes, pulling at restraints, etc.) 5. Patient intermittently unsafe (e.g., biting ETT) 6. Patient unsafe (e.g., attempting to pull at ETT/catheters, cannot be left alone)
Consolability	1. Self-regulates/modulates own behavior 2. Able to calm with comforting touch or voice when stimulus removed; distractible 3. Does not consistently calm despite a 5-minute attempt to console 4. Unable to console
Movement after consoled	1. Does not move 2. Occasional movement of extremities or shifting of position in bed 3. Increased movement (restless, squirming) 4. Excessive movement (thrashing side to side, kicking legs, arched, rigid) 5. Combative

patient, the corneal response is elicited by lightly touching the cornea with cotton and observing for eye closure. Mastication and jaw movements (horizontal and lateral) are the motor functions of cranial nerve V. Cranial nerve VII controls taste, volume of hearing, and facial strength. Facial asymmetry is the most obvious manifestation of cranial nerve VII dysfunction. Cranial nerve VIII, the auditory nerve, is rarely tested in critically ill children while acutely ill. Common risk factors for cranial nerve VIII malfunction are prematurity, asphyxia, hyperbilirubinemia, ototoxic drug exposure, congenital rubella, herpes, or cytomegalovirus infections. In the unconscious patient, the vestibular function of cranial nerve VIII can be assessed with the cold caloric test. Cranial nerve IX is tested by the presence of a gag reflex, and vocal cord paralysis is reflective of injury to cranial nerve X. Cranial nerve XI is tested by voluntary, forceful rotation of the child's head and neck against the examiner's hand; however, cranial nerves XI and XII are rarely evaluated by the intensivist. Cranial nerve XII innervates the tongue.

Table 42.9 Neonatal infant pain scale (NIPS)

Variable	Finding	Points
Facial expression	Relaxed (restful face, neutral expression)	0
	Grimace (tight facial muscles, furrowed brow, chin, jaw)	1
Cry	No cry (quiet, not crying)	0
	Whimper (mild moaning, intermittent)	1
	Vigorous crying (loud scream, shrill, continuous). If infant is intubated, score silent cry based on facial movement.	2
Breathing pattern	Relaxed (usual pattern for this infant)	0
	Change in breathing (irregular, faster than usual, gagging, breath holding)	1
Arms	Relaxed (no muscular rigidity, occasional random movements of arms)	0
	Flexed/extended (tense, straight arms, rigid and/or rapid extension, flexion)	1
Legs	Relaxed (no muscular rigidity, occasional random movements)	0
	Flexed/extended (tense, straight legs, rigid and/or rapid extension, flexion)	1
State of arousal	Sleeping/awake (quiet, peaceful, sleeping or alert and settled)	0
	Fussy (alert, restless and thrashing)	1
Hear rate	Within 10% of baseline	0
	11–20% of baseline	1
	>20% of baseline	2
O_2 saturation	No additional O_2 needed to maintain O_2 saturation	0
	Additional O_2 required to maintain O_2 saturation	1

Limitations: a falsely low score may be seen in an infant who is too ill to respond or who is receiving a paralyzing agent. A score greater than 3 indicates pain.

Assessing motor function, sensory function, tone, and reflexes

Muscle strength is graded on a five-point scale: 0 (no contraction), 1 (flicker or trace contraction), 2 (active movement with gravity eliminated), 3 (active movement against gravity), 4 (active movement against gravity and resistance), and 5 (normal strength). A sensory exam is tested with either pain sensation or light stimulation running up the infant, beginning at the toes and ending with the cranium. Sensory deficits often identify a spinal cord level of injury resulting from trauma, infection, or a spinal cord mass.

Tone is evaluated by assessing the resistance to passive motion at an individual joint. A spastic extremity is associated with decreased spontaneous movements, atrophy, hyperactive deep tendon reflexes, and plantar extensor reflexes. While flexing and extending an extremity, initially the movement is restricted followed by a "clasp-knife"-like release of the increased tone in a spastic limb. The deep tendon reflexes are graded on a scale of 0 (absent) to 4 (markedly increased). Upper motor lesions cause increased deep tendon reflexes; asymmetrical reflexes suggest lateralizing lesions. Reduced or absent reflexes are associated with neuropathies, myopathies, and cerebellar disease. Rigidity refers to constant resistance to both flexion and extension of passive movements and commonly results from lesions in the basal ganglia. Hypotonia is common with injury to the cerebral cortex, cerebellum, spinal cord, or peripheral nerves.

Neuroimaging

In a child with altered mental status, the rapid and accurate recognition of injury clinically guides the medical and surgical strategies, and any delay could result in significant morbidity and mortality. Head trauma can be separated into two categories: primary brain injury, which occurs at the time of trauma, and secondary brain injury, occurring after the initial insult. Examples of primary brain injury are skull fractures, subdural and epidural hematomas, hemorrhagic contusion, and diffuse axonal injury. Secondary brain injury is often due to anoxia, ischemia, metabolic derangements, inflammation, and cerebral edema. Primary brain insults are most commonly identified with rapid head computed tomography (CT) scans, while secondary insults are often better identified with brain MRI.

Diagnosing skull fractures in infants is complicated by normal sutural anatomy, which can be mistaken for fractures (Fig. 42.14A). True fractures generally show a linear course without well-defined sclerotic borders and often cross rather than merge with adjacent sutures [167]. Extra-axial hemorrhage is classified by the space in which it occurs – epidural, subdural, and subarachnoid. Epidural hemorrhage has a lentiform shape and does not cross sutural boundaries but may cross the midline (Fig. 42.14B). Epidural hemorrhage results from injury of the epidural arteries or veins and is often associated with an overlying calvarial fracture [168]. Subdural hematoma is characterized by its crescentic shape and ability to cross sutures (Fig. 42.14C). Subdural hemorrhage is bounded by the midline falx and results from tearing of bridging cortical veins [168]. Subarachnoid hemorrhage appears as increased attenuation in the cerebral sulci and cerebrospinal fluid cisterns on CT (Fig. 42.14D). The presence of subarachnoid hemorrhage in the setting of trauma is common; however, in non-traumatic scenarios it is often associated with ruptured aneurysm or arterial venous malformation.

Cortical contusions are best identified with brain MRI and tend to be multiple, bilateral, and occur along the inferior frontal lobes and anterior temporal lobes, where the brain has a greater chance of direct impact against rigid bone. It is important to look at the soft tissues of the scalp because intraparenchymal contusions are classically coup or contrecoup in location. Cortical contusions occur in the gray matter and tend to spare the adjacent subcortical white matter unless the hemorrhage is large [169]. Diffuse cerebral edema in the pediatric brain will appear symmetrical with loss of gray–white matter differentiation and effacement of the ventricles, cisterns, and sulci. The midbrain and cerebellum are the least vulnerable to hypoxic injury and diffuse cerebral edema, often resulting in the ominous "white cerebellum sign" [170]. Diffuse axonal injury results from shear–strain deformation of the brain due to rotational acceleration and deceleration. Diffuse axonal injury often does not appear on head CT; instead it is typically identified with brain MRI susceptibility-weighted and diffusion-weighted images [171].

Abusive head trauma or "shaken baby syndrome" includes any non-accidental, inflicted injury to a child's head and body often characterized, but not limited to, the repetitive acceleration–deceleration forces with or without blunt head impact. The constellation of subdural hematoma, diffuse axonal injury, and retinal hemorrhage in an infant or child carries a 91% probability of abusive head trauma [172]. All concerns for abusive head trauma should be thoroughly investigated with head imaging – preferably brain MRI, retinal exam,

(D) Head CT without contrast showing subarachnoid hemorrhage.

skeletal survey, coagulation work-up, and referrals to child protective services and local law enforcement. Prompt identification of the site and severity of brain injury can prove to be life saving for the critically ill pediatric patient.

Near-infrared cerebral oximetry and continuous EEG monitoring

Near-infrared cerebral oximetery can be used to monitor oxygenation in a sample volume of the frontal cerebral cortex; newer monitors with multiple wavelengths and spatially resolved algorhithms are more likely to represent absolute brain tissue oxygen saturation. These monitors are now in wide use in cardiovascular ICUs, with 65% of 42 pediatric cardiovascular ICUs in Europe responding that near-infrared spectroscopy was in regular use in their units [173]. Additional information is presented in Chapter 19.

Continuous electroencephalography (EEG) monitoring can be utilized in the PICU for monitoring and treatment of status epilepticus, and for other patients at high risk for seizures such as those with TBI, postcardiac arrest, ECLS, or postcardiac surgery [174]. In addition, in comatose patients this modality can be useful to monitor for new slowing, laterality of findings, or burst suppression. The increasing availability of this monitoring technology and outcome data associating early seizure recognition and treatment with improved outcomes will likely translate into more widespread use of this approach. Drawbacks include expense and complexity, and the need for trained personnel, or automated computer algorithms, to monitor the EEG and notify clinicians.

KEY POINTS: NEUROLOGICAL EXAMINATION AND NEUROIMAGING

- Early Glasgow coma scale scores are strongly associated with neurological morbidity and death after traumatic brain injury
- Comfort, pain, and sedation scales are a crucially important component of neurological assessment
- CT scans, MRI, transfontanelle ultrasound, near-infrared spectroscopy, and continuous EEG are important neuromonitoring modalities

Traumatic brain injury

Evidence-based guidelines for children suffering from severe traumatic brain injury were first published in 2003 [175] and revised in 2012 [176] (Figs 42.15 and 42.16). The ADAPT trial is a large, multicenter, observational cohort study that intends to develop new evidence-based recommendations that will evolve into universal standards of care for treating pediatric TBI [177]. An infant and pediatric GCS should be utilized to accurately determine the child's GCS score. Current guidelines support a stat head CT to rule out a neurosurgical emergency in all TBI patients with a GCS score ≤8. An ICP monitor should be placed if the GCS score remains ≤8, the child requires prolonged surgical intervention regardless of GCS score, or the child's neurological exam cannot be monitored due to neuromuscular blockade or long-acting sedatives. Criteria for tracheal intubation of children with TBI and other forms of acute brain injury include hypoxemia unresponsive to supplemental oxygen, apnea, hypercarbia ($PaCO_2$ >45 mmHg), GCS score ≤8, any rapid decrease in GCS score of >3 points, anisocoria >1 mm, spinal injury compromising ventilation, inability to protect airway, or any clinical signs of herniation syndrome [178].

Neuroprotective intubation and sedation

Approximately half of all children with cervical spinal injury also have a simultaneous TBI [179]. Pediatric Advanced Life Support Guidelines advise that oral intubation should be performed while maintaining spine immobilization using a cuffed endotracheal tube in children with TBI [180]. A multicenter, randomized control trial demonstrated no increase in postextubation stridor or long-term complications when using cuffed tubes [181]. Always assume a full stomach and use a cerebral-protective rapid-sequence induction with cricoid pressure and preoxygenation. Because the apnea tolerance of an infant less than 6 months old is less than 100 s with optimal bag–mask ventilation using 100% oxygen [182], many pediatric anesthesiologists use a modified rapid-sequence induction with gentle pressure-limited mask ventilation (10–12 cmH_2O) with 100% oxygen after induction of anesthesia to avoid hypoxemia [183].

Pretreat all children [184] with lidocaine (1.5 mg/kg IV with maximum dose 100 mg), and in children ≤1 year old [185] pretreat with atropine (0.02 mg/kg IV with minimum dose

0.1 mg and maximum single dose 0.5 mg). For hemodynamically unstable children, the combination of etomidate (0.2–0.6 mg/kg) and neuromuscular blockade with rocuronium (1 mg/kg) or vecuronium (0.3 mg/kg) IV is often used. Succinylcholine is avoided because of the risk of malignant hyperthermia, possible ICP elevation [186], hyperkalemia, and life-threatening complications associated with unknown occult metabolic or neuromuscular disease [187,188]. Fentanyl (2-4 μg/kg) or ketamine (1–2 mg/kg) IV are alternative sedatives, and recent pediatric studies show that ketamine does not increase ICP and may be neuroprotective [189–191]. If hemodynamically stable, midazolam (0.1–0.2 mg/kg) can be added to any of the above combinations. After successful intubation, oxygen saturation of 100% and normocarbia (35–39 mmHg) should be confirmed by arterial blood gas. Unless the child has signs of herniation, prophylactic hyperventilation ($PaCO_2$ <35 mmHg) should be avoided [192].

Hemodynamic status must be maintained when administering sedatives to assure adequate cerebral perfusion pressure (CPP). An age-based CPP between 45 and 65 mmHg has been recommended for infants and children [193,194]. Overall, there is limited research or evidence-based recommendations regarding the use of sedatives, analgesics, and neuromuscular blocking agents in pediatric patients with acute brain injury. Continuous infusions of propofol, especially over a 24 h period have been associated with lethal cases of propofol infusion syndrome (metabolic acidosis and death); therefore, a continuous infusion of propofol is not recommended for pediatric TBI treatment or for continuous sedation in pediatric patients with acute brain injury [195,196]. The ideal continuous sedative for intubated children with TBI is remifentanil (0.05–1 μg/kg/min), because its rapid onset and short duration of action allow for frequent reliable neurological checks with only brief infusion pauses. If remifentanil is unavailable, a continuous infusion of fentanyl (0.5–5 μg/kg/h) is used for sedation of intubated children with TBI. More frequently, aggressive hyperventilation is being replaced with the use of barbiturates to treat refractory intracranial hypertension. All endotracheal tube suctioning should be pretreated with lidocaine (1 mg/kg IV) and additional sedation if needed to blunt rises in ICP.

Intracranial pressure and cerebral perfusion pressure

A continuous ICP monitor is essential when utilizing medical therapies to normalize ICP and assure an adequate CPP. The calculation for determining cerebral perfusion pressure is CPP = mean arterial pressure – intracranial pressure (CPP = MAP – ICP). Ideally, the ICP should be maintained <20 mmHg, and the CPP should be within the following age-based ranges:

0–1 year ≥45–50, 1–12 years ≥50–60, and >12 years ≥65 [193,197]. To assure adequate CPP, the MAP can be increased with rapid fluid resuscitation assuring a CVP of 5–10 mmHg, vasopressors/inotropes, or blood transfusion to maintain the hemoglobin >8 g/dL [198]. The ideal vasopressor infusion in pediatric TBI is phenylephrine (0.1–0.5 μg/kg/min) providing pure α-adrenergic stimulation; however, if myocardial depression from either polytrauma or sedative agents is present, dopamine (3–20 μg/kg/min) or epinephrine (0.05–0.2 μg/kg/min) infusions are commonly utilized.

The ICP should be maintained <20 mmHg. If the ICP is >20 mmHg, ensure that the patient's head of bed is at 30° and their neck is in a neutral position to facilitate blood flow through the internal jugular arteries. Next, optimize sedation and analgesia while supporting hemodynamics to assure an adequate CPP. If the ICP does not normalize with these measures, give hyperosmolar therapies while considering the need for repeat head CT to rule out new intracranial pathology or EEG to detect seizure activity. Hypertonic saline is available in 2%, 3%, 7%, 9%, and 23% formulations [199,200]. In pediatrics, the use of 2% or 3% hypertonic saline is preferred. Give a rescue bolus of 3% hypertonic saline (5 mL/kg with maximum dose of 500 mL) or 2% hypertonic saline (10 mL/kg) and consider starting a continuous infusion of 3% (0.1–2 mL/kg/h) titrating to the minimum dose needed to maintain a serum sodium goal of 150–160 and an ICP <20. Hypertonic saline should not be utilized if serum osmolarity is >360 mOsm/L. Alternatively, if hypertonic saline does not lower the ICP below 20 mmHg, consider administering a bolus of mannitol (0.25–1 g/kg) over 20 min [199] To minimize cerebral metabolic demands, avoid hyperthermia with a goal core temperature of 35.5–37°C, provide seizure prophylaxis, maintain normoglycemia (80–180), avoid hypoxia or hyperoxia (goal PaO_2 75–125), and avoid hypercarbia (goal $PaCO_2$ 35–45 mmHg) [176]. If the ICP remains consistently >20 mmHg remove cerebral spinal fluid if ventriculostomy is present, obtain continuous EEG readings, and treat for seizures if suspected clinically or electrographically.

Post-traumatic seizure management

Current evidence-based guidelines for the management of post-traumatic seizures in children contain no level I or level II recommendations; however, reports from the ADAPT trial show that most pediatric trauma centers provide seizure prophylaxis and aggressive seizure treatment in children with TBI [201]. The two most utilized prophylactic medications for post-traumatic seizures are levetiracetam (20–60 mg/kg/day divided bid) and fosphenytoin (4–8 mg phenytoin sodium equivalents per kg/day divided bid) [201]. First-line treatment for active, post-traumatic seizures is with benzodiazepines, typically either lorazepam (0.1 mg/kg, maximum 2 mg for babies and 4 mg for children) or midazolam (0.15 mg/kg, maximum 3 mg for babies or 6 mg for children). If the seizure persists, the following are second-line agents: Phenytoin (20 mg/kg load with a maximum infusion rate of 1 mg/kg/min), fosphenytoin (20 mg/kg load with a maximum dose of 1500 mg and a maximum infusion rate of 3 mg/kg/min), phenobarbital (20 mg/kg), or levetiracetam (60 mg/kg, maximum dose 4500 mg) [202]. If seizures persist after administering 2–3 adequate doses of these anticonvulsants, refractory status epilepticus has developed, and the initiation of either a high-dose midazolam or pentobarbital infusion should be started. Continuous EEG must be in place with the goal of either midazolam or pentobarbital infusions to stop the seizures by achieving burst suppression detected on EEG. If utilizing midazolam, give a loading dose of 0.2 mg/kg IV followed by an infusion of 0.1 mg/kg/h, increasing the infusion by 0.1 mg/kg/h every 5–15 min until seizures resolve or until a maximum of 2 mg/kg/h is reached [203]. If utilizing pentobarbital, give an initial loading dose of 1–5 mg/kg followed by an infusion of 1 mg/kg/h, titrating up every 15–30 min to a maximum dose of 3 mg/kg/h [203]. Often the limitations of either of these high-dose infusions is hemodynamic instability refractory to fluid and vasoactive support.

Refractory intracranial hypertension

Decompressive craniectomy is a controversial, emergency procedure for the treatment of refractory intracranial hypertension following severe TBI. Large decompressive craniectomy with duraplasty, leaving the bone flap out, may be considered for pediatric patients with TBI showing early signs of herniation or who have refractory intracranial hypertension during the early stages of their treatment. While decompressive craniectomy can be acutely life saving, there is a high incidence of complications, with over 70% of patients requiring multiple additional surgeries, with long-term sequela from neurological devastation, hydrocephalus, infection, epilepsy, and often no improvement in overall GCS than similar patients not decompressed [204]. Studies have shown a favorable outcome after decompressive craniectomy in children with severe TBI [205–207]; however, others have shown poor outcomes [208–211].

High-dose barbiturate therapy, accompanied with continuous EEG monitoring, may be considered in hemodynamically stable patients with refractory intracranial hypertension despite maximal medical and surgical management. Potentially toxic cardiorespiratory side-effects are common – decreased cardiac output, hypotension, lower systemic vascular resistance, decreased left ventricular stroke volume, and increased intrapulmonary shunt resulting in lower CPP and hypoxia. Continuous arterial blood pressure monitoring and cardiovascular support are required to assure adequate CPP when high-dose barbiturate therapy is used to treat refractory intracranial hypertension [175]. High-dose barbiturates lower ICP through metabolic suppression and alteration of the vascular tone resulting in higher brain oxygenation with lower cerebral blood flow and decreased ICP from decreased cerebral blood volume [212]. Barbiturate levels are poorly correlated with electrical activity; hence, monitoring electrographic patterns to achieve burst suppression is more reflective of therapeutic effect than drug levels [176]. Begin pentobarbital therapy with a loading dose of 1–5 mg/kg slow IV push followed by initiation of an infusion (0.5–1 mg/kg/h). Every 30–60 min give an additional 1–5 mg/kg slow push IV bolus followed by an increase in the pentobarbital infusion to a maximum infusion of 3 mg/kg/h. Due to the high precipitation risk, the infusion should be given through a dedicated peripheral IV rather than a central line [175]. Near maximum reduction in cerebral metabolism and cerebral blood flow occurs when burst suppression is induced. Clinicians typically wait for at least a 24 h period of ICP control without

sustained elevations with stimulation before beginning to taper the barbiturate infusion [176].

Although not evidence based, hypothermia and hyperventilation can be considered in extreme cases of traumatic refractory intracranial hypertension in children. Hyperventilation reduces ICP by unpredictably increasing cerebral vasoconstriction, resulting in decreased cerebral blood volume that may also decrease cerebral oxygenation and induce brain ischemia. If utilized, advanced neuromonitoring evaluation of cerebral ischemia must also be considered [213]. Hyperventilation is also known to reduce the buffering capacity of cerebrospinal fluid and is associated with poor outcomes in children. Avoidance of hypercarbia (goal $PaCO_2$ 35–45 mmHg) is standard of care for treating children with severe TBIs; however, mild hyperventilation ($PaCO_2$ <35 mmHg) and moderate hyperventilation ($PaCO_2$ <30 mmHg) is not supported but can be acutely life saving [212]. Large, multicenter pediatric trials have shown no benefit and potential harm with therapeutic hypothermia (32–33°C) treating refractory intracranial hypertension in children with TBI [214–216]. Therapeutic hypothermia theoretically works by reducing secondary injury through decreased cerebral metabolic demands, inflammation, lipid peroxidation, excitotoxicity, cell death, and seizure activity [58]. If hypothermia is induced for any indication, rewarming at a rate of >0.5°C/h should be avoided. Avoidance of hyperthermia with a targeted core body temperature goal of 35.5–37.0°C is strongly supported by the literature and is routinely practiced [175–177,215].

Pediatric brain death

In 1987, a multi-society task force published guidelines for the determination of pediatric brain death and revised the guidelines in 2011 [217]. The timely diagnosis of brain death is important for a variety of reasons, including the allocation of medical resources, facilitating organ donation [218], and relieving family members from end-of-life decisions. Brain death is defined as the irreversible cessation of functions of the entire brain, including the brainstem [217]. In children, brain death is diagnosed following two standardized neurological exams with apnea tests that are consistent with the absence of complete neurological function in the setting of a known irreversible cause of coma [217]. Ancillary studies are only utilized to confirm brain death when the full clinical exam is unable to be adequately performed due to underlying medical conditions, findings are uncertain, concern for medication effect, or to reduce the time interval between exams [217]. Initial requirements for brain death evaluation are clinical or radiographic evidence of an acute catastrophic cerebral event, exclusion of neurological confounders such as drugs, seizures, metabolic derangements (Na^+, BUN, NH_4^+, glucose), absence of drug intoxication or poisoning, core body temperature >35°C, and mean arterial pressure at an age-appropriate level [217]. The 2011 taskforce showed strong evidence to defer the initial brain death evaluation for 24 h from the last cardiopulmonary arrest, if possible [217]. Brain death examinations should be performed by two separate attending physicians with the age-appropriate waiting period between; however, the apnea test may be performed by the same physician [217]. Brain death testing cannot be performed in a neonate less than 37 weeks' gestational age. In a neonate of 37 weeks' gestational age up to 30 days old, there must be a minimum 24 h waiting period between brain death evaluations [217]. If the child is >30 days to 18 years of age, a minimum 12 h waiting period must be observed between exams. If the child is not stable enough to perform certain parts of the exam, ancillary testing may be used to assist in the diagnosis; however, if unnecessary, ancillary testing is avoided.

The same physiological parameters required for the neurological exam are also required for the apnea test, with the addition of normalizing the pH and $PaCO_2$ as much as physiologically possible [217]. Placement of an arterial line is suggested for hemodynamic monitoring and frequent arterial blood gas sampling. Preoxygenate with 100% oxygen for 10–60 min with the ventilator prior to the apnea test, while providing 100% oxygen without ventilation (self-inflating bag) throughout the test. There must be no spontaneous respiratory efforts observed despite a final $PaCO_2$ ≥60 mmHg and a ≥20 mmHg increase above baseline [217]. Arterial blood sampling should occur in 5–10 min intervals throughout the apnea test documenting the rise in $PaCO_2$.

Abusive head trauma

Any infant less than 3 years old presenting with TBI, especially with subdural hemorrhages, should be considered for possible abusive head trauma workup and investigation. Abusive head trauma (AHT) is the leading cause of child abuse deaths in the United States, with a cost of $7.2 million dollars per AHT death [219]. At least one-third of AHT cases are not identified upon initial presentation to the emergency department [220–221]. AHT, often characterized but not limited to repetitive acceleration–deceleration forces with or without blunt head impact, has a mortality rate of 30%, and 80% of survivors suffer permanent neurological damage [221–223]. Ocular manifestations of AHT are typically identified by a dilated ophthalmic exam showing retinal hemorrhages that are too numerous to count, multilayered, and extending to the periphery [224]. Extensive retinal injury occurs when a baby is forcefully shaken. With infants who cannot speak for themselves, this retinal injury often distinguishes AHT from accidental head trauma in the early diagnostic period. The probability of AHT in a baby found with both head trauma and retinal hemorrhages is 91% with an odds ratio of 14.7 [225]. Given this high probability, the American Academy of Pediatrics recommends that ophthalmological examination should take place within the first 24–72 h of suspected AHT [226].

The common injury profile of abusive head trauma is the combination of TBI, retinal pathology, rib fractures, and metaphyseal chip fractures in an infant who has little to no visible signs of physical injury [221]. Intracranial injury most associated with abusive head trauma are subdural hemorrhage, subarachnoid hemorrhage, diffuse axonal injury, and hypoxic-ischemic injury. If abusive head trauma is suspected, the initial investigation will include brain imaging, retinal examination, a full radiographic skeletal survey, and urgent consultation to the child abuse protection team and child protective services. Further genetic, metabolic, coagulopathic, and radiological investigations may be required by the child protective services if evidence of abusive head trauma is discovered.

KEY POINTS: TRAUMATIC BRAIN INJURY

- A GCS score ≤8 indicates severe traumatic brain injury; protective intubation, neuroimaging, ICP monitoring to maintain adequate CPP, and, if needed, decompressive craniectomy are all used to salvage as much viable brain tissue as possible
- Treatment of seizures, normocarbia, or slight hypocarbia, vasopressor support, and osmotic diuresis are also utilized
- Any infant <3 years old with traumatic brain injury, especially with subdural hemorrhages, should be considered for abusive head trauma work-up

Renal diseases

Acute kidney injury

Acute kidney injury is a common occurrence in the PICU. By some estimates, close to 6% of children have some degree of AKI at the time of PICU admission, and as many as 30–70% of critically ill children develop AKI during their hospitalization [227–230]. AKI is associated with poor outcomes, including increased risk of death, use of mechanical ventilation, and RRT [229]. The pathogenesis of AKI in critically ill children is multifactorial. Multiple risk factors are implicated in the development of AKI, including prerenal (e.g. low cardiac output, low systemic vascular resistance such as seen in warm septic shock, dehydration), intrinsic (e.g. acute tubular necrosis, including aminoglycoside toxicity, acute interstitial nephritis due to drug toxicity and toxic ingestions, chronic kidney disease), and postrenal (e.g. obstructive uropathy, mechanical obstruction) factors. Cardiac surgery, solid organ transplantation, bone marrow transplantation, sepsis, shock, and multiple organ dysfunction syndrome have all been implicated in the development of AKI.

The determination of AKI in hospitalized children has been the subject of much collaborative study. A rise in serum creatinine, which was used in the past to diagnose AKI, is associated with increased mortality even if modest. Reliance on serum creatinine only hampers early AKI recognition. Three definitions of AKI have been used to define AKI in hospitalized children in the last decade, including: (1) the Pediatric Risk, Injury, Failure, Loss of kidney function, and End-stage kidney disease (pRIFLE); (2) the AKI Network (AKIN); and (3) the Kidney Disease Improving Global Outcomes (KDIGO) criteria [230]. Applying the three definitions to the same cohort of hospitalized children can lead to differences in AKI incidence and severity staging [230]. The KDIGO criteria represent the most recent modification of the AKI definitions; its components include plasma creatinine, urine output, estimated glomerular filtration rate (eGFR) and initiation of RRT (Table 42.10).

The glomerular filtration rate is estimated using the Schwartz formula:

$$\text{eGFR}\left(\text{mL/min/1.73 m}^2\right) = \text{k} \times \text{height}\left(\text{cm}\right) / \text{plasma creatinine}\left(\text{mg/dL}\right)$$

where k is a constant defined as 0.45 for infants <1 year of age, 0.55 for children and for adolescent females, and 0.70 for adolescent males.

Table 42.10 Kidney Disease Improving Global Outcomes (KDIGO) criteria for acute kidney injury: definition and staging

	Plasma creatinine	Urine output
Definition	Increase by ≥0.3 mg/dL (≥26.5 µmol/L) within 48 h *OR* Increase by ≥1.5 times baseline, which is known or presumed to have occurred within the prior 7 days	Urine volume <0.5 mL/kg/h for 6 h
Staging		
Stage 1	1.5–1.9 times baseline *OR* ≥0.3 mg/dL increase	<0.5 mL/kg/h for 6 -12 h
Stage 2	2.0–2.9 times baseline	<0.5 mL/kg/h for ≥12 h
Stage 3	3.0 times baseline *OR* Increase in plasma creatinine to ≥4.0 mg/dL *OR* Initiation of renal replacement therapy *OR* In patients <18 years of age, a decrease in eGFR to <35 mL/min/1.73m^2	<0.3 mL/kg/h for ≥24 h *OR* Anuria for ≥12 h

eGFR, estimated glomerular filtration rates.
Source: Reproduced from Sutherland et al [230] with permission of American Society of Nephrology.

At the bedside, the following markers should be integrated to evaluate for AKI, ideally at baseline and then serially during the PICU stay: serum creatinine, creatinine clearance to estimate glomerular filtration rate, BUN, urine output, total fluid input to output ratio, and serum electrolytes. Laboratory and imaging studies can be used to evaluate for potential causes of AKI, including urinalysis to evaluate for bacteriuria, proteinuria, hematuria, casts; renal ultrasound including Doppler to evaluate for intrinsic, vascular, or obstructive causes of AKI; and the fractional excretion of sodium (FE_{Na}). FE_{Na} is calculated as:

$$\text{FE}_{\text{Na}} = \left[\left(\text{Na}_{\text{urine}} \times \text{creatinine}_{\text{plasma}}\right) / \left(\text{Na}_{\text{plasma}} \times \text{creatinine}_{\text{urine}}\right)\right] \text{x}\,100$$

Usually, FE_{Na} <1% represents prerenal disease, and ≥2% represents intrinsic disease or postrenal obstruction. Of note, FE_{Na} cannot be interpreted during therapy with diuretic agents.

Many contemporary PICUs have systems in place for monitoring for AKI using an active surveillance process that integrates clinical and laboratory data collected in the electronic medical record. Emphasis is placed on early identification and treatment of causes for AKI, removing or replacing nephrotoxic medications, adjusting medication doses, and monitoring for adverse effects of medications whenever AKI is suspected or diagnosed. Promising new work is currently being conducted on the prediction of AKI in critically ill children, using the concept of "renal angina," a composite of early injury signs and risk of disease with incorporation of urinary biomarkers (e.g. neutrophil gelatinase-associated lipocalin, human kidney injury molecule, interleukin-18, liver-type fatty acid-binding protein) in future scoring systems [231].

Renal replacement therapy

An estimated 3–5% of children admitted to the PICU require RRT [228,232]. The main indications for RRT in critically ill children are management of severe AKI, fluid overload, acid–base imbalance, and electrolyte and/or metabolic abnormalities [232]. Occasionally, patients with chronic renal failure on intermittent hemodialysis are admitted to the PICU but are stable enough to continue intermittent therapy. More frequently, critically ill children in the PICU undergo continuous RRT (CRRT) using continuous venovenous hemofiltration, hemodialysis, or hemodiafiltration via double-lumen acute dialysis catheters, or peritoneal dialysis via a peritoneal catheter. Peritoneal dialysis in the PICU is primarily utilized in neonates and infants following cardiac surgery [232].

Nephrology and critical care services typically work in conjunction at initiation and during the course of RRT. There is no clear consensus on the timing of CRRT initiation in the PICU, although data suggest that outcomes including mortality are worse when children develop greater fluid overload prior to CRRT initiation [233]. It is generally accepted that CRRT should be initiated at a fluid overload >20%, with more studies needed to determine whether fluid overload between 10% and 20% should prompt consideration of CRRT [234].

Water removal during CRRT occurs due to a hydrostatic pressure gradient across the membrane. Solutes are removed by transmembrane movement in association with ultrafiltered plasma water (convection) or due to a concentration gradient (diffusion). Anticoagulation is typically needed to avoid circuit clotting, and is achieved using regional citrate or systemic heparin. Some data suggest that regional citrate may be superior to systemic heparin in children, but citrate can pose a safety hazard in small infants with an inability to adequate metabolize it [235]. Hypocalcemia due to citrate utilization can be avoided by using a calcium infusion postfilter (citrate is infused prefilter). Circuit clotting can lead to interruptions in therapy, blood loss, and increased cost [235]. Children on CRRT are also at risk for volume shifts (both hypovolemia and hypervolemia), electrolyte imbalance, acid–base imbalance, hypothermia, and citrate toxicity. Therefore, close monitoring of the critically ill child on CRRT with strict intake and output measurements, continuous cardiorespiratory monitoring, serial chemistries, complete blood cell counts, and coagulation profile, is needed to avoid complications.

KEY POINTS: RENAL DISEASES

- AKI is common, with up to 30–70% of children in the PICU developing this condition
- Serum BUN/creatinine, creatinine clearance, AKI definitions, fractional excretion of sodium, and biomarkers such as neutrophil gelatinase-associated lipocalinare used to monitor renal injury
- Renal replacement therapy using perioneal dialysis, continuous venovenous hemofiltration, or continuous venovenous hemofiltration with hemodialysis or hemodiafiltration is reserved for the approximately 3–5% of patients with severe renal insufficiency with electrolyte abnormalities or severe fluid overload

Hematology/oncology

Oncological disease

Among children with oncological disease, 15–40% require intensive care during their illness [236]. The mortality of children with cancer admitted to the PICU has been reported to be as high as 35% [236]. Risk factors for mortality include high pediatric risk of mortality score at admission, diagnosis of sepsis or septic shock, neutropenia, number of organ failures, use of mechanical ventilation, and inotropic support [236]. Delay in transfer of hospitalized children from the floor to the PICU has been shown to be associated with worse 1-month survival [236].

The main reasons for PICU admission in children with oncological disease are complications related to the primary disease, toxicity related to chemotherapy, and immunodeficiency stemming from the oncological disease and/or its therapy. Oncological emergencies include airway and respiratory compromise (e.g. mediastinal mass, infection, hemoptysis), neurological emergencies (e.g. spinal cord compression, increased ICP, seizures, stroke, posterior reversible encephalopathy syndrome), cardiac failure (e.g. due to chemotherapy toxicity), metabolic and electrolyte disturbances (e.g. tumor lysis syndrome, hypercalcemia, diabetes insipidus, cerebral salt-wasting syndrome), and hemorrhagic emergencies (e.g. due to profound thrombocytopenia and/or coagulopathy). As innovative therapies are being developed, new pathologies are also emerging. Recently, cytokine release syndrome has been described in 46% of children with relapse and/or refractory B-precursor acute lymphoblastic leukemia who were treated with chimeric antigen receptor-modified T-cell therapy [237]. Cytokine release syndrome can result in rapidly evolving shock and MODS that require intensive care [237].

Pediatric hematopoietic stem cell transplantation

Overall outcomes of pediatric hematopoietic stem cell transplantation (HSCT) have improved over the last decades and data published in the last years suggest that intensive care in these children is associated with encouraging outcomes. In a multicenter study published in 2013, intensive cardiopulmonary support during HSCT, including continuous positive pressure ventilation, dopamine infusion ≥10 μg/kg/min, or the use of any other vasoactive infusion, was not significantly associated with worse 1-year survival, rates of chronic graft-versus-host disease, creatinine, forced expiratory volume in 1 min, cardiac shortening fraction, or performance status, compared with non-intensive support [238]. Intensive therapies including high-frequency oscillatory ventilation and ECLS have been reported in pediatric as well as adult HSCT recipients, with mixed results [239–241].

Amongst HSCT children admitted to the PICU, as many as 73–88% have pulmonary complications [242]. PICU mortality in pediatric allogeneic HSCT recipients with acute respiratory failure requiring mechanical ventilation is 60.4% [241]. In a cohort of 222 pediatric HSCT recipients from 12 PICUs in the USA, non-invasive ventilation use prior to intubation and delayed high-frequency oscillatory ventilation in those who transitioned from conventional mechanical ventilation to the latter were associated with increased odds of death [241]. The

conclusion drawn by the investigators was that earlier and more aggressive interventions in pediatric HSCT recipients admitted to the PICU with acute respiratory failure may be warranted and potentially offer an opportunity to improve outcomes [241]. In this same cohort of pediatric HSCT patients, a secondary analysis revealed that 91.5% met the criteria for pediatric ARDS based on the PALICC definition (11% mild, 28% moderate, and 61% severe), during the first week of mechanical ventilation [242]. The degree of severity of pediatric ARDS was associated with mortality, as was the median maximum oxygenation index [242].

Sickle cell disease

The most common hemoglobinopathy treated in the PICU is sickle cell disease (Hb SS) followed by sickle cell trait (Hb SC). Historically associated with significant morbidity and mortality, sickle cell disease was once considered a pediatric disease; however, with medical advancements, children with sickle cell disease are now expected to live through young adulthood [243–245]. As mortality has decreased in these children, the primary focus has shifted to improvements in quality of life and decreases in the major causes of morbidity, particularly vaso-occlusive pain, acute chest syndrome, stroke, sepsis, priapism, sudden deafness, and acute anemia, particularly from aplastic crisis and splenic sequestration. The clinical manifestations of Hb SS range from asymptomatic to multiple potentially fatal complications, creating the need for individualized patient treatment plans based on general evidence-based guidelines [246,247].

Preventive treatments

The only proven curative treatment for sickle cell disease is hematopoietic stem cell transplant [248,249]. Preventive measures are the hallmark for the management of both acute and chronic manifestations of sickle cell disease. Due to functional asplenia, upon diagnosis, all infants are provided daily penicillin prophylaxis and when age appropriate are given meningococcal and pneumococcal vaccines, in addition to routine childhood immunizations for added protection against encapsulated bacteria. Stroke prevention with daily hydroxyurea and chronic blood transfusions monitored with transcranial Doppler changes have resulted in a significant reduction of cerebral infarcts and improved quality of life [250]. However, chronic, monthly blood transfusions are not without potential sequelae, most notably iron overload, alloimmunization, and transfusion reactions. Frequent use of incentive spirometry, optimizing pain control, and generous hydration are supportive measures used to prevent acute chest syndrome in children hospitalized with vaso-occlusive pain [251,252].

Acute treatments

Acute manifestations of sickle cell disease are managed by treating the associated symptoms. For example, pain crises are treated with hydration, warm packs, and analgesics ranging from non-steroidal anti-inflammatory drugs to opioids. In splenic sequestration, severe, acute anemia is a life-threatening symptom, and is thus treated with blood product transfusions and possible splenectomy. Acutely, a stroke is treated as it would be in any non-sickle cell disease patient, with the addition of providing urgent exchange blood transfusions rapidly decreasing the Hb S concentration to <30% for the remaining HbSS red blood cells. Serious bacterial infections are treated per standard of care, with the addition of avoiding glucocorticoids if possible, and carefully considering the increased hemorrhagic risks due to Hb SS.

Acute chest syndrome

The presentation, natural course, etiology, and mortality rate of acute chest syndrome are highly variable and differ considerably with age. Most importantly, acute chest syndrome in young children rarely results in death (<1% of episodes); whereas, in adults, about 9% of all episodes result in death [253]. Children are far more likely to present with a fever and cough, possibly a normal physical exam, and initially no distinct infiltrate on chest radiograph [254]. The most likely cause of acute chest in children is infection [253].

Treatment of acute chest syndrome typically includes supportive measures with broad-spectrum antibiotics effective against *Streptococcus pneumoniae*; a macrolide should be started for possible treatment of *Chlamydia pneumoniae* or *Mycoplasma pneumoniae* [255]. Efforts are made to increase oxygen-carrying capacity with incentive spirometry, supplemental oxygen, non-invasive (BiPAP) and invasive positive pressure (intubation), and simple and/or exchange blood transfusions. A simple transfusion will be given to raise the hemoglobin concentration up to approximately 10 g/dL if the patient's current Hb level is <9 g/dL [256]. If the current Hb is ≥9 g/dL, an exchange transfusion is given to prevent an increase concentration to higher than 10 g/dL while reducing the Hb S concentration to <30% [256]. Common risks associated with exchange transfusion in the setting of acute chest syndrome are posterior reversible encephalopathy syndrome, alloimmunization, stroke, and iatrogenic complications associated with arterial and central line placement. Other respiratory support measures such as BiPAP devices might be started, but these do not replace the use of blood transfusion therapy. If pain is associated with acute chest syndrome, analgesics are provided to remove the associated reduction in ventilation.

KEY POINTS: HEMATOLOGY/ONCOLOGY

- Children with cancer can become critically ill from sepsis, neurological emergencies, coagulopathy, chemotherapy toxicity, cytokine release syndrome, and airway/respiratory compromise
- Stem cell transplantation patients admitted to the ICU with respiratory compromise, sepsis, hemodynamic compromise, or neurological change have significantly high morbidity and mortality
- Supportive measures for acute chest syndrome in sickle cell disease include antibiotics and chest physiotherapy, oxygen including non-invasive ventilation, pain control, and simple or exchange transfusion

Transfusion therapy

Blood product transfusion is a common practice for many patients in the PICU. For RBCs, the estimated incidence rate is 304 transfusion per 1000 PICU admissions [257]. Transfusions of blood products are an essential, life-saving component of critical care. However, transfusion is an independent variable for morbidity and mortality in PICU patients, and this finding has led to significant modifications of transfusion practices over the last 10 years [257–261]. There is increasing evidence that a restrictive RBC transfusion strategy is beneficial in PICU patients [45,262–265]. Furthermore, there is limited evidence on the transfusion practices for other blood products.

The balance between the benefits and the potential for harm must be evaluated for each PICU patient. This balance is rarely static and can change from minute to minute. Further complicating this process is the wide variety of patients and physiology found in the PICU environment. Cyanotic congenital heart patients may have different needs to those with traumatic brain injury. Many PICUs care for these patients in the same location and the variability in transfusion practices can lead to confusion for both primary providers and consultants.

Red blood cell transfusion

Anemia in the pediatric critical care patient can occur for many reasons including bleeding due to trauma or surgery, frequent blood draws, hemolysis, or coagulopathy. Anemia is a common finding in the PICU and is seen in 74% of patients during their PICU stay [266]. The easiest method to treat anemia is to transfuse RBCs, but there are many risks with transfusion including infection and non-infectious serious hazards of transfusion such as hemolysis, transfusion-associated circulatory overload, transfusion-associated lung injury, and transfusion-related immune modulation among many others [267]. There has been an increase in studies, including randomized prospective trials, attempting to answer the question of the optimal threshold to transfuse in a critically ill patient.

The landmark TRIPICU study [45] evolved from the adult Transfusion Requirements in Critical Care (TRICC) trial published in 1999 [268]. The study came to the relatively simple conclusion that using a Hb threshold of 7 g/dL for RBC transfusion can decrease transfusion requirements, without increasing adverse outcomes in the hemodynamically stable critically ill child [45]. The concept of a restrictive transfusion strategy first proposed after the TRICC trial has become pervasive no matter what type of ICU the patient is in.

Cardiac surgical patients represent a unique patient population and were not included in many of the initial studies and trials on PICU transfusions. Cyanotic patients in particular were excluded from enrollment due to their physiological need for higher Hb for oxygen delivery. Many prospective trials have been published in the last few years that have addressed this concern, and have suggested that a restrictive transfusion strategy with Hb thresholds adapted to the cardiac physiology decreases the number of transfusions, donor exposures, and potential risks [264,265,269].

Plasma and cryoprecipitate

There is limited evidence on the use of plasma and pooled or recombinant coagulation factors in the pediatric critically ill population. Plasma had been used as a volume expander in many disease states, in exchange transfusions, disseminated intravascular coagulation, and to correct coagulation factor deficiencies. However, there is limited evidence to support its use in many of these conditions [270]. Evidence-based practice guidelines for plasma transfusion developed by the American Association of Blood Banks recommend that plasma be transfused for a limited number of indications: trauma patients requiring massive transfusion and warfarin anticoagulation-related intracranial hemorrhage [271].

The evidence for cryoprecipitate is even further lacking as there are no clinical studies that evaluate its use in critically ill children. Cryoprecipitate contains an enriched proportion of factor VIII, von Willebrand factor (vWF), factor XIII, and fibrinogen. Therefore, its use is limited to procedures and bleeding due to a lack of these specific factors.

Platelets

Platelets are transfused in the PICU for two general reasons, as prophylaxis or as treatment for ongoing blood loss. The data for prophylactic transfusion come primarily from patients with oncological diseases to prevent the risk of spontaneous bleeding [272]. The threshold for prophylactic platelet transfusions is now considered to be 10,000 cells/mm^3. The risk of spontaneous bleeding is thought to be higher in children compared with adults [272]. Generally recommended goals for platelet counts are >50,000 cells/mm^3 for certain surgical procedures and bleeding, and between 75,000 and 100,000 cells/mm^3 for neurological surgery and ECMO [273–275].

Current transfusion practices in the PICU

General dosing recommendations for blood products are presented in Table 42.11. Recently, there has been a push for goal directed transfusion practice given the lack of evidence for indications for blood product administration in the PICU. This transition is more than just the use of laboratory numbers but functional studies using thromboelastography (TEG) and thomboelastometry. Both of these methods use measurements of clot strength and formation to evaluate the potential causes of bleeding. A recent study showed a change in treatment plan in 47% of the cases in which TEG was used [276]. These tests have become routine for surgical cases that have

Table 42.11 Blood component therapy

Product	Dose	Comments
Red blood cells	10 mL/kg	Raises hemoglobin 2–3 g/dL
Random donor platelets	1 unit/10 kg or 5–10 mL/kg	Pooled units from multiple donors
Apheresis platelets	10 mL/kg	Donation from a single individual
Fresh frozen plasma	10–15 mL/kg	Will provide 20–30% of coagulation factors, often resulting in normal clotting
Cryoprecipitate	1 unit/10 kg	Contains a significant amount of fibrinogen (60–80 mg/dL)

significant bleeding risks (e.g. neonatal cardiac surgery, liver transplants) and there may be an increase in utilization in the future in the PICU too.

Use of massive transfusion protocols is another concept that has moved from the operating room to the PICU. Generally those treated under these protocols are trauma patients but they can also be patients who have massive amounts of bleeding from surgical procedures. Many of these patients transition to and from the emergency room, operating room, and PICU. The current studies on massive transfusion protocols are primarily about implementation and policies and more studies will have to be conducted before such protocols become widely implemented [277–279]. It is generally accepted that platelets, plasma, and RBCs should be administered in 1:1:1 or 1:1:2 ratios [280], but prospective, randomized controlled trials in children do not exist at this time.

Coagulopathy in the critically ill child

Coagulopathy is defined as an impairment in the ability of blood to form clots. While many children admitted to the PICU may have an impairment based on laboratory findings, few actually have any active bleeding because of it. There are many reasons for a child to have bleeding in the PICU, but there are only a few where the primary cause is a true coagulopathy.

Disseminated intravascular coagulation

The human body is in a perpetual state of balance between the systems of coagulation and fibrinolysis. Disseminated intravascular coagulation (DIC) occurs when this homeostasis becomes unbalanced and thrombin formation occurs in multiple areas along the microvascular bed. Consumption of clotting factors and platelets ensues, leading to a coagulopathic state with a high likelihood of bleeding [281]. The most common inciting causes of DIC in children are sepsis, liver disease, and trauma [282,283]. Regardless of the cause, DIC is associated with mortality as high as 56%, and as high as 66% when combined with MODS [284].

There is no single test that has high specificity and sensitivity for DIC. Therefore multiple laboratory tests are used in an attempt to make a diagnosis, including platelet count, fibrinogen, prothrombin time, fibrin degradation products, and D dimer (Table 42.12) [282]. DIC is managed by treating the underlying cause and providing supportive care for bleeding and coagulopathy via blood products, although there are no established goal values for coagulation studies. Transfusion amounts and goals are usually based on the clinical status of the patient and can vary depending on the underlying cause of the DIC.

Table 42.12 Laboratory tests for the diagnosis of disseminated intravascular coagulation

Test	Discriminator value
Platelet count	<80,000–100,000 or a decrease of >50% from baseline
Fibrinogen	<100 mg/dL or a decrease of >50% from baseline
Prothrombin time	>3 s prolongation more than upper limit of normal
Fibrin degradation products	>80 mg/dL
D dimer	Moderate increase

Liver disease

The liver is an integral organ system for the clotting cascade. The liver is the organ of synthesis for factors II, V, VII, IX, and X and fibrinogen. Acute and chronic liver disease can cause these derangements and can lead to elevated prothrombin time, partial thromboplastin time, and INR. Derangements and likelihood of bleeding are two separate components, and there is no evidence that supports the administration of blood products for patients with liver dysfunction and associated coagulation laboratory derangement in the absence of active bleeding. When bleeding, some investigators have suggested using functional studies (e.g. TEG) as a means of assessing each component of the coagulation cascade because of the liver's unique role in clotting homeostasis [285].

Acquired factor deficiencies

Acquired coagulation factor deficiency is a relatively rare but potentially unique finding in the critical care environment. The most common of these deficiencies is vWF – a large glycoprotein that promotes platelet adhesion to each other and to vessel walls at sites of injury. Acquired vWF deficiency in the PICU population is caused by shear stress usually due to ventricular assist or ECMO devices. However, vWF deficiency can also be seen in pediatric patients with valvular abnormalities [286]. Some studies have suggested the majority of patients on ventricular assist device or ECMO support have some component of vWF deficiency [287]. Typical coagulation tests including functional studies do not diagnose this disorder; diagnosis requires multimer analysis. Administration of vWF concentrate requires further studies of safety and efficacy.

Thrombosis

Thrombosis has become an increasing concern in the PICU and is associated with increased morbidity and cost [288–290]. There is little consistency in the use and type of thromboprophylaxis, which may be complicated by the difficulty in creating a valid risk assessment tool [288,291]. The most common pharmacological agents used are aspirin, clopidogrel, unfractionated heparin, low molecular weight heparin (LMWH), and warfarin. These drugs have different targets along the coagulation cascade and different therapies for reversal, potentially impacting patients who have long ICU stays and require multiple trips to and from the operating room.

Despite the increasing attention to thrombosis, a larger number of pediatric patients are being placed on long-term anticoagulation primarily due to catheter-related thrombi [292]. Generally, a risk–benefit analysis should be done before discontinuing long-term anticoagulation prior to surgery. Although not evidence based in pediatric patients, many practitioners suggest maintaining long-term anticoagulation

only if the bleeding risk of the surgery or procedure is high. Many would bridge the patient with LMWH or unfractionated heparin until the day of surgery, but practices vary from institution to institution. There also are no data on the timing of reinitiation of anticoagulation postoperatively, with a high degree of variability even in adult practice where the data are generally more robust [293].

KEY POINTS: TRANSFUSION THERAPY AND COAGULOPATHY IN THE CRITICALLY ILL CHILD

- Blood transfusion is common and life saving, but also an independent variable for morbidity and mortality in the PICU
- A restrictive RBC transfusion protocol targeting 7 g/dL for hemodynamically stable PICU patients can decrease transfusion requirements without adverse outcomes
- Plasma, cryoprecipitate, and platelet transfusions are reserved for specific deficiencies in coagulation components, postsurgical bleeding, and to maintain hemostasis in ECMO patients

Endocrine disease

Glycemic control

Both hypoglycemia and hyperglycemia are relatively common occurrences in the PICU and have been associated with unfavorable outcomes in critically ill children [294–296]. A randomized controlled trial of postoperative tight glycemic control versus standard care conducted in 980 children 0–26 months of age undergoing cardiac surgery at two centers, showed that glycemic control (with the use of an insulin-dosing algorithm targeting a blood glucose level of 80–110 mg/dL (4.4–6.1 mmol/L)) did not significantly change the infection rate, mortality, length of stay, or measures of organ failure compared with standard care [297]. A secondary analysis of this trial showed that tight glycemic control did not impact neurodevelopmental outcomes compared with standard care, but suggested a possible association between moderate to severe hypoglycemia and poorer neurodevelopmental outcomes at 1 year [298]. A more recent randomized controlled trial involving 35 PICUs randomized 713 critically ill children who had not undergone cardiac surgery and who had confirmed hyperglycemia to a lower target glycemic control group (80–110 mg/dL or 4.4–6.1 mmol/L) or a higher target group (150–180 mg/dL or 8.3–10.0 mmol/L) [299]. There were no differences in the primary outcome of ICU-free days between the two arms, and increased rates of healthcare-associated infections and severe hypoglycemia, defined as a blood glucose level below 40 mg/dL (2.2 mmol/L), were observed in the lower target group [299]. The trial was stopped early due to a low likelihood of benefit and possibility of harm [299]. With these results in mind, clinicians should avoid hypoglycemia and treat hyperglycemia in critically ill children. As a cautionary note, data are currently lacking on the optimal blood glucose, duration of glucose control, and methodology (e.g. continuous glucose monitoring) to avoid harm due to hypoglycemia when insulin infusions are used in children.

Diabetic ketoacidosis

Type 1 diabetes mellitus affects approximately 200,000 children in the USA [300]. Children with diabetes remain at high risk for life-threatening complications including hypoglycemia and diabetic ketoacidosis (DKA), although mortality has declined significantly over the last four decades [300]. Multipronged interventions have been credited with this decline in mortality, including increased awareness and education on diabetes symptoms, early treatment, and management of DKA [300]. Increased utilization and advances in insulin pump technology may have also contributed to the decline in rates of acute diabetes complications [301]. In a population-based multi-country cohort study conducted in 30,579 children from 2011 to 2015, insulin pump therapy, compared with insulin injection therapy, was associated with lower risks of severe hypoglycemia and DKA, and with better glycemic control [301].

DKA diagnosis is based on clinical and biochemical criteria. Clinical signs of DKA include dehydration, tachycardia, tachypnea, Kussmaul respirations, nausea, vomiting, abdominal pain, confusion, drowsiness, and eventually loss of consciousness [302]. Biochemical criteria include hyperglycemia (blood glucose >11 mmol/L (~200 mg/dL)), venous pH <7.3 or bicarbonate <15 mmol/L, ketonemia, and ketonuria [302].

DKA is the result of absolute insulin deficiency or stress, infection, or insufficient insulin intake, with high circulatory levels of counter-regulatory hormones such as glucagon, cortisol, cathecolamines, and growth hormone, which in turn lead to increased lipolysis, decreased glucose utilization and increased glycogenolysis, increased proteolysis and decreased protein synthesis, with a cascade of consequences as displayed in Figure 42.17 [302].

Management of DKA needs to be prompt yet deliberate. The goals of therapy are to provide initial stabilization based on pediatric advanced life support guidelines, to treat dehydration, correct acidosis, and reverse ketosis, to slowly restore osmolarity and blood glucose to near normal, to monitor for complications of DKA and its treatment, and to diagnose and treat the inciting cause [302]. Laboratory evaluation includes blood glucose, blood gases, blood or urine ketones, serum electrolytes, and complete blood count. These are repeated serially to guide therapy. Dehydration is corrected with volume expansion using isotonic fluids, if peripheral circulation is compromised, followed by continuous fluid replacement at a rate calculated to correct the fluid deficit evenly over 48 h [302]. Dextrose is generally added to intravenous fluids when blood glucose declines to 250–280 mg/dL. Insulin therapy via continuous intravenous infusion should be initiated after fluid replacement therapy has begun, at a rate of 0.05–0.1 U/kg/h. Potassium supplementation is deferred in patients who present with hyperkalemia, otherwise potassium is added to the intravenous fluids at a concentration of 20 or 40 mmol/L in patients receiving fluids at rates >10 mL/kg/h [302] and after urine output is documented. Phosphate correction may be needed in case of hypophosphatemia. Bicarbonate is not recommended outside of acute therapy for hyperkalemia.

Providers should pay utmost attention to signs and symptoms of cerebral edema, a severe, multifactorial complication of DKA and its therapy. Clinically apparent cerebral edema occurs in 0.5–0.9% of children with diabetes and has a mortality rate of 21–24% [302]. Cerebral edema manifests by

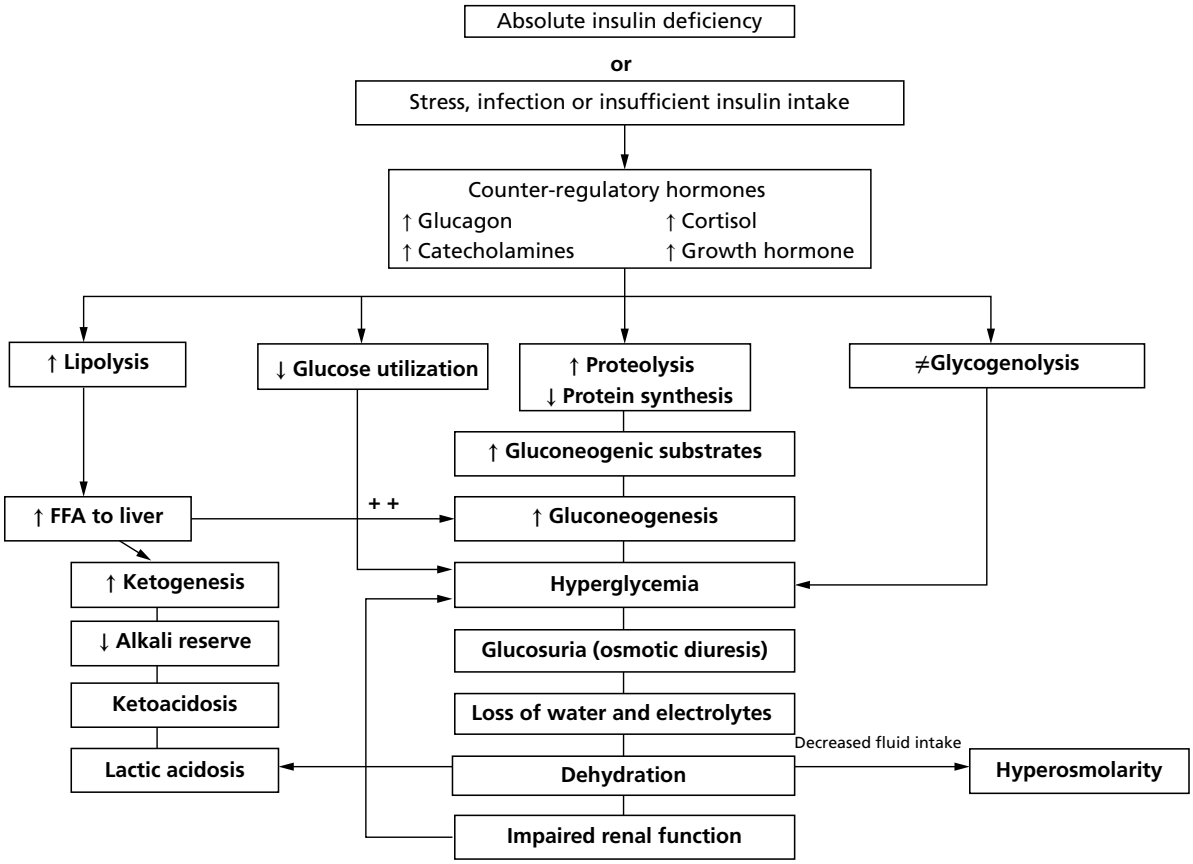

Figure 42.17 Pathophysiology of diabetic ketoacidosis. FFA, free fatty acids. *Source*: Reproduced from Wolfsdorf et al [339] with permission of American Diabetes Association.

headache, decline in mental status (restlessness, irritability, drowsiness, incontinence) and changes in neurological exam (cranial nerve palsies), bradycardia, hypertension, and respiratory depression [302,303]. Prompt intervention with mannitol or hypertonic saline is recommended for acute deterioration in neurological status [214]. Impending uncal herniation should be treated with standard measures (hyperosmolar therapy, head of bed elevated at 30°, endotracheal intubation, and mechanical ventilation). A brain CT may be obtained, only after acute stabilization [302,304], to determine degree of edema and to investigate if other acute intracranial pathology is present (e.g. intracranial hemorrhage, stroke, venous sinus thrombosis). The pathogenesis and risk factors for cerebral edema are still subject to debate, and include disruption of the blood–brain barrier, regional differences in cerebral perfusion with hyperemia in some brain regions coexisting with hypoperfusion of others (specifically the brainstem), as well as a rapid decrease in osmolarity leading to fluid shifts, as a side-effect of DKA treatment [302,303].

Inciting events for DKA, including viral and bacterial infections, should be investigated (e.g. respiratory viral testing, blood, urine, or throat cultures) and treated (e.g. antibiotics if bacterial infection is suspected).

Adrenal dysfunction

During critical illness, dysregulation of the hypothalamic–pituitary–adrenal axis, altered cortisol metabolism, and tissue resistance to glucocorticoids contribute to the development of critical illness-related corticosteroid insufficiency (CIRCI) [305]. Pathophysiological mechanisms of CIRCI are presented in Table 42.13 [305].

CIRCI has been described in a variety of disease entities, including sepsis, ARDS, trauma, burns, and major surgery [306]. CIRCI can develop at any point during critical illness, and therefore clinicians are encouraged to remain vigilant throughout a patient's hospitalization in recognizing its signs and symptoms (Table 42.14) [307]. There is no consensus on the optimal diagnostic test for CIRCI [307]. A random plasma cortisol concentration of <10 μg/dL can be used to diagnose CIRCI, as can a total cortisol level response of <9 μg/L from baseline to 60 min after administration of 250 μg of adrenocorticotropic hormone.

In adults, current evidence-based recommendations are to use corticosteroids in patients with septic shock that is not responsive to fluid and moderate- to high-dose vasopressor therapy, and in early moderate to severe ARDS, and to not use corticosteroids in hospitalized adult patients with major trauma and sepsis without shock [307]. Studies of corticosteroid therapy in critically ill children are not conclusive, and some observational studies have suggested no benefit or potential harm [308]. For children, guidelines for corticosteroid therapy have been developed only for septic shock: "if a child is at risk of absolute adrenal insufficiency or adrenal pituitary axis failure (e.g. purpura fulminans, congenital adrenal hyperplasia, prior steroid exposure, hypothalamic/pituitary abnormality, intubation with etomidate induction) and remains in shock despite epinephrine or norepinephrine

Table 42.13 Main pathophysiological mechanisms of critical illness-related corticosteroid insufficiency (CIRCI)

General defect	Main mechanisms	Key factors
Decrease in cortisol production		
Altered adrenal synthesis of cortisol	Necrosis/hemorrhage	Acute kidney failure
		Hypocoagulation
		Disseminated intravascular coagulation
		Cardiovascular collapse
		Tyrosine kinase inhibitors
	Decreased availability of esterified cholesterol	Depletion in adrenal storage regulated by annexin A1-formyl peptide receptors
		Downregulated scavenger receptor B1
	Inhibition of steroidogenesis	Immune cells/Toll-like receptors/cytokines
		Drugs (e.g. sedatives, corticosteroids)
		ACTH-like molecules (e.g. corticostatins)
Altered synthesis of CRH/ACTH	Necrosis/hemorrhage	Cardiovascular collapse
		Disseminated intravascular coagulation
		Treatment with vasopressor agents
	Inhibition of ACTH synthesis	Glial cells/nitric oxide-mediated neuronal apoptosis
		Increased negative feedback from circulating cortisol following upregulation of ACTH-independent mechanisms of cortisol synthesis
		Drugs (e.g., sedatives, anti-infective, psychoactive agents)
		Innapropriate cessation of glucocorticoid treatment
Alteration of cortisol metabolism	Decreased cortisol transport	Downregulation of liver synthesis of cortisol-binding globulins and albumin
	Reduced cortisol breakdown	Decreased expression and activity of the glucocorticoid-inactivating 5-reductase enzymes in the liver with putative role of bile acids
		Decreased expression and activity of hydroxysteroid dehydrogenase in the kidney
Target tissue resistance to cortisol	Inadequate GR-α activity	Multifactorial etiology including reduced GR-α density and transcription and excessive NFκB activation

ACTH, adrenocorticotropic hormone; CRH, corticotrophin-releasing hormone; GR-α, glucocorticoid receptor α; NFκB, nuclear factor κ B.

infusion, then hydrocortisone can be administered ideally after attaining a blood sample for subsequent determination of baseline cortisol concentration" [82]. Stress dose hydrocortisone is 50–100 mg/m²/day and can be continued and then tapered over 5–14 days with assistance from endocrinology consultation.

KEY POINTS: ENDOCRINE DISEASE

- Tight glucose control regimens in the PICU do not improve outcomes and hypoglycemia can cause harm; clinicians should avoid hypoglycemia and treat hyperglycemia
- DKA is treated by addressing shock, giving insulin infusion to reduce serum glucose, adding potassium in most patients, and being vigilant for cerebral edema
- Adrenal insufficiency can be a cause of catecholamine-resistant hypotension in shock states; stress dose hydrocortisone can be given

Gastroenterology and nutrition

The response to critical illness is characterized by increased protein breakdown and glucose and lipid intolerance, leading to a catabolic state with loss of lean body mass. Nutritional support in the PICU revolves around providing an adequate supply of nutrients that is balanced and adapted to the patient's needs.

Nutrition practices in critically ill children have been highly variable. In a worldwide survey disseminated to members of the World Federation of Pediatric Intensive and Critical Care Societies, with 189 respondents from 156 PICUs in 52

countries, nutritional protocols were available in 52%, and nutritional support teams were available in 57%, of the PICUs, respectively [309]. Important differences were found in macronutrient goals, equations used to estimate energy requirements, timing of nutrition initiation, and thresholds for supplemental parenteral nutrition [309].

In general, perceived barriers to initiation of nutrition are ongoing fluid resuscitation and need for frequent correction of electrolyte abnormalities. Safety concerns related to the use of vasoactive infusions have also impeded early initiation of enteral nutrition, although two single-center studies published in 2004 ($n = 52$) and 2016 ($n = 339$) suggested that enteral nutrition in children on continuous vasoactive infusions is not associated with adverse events and may be associated with improved survival [310,311].

Best practice recommendations for nutrition therapy in critically ill children were published in 2017, as a collaboration between the American Society for Parenteral and Enteral Nutrition and the Society for Critical Care Medicine [312]. The recommendations provide guidance on establishing a baseline nutrition status, and on the timing, type, and amount of nutrients to be provided to critically ill children [312]. It is recommended that PICU patients undergo detailed nutrition assessment within 48 h of admission, based on observational studies suggesting that malnutrition is associated with worse clinical outcomes, including higher risk of hospital-acquired infections, longer duration of ventilation, longer PICU and hospital stay, and increased mortality [312].

Resting energy expenditure, or the caloric requirement during a non-active 24 h period, increases during critical illness. Clinical guidelines recommend the use of indirect calorimetry to measure energy expenditure and guide prescription of the daily energy goal [312]. Indirect calorimetry in the PICU, however, can be technically difficult in children who are intubated, have temperature instability, or varying degrees of sedation and movement. When indirect calorimetry is not feasible, energy expenditure can be estimated using the Schofield or Food Agriculture Organization/World Health Organization/United Nations University equations, without the addition of stress factors [312].

Delivery of at least two-thirds of the prescribed daily energy requirement should be achieved by the end of the first week of PICU admission. Protein intake should be at least 1.5 g/kg/day, as higher protein intake has been shown to prevent cumulative negative protein balance. Infants and young children may require a much higher protein intake in order to achieve a positive protein balance. A negative protein balance can lead to loss of lean muscle mass, which is a poor outcome predictor in critically ill patients [312].

In recent years, mounting evidence suggests that early enteral nutrition is associated with improved outcomes, at least in part by reducing complications related to parenteral nutrition [313,314]. In a seminal multicenter, randomized controlled trial conducted in 1440 critically ill children, late parenteral nutrition (initiated 1 week after PICU admission) was compared with early parenteral nutrition [314]. Enteral nutrition was attempted early and intravenous micronutrients were provided in both groups. Mortality (not a primary end point) was similar in the two groups, but, compared with children randomized to early parenteral nutrition, children randomized to late parenteral nutrition had significantly lower new infection rates, shorter duration of ICU stay, and higher likelihood of an earlier live discharge from the ICU [314]. In addition, children in the late parenteral nutrition group had shorter duration of mechanical ventilation, a smaller proportion receiving renal replacement therapy, a shorter length of hospital stay, lower γ-glutamyltransferase and alkaline phosphatase plasma concentrations, and higher bilirubin and C-reactive protein plasma concentrations [314].

Based on the data presented above as well as other studies not detailed here, current clinical practice recommendations are to use enteral nutrition as the preferred mode of nutrient delivery to the critically ill child. Enteral nutrition should be initiated early (i.e. within 24–48 h of PICU admission), and follow a stepwise algorithm with criteria for: (1) eligibility for enteral nutrition; (2) timing of initiation of enteral nutrition; (3) detection and management of intolerance of enteral nutrition; and (4) the optimal rate of increase in enteral nutrition [314]. The gastric route for delivery of enteral nutrition is preferred over the transpyloric route, except for patients at high risk for aspiration and patients who do not tolerate gastric feeding [314].

Liver failure and extracorporeal liver support

Liver dysfunction is very common in the PICU and is multifactorial. Shock states, including from sepsis, cardiogenic causes, and postresuscitation hepatic injury, are some frequent etiologies. Hepatic failure may result in hepatorenal syndrome and hepatic encephalopathy. The etiologies and pathophysiology of end-stage liver disease and extracorporeal liver support ("hepatic dialysis") are discussed in Chapter 30.

Pancreatitis

Acute pancreatitis can be associated with a variety of critical illnesses, and although the mortality rate in children, unlike adults, is low, this condition can complicate and prolong ICU stay. In a very large, retrospective, multicenter cohort study of over 360,000 PICU admissions from 2009 to 2013, 2076 discharges (0.58%) had a diagnosis of acute pancreatitis [315]. Of these 16% were a primary diagnosis, and 84% a secondary diagnosis. The most common diagnoses associated with secondary acute pancreatitis were bacterial infections/sepsis, hypotension, seizure disorders, pneumonia/ARDS/acute lung injury, and trauma, accounting for over 50% of cases. Mortality in primary acute pancreatitis was 0.3%, and for patients with the secondary condition was 6.8%. Treatment of the primary condition, along with bowel rest and adequate parenteral nutrition, is usually effective.

Immunity and infection

Immune dysfunction in the critically ill child

Immune dysfunction is common in the PICU. Children may present with life-threatening infections due to primary immunodeficiency, have secondary immunodeficiency due to their medical condition or therapy, or have immunoparalysis associated with critical illness.

The incidence of primary immune disease is one in 2000 children aged less than 18 years [316]. Primary immune disorders are classified as antibody deficiency (B-cell disease) T-cell dysfunction, combined T- and B-cell disease, and phagocytic or complement disorders. Children with primary immunodeficiency present with recurrent infections with typical organisms or serious infections with rare organisms. When an immune disorder is known or suspected, antibiotic choices and other therapy can be tailored appropriately. Consultation with infectious disease expertise is often required to select empirical or treatment antibiotics for patients with primary immunodeficiency.

Secondary immune dysfunction is more common in the PICU and can be due to multiple causes. Patients are often immunosuppressed due to medical therapies such as during the treatment of oncological disease, immunosuppression for transplantation, cardiopulmonary bypass, or long-term steroid use. Diseases such as human immunodeficiency virus may also cause secondary immunodeficiency. Infection in this group of patients can be serious, and careful consideration of empirical antibiotic choice is indicated.

Another form of secondary immunodeficiency specific to the PICU is immunoparalysis associated with critical illness. The proinflammatory surge that accompanies critical illness is balanced by an anti-inflammatory response. When the anti-inflammatory response is out of proportion or prolonged, it can cause immunosuppression that has been termed "immunoparalysis." The degree of immunoparalysis is identifiable by blood laboratory tests. Immunoparalysis is typically treated by stimulation of the immune response and stopping any present immune-modulating therapies. Decision making regarding antibiotic coverage and immune-modulating therapies in this patient population is complex, and consultation is recommended [317].

Bacterial resistance and empirical antibiotics

The PICU population has a high rate of antibiotic-resistant bacterial colonization due to the large number of patients with multiple medical problems and medical care exposures. Vancomycin-resistant enterococcus colonization in the PICU population has been found to be as high as 5% [318]. Similarly, methicillin-resistant *Staphylococcus aureus* (MRSA) colonization has been reported in 4–10% of PICU patients. The rate of colonization with MRSA increases with previous hospitalization and family members who work in medicine [319,320].

Because of organ dysfunction, reliance on life-saving equipment and prevalent hemodynamic instability, concern for infection in PICU patients is common. Infection or sepsis can be a primary problem or secondary to critical illness or PICU interventions. Empirical antibiotic treatment is common, and antibiotic selection can be challenging. Factors that should be considered in empirical antibiotic treatment are: location of suspected infection, immune status of the host, degree of symptoms such as hemodynamic instability, previous bacterial culture sensitivities, and antibiotic exposure and colonization. Many PICUs have developed antibiotic stewardship programs to improve empirical antibiotic selection and treatment plans. Protocolized antibiotic selection, electronic medical record risk stratification, and antibiotic stewardship programs have been associated with improved antibiotic selection and time to treatment, decreased antibiotic duration, and reduced risk of bacterial resistance [321,322]. When caring for a PICU patient in the OR, discussion of current antibiotics and recommended empirical coverage with the intensivist may be helpful.

Transport of the critically ill pediatric patient

Anesthesiologists have expertise in the transport of patients and recognize the significant risks in moving critically ill patients. Monitoring and medication delivery can be less reliable than in stationary patients and risk of dislodging or disrupting life-sustaining therapy is present. In single-center studies, intrahospital transport of PICU patients, to and from the OR, procedure, or imaging area, has been associated with significant untoward event rates: change in hemodynamic parameters requiring treatment (13.9%), equipment-related adverse events (10%), urgent intubation (5%), loss of endotracheal tube (3.75%) or central line (3.75%), or cardiopulmonary resuscitation (7.5%) [323,324]. Preplanning, anticipation of potential problems, ensuring patient optimization prior to transport, and adequate staff are key to managing the risk and resultant untoward events associated with intrahospital transport.

Interhospital transport (typically from referring hospital to pediatric subspecialty service-associated hospital) is common in pediatric critically ill patients due to the centralization of subspecialty care for children. Pediatric subspecialty critically ill transport is a large practice with consensus statements on accreditation, medical direction, team composition, research, and economics [325,326]. Pediatric subspecialty teams bring critical care skill and expertise to the bedside of pediatric patients; patient transport with a pediatric subspecialty team is associated with less unplanned events than transport with non-pediatric specialty teams [327]. Anesthesiologists may interact with pediatric transport teams during interfacility transport when a pediatric patient needs urgent surgical intervention, sometimes being transferred directly into the OR. Similarly, an anesthesiologist at a non-pediatric subspecialty center may initiate interfacility patient transfer directly from the OR to a referral center when the patient condition or needs exceed resources available locally.

PICU outcomes

Survival following PICU admission has improved significantly over the last decades, with recent reports of 98% survival to PICU discharge and 97.6% survival to hospital discharge [328]. Of critically ill children requiring PICU admission, 4.8% suffer new morbidity, 3.4% acquire global cognitive disability, and 10.3% acquire global functional disability by Pediatric Cerebral Performance Category and by Pediatric Overall Performance Category at hospital discharge [328,329]. Intervention risk factors for acquiring cognitive and functional disability include mechanical ventilation, RRT, cardiopulmonary resuscitation, and ECMO [329]. Longer length of PICU stay is also associated with unfavorable neurofunctional outcomes [330].

KEY POINTS: GASTROENTEROLOGY AND NUTRITION, IMMUNITY AND INFECTION, AND OUTCOMES

- At least two-thirds of energy requirements, and adequate protein intake, should be met by the first week of admission, via enteral or parenteral nutrition
- Imuunoparalysis of critical illness and bacterial resistance from empirical antibiotic coverage are important causes of infection
- PICU survival has improved significantly, with 97–98% survival to hospital discharge; however, about 10% acquire a global functional disability

CASE STUDY

A 6-year-old, 20 kg girl with a history of severe bronchial asthma treated with daily inhaled β-agonists, inhaled corticosteroids, and montekulast was admitted to the PICU from the emergency department. She had a severe asthma exacerbation after an upper respiratory infection consisting of inspiratory/expiratory wheezing with poor air movement, severe retractions, hyperinflation on chest radiograph, and mild cyanosis with SpO_2 85% in room air, improving to 90% with non-rebreathing O_2 facemask at 10 L/min flow [331].

Rapid testing of nasal secretions revealed the presence of parainfluenza virus antigens. After inhaled β-agonist treatments, IV corticosteroids, and IV magnesium sulfate there was little improvement, and she was started on nasal BiPAP mask, with 100% oxygen, and pressure settings of 12/6 cmH_2O. A radial arterial line was placed, and arterial blood gas (ABG) on this therapy was pH 7.15, $PaCO_2$ 90 mmHg, and PaO_2 65 mmHg. Continuous albuterol inhalation was started, but her condition worsened over the next 4 h, with increasing use of accessory muscles, and tiring to the point that respiratory arrest was imminent. After preoxygenation by facemask with FiO_2 1.0, ketamine 2 mg/kg IV, and rocuronium 25 mg, her trachea was orally intubated with a 4.5 mm cuffed endotracheal tube (ETT). After intubation, chest radiograph revealed the ETT in midtrachea, and severe hyperinflation with areas of atelectasis in the right lower and left upper lobes, without pneumothorax or pneumomediastinum. Continuous albuterol, IV corticosteroids, and IV magnesium were continued, but gas exchange continued to worsen, with ABG pH 7.05, $PaCO_2$ 105 mmHg, and PaO_2 50 mmHg 4 h after intubation, on pressure control ventilation with peak inspiratory pressure (PIP) 38 cmH_2O, positive end-expiratory pressure (PEEP) 10 cmH_2O, I:E ratio of 1:4, and respiratory rate of 20 on FiO_2 1.0. Capnography tracing revealed a sharp upslope during expiration, and flow–volume loops indicated severe expiratory obstruction with an exhaled tidal volume of only 65 mL (3.25 mL/kg). Heart rate was 175 bpm, blood pressure 75/45 mmHg, and peripheral perfusion was abnormal with mottling and capillary refill time 3 s. A triple-lumen femoral central venous catheter was placed using ultrasound guidance, a fluid bolus of 20 mL/kg normal saline was administered, and low-dose epinephrine at 0.03 μg/kg/min was started, for inotropic support and bronchodilation. Ketamine, dexmedetomidine, and fentanyl infusions had been initiated for sedation. After a discussion among the ICU team about whether a course of volatile anesthetic agent treatment or venovenous ECMO was more appropriate, it was decided to consult with the anesthesia service and use inhaled sevoflurane [332].

Following the hospital's policy for inhaled volatile anesthetic agent treatment of asthma in the PICU, a late-generation anesthesia machine was brought to the PICU room, and respiratory gas and anesthetic gas scavenging lines were connected. Because the anesthesia machine ventilator was piston driven without a bellows, and had low internal deadspace and high driving pressures, initial settings matching the ICU ventilator were able to maintain the same gas exchange, albeit it was poor. Sevoflurane inhalation was stared at 0.5% inspired concentration, and increased over the next 2 h gradually to 3.5%. The continuous albuterol was gradually decreased and discontinued, as was the ketamine infusion. Blood pressure and heart rate were carefully monitored, and epinephrine gradually increased to 0.05 μg/kg/min to maintain systolic BP above 75 mmHg, and HR less than 180 bpm. The goal was to maintain end-tidal sevoflurane concentration at 3–3.5% for 4 h, and then decrease gradually if there was improvement in gas exchange and flow–volume loops. ABG was assessed every 30 min. $PaCO_2$ gradually decreased to 55 mmHg, PaO_2 increased to 205 mmHg, and pH improved to 7.30. End-tidal CO_2 waveform also improved and had only a slight upslope, and air exchange by auscultation also improved, with a decrease in inspiratory and expiratory wheezing. Finally, flow–volume loops improved, indicating much less expiratory obstruction, and exhaled tidal volumes increased to 140 mL (7 mL/kg) on a lower PIP of 30 cmH_2O. At the end of 4 h of steady-state sevoflurane, the volatile agent was gradually decreased over 2 h, then discontinued, with ongoing careful respiratory and hemodynamic monitoring, ensuring no deterioration of gas exchange and respiratory mechanics. Toward the end of the sevoflurane inhalation, continuous albuterol and ketamine infusion were restarted. The patient was transitioned to the ICU ventilator, and continued

to improve, with her trachea being extubated 48 h later. She was discharged from the ICU on the following day and home 3 days later.

This case demonstrates an approach to severe status asthmaticus with respiratory failure, use of multiple modalities to increase bronchodilation, and multidisciplinary decision making ultimately deciding on inhaled volatile anesthetic agent for treatment. Involvement of the pediatric anesthesiologist in ICU care, both for operative cases and in medical cases, is a major responsibility, and collaborative communication and planning with the ICU physicians facilitates patient care.

CHAPTER 43

Anesthesia for the Patient with a Genetic Syndrome

David Mann, Priscilla J. Garcia, and Dean B. Andropoulos

Texas Children's Hospital, and Department of Anesthesiology, Baylor College of Medicine, Houston, TX, USA

General approach to patients with a genetic syndrome

A syndrome is the occurrence of more than one recognizable phenotypic trait that occurs together in a specific association, with a cause that is thought to be from a specific genetic defect. A geneticist or dysmorphologist is usually able to determine a diagnosis from the phenotype of the patient, but as the science of molecular genetics advances, more of these syndromes have a known genetic cause and inheritance. It is presumed that many of those without a known cause will have their genetic bases determined in the near future. Definitive diagnosis of the more common genetic disorders is most often made from conventional karyotyping, chromosomal microarray, or fluorescence *in situ* hybridization (FISH), from peripheral blood lymphocytes. As newer genetic testing such as whole exome sequencing and whole genome sequencing becomes more clinically available because of lower cost, the precision of genetic diagnoses and the potential for "personalized medicine" is continuously improving [1,2]. Whole exome or genome sequencing has a diagnostic yield of 30–60% in infants and children in neonatal and pediatric critical care units, and may alter clinical care 50–70% of the time, with a turnaround time of several days to 2 weeks. It is likely that the clinical use of this approach will expand in the coming years [3].

An association is a constellation of several recognizable phenotypic traits, either without a known genetic cause, or with a variety of genetic causes. The distinction between a syndrome and an association is often not clear, and this chapter will use these terms interchangeably. The term "sequence" is also often used, as in "Pierre Robin sequence," but in modern terminology this term is also normally replaced with "syndrome." Because many of these children will require anesthesia or sedation for diagnostic or therapeutic procedures, the pediatric anesthesiologist will encounter patients with syndromes frequently, often almost on a daily basis. This chapter will first review the general approach to the patient with a genetic syndrome, and then review in more detail a few of the most common syndromes associated with challenges in anesthetic care. Finally, a listing of 120 syndromes associated with anesthetic management issues will be presented alphabetically (Appendix 43.1, see ebook).

Airway considerations

Management of the airway is always a central consideration for the pediatric anesthesiologist, and many patients with genetic syndromes have abnormal airways. Among the most common are syndromes with mandibular hypoplasia (see section "Micrognathia syndromes"), including Pierre Robin sequence, Treacher Collins syndrome, and Goldenhar syndrome (hemifacial microsomia). Other conditions include cleft lip and palate, high arched palate with small mouth opening, cervical vertebral fusion limiting neck movement, and soft tissue obstruction from macroglossia or other causes. A thorough preoperative history of airway problems, including snoring, airway obstruction during sleep, and acute life-threatening events is important to elicit. The history of previous anesthetics and tracheal intubations is crucial to understand, and whenever possible examination of previous anesthetic records, or speaking to the patient's previous anesthesiologist, otolaryngologist, or craniofacial surgeon is very important. Examination of the airway for mouth opening, and visualization of the pharynx and soft palate, as well as neck

Gregory's Pediatric Anesthesia, Sixth Edition. Edited by Dean B. Andropoulos and George A. Gregory.

range of motion, should be done carefully. Finally, any imaging studies such as chest, neck, and facial radiographs, computed tomography (CT) scans, or magnetic resonance imaging (MRI) scans should be reviewed. A management plan for the difficult airway should be developed. Details of difficult airway management are presented in Chapter 15. Details of anesthetic management for craniofacial surgery are presented in Chapter 35. Appendix 43.1 includes airway considerations for each of the syndromes listed.

Cardiac manifestations

A number of genetic syndromes have a cardiac component, and the importance of a thorough cardiac history and physical examination cannot be overemphasized. In the presence of an abnormal cardiac examination consisting most often of systolic and/or diastolic murmurs, the cardiac anatomy and pathophysiology must be understood, and any recent diagnostic studies such as echocardiography must be reviewed. In neonates without a cardiac diagnosis presenting for some types of surgery, e.g. a patient with VACTERL association (see later) presenting for tracheoesophageal fistula repair, cardiac consultation and echocardiography should be obtained if possible because of the high incidence of cardiac abnormalities of 30–40% [4]. Other common syndromes with patients presenting for non-cardiac surgery, with frequent cardiac involvement, include CHARGE, trisomy 13, 18, and 21, and velocardiofacial syndromes (see later). A discussion with the patient's cardiologist is indicated for severely affected patients. Details of cardiac development are reviewed in Chapter 5, and anesthetic management and pathophysiology in cardiac disease are discussed in Chapters 26 and 27.

Neurodevelopmental abnormalities

Many patients with genetic syndromes have malformations of the central or peripheral nervous systems, and for many without obvious malformations, there is associated neurodevelopmental delay. This may manifest as general intelligence lag, gross or fine motor problems, speech and language delay, and behavioral problems. It is important to understand neurodevelopmental status in any patient with a genetic syndrome; the chronological age may be very different than the developmental age and the approach to preoperative preparation, communication, premedication, and parental presence may need to be altered accordingly. Many of these patients have undergone multiple medical encounters and interventions, and may be very anxious in the preanesthetic period.

Vascular access

Patients with genetic syndromes may have limb abnormalities that preclude conventional intravenous access, and alternate sites may need to be planned. This may include external or internal jugular vein access if the limbs are not available. In addition, patients with genetic syndromes often have had multiple hospitalizations and procedures, and peripheral venous access may be very difficult, and central veins may also be thrombosed from previous catheters. The absence of typical superficial veins, and the presence of cutaneous collateral vessels, should increase suspicion for difficult access. If indicated, additional studies (i.e. ultrasound, MRI, or CT scanning) may be necessary to plan for vascular access. Ultrasound guidance for vascular access, including peripheral venous access, can greatly facilitate care of these patients. Chapter 18 contains a detailed discussion.

Orthopedic considerations

Scoliosis, hip dysplasia, and limb contractures are common in patients with genetic syndromes. Severe scoliosis should prompt an evaluation of the respiratory and cardiac status of the patient and may alter plans for postoperative ventilation and intensive care. Positioning of anesthetized patients with these problems must be done very carefully so as not to injure affected areas. Chapters 28 and 32 present spine and orthopedic considerations.

Other considerations

Particularly with rare disorders, or disorders with which the anesthesiologist is not familiar, it is important to consult a reference source whenever possible to become familiar with the basic problems of the particular syndrome, and to devise a rational anesthetic plan. Appendix 43.1 lists 120 syndromes, ranging from the most common (fetal alcohol syndrome, Down syndrome, autism spectrum disorder), to the most rare. Another excellent general source is the US National Institutes of Health MedGen website: https://www.ncbi.nlm.nih.gov/medgen/ [5]. The US National Institutes of Health online Mendelian Inheritance in Man database (www.ncbi.nlm.nih.gov/omim) and the US National Institutes of Health Genetic and Rare Diseases Information Center (https://rarediseases.info.nih.gov/) also have excellent information including the gene map locus, if known [6,7]. Many other published and electronic resources are available; including general review articles [8] and textbooks [9]. It behooves the pediatric anesthesiologist to have these resources at hand because of the frequent presentation of these patients on the day of surgery, when the luxury of time for a thorough search for information is not available. In addition, the parents and other caregivers are usually extremely knowledgeable about the patient, and often the condition itself, and can offer valuable information about how the patient has responded to particular interventions in the past. It is important to listen to the parents' and patient's requests and concerns when approaching the patient with a genetic syndrome.

KEY POINTS: GENERAL APPROACH TO PATIENT WITH A GENETIC SYNDROME

- Fluorescence *in situ* hybridization, chromosomal microarray, or newer genetic testing such as whole exome or whole genome sequencing can greatly increase diagnostic yield
- Airway and cardiac abnormalities are seen in a large number of genetic syndromes; careful evaluation is necessary for these organ systems
- Neurodevelopmental and orthopedic problems are also frequently seen in patients with genetic and dysmorphic syndromes

Management of common important syndromes

Down syndrome

Down syndrome (DS), or trisomy 21, is the most commonly identified genetic form of mental retardation, and the leading genetic cause of specific birth defects and medical conditions [10]. Approximately 95% of children with DS have an extra chromosome 21 due to abnormal segregation of chromosomes during gamete formation; about 4% due to chromosome 21 translocations, and 1% due to chromosome 21 somatic mosaicism [10]. The estimated maternal age adjusted prevalence of DS in the United States is 14 per 10,000 livebirths, or one in 732, suggesting that approximately 5400 infants are born annually with DS. Advanced maternal age is by far the most significant risk factor for DS.

DS patients experience a number of problems that result in them presenting to the anesthesiologist for diagnostic and therapeutic reasons, and common features which present a challenge to the anesthesiologist [11]. All DS patients by definition have the characteristic facial features of upslanting palpebral fissures, flat facial profile, and relatively large tongue, as well as mental retardation and hypotonia (Fig. 43.1) [12]. About 50% of DS patients have congenital heart disease (CHD) consisting of complete atrioventricular canal in the majority of patients, but ventricular septal defect, tetralogy of Fallot, and other lesions are also seen. Neonates with DS should be screened for CHD, and parents questioned about cardiac history before any anesthetic. Of particular note is that for reasons incompletely understood, DS patients develop pulmonary hypertension much earlier, and to a more severe degree, than patients without DS with the same cardiac lesion. Especially in unrepaired CHD in DS, an assessment of pulmonary artery pressures should be considered; echocardiography is often sufficient for this purpose. DS patients are more likely to experience bradycardia with sevoflurane induction, even if they do not have CHD; careful monitoring and availability of anticholinergic agents like atropine or glycopyrrolate is prudent [13]. Chapters 26 and 27 discuss anesthetic management in CHD.

Figure 43.1 Typical facial features of Down syndrome. Note the epicanthal folds, upslanting palpebral fissures, flat facial profile, and relatively large tongue. *Source*: Reproduced from Davidson [12] with permission of Elsevier.

Airway obstruction is common in children with DS; caused by the relative midface flattening with constricted oropharyngeal space, small nasal passages, and relatively large tongue, tonsils, and adenoids [14]. This may lead to obstructive sleep apnea, which may further exacerbate any pulmonary hypertension. DS children present frequently for tonsillectomy and adenoidectomy; and may require special diagnostic testing, and postoperative admission and monitoring. Despite this propensity for upper airway obstruction, the vast majority of DS patients are suitable for a straightforward mask airway and tracheal intubation.

Atlanto-occipital instability occurs in up to 15% of DS patients, defined by excessive movement on cervical flexion–extension radiographs [14]. However, the vast majority of these patients are asymptomatic, and the many infants with DS who present for an anesthetic have incompletely ossified cervical spine vertebrae, and radiographs are not reliable. Therefore, cervical spine radiographs are not indicated in the asymptomatic DS patient before anesthesia. A careful history of neck pain or neurological symptoms, and previous anesthetics or tracheal intubations is important for every DS patient. If such a history is positive, elective anesthetics should be postponed until a thorough evaluation, often involving cervical spine radiography, CT scan, or MRI, is done. Very careful handling of the cervical spine during airway management, and surgical positioning is indicated. This includes avoiding extremes of flexion, extension, and rotation, and holding the cervical spine in a neutral position whenever possible. The majority of DS patients' tracheas can be intubated easily by direct laryngoscopy with these precautions.

Gastrointestinal problems occur in about 10% of patients with DS, with duodenal atresia and annular pancreas accounting for the majority of these findings [10]. Esophageal atresia/tracheoesophageal fistula may also be present in patients with DS. These conditions often result in a neonate with DS presenting for urgent surgery for bowel obstruction; a careful search for associated conditions, especially CHD, is important in such patients.

Down syndrome patients frequently have abnormal thyroid function, with about 2% having congenital hypothyroidism, and up to 25% of patients from birth to 10 years having compensated hypothyroidism, with elevated thyroid-stimulating hormone levels, and low normal T4 levels [14–16]. These patients often go undetected due to the other characteristics of DS, i.e. developmental delays, hypotonia, and obesity. Hypothyroidism is especially important in cardiac or other major surgery, where a subclinical state may be unmasked by the major stress in the perioperative period, which can affect myocardial function by desensitizing the heart to endogenous and exogenous catecholamines. Therefore, it is recommended that DS patients have screening thyroid function testing before major surgery.

Down syndrome children are at increased risk for acute leukemias, both myeloid (AML) and lymphocytic (ALL) [17]. DS children are different in their outcomes and response to treatments, as well as treatment toxicity and side-effects, compared to non-DS children. Survival and outcome is improved

in DS patients with AML, but equivalent to non-DS patients in ALL. Side-effects, particularly mucositis and severe infections, are more frequent in DS patients undergoing intensive chemotherapy-induction regimens. The anesthesiologist must evaluate the DS patient with leukemia for all of the other manifestations of DS noted above.

Finally, vascular access may be challenging in patients with DS, with peripheral venous access difficult due to increased adipose tissue, internal jugular access made difficult due to a short webbed neck and increased adipose tissue, and radial arterial access difficult due to the small size of this artery [18]. Again, ultrasound guidance can be extremely effective in facilitating peripheral and central venous, and arterial access.

In a recent study from a major US children's hospital, 9% of 479 anesthetics in children with complex special healthcare needs were for children with DS, representing 1.25% of all anesthetic cases [19]. This series indicates the frequency with which the pediatric anesthesiologist will encounter patients with DS, and a thorough understanding of the above noted disorders with DS is important to deliver appropriate anesthetic care to these patients.

Trisomy 18 and 13

Trisomy 18 (Edwards syndrome, incidence 1:6000–8000 live-births) and trisomy 13 (Patau syndrome, incidence 1:10,000) are the second and third most common autosomal trisomy disorders, after Down syndrome, in neonates who survive to birth [20]. Both syndromes have developmental delay, microcephaly, micrognathia, hypotonia, and a high incidence of CHD – of about 90% (Fig. 43.2). Atrial septal defects, ventricular septal defects, and patent ductus arteriosus, often with all three lesions together, represent the vast majority of lesions, at about 60–70% of CHD [21]. The majority of the remainder of CHD is found in two-ventricle anatomy such as aortic valve disease, coarctation of the aorta, double outlet right ventricle, tetralogy of Fallot, and complete atrioventricular canal. Single-ventricle disease, such as hypoplastic left heart syndrome, comprises less than 10% of CHD cases. Disorders in multiple other organ systems, including gastrointestinal, genitourinary, orthopedic, and neurological, are frequent. Both syndromes carry a poor overall prognosis, and median survival has been reported as 1–2 weeks for both syndromes. Mosaic or translocation-type trisomy 18 and 13 may confer improved survival versus complete trisomies.

Figure 43.2 A 3 month old infant with trisomy 18 (Edwards syndrome). Note the microphthalmia, micrognathia, short neck, and failure to thrive. The infant was also hypotonic with club foot, and had ventricular and atrial septal defects. *Source*: Reproduced from Bali et al [25] with permission of Turk J Anaesthesiol Reanim.

The most common causes of death in trisomy 18 and 13 patients are pneumonia, apnea, and CHD. There are a number of recent reports about longer survival, including a large report of 10–12% 5–10-year survival for both trisomy 18 and 13. Although many of these patients will receive only comfort care, an increasing number are being actively treated, and will require anesthetic care [22]. Gastrostomy tube placement and cardiac repairs are among the most common surgeries, but major, intermediate, and minor surgery on essentially every organ system has been reported. This includes gastrointestinal, urological, spine, craniofacial (cleft lip and palate, maxillary reconstruction), tracheostomy, ventriculoperitoneal shunt, myringotomy, tonsillectomy, and many others. In a recent series of over 400 trisomy 18 and 13 patients in Ontario, Canada, 18% underwent at least one surgical procedure; 1-year survival after the first surgery was about 70% for both diagnoses [23]. Twenty to 40% of these children have four or more lifetime surgical procedures. In a large administrative database study of 1480 patients with trisomy 18 and 13, 90% had CHD, and CHD repair was performed in 7% of patients. In-hospital mortality was 48% in the unoperated CHD patients versus 21% in the repaired patients ($p < 0.03$) [21]. Anesthetic considerations include a thorough evaluation of all associated defects, particularly cardiac and airway considerations because of the high incidence of micrognathia [24–27]. Preparations for difficult airway management should be made as appropriate. A thorough discussion with the surgeon about planned procedures, and with the parents about the procedures and risks of the anesthetic, and the likely increased rate of major complications and mortality in the perioperative period, is essential. The expectations and wishes of the parents are crucially important to understand when approaching the care of trisomy 18 and 13 patients.

KEY POINTS: TRISOMY 21, 18, AND 13

- Common Down syndrome problems include cardiac disease, atlanto-occipital instability, pulmonary hypertension, hypothyroidism, duodenal atresia, and leukemias
- Trisomy 18 and 13 patients have a very high early infancy mortality, but increasingly are being treated for a variety of surgical conditions; congenital heart disease is present in 90%

VACTERL association

The VACTERL association was first proposed in 1972; the acronym comprises *V* for vertebral defects, *A* for anal or other intestinal atresia, *C* for cardiac defects, *TE* for tracheoesophageal

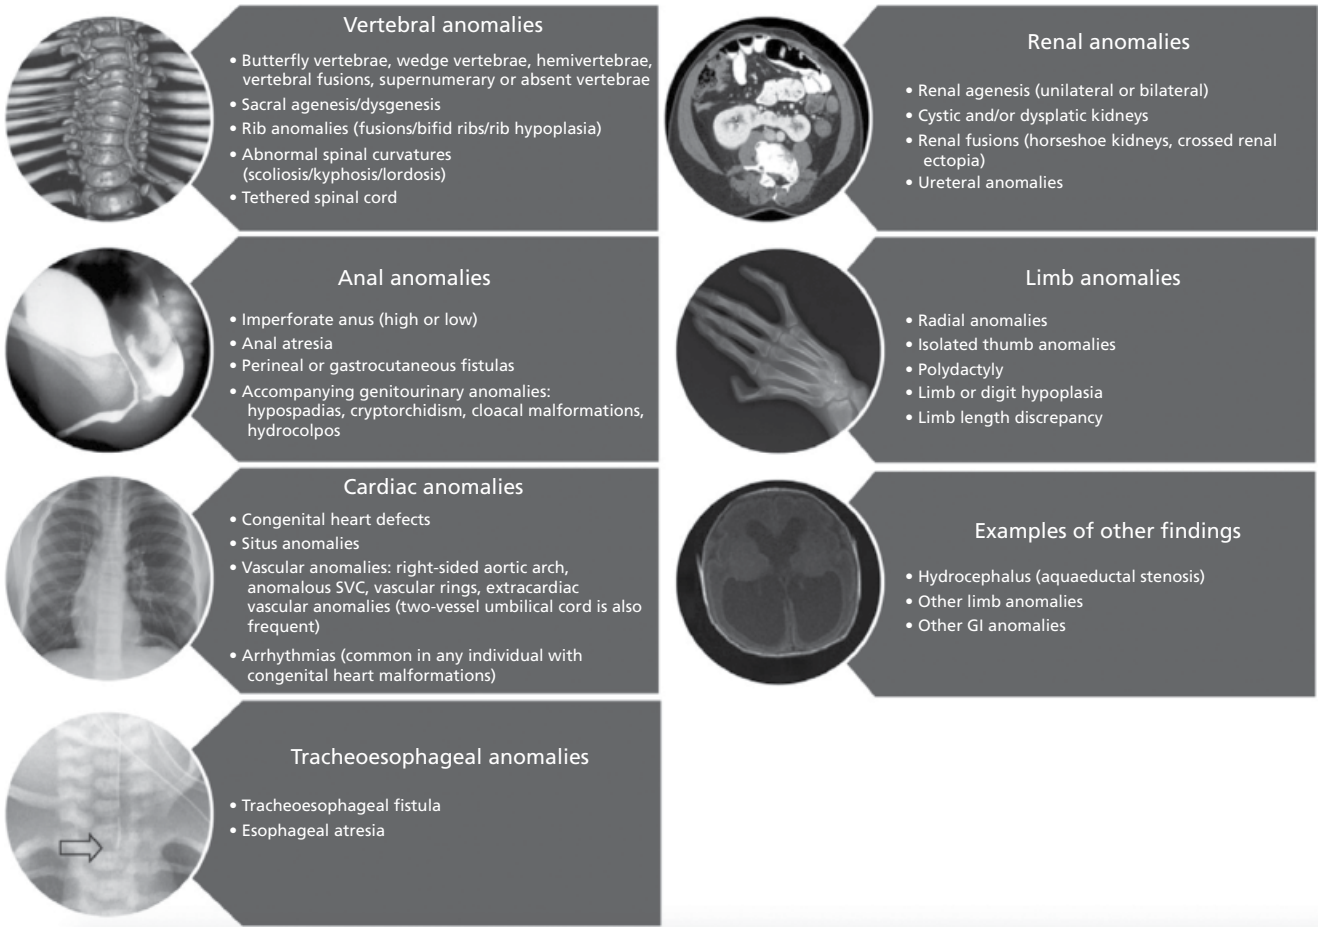

Figure 43.3 Examples of findings in the VACTERL association. The images in the circles represent radiological examples. Vertebral anomalies: 3D CT reconstruction showing thoracic segmentation anomalies; anal anomalies: contrast imaging showing rectoprostatic urethral fistula in a patient with ano-rectal malformations (ARMs); cardiac anomalies: chest radiograph showing midline heart in a patient with situs anomalies as part of the VACTERL association; tracheo-esophageal anomalies: radiograph showing the position of feeding tube placement (arrow) due to a tracheal pouch; renal anomalies: axial view from an abdominal CT showing horseshoe kidney; limb anomalies: skeletal anomalies affecting the radius, wrist, and thumb; examples of other findings: axial view from brain MRI showing hydrocephalus (due to aqueductal stenosis). GI, gastrointestinal; SVC, superior vena cava. *Source*: Reproduced from Solomon et al [31] with permission of Elsevier.

fistula (TEF), *R* for renal malformations, and *L* for limb defects. It was first proposed as the VATER association and this is occasionally still used; the frequent inclusion of cardiac and limb defects necessitated the change [28]. The incidence is estimated to be 1:10,000-40,000 livebirths. The genetics of this disorder are complex, but candidate genes in patients and animal models include defects or deletions in the sonic hedgehog gene on chromosome 7, FOX transcription gene cluster on chromosome 16, and Gli2 gene on chromosome 2 [29,30]. Not all patients have all features of this association, but the TEF is often accepted as essential for the diagnosis, along with at least one other major defect in one of the five additional categories. Recent publications have indicated an increased incidence of anomalies in these categories with more sophisticated imaging techniques to diagnose more subtle malformations (Fig. 43.3) [31,32]. In the other categories, cardiac lesions are the most prevalent, seen in 40–80% of patients [29]. Ventricular septal defect and tetralogy of Fallot are common, and most CHD is acyanotic at presentation. In the case of the VACTERL association with complex CHD with patent ductus arteriosus-dependent systemic or pulmonary circulation, mortality after TEF repair exceeds 50% [33]. Vertebral anomalies are seen in about 60–90% of patients, including hemivertebrae, fused or butterfly vertebrae, or extra vertebrae. Renal system anomalies are found in approximately 50–80% of patients and include horsheshoe kidney, renal agenesis, vesicoureteral reflux, hypospadias, dysplastic kidney, and cryptorchidism. Atresias of the gastrointestinal tract and other anorectal malformations are seen in approximately 55–90% of patients, with the significant majority of these being anal atresias. Limb anomalies are observed in about 40–55% of patients, with digital anomalies and absent radius the predominate defects.

The frequent and significant defects in the VACTERL association mean that these children are often presenting for repeated anesthetics for both diagnosis and treatment, necessitating a thorough preoperative evaluation encompassing an assessment of the lesions in all categories, and also of the developmental and emotional state of the child who has often endured multiple medical interventions. These children are most often developmentally normal.

CHARGE syndrome

The CHARGE syndrome was described in 1979, and the acronym is designated *C* for coloboma, *H* for heart defect, *A* for atresia choanae, *R* for retarded growth and development, *G* for genital hypoplasia, and *E* for ear anomalies/deafness (Table 43.1) [34,35]. Further refinement of diagnostic criteria in 1998 designated the major features seen in most CHARGE patients, but rare in other patients, as the four Cs: (1) coloboma of the iris or retina with microphalmia (80% of patients); (2) choanal atresia/stenosis, either unilateral or bilateral or membranous or bony; (3) cranial nerve anomalies – olfactory tract, facial paralysis, sensorineural deafness, and incoordination of swallowing; and (4) characteristic ear anomalies including cup-shaped ears (80–100% of patients). The minor criteria, seen less frequently in CHARGE syndrome and less specific, include cardiac malformations (75–80% of patients), most often conotruncal defects including tetralogy of Fallot, aortic arch anomalies, and atrioventricular canal; genital hypoplasia, including micropenis and cryptorchidism; cleft lip and palate; TEF; distinctive CHARGE facies and features (sloping forehead and flattened tip of nose); growth deficiency; and developmental delay [34,35]. Typical clinical features of the CHARGE syndrome are shown in Table 43.1 and Figure 43.4.

The incidence of CHARGE syndrome is estimated to be approximately one per 10,000 livebirths [34,35]. A leading candidate gene, discovered recently, is the *chromodomain helicase DNA binding protein 7* (*CHD7*) gene on the long arm of chromosome 8. This results in the expression of a protein that participates in chromatin remodeling during early development and allows a level of epigenetic control over target genes expressed in mesenchymal cells derived from the cephalic neural crest [36]. Mutations of this gene are found in 60–65% of individuals with the CHARGE syndrome, and over 150 mutations have been discovered that encode for short, nonfunctional CHD7 protein.

A thorough evaluation of all organ systems is required before anesthetizing a patient with CHARGE syndrome. Neonatal choanal atresia or stenosis may be particularly challenging – requiring repeated anesthetics for imaging, the repair itself, and re-evaluation and follow-up procedures. The cardiac procedures are particularly common. With the advent and more widespread use of the cochlear implant, many CHARGE patients will also undergo this procedure. Although mental retardation and other developmental delays are common, this feature is variable and some patients may have normal intelligence. Autism spectrum disorder behavioral syndromes are increasingly recognized in these patients [34,35].

Micrognathia syndromes

Among the most common causes for difficult airway management and tracheal intubation in pediatric patients is micrognathia, and an evaluation for this problem is done in

Table 43.1 Phenotypic features of the CHARGE syndrome

Features	Details	Frequency
Coloboma	Iris, retina, choroid, disk, or microphthalmia	75–90%
Choanal atresia/stenosis	Unilateral or bilateral, bony or membranous	65%
Cranial nerve anomalies	Facial nerve palsy, auditory, vestibular, or vagal (swallowing problems)	Facial: 50-90%
	CNS abnormalities can also involve arhinencephaly, holoprosencephaly spectrum, or forebrain and hindbrain abnormalities	CNS abnormalities 55–85%
Characteristic ear anomalies	Outer ear tends to be symmetrically misshapen, low set, anteverted, cup shaped, and wide with reduced vertical height	Outer ear 95–100%
	Triangular concha is a common finding	Inner ear: 90%
	Microtia, hypoplasia of the auditory canal, and preauricular tags can also be seen	
	Middle: ossicular malformation	
	Cochlear: Mondini defect	
	Temporal: absent/hypoplastic semicircular canals; highly predictive of the presence of a *CHD7* mutation	
Genital hypoplasia	Males: micropenis/cryptorchidism	50–70%
	Females: hypoplastic labia	
	Delayed puberty	
Developmental delay	IQ <70 is present in over 70%	70%
Cardiovascular malformation	Usually conotruncal, AV canal, and aortic arch abnormalities	50–85%
Growth deficiency	Hypothalamo-hypophyseal dysfunction leading to short stature and pubertal delay	70–80%
	Often birth centiles are low normal, around the 10th centile	
Orofacial cleft	Cleft lip/palate	15–20%
Distinctive facial features	Square face, prominent forehead, prominent nasal bridge and columella, and flat midface	NA
Additional features	Omphalocele/umbilical hernia	NA
	Bony scoliosis/hemivertebrae	
	Renal anomalies: dysgenesis or horseshoe/ectopic kidney	
	Hand and limb anomalies in 37%: polydactyly, J-shaped 'hockey stick' palmar flexion crease	
	Short neck, sloping shoulders, and nipple anomalies	
	Immune deficiency	

AV, atrioventricular; CNS, central nervous system; IQ, intelligence quotient; NA, not applicable.

Figure 43.4 Clinical features of the CHARGE syndrome. (A) Cleft lip/palate repair, mild left facial palsy, and broad forehead in a 10-year-old girl. (B) Cleft lip/palate and square face with mild right facial palsy in a 6-year-old boy. (C) Left-sided microphthalmia, with prosthesis in situ, and a square face with broad forehead and broad nasal root in a 2.5-year-old boy. (D) 'J'-shaped hockeystick palmar crease (yellow arrow). (E) Typical CHARGE ear with hypoplastic, overfolded helix and lobe, and a triangular concha. (F) Less typical appearing ear with a squared superior helix and crease on the lobe. *Source*: Reproduced from Hsu et al. [35] with permission of John Wiley and Sons.

every patient. There are a number of craniofacial syndromes leading to micrognathia, including the Pierre Robin sequence, Treacher Collins syndrome, and hemifacial microsomia (Goldenhar syndrome).

Pierre Robin sequence

The Pierre Robin sequence (PRS) is defined as micro- or retrognathia, glossoptosis, and cleft soft palate. Isolated PRS does not have a known genetic cause and is not associated with other syndromes; the isolated form is seen in approximately half of the patients, but the published series vary from 11% to 81%. Incidence is approximately one per 8500 livebirths, with mortality during childhood at 2.2–26% [37]. PRS associated with genetic syndromes is most often associated with Stickler syndrome, Treacher Collins syndrome, and velocardiofacial syndrome. Fetal alcohol syndrome may also be associated with PRS [38]. Mildly affected patients may need minimal medical intervention, while severely affected patients manifest airway symptoms in the neonatal period. The constellation of upper airway anomalies frequently leads to obstructive apnea, and the intensity of medical intervention is proportional to the degree of upper airway obstruction. In significantly affected neonates, airway interventions such as prone positioning, nasal continuous positive airway pressure, endotracheal intubation, or tracheostomy may be required. Feeding difficulties are common, and feeding gastrostomy may be required. Airway surgery including cleft palate repair, veloplasty, tongue–lip adhesion, and mandibular operations may be necessary (Fig. 43.5) [38]. Airway management techniques such as laryngeal mask airway, video laryngoscope, fiberoptic intubation, or retromolar laryngoscopy technique may be required [39]. Details of difficult airway management are presented in Chapter 15.

Treacher Collins syndrome

Treacher Collins syndrome (TCS) is an autosomal dominant disorder of bilateral facial development, which affects approximately 1 in 50,000 livebirths; however up to 60% of

(A) (B)

Figure 43.5 Pierre Robin sequence in an infant. Clinical results of mandibular distraction: (A) before distraction and (B) after distraction. *Source*: Reproduced from Cladis et al [38] with permission of Wolters Kluwer.

Figure 43.6 Treacher Collins syndrome in an adolescent. Note the hypoplasia of the maxilla, zygoma, and mandible, lateral downward sloping of the palpebral fissures, coloboma of the lower eyelids, and defects of the external and middle ears. *Source*: Reproduced from Marszalek et al [39].

cases appear to be a *de novo* genetic mutation. TCS is a genetic developmental disorder of the first and second branchial arches, resulting in extensive neural crest cell abnormal development. The TCS phenotype includes hypoplasia of the maxilla, zygoma, and mandible, lateral downward sloping of the palpebral fissures, coloboma of the lower eyelids, defects of the external and middle ears, and sensorineural deafness (Fig. 43.6). The protein coded by this gene is called Treacle, and the hypothesis is that it assists in ribosomal DNA transcription during particular stages in embryonic development, particularly that of the structures of the head and face [39,40]. These patients may require extensive bony and soft tissue facial reconstruction over multiple procedures, including orbital and zygomatic reconstruction before the age of 10, external ear reconstruction, and mandibular advancement as teenagers with bony growth is completed. Difficulties in airway management for the anesthesiologist arise from the mandibular hypoplasia and high arched palate frequently encountered in TCS patients. Video laryngoscopy has been reported to be successful for airway management in this syndrome [41].

Goldenhar syndrome

Goldenhar syndrome, also known as oculo-auriculo-vertebral syndrome, or hemifacial microsomia, is a developmental disorder of the first and second branchial arches that affects approximately one in 5600 livebirths. It is most frequently unilateral, and is characterized by malformations/hypoplasia of the external and middle ear often with sensorineural hearing loss, mandibular hypoplasia, eye abnormalities such as microphthalmus and epibulbar dermoids, and vertebral anomalies including cervical spine malformations and scoliosis (Fig. 43.7) [42]. Most cases of Goldenhar syndrome are sporadic, and heterogenous manifestations of the phenotype are common, ranging from very mild hemifacial asymmetry, preauricular ear tags or pits, to severe deformity and mandibular hypoplasia. Congenital heart disease is present in approximately one-third of patients, most commonly septal and conotruncal defects [42].

Figure 43.7 Goldenhar syndrome in a 7-year-old male. Note the facial asymmetry with hypoplastic mandible and ear deformity on the left side. *Source*: Reproduced from Vendramini-Pittoli and Kokitsu-Nakata [42] with permission of Wolters Kluwer.

Developmental delay and autism spectrum disorder is seen in some patients [43]. Difficulties with airway management and tracheal intubation are common in this syndrome due to the mandibular hypoplasia and lack of space for direct laryngoscopy. These patients frequently present for anesthesia and sedation for diagnostic and therapeutic procedures for ear, facial, and cardiac anomalies. Techniques such as fiberoptic or video-assisted laryngoscopy are frequently required for airway management [44,45]. In a series of 13 patients with Goldenhar syndrome undergoing cardiac surgery, six had difficult intubation: two required surgical tracheostomy after multiple failed intubation attempts; one required retrograde intubation; the other three required 2–5 attempts with direct laryngoscopy [46]. It should be noted that video laryngoscopy was not available in this series and would likely have facilitated airway management, as noted earlier.

Figure 43.8 Williams syndrome facies in a young child. Note the periorbital puffiness, flat nasal bridge, long philtrum, wide smile, full cheeks, and full lower lip. *Source*: Reproduced from Waxler et al [48] with permission of SLACK Incorporated.

KEY POINTS: VACTERL, CHARGE, AND MICROGNATHIA SYNDROMES

- VACTERL association varies widely but tracheoesophageal fistula plus one other major defect must be present; cardiac disease is seen in 40–80%
- CHARGE syndrome major criteria are coloboma, choanal atresia, cranial nerve anomalies, and cup-shaped ear
- Micrognathia syndromes are among the most common causes of difficult tracheal intubation

Cardiac syndromes

Williams syndrome

Williams syndrome is a genetic syndrome whose phenotype involves supravalvular aortic stenosis, and characteristic facial features including periorbital puffiness, flat nasal bridge, long philtrum, full cheeks, and full lower lip (Fig. 43.8). Other features include developmental delay, friendly or outgoing personality, hypercalcemia, hypotonia, joint laxity, and hypertension. Williams syndrome affects approximately one in 10,000 livebirths, and has been localized to a 1.5 Mb base pair deletion on one copy of chromosome 7, involving 26–28 genes, including the elastin gene, at 7q11.23 [47]. This deletion can arise from a spontaneous mutation, or inherited as an autosomal dominant familial form. Fifty to 75% of patients with Williams syndrome have cardiac disease, most frequently supravalvar aortic stenosis, and peripheral pulmonary artery stenosis. These changes

are characterized as an elastin arteriopathy, and the usual large quantity of elastin present in the medial layer of the large arteries is absent, resulting in limited distensibility and stenosis of the artery. In addition, adhesion of the aortic valve leaflet edges to the narrowed sinotubular junction can result in obstruction of the coronary artery ostia, resulting in impaired coronary blood flow [48]. It is this feature that leads to sudden death in Williams syndrome patients, both spontaneously, and during diagnostic and therapeutic procedures requiring anesthesia and sedation [49]. The patients with highest anesthetic risk have severe supravalvar aortic stenosis (mean gradient >40 mmHg), electrocardiogram (ECG) findings or symptoms of coronary ischemia, coronary disease on imaging, severe left ventricular hypertrophy, biventricular outflow tract obstruction, and prolonged corrected QT interval [50].

Careful anesthetic management to balance myocardial oxygen supply and demand, including avoidance of excessive tachycardia, hypotension, and hypovolemia, are important principles. The peripheral pulmonic stenosis is often present during infancy but improves over time. Details of anesthetic management for left heart obstructive lesions are presented in Chapters 26 and 27.

Noonan syndrome

Noonan syndrome is characterized by cardiac disease and distinctive facial features including hypertelorism with downslanting palpebral fissures, ptosis, and low-set posteriorly rotated ears. The cardiovascular manifestations are most commonly valvar pulmonary stenosis in about 60%, hypertrophic cardiomyopathy in 20%, atrial septal defects and ventricular septal defects in approximately 10% and 5%, respectively, and patent ductus arteriosus in 3% [51]. Other defects include webbed neck, shield chest, and abnormal lymphatic drainage resulting in lymphedema. The syndrome occurs in approximately one in 1000–2500 livebirths, and may occur sporadically, or with an autosomal dominant inheritance, predominately by maternal transmission. Approximately 50% of cases have a missense mutation in the *PTPN11* gene on chromosome 12, which encodes for a protein, tyrosine phosphatase SHP-2. This enzyme is involved in a variety of signal cascades for receptors for hormones, cytokines, and growth factors and is involved in a number of developmental processes [51]. Intervention requiring anesthesia is most commonly balloon valvuloplasty or surgery for pulmonary valve stenosis.

Velocardiofacial syndrome

Velocardiofacial syndrome (VCFS) is also known as DiGeorge syndrome or sequence, 22q11 deletion syndrome, CATCH 22, and conotruncal anomalies face syndrome. This disorder has a wide spectrum of phenotypic findings with more than 180 clinical features. It is one of the most common multiple anomaly syndromes, with incidence estimates of approximately 1:2000 livebirths. VCFS is inherited as an autosomal dominant disorder, and is caused by a microdeletion at chromosome 22q11.2 [52]. The phenotype is extremely variable, and there is no single clinical feature present in 100% of cases, and so the diagnosis is defined by the chromosome defect itself. Congenital heart disease is present in 70% of cases, and constitutes a high percentage of all conotruncal cardiac anomalies, including more than 50% of cases of interrupted aortic arch, over 15% of patients with tetralogy of Fallot, about 50% of truncus arteriosus cases, and about one-third of posteriorly malaligned ventricular septal defects. Hemizygosity of the gene *TBX1* is responsible for the cardiac defects. Other defects commonly encountered are cleft palate, most commonly submucous clefts, and facial anomalies often associated include high arched palate, low-set ears, and occasionally varying degrees of micrognathia (Fig. 43.9). Other important features present in a variable percentage of patients are partial hypoparathyroidism resulting in neonatal hypocalcemia, and relative immunodeficiency from abnormal lymphocyte function. Developmental delay is common in VCFS, although in some patients intelligence may be normal. Average mean full-scale IQ is 70–75, with about 55% having an IQ of 70–100; 45% have an IQ of 55–70, and a few have moderate to severe disability [53]. Individuals with VCFS are at an increased risk for developing several psychiatric disorders including attention deficit with hyperactivity disorder, autism spectrum disorder, anxiety and mood disorders, and psychotic disorders and schizophrenia. Patients with the cardiac diseases noted above should be tested for the 22q11.2 deletion using FISH or chromosomal microarray. The other defects, especially hypocalcemia and immune dysfunction, leading to increased infection risk, should be sought as well as these may affect anesthetic management. In patients with simpler forms of CHD and VCFS, i.e. tetralogy of Fallot, ventricular septal defect, and simple truncus arteriosus, surgical outcomes are not worse than patients without a chromosome defect. However, in interrupted aortic arch, surgical outcomes are worse with the 22q11.2 deletion. Finally, the later neurodevelopmental outcomes at 1 year or more after cardiac surgery are definitely worse overall with 22q11.2 deletion [54,55]. In spite of the known mild craniofacial anomalies in this syndrome, airway management and tracheal intubation is most often straightforward.

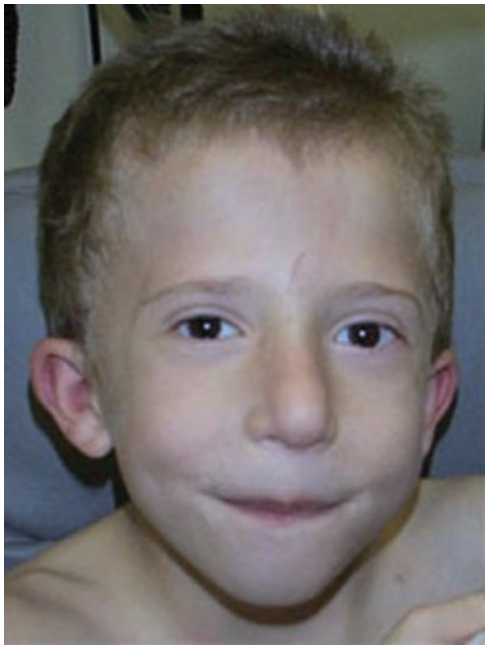

Figure 43.9 Facial features of the velocardiofacial syndrome. Note the small low-set posteriorly rotated ears and slight retrognathia; the patient also has a high arched palate with submucous cleft. *Source*: Reproduced from Shprintzen [53] with permission of John Wiley and Sons.

KEY POINTS: CARDIAC SYNDROMES

- Williams syndrome is a frequent cause of cardiac arrest and death with anesthesia due to coronary ischemia from supravalvar aortic stenosis
- Noonan syndrome is accompanied by pulmonic stenosis in the majority of patients; hypertrophic cardiomyopathy can also be seen
- Velocardiofacial, or DiGeorge, syndrome is a common cause of conotruncal anomalies; these patients may have mild micrognathia but are not usually problematic for endotracheal intubation

Autism spectrum disorder

Autism spectrum disorder (ASD) is an increasingly recognized neurodevelopmental disorder of empathy that encompasses autism, Asperger syndrome, atypical autism, and pervasive developmental disorder not otherwise specified. ASD is characterized by impairments in social communication and social interaction of varying degrees, and also includes restricted and repetitive behaviors and impairments of imaginary thought [56]. Ritualistic and repetitive behaviors include the need for fixed routines and a constant environment, stereotypical repetitive movements (such as hand-flapping), and intense special interests [56]. These behaviors may be an attempt to impose order for their internal world, but the underlying reasons may vary for different children. Children with ASD are more likely to be anxious and exhibit unwanted behaviors if their routine or repetitive behavior is interrupted. On the positive side, introducing predictability of events and environment for a child with ASD can minimize unwanted behaviors and enhance interaction. Autistic children may have problems with managing sensory input. They may over- or under-react to sensory stimulation, including tactile, auditory, visual, gustatory, and vestibular or proprioceptive input. On the other hand, some sensory experiences can evoke intense pleasure, such as the visual input from toys with spinning lights. Parents may report that their child has hyperacusis, and some may find some everyday sounds unbearable, like a vacuum cleaner or hair dryer. The child may dislike to be touched, e.g. hugs from parents or siblings. The texture of some fabrics may cause distress. With the expansion of diagnostic criteria for ASD, the long-held view that the vast majority of patients have significant intellectual disability, defined as an IQ <70, has been challenged. A recent report assessed 156 children aged 10–14 years with ASD. They found 55% of the 75 children with ASD had IQ <70, only 16% had moderate to severe intellectual disability (IQ <50), 28% had average intelligence (IQ 85–115), and 3% had above average intelligence (IQ >115) [56]. Epilepsy is present in about 30% of patients with ASD.

The US Centers for Disease Control and Prevention now estimates the prevalence of ASD in the USA as one in 68 children, with boys affected 4.5 times more frequently than girls (1:42 in boys versus 1:189 in girls) [57,58]. Studies in Europe, Asia, and North America also put the prevalence at between 1% and 2%. There is increasing evidence that ASD has a genetic basis, including data indicating that the relative risk to siblings is 25 times higher than the general population, and twin studies showing higher rates in concordant twins. Genome association studies have identified several candidate genes on different chromosome regions, including 2q, 7q, 15q, 15p14.1, and X. In addition, syndromes such as fragile X, Down syndrome, velocardiofacial syndrome, and others, account for 1–2% of ASD patients [55]. Multiple approaches to behavioral therapy have been used in ASD, and there is also evidence that pharmacological interventions can be effective in reducing some of the negative behaviors [56]. Medications may include risperidone for irritable and aggressive behavior, selective serotonin reuptake inhibitors/selective norepinephrine reuptake inhibitors such as fluoxetine for repetitive behaviors, methylphenidate derivatives for attention-deficit hyperactivity symptoms, and clonidine for hyperactivity and irritability [56].

Anesthetic management of patients with ASD, especially preoperative preparation, premedication, and induction of anesthesia, presents problems unique to this population [59]. When possible, parents of patients with ASD should be contacted in advance of the anesthetic to gain some understanding of the degree of their ASD, their particular behaviors, and interventions to avoid. Outpatient surgery whenever possible, and returning the patient to their home environment and routines as soon as possible, are important for the ASD patient. Parental presence, and/or premedication with oral midazolam, ketamine, clonidine, or in some cases intramuscular ketamine, are reported to be effective in this population. The most common procedures in the ASD population include dental restorations, otorhinolaryngological procedures, electroencephalography, and brain MRI scans [59]. Scheduling these patients first in the day, admitting them a short time before induction of anesthesia to a quiet secluded recovery area, removing intravenous catheters whenever possible, parental presence for induction and in the recovery room, and discharging home as soon as possible are all reported to help in minimizing behavioral disruptions in the ASD population. Recommendations for the preoperative approach to ASD patients are displayed in Table 43.2 [56,60]. Despite the well-founded concerns that ASD children would have a greater degree of anxiety and behavior change after outpatient surgery, a recent controlled prospective study of 60 children (32 ASD, 28 normal development), revealed greater patient anxiety only in the holding area and poorer induction compliance, but no difference in negative behavior change at 1 and 7 days postoperatively [61]. No special preparation was done for the ASD patients, but more children with ASD received a premedication (87% versus 64%), and were much more likely to receive a non-standard medication, usually intramuscular ketamine.

Epidermolysis bullosa

Epidermolysis bullosa (EB) is a group of hereditary bullous skin disorders distinguished by blister formation as a result of mechanical trauma. Although there are over 20 subtypes of EB, it can be divided into three major types: EB simplex (mutations in keratin 5 and 14 genes) where the epidermis only is affected; junctional EB (mutations in laminin 5 or type XVII collagen genes) where the basement membrane is involved; and dystrophic EB (mutations in type VII collagen genes) in which the dermis is primarily involved. Mutations in 10 additional genes encoding protein components of the basement

Table 43.2 Common presentations of the autism spectrum disorder and their management in the perioperative setting

Behavior	Impact on anesthetic	Management
Persistent deficit in social communication	Inability to comprehend accurately the events and communicate their fears	Use simple clear language, visual aid, social story
Restrictive and repetitive interests, behaviors, and activities	Can be irritable with change in routine	Use special interest to comfort and to motivate and for comfort, especially computer/I pad
Sensory hypersensitivity		
Touch	The feeling of hospital gown/local anesthetic cream maybe unpleasant	Change of clothes can be stressful, avoid anything that triggers challenging behavior
Taste	May not tolerate oral premedication, especially bitter midazolam and ketamine	Give clonidine first, it has no taste and can be given in water. Other premedications can be given later (15–30 min later)
Light	Can have temper tantrum (feeling of pain from the light that they cannot express)	Avoid fluorescent lights. Admit in a semi-dark, quiet room and recover in the same environment. Peaceful and low stimulation
Noise	As above, the sound of crying children in particular is very distressing	Admit and recover in a single quiet room
Associated mental health problems		
Anxiety	May not want to come to hospital and be distrustful	Premedication Preparation for 1 week minimum with social story that is factual and calming and includes coping/relaxation skills
Anger	Disruptive and agitated	Premedication including antipsychotic. Preparation as above
Intellectual impairment	Inability to understand and communicate	Use simple language/visual aid and repeat
Epilepsy	Possible risk in perioperative period	Make sure epilepsy is well controlled

Figure 43.10 Dystrophic epidermolysis bullosa. Note the severe blistering with hypertrophic scarring and contractures in the axillae and antecubital fossae. Note also pseudosyndactyly from severe chronic contractures. *Source*: Reproduced from DERMIS Dermatology Information System [64].

membrane have also been implicated in various subtypes of EB [62]. Clinical manifestations vary from mild to severe, with dystrophic EB the most severe and the form most frequently requiring surgical and anesthetic intervention (Fig. 43.10) [63]. The majority of patients with dystrophic EB have blisters and wounds that are present at birth or shortly after, with a variety of blister sizes that heal with atrophic scars, and development of contractions [64]. These occur commonly on the dorsum of the hands, feet, elbows, and knees. Friction caused by scratching, or other mechanical forces, is very damaging in EB. Oral, pharyngeal, and esophageal blistering is common in EB, leading to contractures of the mouth and tongue. The pain associated with these blisters leads to decreased oral intake and poor nutrition. Esophageal strictures, and dental caries and gum disease are also common in dystrophic EB. Contractures on the extremities can cause severe scarring to the point that a pseudosyndactyly is created. Corneal scarring can also occur. General management of EB involves teaching the family to avoid friction and shearing forces, special clothing and feeding techniques, draining of blisters and treatment with silver sulfadiazine for large infected blisters, special dressings with hydrofiber foam with silicone coating, and topical corticosteroids. Feeding via open gastrostomy, dental treatment, and analgesia as well as a multidisciplinary approach are crucial to optimize outcomes for this complicated patient population.

All of these problems lead to the need for anesthesia and sedation for diagnostic and therapeutic procedures, which can be very challenging, and are best carried out in a specialized center that cares for large numbers of these patients. However, these patients may present in a number of settings, and may require emergency interventions and so the pediatric anesthesiologist must be familiar with their care. Common surgical procedures in EB include dressing changes, casting, repair of contractures and pseudosyndactyly, dental restoration, esophagoscopy and esophageal dilation, open gastrostomy, long-term indwelling central venous access, skin biopsy, and eye surgery [64].

The most important principle of anesthetic care of children with EB is that friction and shearing forces, and not direct pressure, are responsible for new bullae formation [65]. Airway management problems are frequent, secondary to

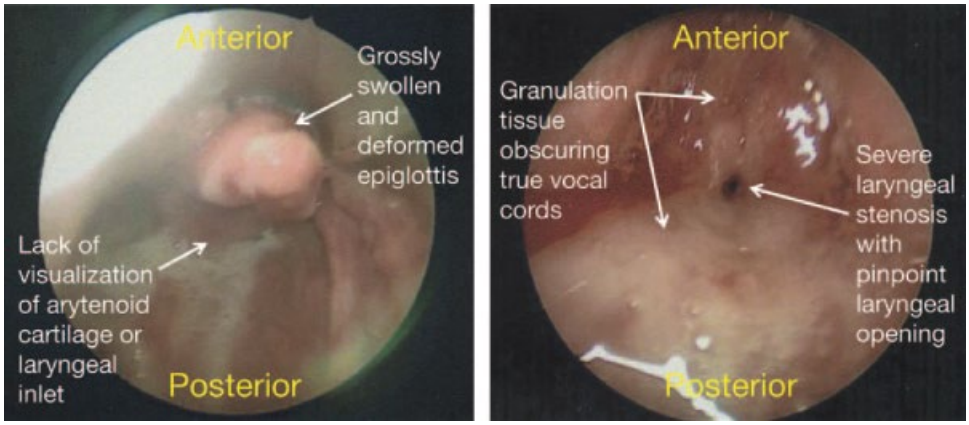

Figure 43.11 Microlaryngoscopic (A) and bronchoscopic (B) views of laryngeal stenosis in epidermolysis bullosa. *Source*: Reproduced from Aronson [66] with permission of Wolters Kluwer.

neck contractures and pharyngeal bullae. After thorough evaluation of preoperative condition, an oral premedication can be given if needed. Veins are often easily visualized and cannulated in these patients and are often an option for premedication and anesthetic induction. The number of transfers of the patients should be minimized, as sliding causing shearing forces between stretcher and operating room bed, for example, may contribute to bullae formation. For the attachment of monitors, IV cannulas, or airway devices, adhesives should be assiduously avoided. It is often preferable to secure a peripheral IV cannula with a single suture. A clip-on pulse oximetry probe is used. ECG electrodes can be used by cutting away the adhesive portion and laying only the gel part on the skin, or covering the skin with paraffin gauze or a gel pad. Non-invasive blood pressure is used, but the skin should be first padded with Webril® soft gauze. Conformable foam dressings such as Mepilex® (Mölnlycke Health Care, Norcross, GA, USA) can also be used to protect the face or facemask placement, and other sensitive areas for protection from monitoring devices. Nasopharyngeal and rectal temperature probes are avoided. Inhalation induction can be used, but the facemask must be thoroughly lubricated with petrolatum jelly or protected with Mepilex, and great care should be taken to avoid shearing forces on the skin of the face and neck. In general, tracheal intubation has been the preferred airway management method, with the tube half a size smaller than normal; with gentle laryngoscopy the incidence of new laryngeal or pharyngeal bullae is low [64].

Anticipated difficult airway management because of contractures or severe intraoral bullae must be accompanied by a careful plan, including the availability of video laryngoscopy, fiberoptic bronchoscopy, and laryngeal mask airways. The laryngeal mask airway can also be used for airway maintenance successfully with little risk of new severe intraoral bullae, but maintenance of the airway with a facemask for long periods of time should be avoided. Non-depolarizing muscle relaxants can be used, but succinylcholine should be avoided. Standard intravenous induction agents, maintenance agents, and opioid and regional anesthesia may be used safely in these patients. Emergence from anesthesia and tracheal extubation must be done carefully, again avoiding shearing forces on the face; intraoral suctioning must be done gently. Avoidance of use of conventional facemasks for oxygen administration in postanesthesia recovery is important; increasing oxygen concentration by blowing humidified oxygen over the face from a 22 mm corrugated oxygen tubing is an effective method.

Evaluation for new bullae and communication with the patient's dermatologist about any changes in treatment plan after an anesthetic is very important. Airway lesions can be particularly challenging, with laryngeal stenosis, obstruction, or stricture seen in as many as 10–40% of patients with junctional EB (Fig. 43.11) [66]. There is a case report of a video laryngoscope rescuing a failed fiberoptic intubation in a 13-year-old with dystrophic EB undergoing elective syndactyly repair and dental surgery [67]. A Glidescope® with GVL stat 3 blade (Verathon Medical, Bothell, WA, USA) was able to visualize the glottis (direct laryngoscopy had been grade IV Cormack–Lehane view), and allow the nasal endotracheal tube to be directed into the airway using the fiberscope, after fiberoptic visualization of the vocal cords proved extremely difficult and ultimately unsuccessful. The soft tissues were extremely friable resulting in obscured visibility.

A recent single-center series of 14 children with dystrophic EB undergoing 148 anesthetics is instructive [68]. Common procedures were esophageal dilation (38%), syndactyly (9%), percutaneous endoscopic gastrostomy (6%), or combinations of these procedures (26%). General anesthesia was utilized for 55% of cases: of these, 81% were endotracheal intubations using direct laryngoscopy, 15% fiberoptic intubations, and 4% laryngeal mask airways. Intubation difficulties were encountered in a third of patients undergoing general anesthesia. Sedation was used for 45% of the cases (wound dressing change and esophageal dilation were the most common sedation procedures), with midazolam and ketamine the most frequently used agents. New oropharyngeal blisters were seen in 10% of patients receiving general anesthesia, versus 1/67 receiving sedation. The same group reported a series of 19 syndactyly procedures in nine EB children performed with sedation plus ultrasound-guided axillary block with excellent intraoperative and postoperative analgesia [69].

CASE STUDY

A 6-month-old female presented for an MRI of the brain, spine, and heart. She was born at 39 weeks' gestation weighing 3.4 kg with polyhydramnios and multiple congenital anomalies. Because an orogastric tube could not be passed, yet there was abdominal gas present on radiograph, a diagnosis of type C esophageal atresia with distal tracheoesophageal fistula (TEF) was made. She did not have respiratory distress, and room air oxygen saturation was 92%. Other findings included a systolic II/VI cardiac murmur, and an echocardiogram revealed a double outlet right ventricle, with large subaortic ventricular septal defect, and large patent ductus arteriosus, as well as a hypoplastic aortic arch. Additional findings on renal ultrasound were bilateral hydronephrosis with a multicystic and dysplastic right kidney and an enlarged and abnormally positioned left kidney. She also had imperforate anus and ambiguous genitalia. On chest and abdominal radiograph it was evident that she had vertebral anomalies, including partial fusion of C5 and C6 vertebrae, complete fusion of L3–4 vertebrae, and sacral agenesis beginning at the S4 level. Finally, she exhibited rocker bottom feet.

A diagnosis of VACTERL association was made. PGE1 infusion was begun in the neonatal period, and repair of the TEF was done as the first priority on the first day of life, via a right thoracotomy. No ventilation difficulties were encountered, and a small TEF was ligated and divided, and the esophageal atresia was repaired primarily without problems. Then, a colostomy and a feeding gastrostomy were performed, again without incident. The patient's trachea was left intubated, and 5 days later she was taken to the cardiac operating room for an aortic arch repair, and pulmonary artery banding via median sternotomy on cardiopulmonary bypass, and again did well with postoperative oxygen saturations of 80–85% on room air, and an appropriate mean echocardiographic gradient of 3.5 m/s across the pulmonary artery band. Ten days postoperatively from the cardiac repair, she underwent placement of a percutaneous left nephrostomy tube because of progressive hydronephrosis, to preserve renal function until more definitive surgery could be done. After a 4-week hospitalization she was discharged home.

On the day of the MRI the patient's only medication was trimethoprim/sulfamethoxazole for urinary tract infection prophylaxis. She had undergone three additional anesthetics to replace the nephrostomy tube, all without incident. The MRI was scheduled to image her spine defects in detail, and rule out any brain anomalies. She was alert and responsive, room air saturation was 76%, HR 135, RR 24, and she was afebrile; her weight was 6.5 kg (10th percentile). Examination of the airway revealed no abnormalities; her mandible was normal size. Her neck appeared slightly short but had full range of motion. Lungs were clear to auscultation bilaterally, and she had no signs of respiratory distress. There was a long harsh IV/VI systolic murmur at the right sternal border. There were well-healed right thoracotomy and median sternotomy scars, as well as a colostomy and gastrostomy button, and a percutaneous nephrostomy tube. She had significant kyphoscoliosis. The echocardiogram done at the cardiology clinic visit the week before revealed good biventricular function, a large subaortic ventricular septal defect (VSD) measuring 12 mm, and a 4.8 m/s pulmonary artery band gradient. Plans had been made for a complete biventricular repair vsersus bidirectional cavopulmonary connection when she was 8–9 months of age. Laboratory studies at that time included a hemoglobin concentration of 17 g/dL, normal electrolytes, BUN of 11 mg/dL and creatinine 0.3 mg/dL. Cardiac MRI was requested to further define the size of the left ventricle, and the anatomical relationship of the VSD to the great vessels, to assist in determining whether a full biventricular repair was possible.

Because of the approximately 3 h planned scan time, the patient's age and cardiac lesion with requested apnea for the cardiac imaging, general endotracheal anesthesia was chosen. Emergency drugs were available, including epinephrine, phenylephrine, and atropine, as well as isotonic crystalloid solutions and 5% albumin for intravascular volume expansion. After application of standard monitors, inhalation induction was initiated with sevoflurane in the MRI suite outside the scanner room. The pediatric anesthesia fellow managed the airway while the faculty anesthesiologist attempted peripheral intravenous access. Inhalation induction proceeded slowly with FiO_2 1.0 and increasing inspired sevoflurane concentrations up to 5%. After three attempts a 22 G peripheral IV was started in the left saphenous vein above the ankle using ultrasound guidance. During induction systolic blood pressures were 60–80 mmHg, and HR 120–150 with sinus rhythm. SpO_2 began at 65% with crying, but quickly improved to 80–85%. Rocuronium 1 mg/kg was administered and the trachea intubated with a 3.5 mm cuffed endotracheal tube. After a period of 5 min observation and ongoing stability, she was moved into the MRI scanner with MRI-compatible monitoring. The brain and spine scans were completed first, with 90 min scan time. Brain MRI was normal, and the vertebral anomalies were confirmed and tethered spinal cord noted. Anesthesia was maintained with 1.5–2% end-tidal sevoflurane, and FiO_2 at 0.5. Two periods of mild hypotension and arterial desaturation to SpO_2 70–75% were treated with decreasing the inspired anesthetic, and intravenous boluses of 10 ml/kg lactated Ringer's solution. Intravenous contrast was not used during this phase because of the concern over her renal function. During the cardiac MRI the patient was stable with SpO_2 80–85%. Two 30 s periods of apnea were requested, and were accomplished with preoxygenation with FiO_2 1.0, and manual hyperventilation. A reduced dose of gadolinium MRI contrast was administered, and excellent cardiac images were obtained with the patient stable throughout. After a 3 h 10 min anesthetic, the patient's trachea was extubated with the patient awake after reversal of neuromuscular blockade with neostigmine 70 μg/kg and glycopyrrolate 14 μg/kg. The patient spent 3 h in the recovery area, returned to baseline room air saturations of 75–80%, and was alert, responsive, in no distress, and had resumed gastrostomy and nipple feeds.

After the cardiac surgery, additional procedures planned were colostomy takedown and repair of imperforate anus, and repair of hydroureter. No interventions for the spine or feet were planned at this time. This patient with all the manifestations of VACTERL association illustrates the complex multisystem nature of the disorders of some patients with syndromes, along with the need for multiple anesthetics for therapeutic and diagnostic procedures. A thorough evaluation of all systems, including access to all previous medical records, is important in planning care of these patients.

Listing of 120 syndromes encountered by the pediatric anesthesiologist

Appendix 43.1 lists, in alphabetical order, 120 syndromes encountered by the pediatric anesthesiologist. Please refer to the downloads on the book's product page at the following link, www.wiley.com/go/gregory, for a full version of this appendix which includes considerations for anesthesia noted by organ system, emphasizing airway, cardiac, pulmonary, and neurological disease associations.

Appendix 43.1 120 Genetic and dysmorphic syndromes

No.	Syndrome: name, eponyms, inheritance, incidence, gene locus, gene product
1	**Achondroplasia** autosomal dominant, but almost 90% are spontaneous mutations; mutation chromosome 4p16.3; 1:25,000; fibroblast growth factor receptor 3 (FGFR3)
2	**Adrenoleukodystrophy** X-linked recessive; 1:42,000 males; mutation chromosome Xq28; ABCD1 transporter protein
3	**Alagille syndrome** autosomal dominant; 1:70,000; chromosome 20p12 microdeletion
4	**Angelman syndrome** happy puppet syndrome; maternally inherited chromosome 15 deletion; chromosome 15q11-13 deletion; 1:10,000–20,000; UBE3A ubiquitin pathway
5	**Antley–Bixler syndrome** autosomal recessive; very rare disorder; chromosome 10q26; fibroblast growth factor receptor 2 (FGFR2)
6	**Apert syndrome** acrocephalosyndactyly; Apert–Crouzon syndrome; Vogt cephalodactyly; 1:160,000–200,000; sporadic/autosomal dominant; chromosome 10q26; fibroblast growth factor receptor 2 (FGFR2)
7	**Arnold–Chiari malformation** Chiari II malformation; 1:1000–5000; association with connective tissue disorders, myelomeningocele
8	**Arthrogryposis multiplex congenita** congenital arthromyodysplasia; congenital multiple arthrogryposis; fibrous ankylosis of multiple joints; Guerin–Stern syndrome; Guérin–Stern syndrome; myodystrophia fetalis deformans; Otto syndrome; Rocher–Sheldon syndrome; Rossi syndrome; can be autosomal recessive or dominant; X-linked inheritance, sporadic, or not inherited; 1 in 3000; multiple causes
9	**Ataxia telangiectasia** Louis Bar syndrome; AT1; autosomal recessive; 1:300,000; chromosome 11q22.3 mutations in the ATM gene
10	**Autism spectrum disorder** Asperger syndrome; atypical autism; pervasive developmental disorder; 1/68 to 1/42 boys; 1/189 girls; candidate genes on chromosomes 13, 15, 17, 3, 7, 1, 21, 16, and others
11	**Becker muscular dystophy** benign pseudohypertrophic muscular dystrophy; X-linked recessive; 1:20,000–30,000 males; mutation dystrophin gene; Xp21.2
12	**Beckwith–Wiedemann syndrome** Exophthalmos–macroglossia–gigantism syndrome; 1:13,700; chromosome 11p15.5 mutations, multiple variants; insulin-like growth factor II (IGF2) likely involved
13	**Carpenter syndrome** acrocephalopolysyndactyly type II; Summitt syndrome; autosomal recessive; 1:1 million; chromosome 6p11
14	**Cat eye syndrome** trisomy 22; Schmid–Fracarro syndrome; chromosome 22 partial tetrasomy; sporadic-spontaneous three or four copies of short arm and section of long arm; between 1:50,000 and 1:150,000; cat eye syndrome critical region gene-7 (CECR7) protein
15	**Catel–Manzke syndrome** X-linked recessive; rare: approx. 30 cases reported
16	**Central core disease** central core myopathy; autosomal dominant or recessive; chromosome 19q13.1; mutations in the ryanodine receptor-1 gene
17	**Cerebrocostomandibular syndrome** rib gap defects with micrognathia; autosomal dominant and recessive; fewer than 100 cases reported; heterozygous mutation in the SNRPB gene on chromosome 20p13
18	**Charcot–Marie–Tooth disease** hereditary sensorimotor neuropathy; peroneal muscular atrophy; multiple modes of inheritance; 1:2500; duplication chromosome 17p12 (75%); PMP22; 38 other gene mutations in neuronal proteins: myelins or axons
19	**CHARGE association** parental gonadal mosaicism in some cases; spontaneous mutation; 1:10,000; heterozygous mutation in the CHD7 gene on chromosome 8q12; chromodomain helicase DNA binding protein 7 (CHD7) gene: neural crest epigenetic chromatin remodeling
20	**Cockayne syndrome** Weber–Cockayne syndrome; Neill–Dingwall syndrome; autosomal recessive; 1:250,000; mutation chromosome 5q12; 10q11.23 (80%)
21	**Cornelia de Lange syndrome** De Lange syndrome; Brachmann–de Lange syndrome; typus degenerativus amstelodamensis; sporadic mutation or autosomal dominant; 1:30,000; mutation chromosome 5p13.1
22	**Costello syndrome** faciocutaneoskeletal syndrome; spontaneous mutation; 300 reported cases; mutation chromosome 11p15.5; mutation Harvey rat sarcoma viral oncogene (HRAS) gene: proteins controling cell growth and division
23	**Cri du chat syndrome** chromosome 5p deletion syndrome; 5p minus syndrome; Lejeune syndrome; sporadic deletion: new mutation (88%); 1:20,000–50,000; deletion chromosome 5p15.2
24	**Crouzon syndrome** craniofacial dysostosis type; autosomal dominant; some are new mutations with advanced paternal age; 1:60,000; heterozygous mutation in the gene encoding fibroblast growth factor receptor-2 (FGFR2) on chromosome 10q26; fibroblast growth factor receptor 2 (FGFR2)
25	**Cystic fibrosis** Mucoviscidosis; autosomal recessive; 1:4000

(*Continued*)

No.	Syndrome: name, eponyms, inheritance, incidence, gene locus, gene product
26	**Diastrophic dysplasia** diastrophic dwarfism; diastrophic nanism; autosomal recessive; 1:100,000; homozygous or compound heterozygous mutation in the DTDST gene (SLC26A2) on chromosome 5q32
27	**DiGeorge (22q11–) syndrome** velocardiofacial syndrome; CATCH-22; conotruncal anomaly face syndrome; sporadic or autosomal dominant; 1:2000; 1.5–3.0 Mb hemizygous deletion of chromosome 22q11.2; TXB1 deletion causes most cardiac defects and other phenotypic features; T-box genes are transcription factors involved in the regulation of developmental processes
28	**Down syndrome** trisomy 21; errors in meiosis that lead to trisomy 21 are overwhelmingly of maternal origin; only about 5% occur during spermatogenesis; 1:650–1000
29	**Duchenne muscular dystrophy** pseudohypertrophic progressive muscular dystrophy; recessive X-linked; 1:3500 males; mutation chromosome Xp21; absent dystrophin
30	**Dutch–Kentucky syndrome** Hecht–Beals syndrome; congenital contractural arachnodactyly; trismus pseudocamptodactyly syndrome; distal arthrogryposis type 7; sporadic inheritance; very rare syndrome
31	**Ehler–Danlos syndrome (EDS)** ***EDS – classic type*** ***EDS – hypermobility type*** autosmal dominant or recessive mutation in tenascin X gene ***EDS – vascular type*** autosmal dominant mutation in type III collagen gene: 1:100,000-250,000 ***EDS – kyphoscoliosis type*** ***EDS – arthrochalasia type*** mutation in type I collagen gene; fewer than 30 cases ***EDS – dermatosparaxis type*** 10 cases reported; 13 subtypes recognized in 2017 reclassification
32	**Ellis van Creveld syndrome** chondroectodermal dysplasia; mesoectodermal dysplasia; autosomal recessive; 1:60,000; mutation in EVC or EVC2 gene on chromosome 4p16
33	**Epidermolysis bullosa (EB)** ***EB simplex*** mutations keratin 5 and 14 genes ***EB junctional*** mutations laminin 5 or collagen XVII genes ***EB dystrophic*** 1:50,000 overall incidence
34	**Fabry disease** Anderson–Fabry disease; angiokeratoma corporis diffusum; α-galactosidase A deficiency; X-linked recessive; 1:55,000 males; mutation chromosome Xq22; alpha-galactosidase A
35	**Familial dysautonomia (Riley-Day syndrome)** hereditary sensory and autonomic neuropathy, type III; autosomal recessive; 1:3700 Ashkenazi Jewish ancestry; mutation chromosome 9q31-33
36	**Familial periodic paralysis (FPP)** autosomal dominant myopathy; variable penetrance ***FPP: hypokalemic*** mutation chromosome 1q32; HOKPP gene ***FPP: hyperkalemic*** mutation sodium channel gene SCN4A on chromosome 17 ***FPP: Anderson syndrome*** Anderson–Twail syndrome, long QT syndrome 7, Andersen cardiodysrhythmic periodic paralysis; mutation chromosome 17q23.1-q24.2
37	**Fibrodysplasia (myositis) ossificans progressiva syndrome** autosomal dominant; complete penetrance; 1:1.5 million; heterozygous mutation in ACVR1 gene on chromosome 2q24.1
38	**Fetal alcohol syndrome** teratogenic syndrome from exposure *in utero*; GABA receptor binding and neuroapoptosis thought to be etiology; 1:100
39	**Fragile X syndrome** X-linked mental retardation; marker X syndrome; Martin–Bell syndrome; X-associated tremor–ataxia syndrome; X-linked dominant; 1:3600 males; 1:4000–6000 females; mutation chromosome Xq27.3
40	**Fraser syndrome** cryptophthamos–syndactyly syndrome; cryptophthalmos syndrome; autosomal recessive; 1:230,000; FRAS1 or FREM 2 genes (extracellular matrix proteins); mutation chromosome 13q13.3 or 4q21
41	**Friedreich ataxia** autosomal recessive; 1:50,000
42	**Glycogen storage diseases (GSD)** ***GSD type 0***: glycogen synthase deficiency ***GSD type I***: von Gierke disease glucose-6-phosphate deficiency; 1:50,000–100,000 ***GSD type II***: Pompe disease acid maltase deficiency; 1:60,000–140,000 ***GSD type III***: Debrancher deficiency (Cori or Forbes disease) glycogen debrancher deficiency; 1:100,000

No.	Syndrome: name, eponyms, inheritance, incidence, gene locus, gene product
	GSD type IV: brancher deficiency (Andersen disease) glycogen branching enzyme deficiency; very rare ***GSD type V***: McArdle syndrome muscle glycogen phosphorylase deficiency; 1:100,000 ***GSD type VI***: Hers disease liver glycogen phosphorylase deficiency; 1:65,000–85,000 ***GSD type VII***: phosphofructokinase deficiency (Tarui disease) muscle phosphofructokinase deficiency; very rare ***GSD type VIII (IX)***: phosphorylase kinase deficiency phosphorylase kinase deficiency; very rare
43	**Goldenhar syndrome** hemifacial macrosomia; oculo-auriculo-vertebral syndrome; facio-auriculo-vertebral syndrome; most cases are sporadic mutations; autosomal recessive or autosomal dominant reported; 1: 5600; mutation in hemifacial microsomia gene on chromosome 14p32 in some patients
44	**Hajdu–Cheney syndrome** arthrodento-osteodysplasia; Cheney syndrome; acro-osteolysis syndrome; autosomal dominant; rare: 50–100 cases reported; heterozygous mutation in the NOTCH2 gene on chromosome 1p12
45	**Hallermann–Streiff syndrome** Francois dyscephalic syndrome; autosomal recessive; 200 reported cases; genetic defect not known
46	**Hallervorden–Spatz disease** neurodegeneration with brain iron accumulation; pantothenate kinase-associated neurodegeneration; autosomal recessive or X-linked autosomal dominant; 1–3:1 million
47	**Hemophilia** ***Hemophilia A*** X-linked recessive; 1:5000 males; mutation chromosome Xq28; factor VIII gene ***Hemophilia B*** Chirstmas disease; X-linked recessive; 1:30,000 males; mutation chromosome Xq27.1-q27.2; factor IX gene
48	**Hereditary angioedema (C1 esterase inhibitor deficiency)** hereditary angioneurotic edema; autosomal dominant; 1:10,000–50,000; deficiency C1 esterase inhibitor gene
49	**Holt–Oram syndrome** heart–hand syndrome; cardiac–limb syndrome; atriodigital dysplasia; autosomal dominant; 1:100,000; heterozygous mutation in TBX5 gene on chromosome 12q24.21
50	**Homocystinuria** cystathionine β-synthase deficiency; autosomal recessive; 1:344,000; mutation chromosome 21q22.3 ***Type I and II***: B6 (pyridoxine) responsive and non-responsive types ***Type III*** with tetrahydrofolate reductase deficiency
51	**Hunter syndrome** mucopolysaccharidosis type II; X-linked recessive; 1:110,000–320,000 males; mutation in the gene encoding iduronate 2-sulfatase (IDS) on chromosome Xq28; deficient enzyme, iduronate-2-sulfatase, is involved in the lysosomal degradation of the glycosaminoglycans heparan sulfate and dermatan sulfate
52	**Hurler syndrome** mucopolysaccharidosis type I; autosomal recessive; 1:100,000; homozygous or compound heterozygous mutation in the gene encoding α-L-iduronidase (IDUA) on chromosome 4p16.3; iduronidase deficiency: hydrolyzes the terminal a-L-iduronic acid residues of the glycosaminoglycans dermatan sulfate and of heparan sulfate; Hurler–Scheie and Scheie are milder forms of disease
53	**Jeune syndrome** asphyxiating thoracic dystrophy; short-rib thoracic dysplasia; thoracic–pelvic–phalangeal dystrophy; autosomal recessive; very rare; mutation 15q13; multiple genes can be affected
54	**Kabuki syndrome** Kabuki make-up syndrome; Niikawa–Kuroki syndrome; autosomal dominant; 1:32,000 Japanese individuals; heterozygous mutation in MLL2 gene on chromosome 12q13.; lysine (K)-specific methyltransferase 2D
55	**Kartagener syndrome** primary ciliary dyskinesia; immotile cilia syndrome; dextrocardia, bronchiectasis, and sinusitis; Polynesian bronchiectasis; Siewert syndrome; autosomal recessive or heterogeneous; rare; no estimates of incidence in literature; dynein arms of the primary ciliary apparatus
56	**Kearns–Sayre syndrome** mitochondrial cytopathy; ophthalmoplegia plus; oculocraniosomatic disease; oculocraniosomatic neuromuscular disease with ragged red fibers; spontaneous inheritance; 1:125,000; various mitochondrial DNA deletions transmitted from mother
57	**King–Denborough syndrome (KDS)** malignant hyperthermia susceptibility 1; King syndrome; autosomal dominant; 1:5000–15,000 children
58	**Kleeblattschladel syndrome** cloverleaf skull syndrome; autosomal dominant or sporadic; gene locus not identified
59	**Klinefelter syndrome** 47, XXY, XXY trisomy; variants with XXXY, XXXXY, and XXYY karyotypes
60	**Klippel–Feil syndrome** autosomal dominant and recessive forms; some sporadic; 1:1500–5000; mutation chromosome 8q22.1 or 12p13 (dominant); or 17q21 or 22q12(recessive) or GDF6 or GDF3 gene (dominant) or MEOX1 or MYO18B gene (recessive); cartilage and bone growth factor proteins
61	**Klippel–Trenaunay–Weber syndrome** angio-osteohypertrophy syndrome; sporadic inheritance; mutation on chromosome 8q22.3; rare, several hundred cases reported; AGGF1: angiogenic factor 1 gene may be involved

(*Continued*)

No.	Syndrome: name, eponyms, inheritance, incidence, gene locus, gene product
62	**Larsen syndrome**
	autosomal dominant; a recessive form also exists
63	**LEOPARD syndrome**
	multiple lentigenes syndrome; cardiomyopathic lentiginosis; autosomal dominant; very rare: approximately 100 reported cases; heterozygous mutation in the PTPN11 gene on chromosome 12q24.13; protein-tyrosine phosphatase, non-receptor-type 11 (PTPN11): regulates intercellular signaling
64	**Limb–girdle muscular dystrophy**
	autosomal recessive or dominant; 1–9:100,000
65	**Loeys–Dietz syndrome**
	Furlong syndrome; autosomal dominant
66	**Long QT**
	prolonged QT syndrome including Jervell–Lange–Nielson, Romano–Ward, and Andersen syndromes; autosomal dominant or recessive; approx. 1:10,000; at least 12 different mutations mostly of sodium and potassium channel protein genes
67	**Marfan syndrome**
	variable inheritance; often autosomal dominant; 1:3000–10,000; mutation fibrillin-1 gene: connective tissue protein
68	**Maroteaux–Lamy syndrome**
	mucopolysaccharidosis VI; arylsulfatase B deficiency autosomal recessive 1:238,000–433,000 homozygous or compound heterozygous mutation in the ARSB gene on chromosome 5q14.1 deficient arylsulfatase B; lysosomal enzyme that removes the C4 sulfate ester group from the N-acetylgalactosamine sugar residue at the non-reducing terminus of the glycosaminoglycans dermatan sulfate and chondroitin sulfate
69	**McCune–Albright syndrome**
	somatic mosaicism, not inherited; rare, 1–9:1 million; encoding guanine nucleotide-binding protein, α-stimulating polypeptide; stimulatory G protein involved in numerous adenylyl cyclase-mediated intracellular functions, including ACTH, TSH, FSH
70	**MELAS syndrome**
	spontaneous inheritance; rare disease; various mitochondrial DNA deletions transmitted from mother
71	**Menkes kinky hair syndrome**
	kinky hair syndrome, Menkes disease; steely hair disease; copper transport disease; X-linked recessive; 1:254-357,000; mutation chromosome Xq21.1
72	**MERFF syndrome**
	myoclonic epilepsy with ragged red fibers; spontaneous inheritance; 1:400,000; various mitochondrial DNA deletions transmitted from mother
73	**Miller syndrome**
	postaxial acrofacial dysostosis syndrome; Genee–Wiedemann syndrome; autosomal recessive; extremely rare; compound heterozygous mutation in the DHODH gene on chromosome 16q22.2
74	**Moebius syndrome**
	variable inheritance; 1:50,000; mutation chromosome 13q12.2-q13; gene product unknown
75	**Morquio syndrome**
	mucopolysaccharidosis IV, mucopolysaccharidosis IVA, galactosamine-6-sulfatase deficiency; autosomal recessive; 1:216,000–640,000 (A and B); mutation chromosome 16q24.3; deficiency in galactosamin-6-sulfatase; lysosomal enzyme involved in the catabolism of keratan and chondroitin sulfate
	Mucopolysaccharidosis IVB
	autosomal recessive; 1:216,000–640,000 (A and B); mutation chromosome 3p22.3
76	**Myotonic dystrophy, type I**
	Steinert disease; congenital myotonic dystrophy; autosomal dominant, variable penetrance; all forms: 1:8000, congenital variety is a small proportion; DMPK gene: myotonic dystrophy protein kinase
77	**Nager syndrome**
	mandibulofacial dysostosis with proximal limb anomalies; autosomal dominant and recessive reported; very rare disorder: approximately 100 reported cases; heterozygous mutation in the SF3B4 gene on chromosome 1q21.2; ZFP37 candidate gene; protein for cartilage development
78	**Neurofibromatosis (NF)**
	neurofibromatosis type 1
	von Recklinghausen disease; autosomal dominant; 50% arise as new mutations; 1: 3500; mutation chromosome 17q11.2; neurofibromin gene 1: GTPase activating enzyme
	neurofibromatosis type 2
	autosomal dominant; 50% arise as new mutations; 1:50,000–120,000; mutation chromosome 22q12.2; neurofibromin 2 gene; merlin: cytoskeletal protein
79	**Noonan syndrome**
	male Turner syndrome; female pseudo-Turner syndrome; Turner phenotype with normal karotype; autosomal dominant; 1:1000–2500; heterozygous mutation in the PTPN11 gene on chromosome 12q24.13 (about 50% of patients); wide genotypic and phenotypic variability; PTPN11 gene: protein tyrosine phosphatase SHP-2: modulates intercellular signaling including epidermal growth factor receptor
80	**Oral–facial–digital syndrome (OFDS)**
	OFDS type 1
	Papillon–Leage syndrome; Psaume syndrome; X-linked recessive; very rare; mutation chromosome Xp22.2; CXORF5 gene: unknown gene product
	OFDS type 2
	Mohr syndrome; sporadic inheritance; very rare; chromosome defect not identified

No.	Syndrome: name, eponyms, inheritance, incidence, gene locus, gene product
81	**Osler–Weber–Rendu syndrome** hereditary hemorrhagic telangiectasia; autosomal dominant; 1:5000–8000; HHT 1; mutation cromosome 9q34.1; ENG gene: endoglin, a receptor of TGF-β1; HHT2 mutation chromosome 12q11-14; ACVRL1 gene: codes for Alk-1, a TGF-β1 receptor
82	**Osteogenesis imperfecta** brittle bone disease; autosomal dominant; 1:20,000; mutation chromosome 17q21.31-q22, 7q22.1; COL1A1 or 1A2 gene: abnormal amount collagen I
83	**Pallister–Hall syndrome** hypothalamic hamartoblastoma; hypopituitarism; imperforate anus; postaxial polydactyly; autosomal dominant; very rare; heterozygous mutation in the GLI3 gene on chromosome 7p14.1; GLI3 gene (Gli-Kruppel family member 3): protein controlling gene expression: zinc finger transcription factor that functions in the hedgehog signal transduction pathway
84	**Pentalogy of Cantrell** thoracoabdominal syndrome; Cantrell pentalogy; sporadic; some cases X-linked; very rare, 5.5:1 million; mutation chromosome Xq25-q26.1 in some patients
85	**Pfeiffer syndrome** acrocephalosyndactyly type V; Noack syndrome; autosomal dominant; 1:100,000; mutation chromosome 8p11.23 in some patients; FGFR1 gene: fibroblast growth factor receptor 1; mutation chromosome 10q26.13 in some patients; FGFR2 gene
86	**PHACE association** posterior fossa malformations–hemangiomas–arterial anomalies–cardiac defects–eye abnormalities–sternal cleft and supraumbilical raphe syndrome
87	**Pierre Robin syndrome** Robin sequence; sporadic if non-syndromic, familial if syndromic; 1:8500–14,000; mutation chromosome 17q24.3-q25.1 in some patients; candidate genes: SOX9, KCNJ2, KCNJ16, MAP2K6
88	**Potter syndrome** oligohydramnios sequence; Potter sequence; sporadic; syndrome from many causes of oligohydramnios
89	**Prader–Willi syndrome** sporadic or autosomal dominant; 1:16,000–45,000; absence of paternal genes from the 15q11-q13 segment; SNRPN, P, UBE3A, and necdin gene involvement
90	**Progeria** Hutchinson–Gilford syndrome; sporadic; 1: 8 million; de novo heterozygous mutation in the lamin A gene (LMNA) on chromosome 1q22; lamin A gene: componenet of nuclear envelope
91	**Proteus syndrome** partial gigantism of hands and feet, nevi, hemihypertrophy, and macrocephaly syndrome; sporadic; very rare, about 200 reported cases; mosaicism for a somatic activating mutation in the AKT1 gene on chromosome 14q32.33; AKT1 gene; antogonizes PI3K and MAPK signaling
92	**Prune-belly syndrome** Eagle–Barrett syndrome; autosomal recessive or sporadic; 1:29,000; CHRM3: muscarinic acetylcholine receptor 3
93	**Rett syndrome** austism, dementia, ataxia, and loss of purposeful hand use syndrome; X-linked dominant; 1:15,000–20,000 females; surviving males have Klinefelter's (XXY); mutation chromosome Xq28
94	**Rubinstein–Taybi syndrome** broad thumb–hallux syndrome; broad thumbs and great toes, characteristic facies, and mental retardation; mostly sporadic from *de novo* mutations; autosomal dominant also reported; 1:100,000–125,000; heterozygous mutation in the gene encoding the transcriptional coactivator CREB-binding protein (CREBBP) on chromosome 16p13.3; CREB-binding protein: a nuclear protein participating as a coactivator in cAMP-regulated gene expression
95	**Russell–Silver syndrome** Russell–Silver dwarf; Silver–Russell dwarfism; sporadic or uniparental disomy (10%);1:300–100,000; mutation chromosome 11p15.5 (20–60% of cases), parental disomy 7p11.2 (10% of cases); gene: epigenetic changes of DNA hypomethylation
96	**Saethre–Chotzen syndrome** acrocephalo-syndactyly, type 3; acrocephaly, skull asymmetry, and mild syndactyly; autosomal dominant; heterozygous mutation in the TWIST1 gene on chromosome 7p21, or a mutation in the FGFR2 gene on chromosome 10q26.13; class of transcriptional regulators that recognize a consensus DNA element called the E-box
97	**Schwartz–Jampel syndrome** chondrodystrophica myotonia; myotonic myopathy, dwarfism, chondrodystrophy, and ocular and facial abnormalities; autosomal recessive; very rare; mutation in the gene encoding perlecan (HSPG2) on chromosome 1p36.12; HSPG2 gene, which codes for perlecan, a heparin sulfate proteoglycan
98	**Sickle cell disease** autosomal recessive; mutation chromosome 11p15.4; beta-globin
99	**Smith–Lemli–Opitz syndrome** Rutledge lethal multiple congenital anomaly syndrome; polydactyly, sex reversal, renal hypoplasia, and unilobar lung; lethal acrodysgenital syndrome; autosomal recessive; 1:20,000–40,000; homozygous or compound heterozygous mutation in the gene encoding sterol delta-7-reductase (DHCR7), on chromosome 11q13.4
100	**Sotos syndrome** cerebral gigantism; chromosome 5q35 deletion syndrome; sporadic, autosomal recessive, or dominant; 1–9:100,000
101	**Spinal muscular atrophy (SMA) types I and II (Werdnig–Hoffmann disease)** autosomal recessive; all types: 1:10,000 total incidence ***SMA I***: acute Werdnig–Hoffman disease, acute infantile SMA autosomal recessive; 1:25,000; gene: SMN1; regulates telomeres ***SMA II***: chronic Werdnig–Hoffman disease, intermediate SMA compound heterozygous mutation in the SMN1 gene on chromosome 5q13.2

(*Continued*)

No.	Syndrome: name, eponyms, inheritance, incidence, gene locus, gene product
102	**Spinal muscular atrophy (SMA) type III (Kugelberg–Welander disease)** juvenile spinal muscular atrophy; mild SMA; Kugelberg–Welander disease; autosomal recessive; gene: SMN1; regulates telomeres
103	**Stickler syndrome** arthro-ophthalmopathy, hereditary progressive; autosomal dominant; 1:7500–9000; mutation chromosome 12q13.11; genes: COL2A1, COL11A1, COL11A2, COL9A1; abnormal collagen type II and XI
104	**Sturge–Weber syndrome** encephalotrigeminal angiomatosis; sporadic; some casued by somatic mosaic mutation in the GNAQ gene on chromosome 9q21.2; 1:50,000
105	**Thrombocytopenia–absent radii syndrome** TAR syndrome; inheritance unclear, some autosomal recessive; 1:250,000; chromosome deletion at 1q21.1
106	**Treacher Collins syndrome** mandibulofacial dysostosis; Franceschetti–Klein syndrome; autosomal dominant, 50% *de novo* mutations; 1:50,000; mutation chromosome 5q32-q33.1; TCOF1 gene (treacle): ribosomal DNA transcription
107	**Trisomy 13** Patau syndrome; sporadic: meotic non-dysjunction; 1:10,000; chromosome 13 trisomy
108	**Trisomy 18** Edwards syndrome; sporadic: meotic non-dysjunction; 1:6000–8000; chromosome 18 trisomy
109	**Tuberous sclerosis** autosomal dominant; 1:12,000–14,000; mutation chromosome 9q34 (TSC1) or 16p12 (TSC2); gene: TSC1–hamartin, TSC2–tuberin–tumor-suppressing proteins
110	**Turner syndrome** XO syndrome; gonadal dysgenesis; meotic non-dysjunction, mosaicism; 1:2500 females; monosomy chromosome X; half of patients are mosaic (45 XO/46 XX) with milder manifestations
111	**Uhl anomaly** arrythmogenic right ventricular dysplasia; autosomal dominant
112	**VACTERL/VATER** sporadic inheritance; 1:17,000; possible defects at chromosome 2, 7, 16 (animal models); candidate genes: SHH, FOX gli
113	**von Hippel–Lindau syndrome** autosomal dominant; 1:36,000–45,000; heterozygous mutation in the VHL gene on chromosome 3p25.3; tumor suppressor gene
114	**Weaver syndrome** Weaver–Smith syndrome; sporadic inheritance; very rare syndrome; heterozygous mutation in the EZH2 gene on chromosome 7q36.1; histone methyltransferase that initiates epigenetic silencing of genes involved in cell fate decisions
115	**Whistling face syndrome** Freeman–Sheldon syndrome; craniocarpotarsal dysplasia; whistling face–windmill vane hand syndrome; craniocarpotarsal dystrophy; craniocarpotarsal dysplasia; distal arthrogryposis type 2A; sporadic or autosomal dominant; very rare syndrome; mutation chromosome 17p13.1; gene: myosin heavy chain 3
116	**Williams syndrome** Williams–Beuren syndrome; autosomal dominant or spontaneous inheritance; 1:10,000; deletion chromosome 7q11.23; gene: elastin
117	**Wilson disease** hepatolenticular degeneration; autosomal recessive; 30:1 million
118	**Wiskott–Aldrich syndrome** eczema–thrombocytopenia–immunodeficiency syndrome; immunodeficiency 2; IMD2; X-linked recessive; 1:250,000 males; mutation chromosome Xp11.23; gene: Wiscott–Aldrich syndrome protein
119	**Wolff–Parkinson–White syndrome** WPW; pre-excitation syndrome
120	**Zellweger syndrome** cerebrohepatorenal syndrome; autosomal recessive; very rare disorder; mutations chromosome 1p36.2, 1q22, 6p, 6q, 7q21, 8q, 12; genes: multiple peroxisome genes, PEX1 most common

ACTH, adrenocorticotrophic hormone; FSH, follicle-stimulating hormone; GABA, γ-aminobutyric acid; IM, intramuscular; TGF, transforming growth factor; TSH, thyroid-stimulating hormone; VSD, ventricular septal defect.

CHAPTER 44
Pediatric Anesthesia in Developing Countries

Adrian T. Bosenberg
Department of Anesthesiology, University Washington; and Seattle Children's Hospital, Seattle, WA, USA

Organization

Children under 15 years constitute more than half the population in many developing countries [1–3]. Many of these children are victims of circumstance, orphaned by human immunodeficiency virus (HIV) [3,4], natural disasters, war, social unrest, economic crises, and famine. Providing anesthesia for children in the developing world can be very challenging [5–9] because for the most part anesthetic practice has not kept pace with the advances made in the developed countries [7]. Our understanding of anesthesia in the developing world is based on personal experience or anecdotal reports provided by local healthcare workers or visitors on medical missions. This reflects the low incentive to publish in the face of a heavy clinical workload and staff shortages.

Many developing countries have a colonial history and were exploited for their raw materials. The infrastructure was developed for the benefit of the colonial power and not the country or region [2,3]. As a result, many of these countries are today characterized by poverty, poor housing and educational standards, and limited health resources and social services (Figs 44.1 and 44.2) [1,5,7–13]. Of the world's poorest countries, 70% are in sub-Saharan Africa [11–13], an area ravaged by HIV, malaria, and tuberculosis [4].

Access to safe anesthesia and pain relief following surgery is considered a basic human right. International standards for the safe practice of anesthesia, adopted by the World Federation of Societies of Anaesthesiologists (WFSA), are seldom met in developing countries [5,14]. As recently as 2015, the World Bank and Lancet Commission on Global Surgery and World Health Assembly have prioritized surgery in low income countries (LIC) and low middle income countries (LMIC) [15,16]. This is consistent with the shift in the global burden of disease from communicable to non-communicable disease [17]. Also for the first time surgery and anesthesia received prominence at the World Health Assembly [15].

Essential surgery needs to be performed safely. Provision of safe anesthesia requires trained anesthetists, essential equipment, consumables, and drugs [18–23]. These essentials are not always available in the operating rooms of the developing world [20–23]. Many issues published in previous decades persist and, in many instances, are remarkably similar to those seen today [2,13,22–25]. Improving the safety of surgery and anesthesia worldwide, but particularly in the developing world, has become the focus of the World Health Organization (WHO), WFSA, and other organizations [19–23].

Different countries have different problems demanding different solutions. Conditions may even vary significantly within the same country [2,5]. The essential differences include the medical personnel and their level of training, the spectrum and nature of disease, the facilities, including access to electricity, running water, and oxygen, the equipment available, and access to cheap, generic, and perhaps outmoded drugs (Fig. 44.3) [8,17,24–26,28–30]. The ratio of anesthetists to population varies greatly (Fig. 44.4). Perioperative mortality and morbidity are high by developed world standards and, not surprisingly, inversely related to the anesthetic manpower (Table 44.1) [31]. The expectations of the local population are often commensurate with the facilities and quality of the available care. Patients may refuse surgery simply because the cost is prohibitive in the face of a meager salary, difficulty in borrowing money from family or the community, or the need to support other children [32].

Anesthesia does not enjoy a high profile and lacks the voice to demand access to resources in developing countries [17]. Anesthesia is not perceived to be an attractive career for many undergraduates [33–35] who receive little, if any, exposure to the specialty [36–38]. Indeed, even today, very few developing countries can afford specialist anesthesiologists, except perhaps in the principal hospitals [14,15,29,39,40]. The "pediatric anesthesiologist" is invariably someone who may have a special interest or affinity for children or simply allocated to

Gregory's Pediatric Anesthesia, Sixth Edition. Edited by Dean B. Andropoulos and George A. Gregory.

pediatric anesthesia for the day because there is no one else. Pediatric anesthesiologists per se are a luxury.

Some two decades ago the Education Committee of the WFSA set out to establish pediatric anesthesia fellowship training programs. The aim was to train individuals from a medically disadvantaged country in a more medically advanced country, ideally in their own language [21]. Whether this training should take place on site within a given country or off site in an established program has been a topic of debate recently [38–49].

Figure 44.1 Victims of war. Mutilating injuries acquired over two decades ago during the Rwandan genocide received basic treatment only. Child survivors face an intense struggle for survival as a consequence of displacement, separation from or loss of parents, poverty, hunger, and disease in countries that are subject to total collapse of economic, health, social, and educational infrastructures.

Through a WFSA-driven sponsorship program, a cohort of pediatric anesthesiologists is being trained in Chile [46], Tunisia, South Africa, and Kenya [21,41,44]. In addition, many institutions and organisations have created partnerships in the LIC and LMIC countries to improve education and training in both surgical and anesthesia care with the overarching goal of sustainability [45]. The advantage of this training is that the trainees are exposed to similar problems to those they would encounter in their own country. On completion of their training, they must return to their country of origin and champion the development of pediatric anesthesia as a speciality [2,21,41]. In those countries where a training program has been developed, the value of a pediatric anesthesiologist is enormous [21,44].

The vast majority of anesthetics are still delivered by non-physicians [2,5,13,50–52], a reality that has remained constant over many decades. Supervision of "non-physician anesthetists" or "anesthetic officers" is invariably inadequate [38,41,51,53,54] and access to textbooks, journals, or other medical literature is limited [2,5,13]. Internet access and communication has made access to educational material easy but is hindered by unreliable electrical supply and telecommunication networks.

Some countries, such as Nigeria, Kenya, and India, have trained significant numbers of physician anesthetists, but these physicians tend to practice in large hospitals in urban areas [2,6,39]. The majority of anesthetics in rural communities are still provided by nurses or unqualified personnel, with little medical background, who are "trained on the job" [2,5,13,39,50]. In many African [17,39,55] and Asian countries [56], the doctor/patient ratio is so low that the ideal of employing a physician specifically to provide routine anesthesia is out of the question [2,31,34]. Salaries are insufficient to attract suitably trained and qualified practitioners for more than short periods. The emigration of scarce trained personnel to developed countries in search of better salaries and an improved lifestyle exacerbates these shortages [2,33,34,57].

Figure 44.2 Traditional healers and tribal customs. Traditional healers play a significant role in healthcare. (A) A potion had been placed over this baby's fontanelle to close it. (B) Extensive keloid formation after injury or tribal scarification is a common complication in Africa. Tribal ear piercing as a child led to this disfiguring keloid formation. Access to specialist treatment is limited. (C) This child had a uvulectomy performed to ward off "evil spirits" and treat a sore throat.

Figure 44.3 Anesthesia equipment. (A) Boyles machine. Considered obsolete in many developed countries, this machine was used to provide anesthesia for a newborn. The 2 L bag on the T-piece was patched with zinc oxide tape and was used by the author to successfully resuscitate a newborn delivered by emergency caesarean section. (B) Drug cupboard. Anesthetic supplies are basic, similar colored glass ampoules are poorly labeled and almost illegible. The risks of administering the wrong drug, as a result, are high. (C) Diathermy. A steel plate with poor connections places the child at risk of an electrical burn.

1987	United Kingdom	1:185,000		25

KEY POINTS: ORGANIZATION OF ANESTHESIA SERVICES

- Most of the children undergoing anesthesia in developing countries do so by inadequately trained people
- Several organizations are working to improve the number of trained anesthetists, but it will take many years to provide them
- Trained anesthetists often leave for better opportunities in developed countries

Equipment procurement and maintenance

Essential equipment to provide safe anesthesia for children, particularly neonates, is often lacking (Fig. 44.3) [2,12–14,20,30,39,50,58–63]. Neonatal or pediatric ventilators are virtually non-existent outside the main centers [12,59,60,62]. Syringe pumps and other control devices are impractical in environments that have an erratic electricity supply. Laryngoscopes, both metal and plastic, are usually available but generally not well maintained. Even batteries may be in short supply and light bulbs unreliable. Endotracheal tubes in the full pediatric range are seldom available; disposable endotracheal tubes are consequently recycled as there is little or no alternative [18,63]. Laryngeal mask airways (LMAs) in pediatric sizes are considered a luxury. Intravenous fluids are expensive if not manufactured locally, and many developing countries do not have any local production facilities [6]. The choice of intravenous fluid is therefore limited and in relative short supply.

Unreliable electrical supplies add to the challenges in the developing world. In many hospitals, particularly in rural areas, neither mains electricity nor reliable and functional back-up generators are available [2,5,14,17,61,64]. General facilities for infection control, such as running water, disinfectants, or gloves (sterile or non-sterile), are not constantly available even though the reuse of disposable equipment is "normal" practice in many countries [5,13,18,65].

Anesthetic machines fall into two categories: modern sophisticated machines or simple low-maintenance equipment [64]. Modern electronic machines, provided by well-meaning international donors, have a poor track record in austere environments [1,2,12,13,18]. Sophisticated equipment needs to be understood but operating manuals provided in a foreign language are of no benefit. Sophisticated machines require maintenance and technicians trained to repair them. Service contracts are not considered viable. Unfortunately, these machines are consequently discarded when the first fault occurs. Guarantees are unlikely to be honored and faults are considered too expensive to repair. Poorly maintained equipment becomes hazardous and even life threatening in untrained hands [64].

Simplicity and safety have long been the key to anesthetic equipment in developing countries [6,13,18,66–68]. Ideally the anesthetic machine should be inexpensive, versatile, robust, able to withstand extreme climatic conditions (temperature (hot or cold), humidity, dust and altitude), able to function even if the supply of cylinders or electricity is interrupted, easy to understand and operate by those with limited training, economical to use, and easily maintained by locally available skills [68--70]. The cheapest, most practical, and most widely used anesthetic is inhalational anesthesia administered through an EMO (Epstein Macintosh Oxford) or OMV (Oxford miniature vaporizer) draw-over vaporizer [18]. Oxygen concentrators supplement oxygen delivery and eliminate the need for expensive oxygen cylinders whose reducing valves are often faulty or destroyed in austere environments. The most appropriate ventilator is the Manley multivent ventilator, which essentially functions like a mechanical version of the OIB (Oxford inflating bellows) and can be used with a draw-over system [70].

A general scheme for inhalation anesthesia in developing countries is shown in Figure 44.5 [71], first proposed by Ezi Ashi et al [72]. Four different modes can be used and can be modified according to the available supplies and services. The basic mode A is for use when there is no electricity and no supply of compressed gases. The apparatus consists of a low-resistance vaporizer, linked by valves to the patient to act as a draw-over system with room air as the carrier gas. The self-inflating bag or hand bellows makes it possible to provide artificial ventilation while the vaporizer remains as a draw-over. The addition of low-flow oxygen to the inspired gas (mode B) is dependent on the availability of an oxygen cylinder. The addition of a length of reservoir tubing to the circuit enables oxygen to be stored on expiration, to be used on the next inspiration, making it substantially more economical [73]. When electricity is available (mode C), the operation of the anesthetic apparatus can be extended by permitting (1) the use of an air compressor to provide continuous gas flow (which in turn will allow the use of a Boyles apparatus and plenum vaporizer); (2) oxygen concentrator; and (3) ventilators. When nitrous oxide is available (mode D) all types of inhalation anesthesia currently available in developed countries can be practiced. In situations where services and supplies are interrupted it is possible to change from one mode to another without requiring other anesthetic apparatus.

Draw-over anesthesia enables inhalation anesthesia to be administered using atmospheric air as the carrier gas [18]. The essential features of this system consist of a calibrated vaporizer with sufficiently low resistance (EMO and OMV) to allow the negative pressure created by the patient's inspiratory effort to draw room air through the vaporizer during spontaneous ventilation. Positive pressure ventilation can be provided by means of a self-inflating bag or bellows (OIB), with a valve to prevent the gas mixture re-entering the vaporizer, as well as a unidirectional valve at the patient's airway to direct expired gases to the atmosphere, preventing rebreathing (mode A, Fig. 44.5). In this way an anesthetic can be administered in the absence of compressed gases. The vaporizer has an inlet for supplementary oxygen that can be attached to the oxygen output tube of an oxygen concentrator, or oxygen cylinder if available (modes B and C, Fig. 44.5).

The EMO and OMV (both Penlon Ltd, Abingdon, UK) are the more commonly used low-resistance vaporizers [18]. The EMO is only calibrated for ether but its performance is linear for other agents. The OMV is calibrated for a variety of agents [68,70]; despite the lack of temperature compensation, its performance is stable under most conditions. Both these vaporizers have been used successfully in pediatric anesthetic

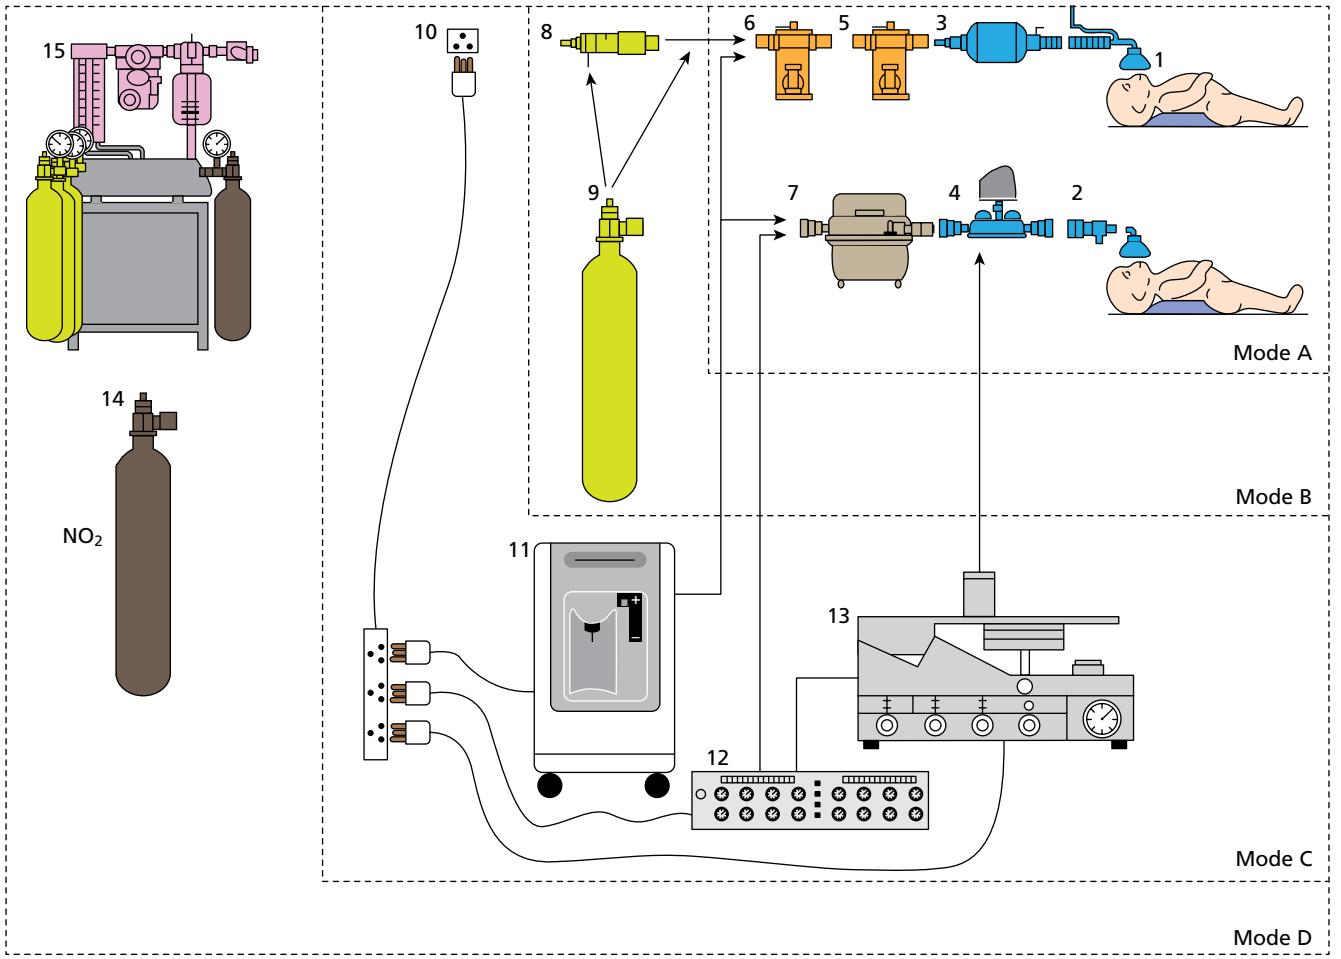

Figure 44.5 A schematic diagram of anesthetic systems that could be used, depending on available resources. Mode A provides basic inhalation anesthesia with air, spontaneous ventilation, or self-inflating bags. Draw-over vaporizers are required. Mode B provides oxygen enrichment but requires the availability of oxygen cylinders. Plenum vaporizers can be used. Mode C requires electricity to power the oxygen concentrator, air compressor, and/or ventilator. A mechanical ventilator (e.g. Manley) does not require electrical power. Mode D requires a Boyles machine and nitrous oxide cylinders. 1, T-piece with reservoir tube and facemask; 2, Ambu paedi valve; 3, self-inflating bag (Ambu); 4, Oxford inflating bellows; 5, Oxford miniature vaporizer (OMV) with halothane; 6, OMV with trichloroethylene; 7, EMO (Epstein Macintosh Oxford) vaporizer with ether. These circuits and manual ventilators are interchangeable and ether, halothane, and trichloroethylene can be used on their own or in series. 8, Farman's entrainer with an oxygen cylinder (9) can be used to supplement oxygen, or an electrical power source (10) is available with an oxygen concentrator (11), air compressor (12), or Manley ventilator (13). Nitrous oxide (14) and Boyles apparatus (15) allow anesthesia practice equivalent to that of developed countries.

practice [27], but it is recommended that they be converted to form a T-piece for greater safety.

The OMV has been evaluated as a simple draw-over system for pediatric anesthesia. Wilson and Walker [58] showed that when a self-inflation bag is used in a draw-over mode, more efficient vaporization occurs despite vaporizer cooling. However, the respiratory efforts of neonates or weak infants are insufficient to operate the valve mechanisms of the self-inflating bag, e.g. Ambu-bag, necessitating continuous assisted ventilation even in the presence of ether, which stimulates ventilation.

Oxygen concentrators can improve oxygen availability, independent of compressed gas and electrical power supply, by linking oxygen concentrators to a draw-over anesthetic apparatus as first described by Fenton [74]. Maintenance requirements are low and servicing is recommended only after approximately 10,000 h of usage. The benefits are enormous, but a reliable electricity supply is critical.

The concentrator functions by using a compressor to pump ambient air alternately through one of two canisters containing a molecular sieve of zeolite granules that reversibly absorb nitrogen from compressed air [70,75]. The controls are simple and comprise an on/off switch for the compressor and a flow-control knob to deliver 0–5 L/min. Flow of oxygen continues uninterrupted as the canisters are alternated automatically so that oxygen from one canister is available while the other regenerates. A warning light on a built-in oxygen analyzer illuminates if the oxygen concentration is <85% and the concentrator switches off automatically when the oxygen concentration is <70%. This is heralded by visual and audible alarms. Air is then delivered as the effluent gas. Modern machines are relatively silent.

The oxygen output of the concentrator depends on the size of the unit, the inflow of oxygen, the minute volume, and pattern of ventilation. The addition of dead space (or oxygen economizer tube) at the outlet improves the performance, and predictable concentrations >90% oxygen can be obtained with flows between 1 and 5 L/min independent of the pattern of ventilation. Much lower concentrations and less predictability were noted when the dead space tubing was omitted [73].

The possible hazards of oxygen concentrators are few, provided they are positioned in the operating room so that the in-draw area is free from pollutants. Failure of power supply or failure of the zeolite canisters will result in the delivery of ambient air. A bacterial filter at the outlet combined with the use of dust-free zeolite should prevent contamination of the delivered gas. Dirty internal air filters may produce lower oxygen concentrations and must be checked. An oxygen storage tank and booster pumps afford protection against the vagaries in electrical supply.

Intravenous fluid administration must also be given careful consideration [2]. Small intravenous cannulas are a precious commodity and butterfly needles are still used (and in some cases reused) [76]. Syringe pumps and other control devices are impractical in environments that have an erratic electricity supply [2]. Unmonitored IV lines can have disastrous consequences including volume overload, sepsis, tissue loss, compartment syndrome, or even loss of limb [2]. The choice of intravenous fluid is often limited and in short supply [2,70,77,78].

KEY POINTS: EQUIPMENT

- Drugs, oxygen, and facilities (e.g. intensive care units) are often unavailable
- Equipment for providing anesthesia for children (masks, endotracheal tubes, etc.) is often absent
- Monitors are often not available; when they are, they may not function because they are broken and cannot be repaired or because the electricity is unreliable
- Much of the equipment donated by developed countries is non-functional and cannot be repaired

Evaluation of patients

The burden of disease in the poorest countries is formidable. Children of the developing world are victims of circumstance, natural disasters, war, social unrest, and economic crises [8,12,79-82]. An estimated 10 million children die annually before their 5th birthday [5,81,83]; that is one of every six children born in Africa, and one of every 12 children born in South Asia [5]. Approximately 50% of these deaths occur in the neonatal period [5] and birth asphyxia, prematurity, sepsis, and tetanus are the major causes. In the older child, diarrhea, pneumonia, malaria, HIV/AIDS, measles, and trauma are major causes [5,81,84].

For many in rural areas, timely access to medical care is a remote possibility (Figs 44.1 and 44.6) [76,77]. Fear, poor understanding, and lack of education often result in delayed presentation to medical facilities [13,85–87]. Illiterate people in rural areas may simply not be aware that surgical treatment is possible [18]. Superstition may also play a role in compounding the anesthetic risk. Frequently, well-meaning traditional healers have had prior involvement, exposing the child to additional risk (see Fig. 44.2) [2,19,88] caused by potions that may be hepatic-renal toxins or enemas that may perforate the bowel [89–91]. Further delays are engendered when patients have to undertake long journeys to hospital. As a result, dehydration, infection, sepsis, and complications

Figure 44.6 In many developing countries worldwide, the failure to provide surgical services may lead to lifelong disability, social exclusion, or even premature death. This family all had an isolated cleft lip that had remained unrepaired until they were successfully treated during a volunteer mission with Operation Smile South Africa.

compound the surgical problem and the anesthetic risk. Tertiary referral is often only made when complications arise [8,12,13,50,64,90–92].

Perinatal mortality in some parts of the developing world is 10 times greater than that in developed countries [5,59,60,83]. The common denominators include early child-bearing, poor maternal health and, above all, the lack of appropriate and quality medical services. One-third of pregnant women still have no access to medical services during pregnancy, and almost 50% do not have access to medical services for childbirth [12,78,82]. The majority of parturients deliver at home or in rural health centers [78] where basic neonatal resuscitation equipment is often deficient or non-existent [12]. Those who require surgery may need to be transferred, but specialized transport teams rarely exist.

The safe administration of anesthesia should take into account the pre-existing condition of the child. Preoperative investigations are generally limited, perhaps stretching to hemoglobin and screening for malarial parasites. There are few functional laboratories in the rural areas and trained technicians are virtually non-existent. Similarly, radiographic studies are often rudimentary and of poor quality [2,9,18]. Even an experienced anesthesiologist with minimal access to laboratory or radiographic investigations and limited in the choice of resuscitation fluid would be challenged to manage these children.

Co-morbidities need to be excluded or treated prior to elective surgery. Tuberculosis (TB) remains an important cause of morbidity and mortality [50,93]. The epidemiology of pediatric TB is shaped by risk factors such as age, race, immigration, poverty, overcrowding, and HIV/AIDS [65,93–96]. The emergence of drug-resistant TB adds to the burden and is a constant danger to healthcare workers in general and anesthesiologists in particular. Primary TB infection usually does not produce clinical illness in well-nourished immunized children, whereas reactivated pulmonary TB is a chronic or subacute disease, which may present a variety of challenges for the anesthesiologist. These range from a need to prevent transmission by contamination of the anesthetic

circuits to the risks associated with pleural effusions, pulmonary cavitation, and bronchiectasis. Mediastinal and hilar lymphadenopathy may severely compromise the airway. Primary TB and its complications are more common in children than in adults. Once infected, young children are at risk of progression to extrapulmonary disease [93,94]. *Mycobacterium tuberculosis* can cause symptomatic disease in any organ, and is usually a reactivation of a latent site of infection. The most common sites of reactivation are lymph nodes, bones, joints, and the genitourinary tract. Less frequently, the disease may involve the gastrointestinal tract, peritoneum, pericardium, or skin. TB meningitis and miliary TB, both more common in children, carry a high mortality [93]. In view of the high prevalence of HIV infection in tuberculous children, HIV testing should be performed on all children with TB; conversely the presence of TB should be sought in all HIV-positive children [95].

Rheumatic heart disease is more common than congenital heart disease in many developing countries, reflecting the socioeconomic problems of poverty, overcrowding, malnutrition, and lack of antibiotics. Children often present late with life-threatening symptoms secondary to repeated infections and superimposed endocarditis. The acute deterioration precipitated by endocarditis may be the factor that prompts the search for medical attention. Valve replacement can be life saving but long-term follow-up of anticoagulant therapy is not feasible without laboratory facilities nearby.

Malaria is caused by one of four species of malaria parasites: *Plasmodium falciparum*, *P. vivax*, *P. ovale*, and *P. malariae*. Effective and safe prophylaxis against malaria has become increasingly difficult because the species that causes the most severe illness, *P. falciparum*, has become widely resistant to chloroquine and in some areas to other antimalarial drugs as well [97]. Severe malaria, even when optimally treated, carries a mortality of 10–25% [97]. Prompt diagnosis and early treatment are important determinants of outcome. Uncomplicated malaria usually presents with flu-like symptoms (fever, headache, dizziness, and arthralgia). Gastrointestinal symptoms may predominate and include anorexia, nausea, vomiting, and abdominal discomfort or pain that may mimic appendicitis. Malaria in children can present with an acute life-threatening disease or run a chronic course with acute exacerbations. The acute manifestations include three overlapping syndromes: respiratory distress secondary to a severe underlying metabolic acidosis (pH <7.3), usually a lactic acidemia, severe anemia (hemoglobin <5 g/dL) that can develop hypovolemia very rapidly even within hours [98], and neurological impairment as a manifestation of cerebral malaria. Seizures are an important presenting feature in 60–80% of cases. Prolonged seizures that are refractory to treatment and those that occur on antimalarial treatment are ominous signs and are usually associated with neurological sequelae or death [98].

Children with chronic malaria adjust physiologically to low hemoglobin levels but may decompensate rapidly when challenged with a febrile illness or surgery. The characteristic physical findings in children with severe anemia are respiratory distress and a hyperdynamic circulation. Blood transfusion may need to be administered rapidly in children with metabolic acidosis since most have a depleted intravascular volume. Although controversial, exchange transfusion has been advocated for severe malaria. Unfortunately, many malaria endemic areas also have a high prevalence of HIV, adding significantly to the risk of blood transfusions.

Chronic recurrent malarial infections may manifest with splenic enlargement. This may cause delayed gastric emptying and pose an aspiration risk on induction of anesthesia. The spleen may also enlarge acutely or rupture spontaneously during coughing, vomiting, or defecation. Rupture during external cardiac massage has also been described. Malaria may cause bloody diarrhea with massive loss of fluid resembling dysentery in children. Development of renal failure with severe malaria is not uncommon. Malaria may present preoperatively or may complicate the postoperative course. Children in endemic areas who develop postoperative fever must be investigated for malaria. This is especially true if they have had a blood transfusion.

KEY POINTS: EVALUATION OF PATIENTS

- The burden of disease is great in developing countries, complicating surgery and anesthesia
- Starvation, chronic infections (HIV/AIDS, TB), and malaria are common and often untreated
- Rheumatic heart disease is still present and often affects the outcomes of surgery and anesthesia

Types of surgery

An estimated 85% of children in developing countries will require surgery of some sort before their 15th birthday [4]. Congenital anomalies, trauma (road traffic accidents, assaults, falls, burns, bites, fractures), and infections (abscess, osteomyelitis) make up the bulk of the surgical workload [11–13,85,88,99]. Burns, particularly in young children, affect resources in many developing countries [77] but especially in sub-Saharan Africa [76,99].

While the burden of disease is dominated by infections and malnutrition [65], pediatric trauma has low advocacy and as such is given scant attention [5,12,50,85]. Socioeconomic advances in some countries have introduced a new danger in the form of faster, more powerful vehicles without the necessary maintenance culture or road discipline. Trauma prevention strategies are given low priority despite the acknowledged impact trauma has on the economy of any country. Road traffic accidents are thus inevitable. Additionally, many developing countries are at war and this has led to massive trauma and injuries to children who are both participants in the fighting and innocent bystanders. Effective systems to handle the polytrauma victims that result are hard to find [50]. Even simple bone fractures may have disastrous outcomes. Inappropriate management by traditional bonesetters can result in compartment syndromes or even gangrene [88].

Many pathological conditions, seldom seen in industrialized countries, are more prevalent in developing countries because of poor health education, malnutrition, the close proximity of livestock to humans, earth-floored homes, poor sanitation, and contaminated water supplies.

In some hospitals, neonates are not considered candidates for surgery because "they always die" [73] whereas, in others,

they undergo surgery without anesthesia [100] or under local anesthesia [101] because "it's safer" and some still believe that neonates do not feel pain. When surgery is performed on neonates, there are additional challenges, particularly in emergency situations [78]. Not only is there a lack of appropriately sized equipment [50], but it may be extremely difficult to maintain normothermia even in relatively warm climates, let alone provide ventilatory support.

Regrettably, even neonates who have skillful anesthesia and surgery may die because of inadequate postoperative care [13,102]. Overwhelming infection, sepsis, respiratory insufficiency, and surgical complications are the main causes of morbidity and mortality [12,78]. The development of highly specialized neonatal anesthetic and surgical services [67,100,102], essential for a good outcome after neonatal surgery [12,50,78], is a low priority.

KEY POINTS: TYPES OF SURGERY

- Congenital anomalies, trauma (road traffic accidents, assaults, falls, burns, bites, fractures), and infections (abscess, osteomyelitis) constitute most of the surgery done
- Trauma (especially from wars) is common and requires surgery. Outcomes may be poor due to lack of basic equipment
- In some countries neonates do not receive surgery because it is believed that they will "all die"

Anesthesia monitoring and drugs

Recent surveys have shown that many anesthesiologists in developing countries were not able to provide safe anesthesia for children [2,30,61–63,103,104]. Minimal requirements for anesthesia were an oxygen supply, suction apparatus, a pulse oximeter, a tilting table, a pediatric breathing circuit, a laryngoscope, facemasks, endotracheal tubes, oropharyngeal airways, and intravenous cannulas suitable for use in children [2]. Implausible as these findings may seem to those who have not experienced the austere conditions in some parts of the developing world, many anecdotal reports, both recent and in the past, bear witness to this stark reality.

Monitoring is therefore very basic – a precordial stethoscope or a finger on the pulse [6]. Electrocardiogram (ECG) monitoring is used when available but is also dependent on a constant supply of electricity, ECG pads, and proper maintenance. Appropriately sized blood pressure cuffs are scarce, non-invasive blood pressure monitors even more so. Even though pulse oximetry has been shown to be the most useful monitor, and should be available in all centers where pediatric surgery is performed [6,12], this ideal is far from reality. The Lifebox project, introduced as part of a WHO initiative (Millennium Goal 4) [5,24] to introduce pulse oximetry globally, has been shown to be effective [105,106].

The supply of anesthetic gases and drugs, particularly to rural medical facilities, is erratic and unreliable [5,18]. Furthermore, the cost of many drugs, particularly the modern agents, has risen beyond the reach of most health budgets. Anesthesiologists in developing countries therefore have to resign themselves to using cheaper agents or generics. Halothane remains the mainstay of anesthesia in many countries [2,9,13,27,75], although there are arguments for maintaining the use of the cheaper ether [107]. Unfortunately, ether, and more recently halothane, has virtually disappeared from operating rooms in the developed world. As a result, the demand for these cheaper agents has fallen and lack of profitability claimed by some manufacturers has threatened the withdrawal of halothane [1,18]. While this may make commercial business sense, these agents sustain the anesthesia services for millions of patients in the developing world and their loss would have a huge negative impact [1,18].

In many remote rural areas anesthesia for children remains largely ketamine based [5,13,18,100,108,109], even when halothane or ether is available. Lack of airway equipment such as tracheal tubes, facemasks, or breathing circuits and the perception that intravenous access is not necessary are further reasons for ketamine's popularity in this setting [5,86,110]. Ketamine is simple to use, relatively inexpensive, provides anesthesia, analgesia, and cardiovascular stability, and some preservation of the airway reflexes [2,6,86]. Ideally, ketamine should be used with midazolam to reduce the hallucinatory side-effects. Benzodiazepines, however, are not commonly available.

For developing countries, the cost of nitrous oxide is prohibitive in terms of storage, erratic delivery, and budgetary constraints [72,74]. Closed or semi-closed anesthetic systems are considered dangerous in an environment where the oxygen supply is uncertain [57] and agent monitors are not available [18,64]. The erratic supply of soda lime and compressed gas cylinders further limits the use of nitrous oxide. Consequently, the potential benefits and cost savings of low-flow anesthesia are lost [72]. Scavenging of waste anesthetics is almost non-existent.

The choice of muscle relaxants is also limited [13]. Succinylcholine, gallamine, curare, alcuronium, or pancuronium are the most likely options, and the choice is dictated by their availability or the availability of reversal agents. For this reason, muscle relaxants are not commonly used. Other drugs considered basic to anesthesia are seldom available in the developing world [2,5,13,27]. These include induction agents (propofol), analgesics (morphine, meperidine), reversal agents (naloxone), and long-acting local anesthetics (bupivacaine, ropivacaine). Opioid analgesia may not be permitted in some cultures. The ability to deal with complications, such as malignant hyperthermia, is virtually non-existent. Dantrolene is simply too expensive and the shelf-life too short to be cost-effective.

Regional anesthesia has many benefits in terms of safety, cost savings, and immediate postoperative analgesia [6,12,50,53,78,102,111–114]. Generally, children in developing countries are very accepting of this form of analgesia. However, there seems to be a general reluctance to perform regional anesthesia in children [13,50,53,115] in some institutions in the developed world. Possible reasons include lack of training or expertise, fear of failure, and the unavailability of drugs, disposables, and other ancillary equipment (nerve stimulators, portable ultrasound) [53]. Improvisation may be the key. Access to the epidural space can be obtained if the appropriate equipment is not available by using a technique first described before the introduction of pediatric epidural needles into clinical practice. A catheter can be threaded well

into the epidural space through an intravenous cannula inserted into the caudal space via the sacral hiatus in neonates and small infants [116]. Furthermore, cheap non-insulated needles can be used with a nerve stimulator for peripheral nerve blocks when more expensive insulated needles are not available [117].

KEY POINTS: ANESTHESIA MONITORING AND DRUGS

- Some countries cannot consistently (if ever) supply oxygen, suction apparatus, pulse oximeter, pediatric breathing circuit, laryngoscope, facemasks, endotracheal tubes, oropharyngeal airways, and intravenous cannulas suitable for use in children
- Choice of anesthetic is often limited to halothane or ketamine alone
- Regional anesthesia is not used as often as possible for many reasons

Postoperative pain relief

Posptoperative pain management in children is another factor that divides the developed world from the developing world. Providing pain relief in the face of limited resources, a limited spectrum of analgesics (if available at all), and inadequately trained staff is a challenge [2,13,18]. Attempting to apply similar standards to those used in sophisticated units is fraught with difficulty. Illiteracy, malnutrition, poor cognitive development, differing coping strategies, and pharmacogenetic, cultural, and language differences all add to the complexity of the problem [118,119].

Children of the developing world learn to cope with vastly different problems. Their attitude towards pain, and tolerance thereof, is different. Children from an impoverished background seem more stoical and indifferent to even severe pain. Following cardiac surgery, for example, some appear to need very little pain relief and are easily soothed by lollipops or play therapy [79]. Pain assessment of children from an impoverished background is difficult and may be inaccurate [118–120]. Many children in acute pain do not show facial expression. Is this stoicism or simply a reflection of malnutrition, lack of social stimulation, severity of illness, or even cultural attitude? Language difficulties, cultural barriers, willingness to share information, emotional expressiveness, and outdated attitudes of the caregiver may sanction this quandary [118,119]. Some societies convey pain readily, while others teach that expression of pain is inappropriate; in many parts of Africa, boys are not supposed to express pain. Reporting the pain of testicular torsion, for example, may be delayed and would be considered taboo if the boy lives with his mother only.

Although there are many pain assessment instruments available, few have been validated in children from the developing world [118,119]. There is an urgent need not only to make analgesics universally available but also to develop strategies that can be safely applied to the children living in these areas. Local conditions will dictate their use and applicability. Simple pain management strategies may produce the most benefit with the least risk, whereas more complex techniques that offer the most benefit require a minimum standard of monitoring and regular reassessment to allow individualized titration of analgesia. These are seldom available. The final choice of analgesia, unfortunately, is dictated by economic pressures or by the facilities available rather than what would be considered in the best interest of the child. In many environments, family members must purchase the analgesics used. Financial constraints often make this difficult or impossible. Nonetheless, it is morally, ethically, and physiologically beneficial to provide children with effective analgesia despite the immense inequalities that exist in our world [118].

KEY POINTS: POSTOPERATIVE PAIN RELIEF

- Postoperative pain relief for children is often unavailable
- Some people still believe children do not feel pain
- Nurses often have little or no training in the use of narcotics and monitoring on the ward is left to the parents. Consequently, narcotics are seldom used

Follow-up care

Perioperative morbidity and mortality are understandably high by developed world standards [5,13,64,66,109]. Facilities considered mandatory for the surgical care of children, such as the provision of adequate analgesia, a recovery area for immediate postoperative observation, ventilatory support, or high-level care following surgery [9,12,13,18], are inadequate or non-existent in many parts of the developing world. In some countries, pediatric surgery is considered too expensive in itself, to justify these additional needs [12,13].

There is precious little information on the anesthesia morbidity or mortality in developing countries [13,66,68,120]. Fisher et al reported on the incidence of anesthesia-related problems seen by volunteer services working over in developing countries over a period of 18 months [66] that reflects the quality assurance data of trained anesthesia providers working in the developing countries. This is vastly different to the reality where the risks associated with surgery and anesthesia vary widely (see Table 44.1) [26,31]. For example, in Ghana, a 0.08% mortality for elective surgery was recently reported [121], while there was a 20% mortality for intestinal obstruction of the newborn in a Nigerian teaching hospital [122].

We have little idea of the incidence of problems associated with anesthesia provided by non-physicians, nurses, or unqualified personnel "trained on the job" [13,26,123,124]. In some areas, even today, neonatal surgery may be performed without anesthesia [102], or simply under local infiltration only in an attempt to improve outcome [122,125,126]. Understandably, late presentation, respiratory failure, infection, or anesthetic complications [102,125,126] are still the major contributors to a poor outcome.

Follow-up care is generally poor. The follow-up visit is usually not considered worth the added financial burden. Long distances, lack of transport, and poor telecommunications prevent patients from returning. Even patients who live

nearby are lost to follow-up and seldom return unless there are complications.

KEY POINTS: FOLLOW-UP CARE

- Perioperative mortality/morbidity is often high due to lack of personel to care for the patients and lack of equipment and facilities (e.g. no postanesthetic care unit)
- Perioperative statistics on mortality/morbidity are lacking in most developing countries. This makes it difficult to know how to improve things
- Postoperative follow-up is poor for many reasons

Summary

The practice of anesthesia in a developing country will always be challenging, particularly for those who provide anesthesia for children. The challenges vary and it is wise to expect the unexpected and have the flexibility to improvise in the face of an ever-changing world racked by famine, war, violence, natural disasters, and political unrest. The nuances of practice in different communities will inevitably vary and may even challenge some fondly held beliefs in pediatric anesthesia.

Different standards may emerge from different parts of the world. Such standards need not necessarily be considered inferior but may well open the way for the assimilation of new ideas [127]. A safe anesthetic is not necessairly the most expensive one. After all, it is generally not the agents that we use but the skill with which we use them that determines outcome. It should never be necessary to depart from the dictum *primum non nocere*. Simplicity may be the key, but there is no place for double standards. Guidelines evolved over time in the UK, USA, and Australia [127,128] may be untenable in many parts of the world, but every attempt should be made to exercise the same standard of care as expected in the developed countries. The children deserve no less!

What can be done to improve the lot of children who undergo anesthesia in the developing world? Audits of morbidity and mortality are the first steps towards improvement, provided action is taken to address the problems uncovered. Publications reflecting outcomes in developing countries have increased over the past decade (see Table 44.1) [129–132]. Sending money is another suggestion [129] but unfortunately, with all the goodwill in the world, there is no guarantee that money will ever reach the right people and be put to the best use. Purchasing equipment without subsequent maintenance is wasteful. Disposables are short-lived even if they are recycled. Human resources are needed.

Attracting trained anesthesiologists to work in the developing world is the challenge [1,132–134]. Temporary sojourns with volunteer medical groups are for the most part stimulating but few, if any, of these volunteers are likely to return for longer periods, let alone permanently. Is it the environment? Is it the lack of home comforts? Is it the family that finds it difficult? How much influence does political uncertainty have? Unfortunately, until these questions and many others can be addressed, anesthesia in the developing world, particularly for children, is unlikely to advance [1].

The WHO has also recognized that surgery is a public health issue and has launched the "Safe Surgery Saves Lives" program. The WHO has also emphasized that safe surgery does not exist without safe anesthesia [2,23–25]. Training anesthesiologists in the skills required for pediatric anesthesia is a slow process. It is hoped that the WFSA program [129,134], the World Bank, the Lancet Commission, and the many universities and organisations involved in healthcare in LMICs can build sustainable programs that will snowball so that children undergoing surgery in developing worlds may reap the benefit.

CASE STUDY

A 1.8 kg newborn male with gastroschisis presented to the emergency room of the regional hospital. The baby had been delivered in a remote hut in a village some 5 h away. His mother, an 18-year-old primigravida, had not attended antenatal clinic because she lived at least a 1 h walk away from the nearest clinic. Her HIV status was unknown. The baby, whose gestational age was unknown, was delivered by a "traditional midwife" who after resuscitation had wrapped the baby in towels and sent the mother to the nearest clinic for further management. On arrival at the clinic after an hour's walk, the baby was clearly hypothermic, had a weak cry, and the bowel, which had extruded further, was covered with a green film suggesting meconium staining.

At this point the baby's lower body was placed in a plastic bag and the local ambulance driver was notified that the baby needed to be transported to the regional hospital. The ambulance was undergoing repairs and would only be ready in an hour. There were no IV fluids or antibiotics available at the clinic. There were no laboratory facilities to check the blood glucose, hematocrit, electrolytes, or acid–base status; the bottle of "Dextrostix" had expired. The initial examination had been conducted in semi-darkness because of another temporary power outage.

The ambulance finally arrived 2 h later and needed to refuel en route. On arrival at the regional hospital, the baby's temperature was 34.1°C. The blood glucose measured 25 mg/dL, the urea was elevated, and the hematocrit was 54%. No incubator was available, but the child was warmed with an overhead radiant heater. The gastroschisis was wrapped in cling film, and the child was prepared for surgery. The surgeon was not immediately available because he was busy with an ectopic pregnancy.

A peripheral IV line was started and a bolus of 10 mL/kg Ringer's lactate was given for resuscitation. Glucose was added after the initial resuscitation. Antibiotics in the form of ampicillin and gentamicin were given intravenously. The general surgeon, who had been working all night, became available after completion of the ectopic pregnancy. The baby was taken to the operating room, anesthesia was induced with halothane, and the trachea was intubated

after succinylcholine administration. No other muscle relaxants were available. The lungs were hand-ventilated with a modified Ayre's T piece by the anesthetist who had recently completed his 6 months of "training on the job." There was no scavenging system or suitable ventilator for postoperative ventilatory support. The surgeon aimed to achieve primary closure to improve the chances of survival. A caudal block using 2.5 mL/kg 0.25% bupivacaine with epinephrine 1:400,000 was placed by the visiting anesthesiologist using a 22 G scalp vein needle. The surgeon, in an attempt to reduce the bowel volume, managed to "milk" approximately 30 mL of meconium from the bowel using normal saline irrigation through a Jacques red rubber catheter (Fig. 44.7). The bladder was also emptied (3 mL) using Crede's method since there were no urinary catheters available. If primary closure was not possible the surgeon aimed to fashion a "silastic" bag from an intravenous bag. Fortunately this was not needed.

Primary closure was achieved with difficulty. The abdomen was tense but the dorsalis pedis pulse was palpable and there was good capillary refill of both feet. The baby was able to breathe spontaneously but there was no way to measure the increase in airway pressure, blood gases, or capnography to evaluate respiratory function. The residual effects of the caudal provided analgesia and some degree of motor block without respiratory depression. Ideally, a caudal catheter could provide continuous or intermittent blockade, but neither a caudal catheter nor a functional infusion pump was available.

The closure was completed within 9 h of delivery. Although closure was achieved as soon as possible, the delay was expected to have a negative influence on the outcome because of the high risk of sepsis [102,135]. The mother's positive HIV status became apparent and both mother and child were started on antiretroviral therapy. The HIV status was not expected to affect the baby's outcome [96].

Figure 44.7 Gastroschisis is a major problem in the developing world. The outcome is poor because of a paucity of facilities for neonates. This baby with significant intrauterine growth retardation was not diagnosed antenatally and presented late for closure. The risk of sepsis is high. The bowel content (in the kidney dish) was emptied as far as possible to facilitate closure. Postoperative ventilatory support was not available.

Early initiation of total parenteral nutrition (TPN) would have been ideal but was not possible because of the budgetary limitations in the regional hospital. Furthermore, neither central venous access nor peripherally inserted central catheters (PICCs) were available nor could these procedures be performed at this hospital. Ten percent glucose in quarter normal saline was the only IV fluid available to provide some calories, but its use placed the infant at significant risk of hyponatremia-induced convulsions.

The postoperative course was stormy, punctuated by episodes of sepsis related to infiltrated peripheral IVs, wound sepsis, and minor dehiscence. Enteral nutrition was tolerated by 28 days of age and the baby was discharged after 40 days in hospital and referred for follow-up at the surgery and HIV clinics.

2 Hodges SC, Mijumbi C, Okello M, et al. Anesthesia services in developing countries: defining the problems. Anaesthesia 2007; 62: 4–11. The shocking reality of the anesthetic services in the Ugandan health system is conveyed in the results of this survey. Twenty-three percent of anesthesia providers, representative of hospitals with an average annual surgical caseload of around 7500, could provide safe anesthesia for adults, 13% for children, and only 6% for caesarean section. Lack of facilities, e.g. no electrical supply in 41% of hospitals, unreliable oxygen source in 20%, and running water in only 56%, affects the whole healthcare system.

4 Andrews G, Skinner D, Zuma K. Epidemiology of health and vulnerability among children orphaned and made vulnerable by HIV/AIDS in sub-Saharan Africa. AIDS Care 2006; 18: 269–76. The many aspects of the HIV/AIDS epidemic in poor countries are outlined, covering the social, economic, and health issues that affect children in the poorest countries which cannot afford to treat their HIV-infected citizens. Difficult decisions need to be made based on the limited available resources.

Anaesthesia 2017; 72(6): 686–93. A very interesting article documenting both the successes, and the difficulties, of introducing a durable pulse oximeter, with training, to anesthetists in Malawi. The incidence of peripheral oxygen desaturation decreased from 17.2% to 6.5%. However, only 82% of the donated pulse oximeters could be located on 8-month follow-up.

134 Dubowitz G. Global health and global anesthesia. Int Anesth Clin 2010; 48(2); 39–46. Current information with regard to global health and surgical outcome is provided, together with strategies to improve the situation worldwide. Perhaps the most important aspect is that "safe surgery saves lives" has been recognized as a strategy by those who have the resources to bring about a change.

CHAPTER 45
Clinical Complications in Pediatric Anesthesia

Introduction

Complications in the perioperative care of children range from very minor to devastating. This chapter describes some of the most common and severe complications that may be encountered in the daily care of children within the perioperative environment. While limited space prohibits an exhaustive topical review, for many complications, data, especially pediatric-specific data, are either lacking or insufficient to provide the reader with thoughtful guidance. Nonetheless, data are available for many common and serious clinical complications in pediatric anesthesia to allow clinicians to minimize risk and provide the best care possible to the children under their care. The perioperative complications covered in this chapter include the following: cardiac arrest, temperature control, malignant hyperthermia, propofol infusion syndrome, local anesthetic toxcity, positioning injuries, perioperative vision loss, anaphylaxis, and latex allergy.

Cardiac arrest

The risk of morbidity or mortality in both adults and children undergoing general anesthesia has declined dramatically over a generation. The decline in mortality, the most robust outcome measure in pediatric anesthesia, observed in children over the past 50 years is depicted in Figure 45.1 [1–14]. The improved safety of pediatric anesthesia over the past several decades has been attributed to improved monitoring, sophisticated equipment, easily titratable anesthetics, and growing subspecialization and regionalization of pediatric care [15,16]. Despite these advances, anesthetic-related complications occur more often in children compared with adults [17]. Specifically, infants and children less than 3 years of age and children with co-morbid conditions are at the highest risk of morbidity associated with general anesthesia [17–19]. Anesthesia-associated cardiac arrest in children has been reported to be between 0.7 and 8/10,000 anesthetics and is inversely proportional to age [13,18,20,21]. In a retrospective review of over 90,000 anesthetics administered between 1988 and 2005 at a tertiary care center, the incidence of perioperative cardiac arrest in neonates undergoing non-cardiac surgery was 39.4/10,000 anesthetics compared with 8.7/10,000 anesthetics for children <1 year of age and 1.9/10,000 anesthetics for children older than 10 years [13]. A prospective cohort study of more than 280,000 anesthetics administered to children more recently between 2000 and 2011 in another tertiary pediatric hospital also found anesthesia-related cardiac arrests were higher in infants <1 year of age, with the highest rates in those younger than 6 months of age [20]. These findings were similar to those of Odegard et al in Boston [22], Tay et al in Singapore [23], Braz et al in Brazil [24–26], and Sanabria-Carretero et al in Spain [27].

The most important contribution to the existing knowledge related to pediatric cardiac arrest in the operative setting comes from the Pediatric Perioperative Cardiac Arrest (POCA) Registry. The POCA Registry was created at the

Gregory's Pediatric Anesthesia, Sixth Edition. Edited by Dean B. Andropoulos and George A. Gregory.

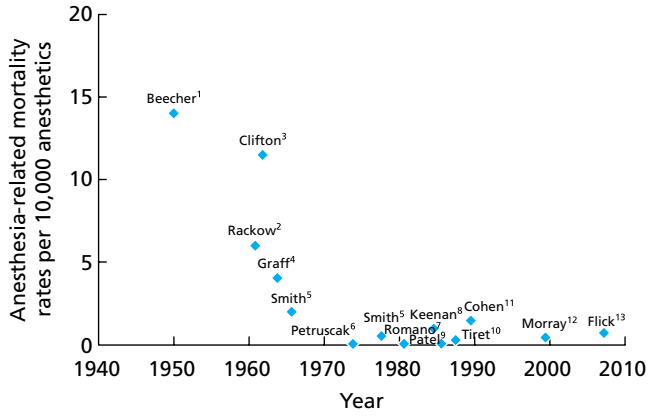

Figure 45.1 Anesthesia-related mortality rates in children from studies published between 1950 and 2010 [1–13]; the year of publication is indicated by the author's surname. *Source:* Reproduced from Morray [14] with permission of Elsevier.

University of Washington in 1994 as an extension of the American Society of Anesthesiologists (ASA) Closed Claims Project and was supported by the American Academy of Pediatrics Section on Anesthesiology and Pain Medicine. In 1985, the ASA Committee on Professional Liability, with the cooperation of 28 insurance providers, began collecting data obtained from closed malpractice cases in the United States. In 1993, Morray and colleagues reported a comparison of pediatric and adult closed claims and found that claims in children disproportionately involved infants, healthy children (ASA physical status [PS] 1), death or permanent injury, and deficiencies in anesthesia care 17]. Claims paid for malpractice involving pediatric care tended to be higher than those paid for adults.

To further study the complications that may arise during the anesthetic care of children, the POCA Registry has subsequently provided valuable insights into the risk factors and outcomes associated with pediatric perioperative cardiac arrest [12]. The registry, now closed, collected data from pediatric anesthesia practices throughout the United States and Canada and reported their findings. The initial report was made in 2000 and provided data gathered from 63 institutions that had submitted a total of 289 cases of cardiac arrest in children [12]. A subsequent report was published in 2007 with cardiac arrest data from as many as 79 academic institutions and information on 397 cases covering a 7-year period [28].

Reports from the POCA Registry grouped events as either related or unrelated to anesthesia and focused the analysis primarily on those judged to be anesthesia related. When comparing data from the first report (289 cases, 1994–1997) to the second report (397 cases, 1998–2004; 193 anesthesia related), the distribution of cases judged to be anesthesia related was similar at 52% and 49%, respectively. These rates are higher than those observed by Flick et al [13] (18%) when the POCA Registry definition of anesthesia related was applied to the Mayo data. Likewise, in a series of 41 arrests among children undergoing cardiac procedures, Odegard et al [22] found that 26.8% were anesthesia related, and Braz et al [24] found that 20% were anesthesia related [29]. The designation of anesthesia related is obviously subjective but allows for the elimination of cases from review that might obscure important patterns, risk factors, or causes.

The children at greatest risk have been identified by Morray et al [12] and others [13,23,28] and include higher ASA PS rating, young age (neonates and infants), presence of congenital heart disease, and the need for emergency procedures. In the initial report from the POCA Registry, 32% of anesthesia-related cardiac arrests occurred in children who were ASA PS classes 1 and 2, whereas in the subsequent report, the frequency of cardiac arrest in PS 1 and 2 children had fallen to 25% [12]. Over a similar time period, Braz et al [24] found in all cardiac arrests that only four of 35 arrests (11%) occurred among the healthiest children. Flick et al [13] found that among those undergoing non-cardiac surgery, half the 26 cardiac arrests occurred in children of ASA PS 3 or less. Clearly, a higher ASA PS is associated with a greater risk of complications of all types, including cardiac arrest [10]. It would appear that fewer healthy children are experiencing cardiac arrests than in the past. This has been attributed by some to the shift from the use of halothane to sevoflurane as the primary inhalational anesthetic used in children [14,30].

Coexisting disease, as reflected by the ASA PS, is without question the strongest predictor of risk for cardiac arrest and death, particularly for those children with congenital heart disease [31,32]. The incidence of anesthesia-related cardiac arrest is high in cardiac patients even when undergoing non-cardiac surgery [33–35]. The decline in the frequency of cardiac arrest among children undergoing cardiac surgical procedures over the 15-year study period in the Mayo Clinic cohort [13] was attributed to the more aggressive use of extracorporeal membrane oxygenation (ECMO) for failure to wean from cardiopulmonary bypass (CPB) [36]. Patients who previously may have experienced cardiac arrest during a cardiac procedure are now placed on ECMO and are no longer captured in analyses of perioperative cardiac arrest. A study of more than 70,000 patients aged less than 18 years from 97 centers participating in the Society of Thoracic Surgeons Congenital Heart Surgery Database (2007–2012) found that 2.6% had postoperative cardiac arrest, and that lower volume centers have increased mortality after cardiac arrest [37].

Unquestionably, neonates and infants are at greater risk. In the study by Olsson and Hallen [38], the risk of cardiac arrest among infants was found to be 17 per 10,000 anesthetics, more than three times the risk for older children and almost six times that of adults less than 60 years old. More recent studies have found somewhat lower rates, ranging from nine to 15 per 10,000 anesthetics [13,24]. More than 50% of cardiac arrests in the 2007 POCA Registry report occurred in infants younger than 6 months (43%) [28]. Among neonates, rates are dramatically increased to as high as 200 per 10,000 anesthetics [24]. Beyond 12 months, rates appear to decline rapidly to levels similar to those found in young adults.

Emergency procedures have been found by some to be associated with greater risk of cardiac arrest and other major complications [13,23,38]. Additionally, Morray et al [12] found in the initial report of the POCA Registry that the odds of mortality from cardiac arrest increased almost fourfold among those experiencing such a problem during an emergency procedure. Similarly, time of day appears in some studies to affect risk, such that those children undergoing procedures during off-hours (typically after 5 pm) and on weekends are at increased risk for cardiac arrest [39]. The cause of this elevated risk is unclear; however, one can speculate that the acuity of

illness and the lack of availability of resources such as experienced personnel and equipment may be less during those times [13]. A recent study of survival rates following pediatric in-hospital cardiac arrests at 354 hospitals participating in the American Heart Association's Get With the Guidelines© – Resuscitation registry from January 1, 2000 to December 12, 2012 found that the rate of survival to hospital discharge was lower for pediatric events occurring at night than for those cardiac arrest events that occur during daytime or evening hours [40].

Of great interest to the pediatric anesthesia community is the question of provider and risk for cardiac arrest. The benefit of specialty-trained pediatric anesthesiologists has been examined, as has the presence of trainees. The data are insufficient, however, to draw clear conclusions. Sprung et al [41] found in a study of adults and children that the provider at the time of the arrest was not predictive of ultimate survival after intraoperative cardiac arrest. Alternatively, Olsson and Hallen [38] suggested that the incidence of cardiac arrest was inversely proportional to the availability of specialist anesthetists. In a pediatric study, Keenan et al [42] examined the effect of subspecialty pediatric anesthesia care on the occurrence of cardiac arrest among infants cared for at a major academic center. They found that of the four cardiac arrests observed in the cohort all occurred in the non-pediatric anesthesiologist group (incidence 19.7 per 10,000 anesthetics; $p = 0.048$). A follow-up study [43] found a similar relationship when the frequency of bradycardia was compared between pediatric and non-pediatric anesthesiologists, and a large study by Mamie et al [44] demonstrated a reduction in critical events among children cared for by specialist pediatric anesthesiologists, especially during ear, nose, and throat surgery.

Analysis of correctable causes of cardiac arrests may lead to improvements in anesthetic care. In the 1950s, deaths related to administration of curare were reported and led to changes in practice [1]. Later in the 1960s and 1970s, airway obstruction and aspiration were common antecedents to cardiac arrest [3,4]. Over subsequent decades, improvements in perioperative care resulted in a reduction in the incidence of cardiac arrest, especially in the predominance of inadequate ventilation and anesthetic overdose as frequent causes [8,38]. Data from the Closed Claims Project in the 1990s [17] suggested a decline in respiratory causes of cardiac arrest; this decline was confirmed by subsequent analysis of POCA Registry and other data [12,14,28,45]. The change may be attributable to the introduction of pulse oximetry and later capnography. Medication-related cardiac arrest declined after the late 1990s and was reflected in the subsequent report of the POCA Registry [14], suggesting that the conversion from halothane to sevoflurane may have been responsible.

The decline in respiratory- and medication-related cardiac arrest was accompanied by a concomitant rise in the proportion of events related to cardiovascular causes in the data reported by Bhananker et al [28] from the POCA Registry. These were primarily related to blood loss and replacement (hyperkalemia secondary to massive transfusion). Similar findings were observed in the Mayo Clinic series [13]. The findings reinforced the need for adequate hemodynamic and electrolyte monitoring as well as avoidance of the use of whole, irradiated, or old blood whenever possible (Fig. 45.2 and Table 45.1).

Respiratory events, although proportionately less common, continue to be an important source of cardiac arrest in children. Laryngospasm was the most frequent antecedent event identified in the POCA Registry data. This is supported by other large series that examine adverse events such as those

by Mamie et al [44], Tay et al [23], and Murat et al [45]. These arrests may be attributed to the failure to rapidly recognize and effectively treat laryngospasm before the onset of bradycardia.

Outcomes of cardiac arrests among children in the perioperative setting are dependent on the cause. The following is overall survival reported in the extant literature: 21% Flick et al [13], 28% Bhananker et al [28], 37% Braz et al [24], 57% Tay et al [23], and 92% Odegard et al [22]. The higher survival reported by Odegard et al [22] was among cardiac surgical cases and did not include those that failed to wean from CPB or were placed directly onto ECMO support. In a recent, large, multicenter study, only half of pediatric cardiac patients who suffered a cardiac arrest survived to hospital discharge [46]. In general, the outcome of in-hospital cardiac arrest among children is better than that of adults, and arrest occurring in the operative setting has improved outcomes compared to arrest occurring elsewhere in the hospital [47]. Cardiac arrest in children outside the hospital has a poor outcome, with only a 12% survival to discharge; this survival rate is based on a meta-analysis by Donoghue et al in 2005 [48]. Survival following cardiopulmonary arrest is reported to be lower for cardiac-induced cardiac arrest than respiratory-induced cardiac arrest [49].

As more robust methods of capturing clinical events become more widely available and organizations such as the Society for Pediatric Anesthesia and others develop and support methods of capturing these data across multiple institutions, the ability to quantify and study these rare events will improve, along with the care of children. See Chapter 48 for further discussion of databases and outcomes research; for treatment of cardiac arrest, see Chapter 13.

KEY POINTS: CARDIAC ARREST

- Cardiac arrest in the pediatric perioperative period is rare
- The improved safety of pediatric anesthesia over the past several decades has been attributed to improved monitoring, sophisticated equipment, easily titratable anesthetics, and growing subspecialization and regionalization of pediatric care
- Children at the greatest risk of perioperative cardiac arrest include higher ASA PS, young age (neonates and infants), presence of congenital heart disease, and the need for emergency procedures

Control of temperature

Physiology of temperature control

The management of temperature is critical in the care of pediatric patients. Much more so than adults, children are susceptible to changes in environmental temperature and the effects of anesthetics on thermoregulatory responses. As mammals, humans are homeothermic and therefore maintain their body temperature within a narrow range. Core temperatures in humans are generally maintained within 0.2°C around the thermal set point of 37°C. To achieve this precise temperature control, a complex array of thermoregulatory processes that are incompletely understood are required. From the earliest experiences in the use of general anesthesia, it has been recognized that general anesthetics impair normal thermoregulatory mechanisms and inevitably result in hypothermia in patients of all ages and sizes. Pickering [50], in a 1958 lecture to the Royal College of Physicians, discussed (among other things) the potential benefits of hypothermia and stated, "The practical difficulty in cooling men is to break through the defences of the body; the most effective means is to give an anaesthetic, which (as we have seen) has been shown to interrupt at some point or points the reflex arcs which protect against cooling, particularly shivering." Although perioperative hypothermia may have a benefit in selected patients and clinical settings, the effects of cold may have profound negative effects, including increased bleeding, infection, renal dysfunction, and alterations in the pharmacology of anesthetic agents and other medications [51–54]. Although relatively rare, severe hyperthermia is much less tolerated than hypothermia and will, in settings such as malignant hyperthermia (MH), result in death unless effectively treated. In this section, the physiology of thermoregulation is discussed along with temperature measurement and disturbances encountered in the perioperative setting.

Temperature regulation in homeotherms is highly complex and incompletely understood. Clearly, temperature regulation is among the most closely guarded of all physiological processes and involves interplay among peripheral and central receptors and controllers distributed widely throughout virtually the entire organism. Temperature control is not symmetrical; much greater control is exerted over increases in central temperature as opposed to central hypothermia. Temperatures higher than 44°C constitute the upper limit of survival in humans, whereas temperatures as low as 30°C are experienced in the operative setting without profound effect [55]. This asymmetry is, in all likelihood, related to the effect of high temperatures on the tertiary structure of proteins (Fig. 45.3).

The dominant control of temperature can be localized in the preoptic anterior thalamus (POAH); however, the dorsomedial nucleus, periaquaductal gray matter of the midbrain, and the nucleus raphe pallidus in the medulla also play an important role [56]. In the most commonly described model, the POAH is at the center of a negative feedback loop that involves afferent input from superficial and deep temperature receptors and efferent output to effectors in the sweat glands, blood vessels (dilation–constriction), muscles (shivering), brown fat deposits (non-shivering thermogenesis), and respiratory centers (hyperpnea). The thalamus functions much like a thermostat to closely maintain core temperature by reducing heat loss and activating heat production in response to cold afferent input and dissipating heat and decreasing thermogenesis in response to warm afferent input [57]. The interthreshold range, i.e. the range over which the thalamus senses temperature as normal, is between 36.8°C and 37.2°C although there are diurnal variations and differences between men and women associated with menstruation. Temperatures within the thalamus outside the normal range will initiate an effector response to return the central temperature to the normal set point.

The POAH contains warm-sensitive, cold-sensitive, and temperature-insensitive receptors; however, warm sensors vastly outnumber cold and insensitive receptors, emphasizing

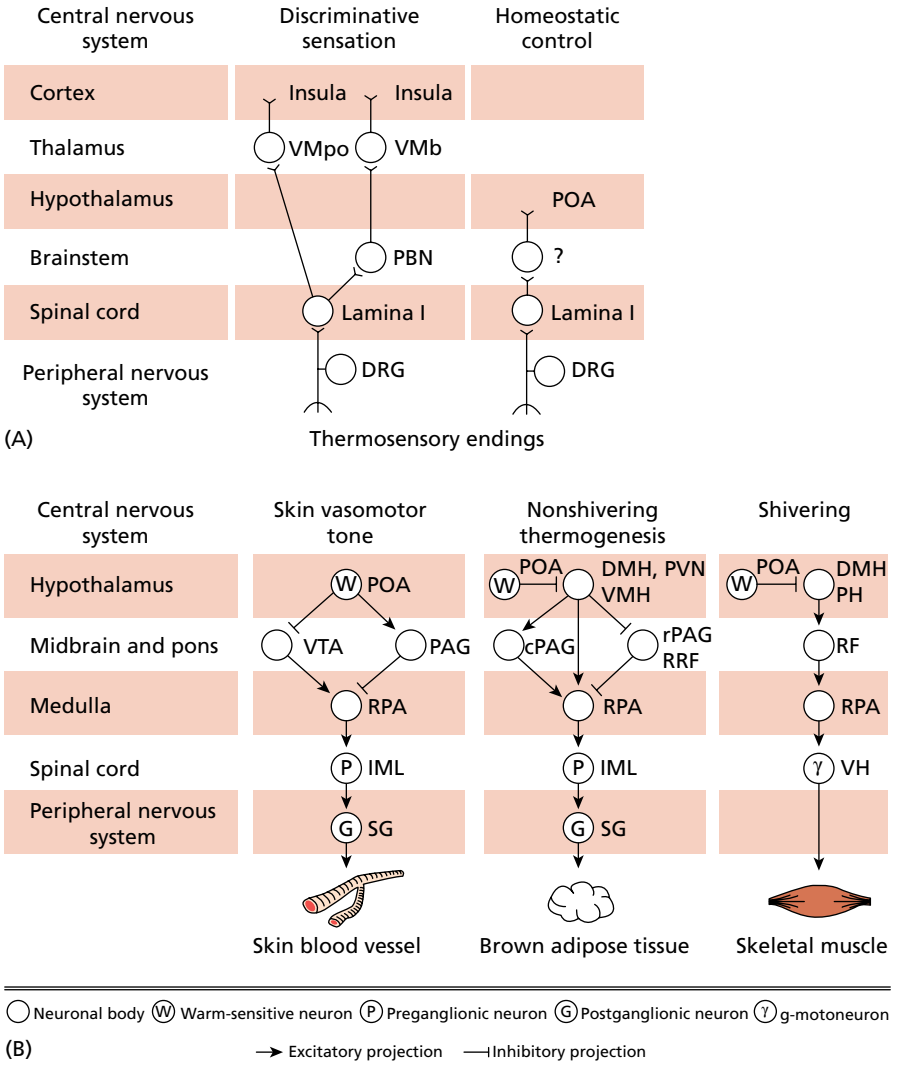

Figure 45.3 (A) Afferent neuronal pathways for discriminative sensation/localization of a thermal stimulus and for homeostatic control of body temperature. DRG, dorsal root ganglion; PBN, parabrachial nucleus; POA, preoptic anterior hypothalamus; VMb, basal part of the ventromedial nucleus of the thalamus (formerly known as the parvicellular part of the ventroposterior medial nucleus); VMpo, posterior part of the ventromedial nucleus of the thalamus; ?, unknown location(s) within the medulla, pons, and midbrain. DMH, dorsomedial hypothalamus; IML, intermediolateral column; PAG, periaqueductal gray matter; cPAG, caudal PAG; rPAG, rostral PAG; PH, posterior hypothalamus; PVN, paraventricular nucleus; RF, reticular formation; RPA, raphé/peripyramidal area; RRF, retrorubral field; SG, sympathetic ganglia; VH, ventral horn; VMH, ventromedial hypothalamus; VTA, ventral tegmental area. *Source:* Reproduced from Romanovsky [55] with permission of The American Physiological Society.

the survival importance associated with guarding against hyperthermia. Warm sensors exert primary control over temperature by integrating thermal inputs from the periphery and by directly sensing thalamic temperature [58]. The dendrites of these warm-sensor neurons lie adjacent to the third ventricle and therefore directly sense cerebrospinal fluid temperatures [59]. As temperature rises, these sensors increase firing rates and initiate autonomic responses to reduce core temperature as well as provide tonic inhibition of cold sensors. Likewise, reduced input to warm sensors is the primary mechanism of initiating sympathetic responses to thermogenesis and thermal preservation. Cold-sensitive neurons are relatively few in number and are much less important in temperature control within the POAH. Temperature-insensitive sensors function to provide inhibition to warm sensors in response to afferent input from the periphery as well as to activate cold-sensor neurons. The integration of input to warm sensors, cold sensors, and insensitive neurons within the POAH establishes separate but highly integrated mechanisms for the response to cold and warm core temperatures. The response to cold relies predominantly on afferent input mostly from skin to inhibit warm-sensor activity rather than a reduction in firing of central cold sensors. At temperatures 0.5°C lower than normal, warm-sensor neurons essentially cease firing [60]. In contrast, a response to increasing core temperature relies primarily on the increased firing of warm-sensor neurons and does not depend on peripheral input.

Afferent input into the central thermoregulatory controllers is derived from receptors distributed throughout the body primarily in the skin and oral and urogenital mucosa. In contrast to the central sensors, peripheral receptors are predominantly cold sensors (a ratio of about 10:1) [60]. Traditionally, these sensors have been thought to provide input only to central sensors where these inputs are integrated

and result in an effector response. This theory of negative feedback has been challenged to the extent that an alternative model has been proposed that suggests that skin receptors may directly activate effectors in a feedforward rather than feedback loop [61]. Direct activation allows for pre-emptive control of temperature, primarily enabling defense against cold. This model of control suggests that the sensation of cold is a byproduct of control rather than an effector. Activation of cold sensors produces the sensation of cold and an effector response as a parallel process rather than a sequential one.

Regardless of the mechanism, input from peripheral sensors (primarily cold) located in the skin are sent to the brain via thin myelinated A δ-fibers through the spinoreticulothalamic tract to the thalamus and other brain regions involved in thermal control. These sensors' peak firing rate occurs at temperatures between 25°C and 30°C. Peripheral sensors in the skin are exquisitely sensitive and respond to temperature changes as small as 0.0003°C. They are most sensitive to rapid rather than gradual change in temperature and are the major source of peripheral thermal input [62].

Sensors (predominantly warm) are found in deep tissues of the core and send afferent signals via unmyelinated C fibers with peak firing rates at temperatures between 40°C and 50°C [63]. These sensors also respond primarily to change in temperature rather than to absolute temperature. Firing rates increase with increasing or decreasing temperature and subsequently accommodate to a new stable temperature [55]. This phenomenon explains both adaptation to temperature change and also the observation that responses to temperature change are most vigorous when change occurs rapidly.

Efferent output to temperature effectors occurs via autonomic and behavioral mechanisms. In humans, behavioral mechanisms predominate either directly, or in the case of a young child, indirectly through the actions of a caregiver. Behavioral control of temperatures allows humans to survive temperatures lower than −100°C and higher than 2000°C (temperature on the surface of the moon and surrounding the shuttle during re-entry) [55]. Behavioral control allows for the use of deep hypothermic circulatory arrest and survival from malignant hyperthermia. In caring for children in the perioperative setting, the pediatric anesthesiologist must provide indirect control of body temperature to avoid the negative consequences associated with both hypothermia and hyperthermia.

Autonomic control of temperature is achieved through thermoeffectors, including piloerection, sweating, cutaneous vasoconstriction or vasodilation, shivering, brown fat metabolism (non-shivering thermogenesis), and to at least a minimal extent, hyperpnea. These effectors function to either conserve or dissipate heat, depending on the specific need. Outputs to the effectors are integrated within the POAH as well as at the level of the spinal cord and potentially through even more direct mechanisms. Clearly, the most effective nonbehavioral means of both heat conservation and dissipation is vasodilation or vasoconstriction of cutaneous blood vessels. In adult humans, skin blood flow can be increased in response to hyperthermia to as high as 6–8 L/min and, when combined with sweating, is the most effective means of heat dissipation [57]. Given the large surface area to weight ratio of infants, heat loss and gain are much more rapid. The normal newborn has a surface area to volume ratio of approximately 1, whereas in the adult, the ratio is closer to 0.4. In the adult in a thermally neutral environment, cutaneous blood flow is approximately 250 mL/min, dissipating approximately 90 kcal/h. When core temperature rises, a gradient is created between the central and skin temperatures resulting in a reduction in peripheral cold sensor activity and subsequent cutaneous vasodilation with a severalfold increase in blood flow. Heat is then effectively transferred from the core to the periphery, and the thermal set point is re-established. In cold environments, blood flow is shunted away from cutaneous vessels by closing arteriovenous shunts that are maximally open in a thermally neutral environment. Reducing blood flow up to 10-fold may result in as much as a 50% reduction in heat loss [64].

Shivering increases heat production in adults by a factor of five for brief periods or by a smaller factor for sustained periods. It is involuntary muscular activity that is central in origin and can be reliably reproduced by cooling of the hypothalamus (POAH). In neonates and young infants, shivering is often believed not to occur; however, it is difficult to find a reference to that effect or to define the age at which shivering can be expected to occur. Darnall [65] has suggested that neonates can indeed shiver although shivering is a secondary mechanism of heat production much less efficient than non-shivering thermogenesis and therefore rarely observed. When β-blocking agents that inhibit non-shivering thermogenesis are given to guinea pigs, they demonstrate shivering at temperatures higher than normally observed [66]. Regardless, shivering, if it occurs in infancy, plays a relatively minor role in heat generation. Instead, neonates and infants are to a large extent dependent on non-shivering thermogenesis.

Non-shivering thermogenesis, resulting primarily from the metabolism of brown fat, is the most important means of thermal response to cold in hibernating animals as well as in neonates and infants. Once thought to occur only in infants, brown fat has been identified in adults and may be important in future research on weight management [67]. Brown fat is adipose tissue that is rich in mitochondria that have a unique capacity to uncouple oxidative phosphorylation, thereby generating large amounts of heat rather than adenosine triphosphate (ATP). The uncoupling of oxidative phosphorylation is dependent on uncoupling protein 1, a 33 kD protein found on the inner membrane of the mitochondria in brown fat [68]. This tissue comprises approximately 2–6% of bodyweight in a newborn and is found in the mediastinum, between the scapulae, around the adrenals, and in the axillae. Non-shivering thermogenesis is mediated by sympathetic stimulation in response to cold stress, and as previously stated, can be inhibited by β-blocking agents. In addition to norepinephrine and epinephrine, thyroxin and glucocorticoids may also stimulate lipolysis of brown fat. Lipolysis of brown fat, compared with that of white adipose tissue, results in oxidation of approximately three times the amount of fatty acid (30% versus 10%) within the lipocyte [69]. A considerable proportion of free fatty acids are released into the bloodstream to be oxidized elsewhere in the body. Ultimately, the metabolic result of maximum oxidation of brown fat is a near doubling of heat production with an increase in oxygen consumption from 5.4 to 9.3 mL/kg/min [70]. The capacity for substantial heat production through non-shivering thermogenesis is present at birth and persists through the 2nd year of life.

In animals, hyperpnea makes a major contribution to thermoregulation – especially of the brain. In humans, the role of panting is less pronounced; however, panting is nonetheless important. There are two phases of the panting response. The first phase, thermal tachypnea, is characterized by increased respiratory frequency with reduced tidal volume, resulting in heat loss but no change in carbon dioxide tension [71]. This pattern produces preferential ventilation of the anatomic dead space, including the nasopharynx, selectively cooling the brain. The second phase, thermal hyperpnea, produces a reduced respiratory rate coupled with an increased tidal volume resulting in alveolar hyperventilation, hypocapnia, and alkalosis. In humans, thermal hyperpnea predominates and can at times account for 46% of cephalic heat loss [72]. Given the relative size of the infant cranium, it could be assumed that this figure may be larger, although no data support this assumption.

An interesting theory is related to the role of yawning in thermoregulation, especially with regard to selective brain cooling [73]. In a study group of college students, contagious yawning was eliminated by selective cooling of the forehead [74]. In preterm and near-term infants, yawning begins at approximately 20 weeks and decreases in frequency between 31 and 40 weeks, coincident with the development of homeostatic control [75]. Also interesting is the role of opioids in yawning behavior. Opioids are known through κ-receptor activity to produce hypothermia in animals and also to inhibit yawning. Additionally, the administration of naloxone increases yawning in opiate-dependent humans [76]. Ultimately, the importance of yawning is uncertain in humans and especially in neonates and infants.

Mechanisms of heat loss

Unintentional hypothermia is the major concern that motivates inclusion of a discussion of thermoregulation in this and every text of pediatric anesthesia. Although heat is lost and gained from the body in similar ways, heat gain is a relatively rare concern, whereas avoiding heat loss is part of the anesthetic management of every child. A basic understanding of the mechanisms of heat loss is central to the prevention of unintentional hypothermia. Hypothermia has beneficial effects in a few select clinical situations such as hypoxic ischemic brain injury, CPB, and deep hypothermic circulatory arrest, but it has clear negative effects in most day-to-day perioperative situations. Hypothermia inhibits immune responses and is a source of renal dysfunction and coagulation abnormalities. It affects the action of various medications, including muscle relaxants, that are components of many anesthetics provided to adults and children.

Heat loss in the operating room environment occurs in order of importance through radiation, convection, evaporation, and conduction. Radiant heat loss is the heat loss that occurs between two objects in the environment. All objects in the operating room, whether animate or inanimate, gain or transfer heat to one another in a process that would in the absence of intervention lead to equilibrium. The heat of the sun and the heat generated by an infrared warming light are typical examples of radiant heat sources. Radiant heat loss is somewhat less easy to imagine but much more important in the operating environment. Radiant heat is transferred as electromagnetic waves in the infrared spectrum and is unaffected by air currents, air temperature, or distance between the radiating surfaces. Radiant heat loss becomes an increasingly important source of heat loss as the temperature of surrounding objects and surfaces decreases. In a neutral thermal environment, radiant heat loss accounts for about 39% of total heat loss, whereas at 22°C, radiant losses increase to nearly 80% of the total [69].

Radiant heat loss can be greatly reduced by the use of simple coverings such as clothing, sheets, or blankets. Even light clothing can dramatically reduce radiant heat losses. It may at times not be possible to cover the child. In this circumstance, the most effective means of maintaining temperature is increasing the temperature of objects within the environment (heating the operating room), or alternatively, providing a source of radiant heat energy such as an infrared heat lamp or other radiant heater. In this example, increasing the ambient temperature to 30°C would reduce radiant heat loss by almost 50%, keeping in mind that in order to achieve this the environment must be at equilibrium. Simply raising the air temperature briefly has little effect until all objects in the environment have had sufficient time to equilibrate.

Convective heat loss is second to radiation as a source of energy loss in the operating room environment. It accounts for approximately 34% of heat loss in a neutral thermal environment. Convection is the loss in heat that occurs as a result of mass motion of a fluid, typically either air or water. The amount of heat loss depends on the velocity of air (water) movement and the difference between the temperature of the object (person) and the surrounding fluid. For those living in northern latitudes, the concept of wind chill is a familiar example of the effects of convection on cooling or heat loss from one object to the surrounding air (termed *forced convection*). Although air currents in the indoor environment are minimal, it is important to keep in mind that a warm object heats the surrounding air (termed *natural convection*). The warmer air is less dense and rises away from the warm object, thus creating an air current that promotes convective heat loss. The addition of even a light covering inhibits this air current and reduces convective heat loss. The rate of convective heat transfer ($\dot{Q}$) is determined by the following formula: $\dot{Q} = hA(T_s - T_b)$, where h is the constant heat transfer coefficient of the fluid, in this case air; A is the surface area in meters squared; T_s is the surface temperature; and T_b is the temperature of the fluid (air). The transfer coefficient is situationally dependent and must be determined for each setting, making use of this formula problematic in the clinical setting.

Heat loss through conduction occurs whenever the body comes in direct contact with a cooler object that is not in motion (air or water are objects in motion) such as the operating table or other solid. Similar to convection, the transfer of heat is dependent on the temperature difference between the two objects, the densities of the objects, and the area of contact. The greater the area of contact and the greater the density of the cooler object, the more heat is transferred. A soft mattress transfers less heat than a solid surface such as an x-ray table. The mathematical expression of this relationship is identical to that for convection: $\dot{Q} = hA(T_s - T_b)$. However, in this case, heat transfer is related to h, the conductivity or thermal properties of the solid; A, the area in contact; and the temperature difference between the body (T_s) and object (T_b)

Table 45.2 Mechanisms of heat loss in anesthetized infants and children (see text for detailed explanation)

Mechanism	Relative % of heat loss	Causes	Prevention/treatments
Radiation	39% in NTE (80% at 22°C)	Cold room temperature	Warm room as high as 26°C; heating lamp; cover with clothing, sheets, blankets, caps; wrap extremities – plastic, cotton wadding
Convection	34% in NTE	Motion of air/fluid	Cover with clothing, sheets, blankets, caps; wrap extremities – plastic, cotton wadding; forced-air warming; warmed IV fluids
Evaporation	25% in NTE	Respiratory losses; drying of skin preparation fluids and other fluids on skin	Condenser humidifier or active warming/humidification of gases; warm skin prep solutions
Conduction	3% in NTE	Direct contact with cooler object not in motion: operating room table	Circulating water blankets; forced-air warming

IV, intravenous; NTE, neutral thermal environment.

in contact. Heat loss via conduction is typically small and accounts for about 3% of heat loss in a neutral thermal environment.

Evaporative heat losses are encountered whenever a fluid evaporates from the surface of an object such as a patient whose abdomen has been prepared with a solution such as povidone-iodine. Evaporation is an important means of cooling the body when the body temperature exceeds 37°C. Heat loss through sweating, evaporation of another liquid from the skin (skin preparation solutions), or insensible losses from an open abdominal wound or via the respiratory tract depend on the vapor pressure gradient between the skin and surrounding air and the velocity of air movement. The formula is familiar from the previous discussion; however, in the case of evaporation, the difference is not in temperature but rather vapor pressure between skin and surrounding air: $\dot{Q} = hA(P_s - P_a)$, where $\dot{Q}$ is heat transfer in watts; h is the coefficient of evaporation and accounts for the latent heat of vaporization of the liquid as well as the airflow velocity; A is the area covered by the liquid in meters squared; and P_s and P_a are the vapor pressures of the liquid at the skin surface and the surrounding air.

Evaporative heat loss accounts for approximately 25% of total heat loss, of which roughly half can be attributed to respiratory losses. In the infant, respiratory losses can be assumed to be greater given the increased minute ventilation per kilogram of bodyweight. The use of warm, humidified inspired gases eliminates this source of heat and free water loss. Table 45.2 summarizes the mechanisms of heat loss, prevention, and treatment in anesthetized children.

Anesthetics and thermoregulation

Anesthetic agents produce consistent effects on thermoregulation in infants, children, and adults. All agents act to increase the interthreshold range both by increasing the upper threshold and decreasing the lower threshold such that the range of temperatures within which thermoregulatory mechanisms are not initiated becomes much wider. Under normal circumstances, the poikilothermic range is limited to 0.2°C. Under anesthesia, that range increases to between 2°C and 4°C, depending on the agent. The interthreshold range is determined at the lower end by measuring the temperatures at which vasoconstriction and shivering are initiated and at the higher end by the initiation of sweating. Vasoconstriction and shivering track consistently at approximately 1°C difference, regardless of the effects of anesthesia, such that vasoconstriction is initiated at a 1°C higher temperature than shivering.

The effects of anesthetics on the interthreshold range are not symmetrical. The upper boundary of the range is increased only by 1.0–1.5°C, whereas the lower threshold is decreased by approximately 2.5°C. The effect is that hypothermia is much more likely to occur than hyperthermia, especially given the typical ambient temperature of most operating rooms. At this point, it is also important to recognize that the most effective responses to both hyperthermia and hypothermia are behavioral, and these responses are absent under general anesthesia. Although the range over which no response to temperature change occurs increases under anesthesia, the intensity of response does not. Cutaneous vasoconstriction under isoflurane anesthesia in healthy volunteers occurred at 34.6°C and was similar in intensity to that achieved in awake volunteers. Shivering can also be observed in anesthetized patients; although, it is much less common because it occurs at a temperature 1°C lower than vasoconstriction. Like vasoconstriction, the intensity of shivering observed is unchanged.

Non-shivering thermogenesis is the predominant means of heat generation in neonates and infants. It too is inhibited in the setting of general anesthesia. Halothane 1.5% inhibits non-shivering thermogenesis by 70% in rodents [77]. Human infants under propofol and fentanyl anesthesia fail to increase metabolic rate despite core temperatures 2°C below the vasoconstrictive threshold, suggesting that non-shivering thermogenesis is absent in this setting [78], although Ohlson et al [79] failed to demonstrate an inhibitory effect on non-shivering thermogenesis by propofol in hamsters.

Inhalational anesthetics affect the thermoregulatory threshold of infants and children in a manner similar to that observed in adults. Bissonnette and Sessler [80] showed that halothane and nitrous oxide reduce the thermoregulatory threshold in children to 35.7°C, whereas in a previous study [81], they found that under isoflurane the threshold was further reduced to levels similar to those observed in adults (34.4–35.3°C). In both studies children were stratified by weight, and in neither study did threshold response vary significantly with weight. Sevoflurane and desflurane have been found to produce similar changes in thermoregulatory responses; although, desflurane is unique in that it reduces the magnitude or gain of the vasoconstrictive response to hypothermia [82–85]. Xenon has been shown to have a greater inhibitory effect on thermoregulation than isoflurane, whereas nitrous oxide is less inhibitory [85]. In general, the thermoregulatory response to inhalational

anesthetic agents appears to be similar in adults and children and is not determined by weight or age. Inhalational anesthetics, with the exception of nitrous oxide, appear to inhibit non-shivering thermogenesis [79].

The effects of intravenous anesthetics on thermoregulation vary. Propofol produces a linear decrease in the threshold temperature for vasoconstriction and shivering, while only slightly increasing the threshold for sweating in humans, as demonstrated by Matsukawa, Kurz, and colleagues [86,87]. Unlike volatile anesthetics, propofol does not appear to inhibit non-shivering thermogenesis. Ohlson et al [79] compared the effects of various anesthetic agents on brown fat metabolism and found that propofol and ketamine did not inhibit non-shivering thermogenesis in hamsters. Midazolam appears to impair thermoregulatory control only minimally compared to the effects of propofol and narcotics [88].

The individual thermoregulatory effects of opioids have not been widely studied. Spencer et al [89] showed that, in rats, different opioid agonists had differing effects on thermoregulation depending on the type of receptor stimulated (μ, κ, δ) with the μ-agonist increasing the set point and κ- and δ-agonists reducing it. Kurz et al [90] examined the thermoregulatory effects of alfentanil in human volunteers and found a minimal increase in set point for sweating and a linear, serum concentration-dependent decrease in set point for vasoconstriction and shivering similar to those observed for other general anesthetics. Meperidine similarly reduces set point and also appears to diminish the threshold for non-shivering thermogenesis by its effects on the α_2-adrenergic receptor [91–93]. Clonidine and dexmedetomidine also act as α_2-agonists and reduce the threshold for vasoconstriction and shivering but have little or no effect on sweating [94].

Postoperative shivering is a problem that primarily affects older children and adults and occurs in two patterns termed *thermoregulatory* and *non-thermoregulatory*. Thermoregulatory shivering is related to hypothermia and appears similar to shivering that occurs in other settings. Non-thermoregulatory shivering seems to have an etiology separate from thermoregulation because it occurs in normothermic patients in the postoperative period and is also seen in patients such as laboring women who have not been exposed to an anesthetic and are not hypothermic. The exact mechanism of this type of shivering is not entirely clear; however, its appearance is distinct in that it is predominantly clonic, resembling the clonus seen in spinal cord-injured patients [95]. Postanesthetic shivering occurs in approximately 50% of patients allowed to become hypothermic and in 27% of non-hypothermic patients, 15% of whom display a primarily clonic pattern of shivering [96]. Pain appears to be a factor also; patients with lower pain scores are less likely to shiver postoperatively [97].

Shivering in children is not well studied; however, a few studies have been published that describe the problem. Akin et al [98] prospectively followed more than 1500 children in the postanesthetic care unit and found the incidence of shivering to be 3.5%. Older children, those undergoing long procedures, and those in whom anesthesia was induced with an intravenous agent appeared to be at greater risk, whereas those whose anesthetic was supplemented with a caudal block appeared to be at lower risk. Lyons et al [99] found a rate of almost 15% in a smaller study and found that anticholinergic use was also a risk factor.

The consequences of shivering are primarily confined to patients who do not have the cardiovascular reserve to tolerate as much as a 380% increase in oxygen consumption that may be associated with shivering [100]. Shivering may also increase intraocular and intracranial pressure and should certainly be treated in those settings. The majority of episodes in children, however, are brief and do not necessarily require treatment other than external warming. When pharmacological treatment is desired for comfort or safety, meperidine appears to be the most efficacious agent. Its usefulness may be the result of its activity as an α_2-adrenergic receptor agonist based on its opioid activity. In keeping with this, other α_2-agonists have been used successfully to treat shivering. Dexmedetomidine and clonidine have been used successfully, although clonidine appears to be most useful in preventing rather than treating this problem. Other opioids have been used but with mixed results and none with the efficacy of meperidine.

Thermoregulation and regional anesthesia

In children unlike adults, regional anesthesia is nearly always combined with a general anesthetic. The thermoregulatory effects of regional anesthesia are confined primarily to neuraxial techniques as the effects of extremity and other blocks tend not to involve a large enough area to greatly affect core temperature. The effects of neuraxial anesthesia on thermoregulation have been extensively studied by Sessler and others, mostly in adults [101–111]. Bissonnette and Sessler, in two studies [80,81], examined the effect of general anesthesia with regional block in children, a situation that has clear relevance to clinical pediatric practice. In the first study [81], in which isoflurane was used in combination with caudal blockade, the authors found that thermal responses in children were similar to those in adults and were independent of bodyweight and age. The use of combined neuraxial and general anesthesia was thought not to be an important factor in determining responses. In the second study [80], halothane was used in combination with either penile or caudal block. Thermal responses were not different between the two groups and were similar to those in adults and children under general anesthesia without regional anesthesia. It appears from these studies that the combination of regional with general anesthesia has little impact on thermoregulation in children.

Temperature monitoring

The ASA requires that temperature monitoring be available for all patients under anesthesia. Accurate measurement of temperature in the operative period is primarily directed at the detection of hypothermia. Less common but no less important are instances of notable fever, especially those related to MH. Temperature is measured using various technologies at multiple sites with accuracy that varies widely. The appropriate unit of measure is degrees Celsius as the Fahrenheit scale is cumbersome, outmoded, and like most aspects of the US customary system ("English units"), should be abandoned in clinical practice.

The measurement of temperature has a rich and fascinating history that cannot be covered in this text. One of the first thermometers, invented by Rhomer at the turn of the 18th century, used red wine as an indicator. Fahrenheit invented the mercury thermometer in 1714 and later the Fahrenheit scale, which remains in use in the United States and a few other countries. The Celsius scale originally designated 0° as the boiling point and 100° as the freezing point of water. Linnaeus inverted the scale to its present format in the middle of the 18th century, and the scale became widely popular as the centigrade scale, later designated the Celsius scale in 1948. The official metric unit of temperature is the Kelvin after its inventor Lord Kelvin in 1848. The Kelvin scale is based on absolute zero and uses the triple point of water (273.16°K) as a reference. The triple point of a substance is the temperature at which all three phases coexist in equilibrium.

Monitoring temperature requires that an accurate instrument be used at an appropriate site that reflects the temperature of interest. Modern thermometers use thermistors, thermocouples, infrared, and liquid crystal technologies. All are sufficiently accurate for most applications, although thermistors are probably the most accurate and liquid crystal thermometers the least accurate.

Typically, in the operative setting, the temperature of interest is an estimation of core temperature; however, the ability to measure core temperature is often limited by the availability of appropriate sites and instruments. Core temperature is undefined but represent the major input into thermoregulation and therefore is of the greatest importance in terms of measurement. Sites such as the tympanic membrane, bladder, esophagus, nasopharynx, and rectum are typically considered to represent core temperature – each has limitations, however. It has been suggested that the core temperature is the temperature of the thalamus; however, the core temperature can more appropriately be described as the temperature at which the thalamus responds rather than its own intrinsic temperature. Since the thalamus receives input from throughout the body, core and thalamic temperatures may differ.

Peripheral temperature varies widely over time and by location and therefore is much more limited as a measure of thermoregulatory input or status. Skin temperature, including axillary measurement, is often the simplest and most accessible site for monitoring. When the sensor has been placed properly, axillary temperature correlates well with measures of core temperature in infants, making it useful for brief procedures during which marked temperature change is not anticipated [112]. Skin temperature measurement over the carotid artery has also been described as a viable non-invasive estimate of core temperature in infants and young children [113]. Placement of skin temperature probes elsewhere on the skin surface are much less likely to reflect core temperature and should be used with that caveat in mind. Figure 45.4 shows the correlation of various temperature measurement sites as measured in children weighing between 5 and 30 kg. Nasopharyngeal, esophageal, and rectal temperature measurements are similar, but forearm and fingertip temperatures are much lower and clearly do not reflect core temperature [112]. The optimal depth of the nasopharyngeal probes is important as misplaced probes will be affected by both ambient air and ventilation gases [114,115].

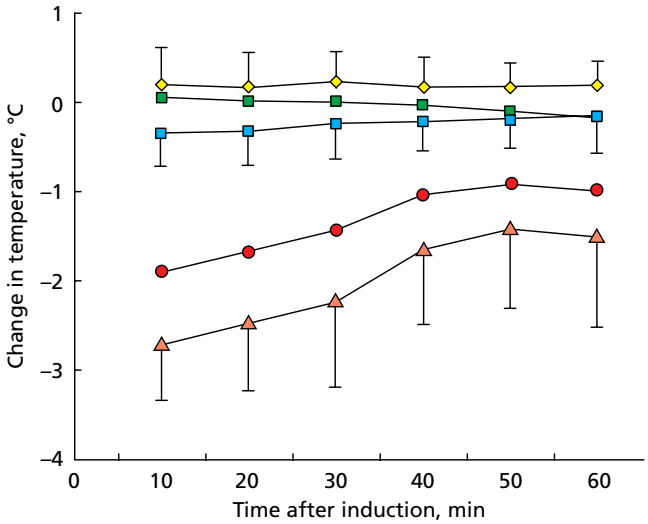

Figure 45.4 The average difference between temperatures at five different measurement sites and tympanic membrane temperature in 20 children weighing between 5 and 30 kg. The central sites (esophagus (◇), rectum (■), and nasopharyngeal (■)) did not differ significantly, whereas the temperatures of the peripheral skin surface (forearm (●) and fingertip (▲)) were significantly lower than the central temperatures. Vertical bars illustrate the standard deviation. Standard deviations of the rectal temperatures (omitted for clarity) were similar to those of the esophageal and axillary temperatures. Standard deviations of fingertip temperatures were similar to those of the forearm temperatures. *Source:* Reproduced from Bissonnette et al [112] with permission of The American Physiological Society.

Hypothermia, hyperthermia, and internal heat transfer

Heat loss or gain in the operative setting results in the transfer of heat either to or from the core. Redistribution hypothermia results from the transfer of heat from the core to the periphery caused by vasodilation that is usually induced by anesthetic agents. This heat transfer is responsible for the initial drop in temperature of 1.0°C to 1.5°C typically observed in the 1st hour under anesthesia. Once initiated, the process is difficult to reverse; it can be prevented, however, through the use of prewarming and active warming immediately after the induction of anesthesia [116–120]. The use of active warming through the use of heated gases, heated forced air, heat lamps, heating pads, or heated intravenous fluids can be effective in slowing or eliminating heat loss during the intraoperative period, but the most effective means of limiting heat loss is increasing the ambient temperature of the operating room.

Warming intravenous fluids is a relatively ineffective means of treating or preventing hypothermia except in situations such as rapid blood loss or CPB in which large volumes of blood are transferred to the patient in a very short time. The ineffectiveness of warming fluids is otherwise true for several reasons. Intravenous fluids can be warmed safely to temperatures only slightly above core temperature to prevent hemolysis, typical procedures require relatively small amounts of fluids, and, finally, fluids warmed in an intravenous bag are often significantly cooler by the time they reach the patient. This is particularly true in small children, infants, and neonates with low intravenous flow rates and when warmed fluids are likely to cool prior to reaching the child. Whereas warm fluids are not an effective means of restoring normothermia, cold fluids are a much more effective means of

cooling, primarily because cold or cool fluids have a much larger temperature gradient (15°C below core temperature for room temperature fluids) than warmed fluids (1–2°C above core temperature). Therefore, it is important to warm fluids when severe hypothermia can be anticipated, but warmed fluids are not an effective means of treating even mild hypothermia.

The use of a heated and humidified breathing circuit is also only modestly effective in either preventing or treating intraoperative hypothermia because heat loss through the respiratory tract accounts for only about 10% of total heat loss. Of that 10%, roughly two-thirds is accounted for in the process of humidifying inspired gases, suggesting that the use of a passive heat and moisture exchanger (artificial nose) is probably sufficient for most situations. In children, especially infants, the role of respiratory heat loss may be greater, given that minute ventilation is much higher than in adults. Insertion of a heat and moisture exchanger increases both the humidity and temperature of inhaled gases, and when coupled with low fresh gas flow in the circuit, is an efficient way to conserve both heat and moisture when anesthetizing infants and young children [121]. Bissonnette and Sessler [122], in a study in infants that compared active heating and humidification with either no intervention or passive humidification, found a marked difference in rectal temperature 2 h after induction. This difference suggests that, at least in infants and neonates, active heating and humidification may be useful, at least for longer or more extensive procedures. For shorter procedures that do not involve major body cavities, the use of an artificial nose (condenser humidifier) maintains sufficient airway humidity above the 50% needed for mucociliary function.

Surface warming using warm, fluid-filled mattresses effectively reduces conductive heat losses, but these losses are a minor contributor to overall heat loss. As with heated airway gases and intravenous fluids, a major limitation of surface warming is the small increment between the temperature of the warming device and that of the patient. The use of high temperatures to warm externally creates an unacceptable risk of thermal injury. Therefore, the use of traditional hot water blankets has limited value in the management of hypothermia in the pediatric operative suite. Newer circulating-water devices have been developed that are more effective than either older systems or current forced-air systems [123]. This is due to the increased capacity of fluids to transfer heat and the increased surface area in contact with the skin. Skube et al [124] recently reported 10 pediatric noncranial surgical patients who maintained ideal core body temperature via the application of a liquid-warming garment applied to the head.

The most widely used and effective means of external warming are forced-air (convective) warming devices [125,126]. They have been in use for more than a decade and have an excellent safety record, despite reports of burns in children [127]. When a sufficient area of the body surface is covered, these systems can eliminate heat losses from the skin. A 2016 Cochrane Database Systematic Review [128] assessing active body surface warming systems to prevent unintended hypothermia in adults found forced-air warming to be benefical in terms of lower surgical site infections and improved patient comfort compared with not applying any active warming device.

Despite the development of new technologies, the most effective means of preventing intraoperative hypothermia remain the maintenance of high ambient temperatures and the use of simple insulators such as plastic sheeting or cloth coverings. Few data suggest that one type of covering is superior, but all are highly effective means of reducing surface heat loss and are of minimal cost. Ultimately, however, to maintain normothermia in infants, an ambient temperature of 29°C is required, which is uncomfortable, especially for the surgical team [129]. For longer or more invasive procedures in which major body cavities are exposed, active warming may be necessary and can be most comfortably and effectively achieved with the use of forced-air convective systems.

Hyperthermia in the operative setting is relatively rare compared with hypothermia. Temperatures exceeding 38°C may result from intrinsic processes such as infection, drug fever, transfusion reaction, or MH, or may be the result of excessive warming. Children – especially infants and neonates – are most susceptible to hyperthermia induced by overly aggressive warming. It is important to investigate and eliminate the cause of the hyperthermia rather than to simply treat with antipyretics. Clearly, the most concerning cause of hyperthermia in the operative setting is MH; however, pyrexia is also associated with worse outcomes in septic shock, acute respiratory distress syndrome, heart failure, acute brain injury, and out-of-hospital cardiac arrest, so continued vigilance to avoid hyperthermia in patients presenting to the operating theatre with these morbidities is warranted [130–132].

KEY POINTS: CONTROL OF TEMPERATURE

- General anesthetics impair normal thermoregulatory mechanisms and result in hypothermia in patients of all ages and sizes
- Non-shivering thermogenesis is the predominant means of heat generation in neonates and infants and is inhibited in the setting of general anesthesia
- Heat loss in the operating room environment occurs in order of importance through radiation, convection, evaporation, and conduction
- Hypothermia inhibits immune responses and is a source of renal dysfunction and coagulation abnormalities
- Despite the development of new technologies, the most effective means of preventing intraoperative hypothermia remain the maintenance of high ambient temperatures and the use of simple insulators such as plastic sheeting or cloth coverings

Malignant hyperthermia

History

Malignant hyperthermia is a pharmacogenetic syndrome characterized by a hypermetabolic state of skeletal muscle typically induced by exposure to specific anesthetic agents, including all halogenated volatile anesthetics as well as the depolarizing neuromuscular relaxant succinylcholine. Patients with MH typically present with hypercapnea (elevated end-tidal CO_2) and tachycardia followed by muscle

rigidity, hyperthermia, rhabdomyolysis, profound acidosis, and if untreated – death [133,134].

Malignant hyperthermia was first described in 1960 in a letter to the editor of *Lancet* and subsequently in an article in the *British Journal of Anaesthesia* entitled "Anaesthetic deaths in a family," reported by Denborough et al [135]. In that paper, the authors described the MH symptoms in a young man and several of his family members who had previously experienced unexplained anesthetic deaths. The young man survived a halothane anesthetic but displayed what are now known to be classic signs and symptoms of what later became known as MH. The term "malignant hyperthermia" was first used in a 1966 paper by Wilson et al [136] describing phosphorylation defects as a possible mechanism for MH. A subsequent 1972 report identified a characteristic phenotype for some affected individuals [137]; this entity was termed King–Denborough syndrome, and Britt et al [138] confirmed the heritability of the syndrome in a 1969 paper. Key to the understanding of MH was the early recognition of the pale, soft, exudative pork or porcine stress syndrome as an animal model for the human disorder.

Genetics and pathophysiology

Both contraction and relaxation of skeletal muscle are energy-requiring processes that depend on the coupling of excitation to contraction through acetylcholine-mediated depolarization of the muscle membrane and sarcoplasmic reticulum (Fig. 45.5). Depolarization results in the release of calcium stored within the sarcoplasmic reticulum. The released calcium binds to actin thin filament proteins, allowing activation of myosin thick filaments, and ultimately initiating muscle contraction. The sequestration of Ca^{2+} is active and required for relaxation of the motor unit. In MH, high levels of intracellular calcium persist, resulting in sustained contraction and continued consumption of ATP in a cellular attempt to restore Ca^{2+} homeostasis. This consumption of ATP leads to the production of heat and ultimately muscle breakdown that is characteristic of MH. Therapy with dantrolene, an inhibitor of Ca^{2+} release from the sarcoplasmic reticulum, is directed at reducing intracellular calcium, thereby allowing for muscle relaxation and elimination of uncontrolled ATP metabolism.

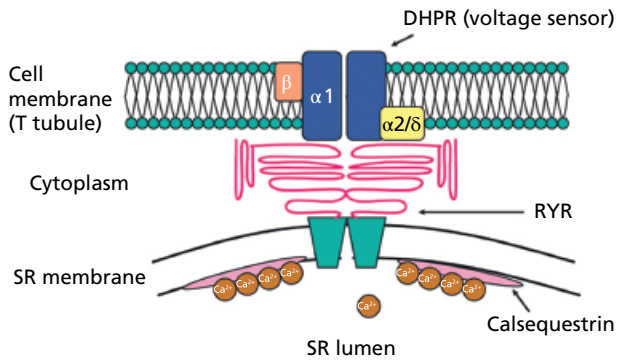

Figure 45.5 A schematic representation of the key structures involved in excitation–contraction coupling, including the ryanodine receptor (RYR) located on the sarcoplasmic reticulum (SR) membrane. DHPR indicates dyhydropyridine receptor. *Source:* Reproduced from Hopkins [256] with permission of Oxford University Press.

Without prompt reversal of this hyperdynamic condition with dantrolene, MH is almost always fatal [134].

Over the generations since its original description, the pharmogenetic origins of MH have has been increasingly described in the extant literature. Mutations in two genes, the ryanodine receptor type 1 (*RYR1*) gene and the voltage-dependent L-type calcium channel alpha 1S subunit (*CACNA1S*) gene, are causally linked to the majority of reported MH cases, with the *RYR1* gene accounting for 70% and *CACNA1S* gene accounting for only 1% of the known cases [139]. Recently, mutations in *STAC3* have been reported in an isolated population of Lumbee Indians in the southeastern United States with myopathy and increased MH susceptibility [139,140]. The remaining cases have not been characterized genetically and may or may not have a genetic basis [134].

Both the *RYR1* gene and *CACNA1S* gene products control intracellular calcium metabolism through the skeletal muscle excitation–contraction coupling complex. The *RYR1* gene encodes the sarcoplasmic reticulum membrane-localized Ca^{2+} channel ryanodine receptor. The *CACNA1S* gene encodes the Ca^{2+} channel-forming voltage-sensing α1-subunit on the T-tubule-localized L-type Ca^{2+} channel (dyhydropyridine receptor or DHPR) [134]. Excitation–contraction coupling occurs through the physical interaction of the voltage-sensing α1-subunit of DHPR with the RyR Ca^{2+} channel (Fig. 45.6). Genetic varaiations in *RYR1* and *CACNA1S* can cause channelopathies, which in the presence of halogenated volatile anesthetics or succinylcholine, can lead to dysregualted Ca^{2+} release from the sarcoplasmic reticulum, uncrontrolled skeletal muscle contraction, and a hypermetabolic state characteristic of MH (Fig. 45.7) [134]. In MH patients, volatile

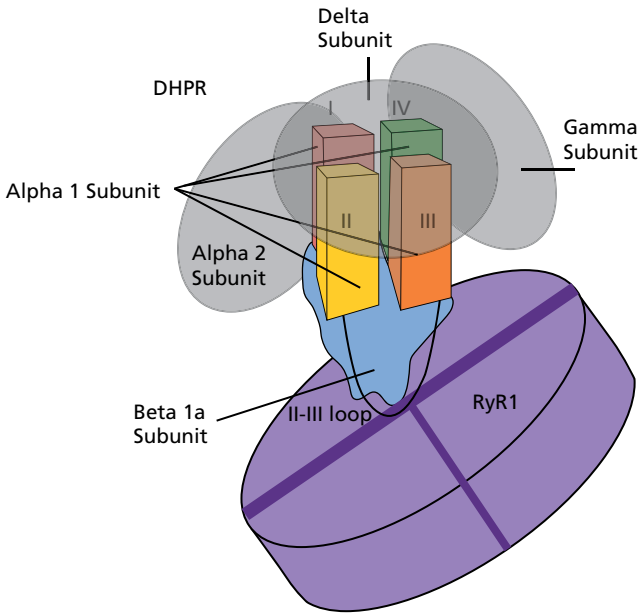

Figure 45.6 Subunit architecture and II–III loop coupling of the voltage-gated calcium channel alpha 1S subunit (CACNA1S) (rainbow blocks) of the dyhydropyridine receptor (DHPR) to the ryanodine receptor type 1 (RyR1) channel (purple). Voltage-induced conformational changes in the α1 subunit are transmitted through the II–III loop–β1a subunit complex, and through direct interactions with RyR1 promote excitation–contraction coupling. *Source:* Reproduced from Beam et al [134] with permission of The American Physiological Society.

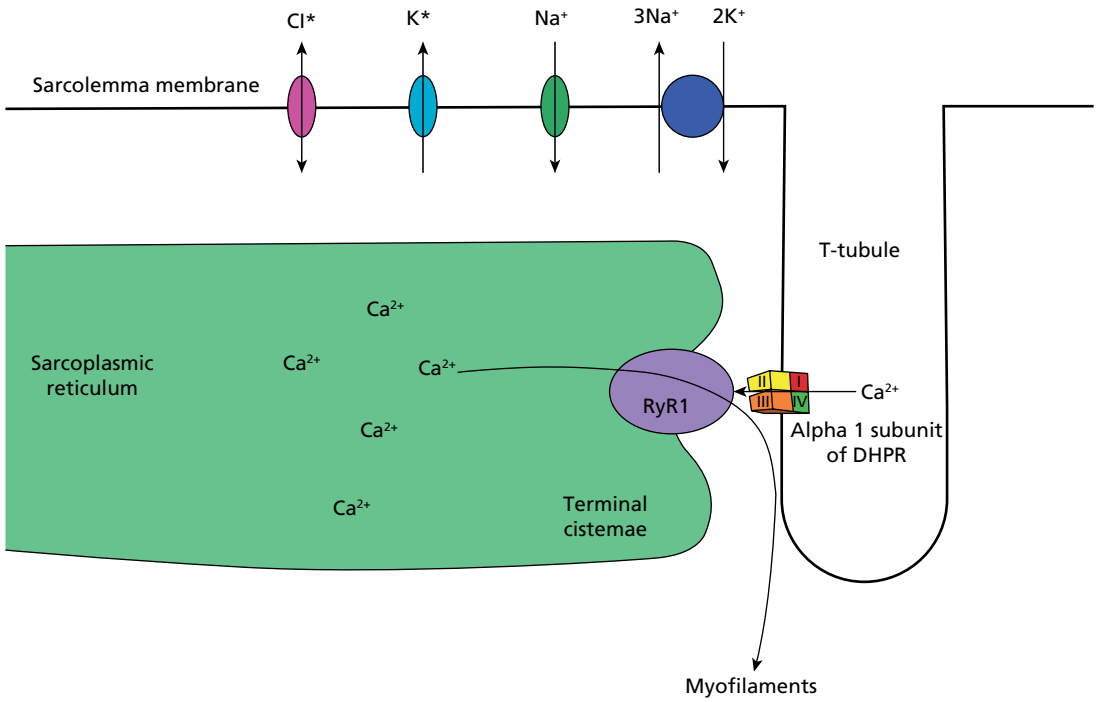

Figure 45.7 Channelopathies of Ca^{2+} channels, dyhydropyridine receptor (DHPR) and ryanodine receptor type 1 (RyR1), confer susceptibility to malignant hyperthermia. The CACNA1S alpha 1S subunit (rainbow cube) of DHPR is the voltage sensor that interacts with RyR1 (purple) to allow excitation–contraction coupling. *Source:* Reproduced from Beam et al [134] with permission of The American Physiological Society.

halogenated anesthetics remove the Mg^{2+} inhibition of the RYR Ca^{2+} channel and have been shown to activate Ca^{2+}-dependent ATPases in the sarcoplasmic reticulum [134]. Succinylcholine targets acetylcholine receptor Na^{2+} channels, and when co-adminsitered with volatile halogenated anesthetics, can worsen clinical MH [134]. As of publication of the text, there are at least 34 known causative *RYR1* mutaitons and two *CACNA1A* mutations diagnostic for MH.

The pattern of inheritance in MH is autosomal dominant although a considerable proportion of affected individuals appear to follow a recessive pattern or no identifiable inheritance pattern. This is likely the result of variable expression or reduced penetrance within or among affected families. The gold standard diagnostic test for MH in North America is still the caffeine–halothane contracture test (CHCT) [133]. In Europe, the diagnostic test is called the *in vitro* contracture test (ICVT) [141]. The CHCT was first developed nearly 40 years ago and requires a muscle biopsy to obtain fresh muscle that can be exposed under controlled conditions to halothane and caffeine [142,143]. Strict criteria are used to define positive, negative, or equivocal tests [144–147]. The sensitivity and specificity is approximately 100% and 80%, respectively. A video of the CHCT can be found at the following link: http://www.mhaus.org/videos [133]. Testing is restricted to a few centers (four in the United States) and can only be accurately performed using fresh muscle from adults and children older than about age 6 years [148]. The European Malignant Hyperthermia Group has recently revised their guidelines for IVCT investigation of MH susceptibility in children to include a minimum age of 4 years; although, the guidelines specify that laboratories testing children younger than 10 years of age must have relevant control data [141]. Because of the invasive nature of this testing and significant cost, including travel for the patient, genetic testing is becoming increasingly popular and an option for first-line testing in place of muscle biopsy in some cases. The indications for CHCT and genetic testing from the Malignant Hyperthermia Assocation of the United States are summarized in Boxes 45.1 and 45.2, respectively. Of note, a single-center recent analysis of the histomorphology in MH-susceptible patients did not reveal any consistent histological abnormalities; however, some MH-suscepitble patients were found to have evidence of other myopathies [149].

Box 45.1: Indications for the caffeine–halothane contracture test (CHCT)

Patient with known MHS* relative (as determined by positive muscle contracture test)

- Patient with MHS family member (as determined by past suspicious MH episode, but *without* a known *RYR1* causative genetic mutation)
- Patient with past suspected MH event (wait 3–6 months after event, depending upon the degree of rhabdomyolysis)
- Patient with *severe* MMR during anesthesia with a triggering agent
- Patient with *moderate to mild* MMR with evidence of rhabdomyolysis
- Patient with unexplained rhabdomyolysis during or after surgery (may present as sudden cardiac arrest due to hyperkalemia)
- Patient with exercise-induced rhabdomyolysis after a negative rhabdomyolysis work-up
- Signs suggestive of but not definitive for MH
- If military service is desired, patients with suspicion of MHS are required to undergo CHCT

*Malignant hyperthermia susceptible: suspicious MH event and predisposing factors to MH in patient/family.
MH, malignant hyperthermia; MHS, malignant hyperthermia susceptibility; MMR, masseter muscle rigidity.

Box 45.2: Indications for genetic testing in United States

- Patient with a confirmed or highly suspicious clinical episode of MH
- Patient with positive CHCT
- Patient with MHS relative as determined by positive CHCT
- Patient with MHS relative as determined by a confirmed or highly suspicious clinical episode of MH
- Patients with relatives with known causal *RYR1* mutation*

*Proband or index case should always be tested first if possible.
CHCT, caffeine–halothane contracture test; MH, malignant hyperthermia; MHS, malignant hyperthermia susceptibility; MMR, masseter muscle rigidity.
Source: Reproduced from http://www.mhaus.org with permission of MHAUS.

Epidemiology

Malignant hyperthermia is a rare disorder affecting fewer than 1:50,000 adults and as many as 1:3000 children [150], representing approximately 13 cases per million hospital discharges in the United States [151] or one per 100,000 in New York State in 2005 [152]. Although large epidemiological studies have not been performed recently, it appears that the frequency of MH has declined with increased awareness and a greater degree of certainty as to the agents that are and are not associated with the syndrome. MH may occur at any age, although it is most common in children and young adults. It has been reported rarely in infants and among the elderly [153,154]. Concentrations of cases can be found among large extended families or among members of closed or relatively closed communities. In a recent review of data compiled by the Malignant Hyperthermia Association of the United States, Larach and colleagues [155] found that of 286 cases reported between 1987 and 2006, 75% were male, most were young (median age, 22 years), a disproportionately large number were of muscular build (29%), and most were white (70%). In a recent study of data obtrained from existing reports in the North American Malignant Hyperthermia Registry, muscular body build and male sex were independently associated with malignant hyperthermia susceptibility [156].

Acute presentation

In the past, agents known to trigger MH included halothane and enflurane. Currently, sevoflurane, isoflurane, desflurane, and succinylcholine have been known to trigger an episode of MH. Desflurane and sevoflurane are weak triggers for MH and therefore may be associated with episodes that are less fulminant than those seen in association with older agents and succinylcholine [157,158]. The rate of triggering may also be slowed or even eliminated by other factors, including the use of non-depolarizing muscle relaxants, barbiturates, and hypothermia [159]. Nevertheless, specific pharmacological triggering agents are not necessary to initiate a reaction among susceptible individuals. Carr et al [160], in a series of more than 2000 biopsy-proven MH patients, observed a rate of triggering of 0.46% despite the use of a non-triggering anesthetic.

The clinical presentation for MH is highly variable and may at times be confused with other conditions such as rhabdomyolysis. The classic features of the disorder are non-specific and can be found in association with many other conditions. The combination of a highly variable presentation with non-specific signs and symptoms in a rare disorder explains the continued association of MH with poor outcomes, including death. This also explains the frequency with which MH is confused with other conditions. To assist in the clinical diagnosis of MH, Larach and colleagues [161] developed a clinical grading scale.

The presentation of MH relates to the underlying hypermetabolic state after exposure to a triggering agent such as a volatile anesthetic or succinylcholine. Hypermetabolism of skeletal muscle produces tachycardia, tachypnea, fever, muscle rigidity, acidosis (both respiratory and metabolic), hyperkalemia secondary to rhabdomyolysis with associated dysrhythmia, and ultimately cardiovascular collapse and death. Each of the symptoms can be traced to the calcium-induced hypermetabolic state within the skeletal muscle. Rigidity, occurring in approximately 40% of patients in the series described by Larach et al [155], is a function of sustained contraction that may lead to muscle breakdown and release of large amounts of potassium. The release of potassium in the setting of profound acidosis is often the proximate cause of ventricular dysrhythmia, cardiac arrest, and mortality unless resuscitation efforts are successful. It must be kept in mind that acute hyperkalemia, fever, acidosis, and other manifestations of MH are associated with other conditions and may be confused with MH, although regardless of the etiology, treatment may be the same. Table 45.3 lists the order of appearance of clinical signs of MH in a series of 255 patients reported by Larach et al [155].

Laboratory evidence of MH reflects the underlying pathology. Thus, along with the aforementioned hyperkalemia and metabolic and respiratory acidosis, a rapid rise in creatine kinase (CK) and myoglobinuria reflect muscle destruction. Coagulopathy is common along with pulmonary edema and cardiac and hepatic dysfunction. Survivors of the acute phase may have evolving evidence of acute renal failure, with increasing serum creatinine, oliguria, or anuria [155].

The onset of symptoms of MH is variable and may occur within minutes or may at times be delayed for hours [162–164]. Many patients with MH have had uneventful anesthetics in the past, with 30% having had as many as three previous exposures without triggering. Tachycardia and, in the spontaneously breathing patient, tachypnea are usually the first signs and are virtually always present, and the absence of tachycardia should cast doubt on the diagnosis of MH. In general, the more rapid the onset, the more severe the presentation; however, fulminant cases of MH have been described in patients whose first symptoms did not appear until after admission to the postanesthesia care unit or even many hours later [163,164]. Accurate and timely recognition requires a high degree of clinical suspicion and vigilance. As many as 20% of patients experience a recrudescence of symptoms an average of 13 h after the initial reaction. Those at greatest risk for recrudescence are those with delayed onset and muscular build [165].

Patients at risk

Recognition of MH must begin with an appreciation of the patient populations at greatest risk. Susceptibility to MH has been a subject of controversy since its original description.

Table 45.3 Order of appearance of clinical signs[a] during 255[b] malignant hyperthermia events

Clinical sign	Medial (first, third quartile) appearance number[c]	Range of appearance number[c]	No. (%) of patients with sign
Masseter spasm	1.00 (1.00, 1.00)	1.00–4.00	68 (26.7)
Hypercarbia	2.00 (1.00, 2.00)	1.00–8.00	235 (92.2)
Sinus tachycardia	2.00 (1.00, 2.00)	1.00–7.00	186 (72.9)
Generalized muscular rigidity	2.00 (1.00, 3.50)	1.00–6.00	104 (40.8)
Tachypnea	2.00 (1.00, 3.00)	1.00–6.00	69 (27.1)
Other	2.00 (1.00, 4.00)	1.00–7.00	43 (16.9)
Cyanosis	2.00 (2.00, 4.00)	1.00–7.00	24 (9.4)
Skin mottling	2.00 (1.00, 3.50)	1.00–7.00	16 (6.3)
Rapidly increasing temperature	3.00 (3.00, 4.00)	1.00–7.00	165 (64.7)
Elevated temperature[d]	3.00 (2.00, 4.00)	1.00–8.00	133 (52.2)
Sweating	4.00 (3.00, 5.00)	1.00–8.00	45 (17.6)
Ventricular tachycardia[d]	4.00 (2.00, 5.00)	1.00–7.00	9 (3.5)
Cola-colored urine	5.00 (3.00, 5.00)	2.00–9.00	35 (13.7)
Ventricular fibrillation[d]	5.50 (4.00, 8.00)	1.00–8.00	6 (2.4)
Excessive bleeding	6.00 (5.00, 6.00)	4.00–8.00	7 (2.7)

[a] Table lists the abnormal clinical sign and appearance order (judged to be inappropriate by the attending anesthesiologist or other physician) during malignant hyperthermia (MH) events. Clinical signs are listed in order of occurrence with the earliest signs listed first and the latest signs listed last. (No points on the clinical grading score are accumulated for the presence of the following adverse signs: cyanosis, skin mottling, sweating, excessive bleeding, and other.)

[b] For 31 cases, clinical sign appearance order was not known. (Appearance order is not required to calculate clinical grading scale score, and no additional points accrue for early appearance.)

[c] Appearance number is the numerical order in which a clinical sign appeared, e.g. the first clinical sign that appeared during an MH event would be assigned the appearance number of 1, the second clinical sign that appeared during an MH event would be assigned the appearance number of 2, and so on.

[d] An early version of the AMRA (*a*dverse *m*etabolic/*m*usculoskeletal *r*eaction to *a*nesthesia) report form did not request these signs in one fatal case in which the maximum temperature was 41°C, but these findings were noted elsewhere in the AMRA report and have been counted in this table.

Source: Reproduced from Larach et al [155] with permission of Wolters Kluwer.

In a 1985 paper, Britt [166] described a series of features that suggest the potential for MH: "While some are perfectly healthy, others complain of: ptosis and strabismus in childhood; kyphoscoliosis or lumbar lordosis; club foot, various kinds of hernias …; joint hypermobility …; … undescended testicle; calcium stones …; poor dental enamel …" [166]. The author's extensive list reflected the lack of knowledge available at the time regarding the disorder. Currently, it is believed that MH is associated with only a few conditions, including King–Denborough syndrome, Evans myopathy, central core disease, multi-minicore disease, congenital-fiber type disproportion, core–rod myopathy, and centronuclear myopathy [13,139,167,168]. The presence of strabismus, scoliosis, or other non-specific findings cannot be considered helpful in identification of those at risk.

Clearly succinylcholine-induced masseter spasm and susceptibility to MH are associated. The combination of halothane and succinylcholine produces masseter spasm in approximately 1% of children anesthetized for otolaryngological procedures [169]. Larach et al [155] noted that, among subjects with probable or certain MH in their database, 20% had masseter spasm as a finding during their MH event. Among those exhibiting masseter spasm, the association with MH depends to a large extent on the presentation. Those with mild jaw stiffness appear to have only a slight increase in susceptibility to MH, whereas those exhibiting what has been termed "jaws of steel" are thought to have as high as an 80% concordance with MH. Patients having masseter spasm and an associated elevation of CK to more than 20,000 units/L have been demonstrated to have a 100% concordance with MH susceptibility [170]. As the use of succinylcholine has declined, especially in children, so has the frequency of masseter spasm; however, succinylcholine is still widely used and can be life saving for emergency airway management [171].

For the clinician, a decision must be made about whether to proceed with a procedure after a patient experiences masseter spasm. Some advocate for canceling the planned procedure [170] and others recommend conversion to a non-triggering anesthetic and then proceeding, provided no further evidence of MH is seen [170,172]. Although clear guidance is unavailable, the decision should probably be based on the severity of the masseter spasm, the urgency of the procedure, the environment, and the resources available to provide care should the event progress to fulminant MH despite a change to a non-triggering anesthetic. A child experiencing masseter spasm should almost certainly be admitted for observation and a serum CK level determined, preferably before any surgical incision to assist in determining risk for MH in the future. Weglinski and colleagues [173] demonstrated that among children with idiopathic elevations of CK and no history of masseter spasm, 49% were found to be susceptible after biopsy and a CHCT. As noted previously, the combination of masseter spasm and CK higher than 20,000 units/L is virtually diagnostic. Follow-up of the child who has experienced masseter spasm should probably include counseling with regard to the risk of MH, diagnostic testing, avoidance of triggering agents in the future for the child and first-degree relatives, and referral to pediatric neurology to evaluate for other potential causes of masseter spasm (e.g. congenital myotonia).

The association between various myopathies and MH continues to remain an area of controversy. Specifically, are children with undiagnosed myopathies at increased risk? And are

Table 45.4 Descriptive risk of malignant hyperthermia (MH)*

Disease	Risk of MH
Duchenne muscular dystrophy	No increased risk over general population. Weak evidence for MH
Becker dystrophy	No increased risk over general population. Weak evidence for MH
Noonan syndrome	Weak evidence for MH. But closer to zero than dystrophinopathies
Osteogenesis imperfecta	Weak evidence for MH. But closer to zero than dystrophinopathies
Arthrogryposis	Weak evidence for MH. But closer to zero than dystrophinopathies
King–Denborough	MHS
Carnitine palmitoyltransferase II deficiency	MHS plausible but unproven. Increased risk of rhabdomyolysis but less risk of MH than in dystrophinopathies. Weak evidence
Myophosphorylase B deficiency (McArdle syndrome)	Weak evidence for MH. Increased risk of rhabdomyolysis but less risk of MH than in dystrophinopathies
Myoadenylate deaminase deficiency	Weak evidence for MH. Increased risk of rhabdomyolysis but less risk of MH than in dystrophinopathies
Brody disease	Weak not zero but treat patients for MH because intracellular Ca^{2+} is abnormal. Less risk of MH than in dystrophinopathies
Asymptomatic hyperkalemia	Weak evidence for MH. Increased risk of rhabdomyolysis but less risk of MH than in dystrophinopathies
Myotonia congenita	No increased risk over general population
Paramyotonia congenita	No increased risk over general population
Potassium aggravated myotonia	No increased risk over general population
Myotonia fluctuans	No increased risk over general population
Myotonia permanens	No increased risk over general population
Aceta/olamide-responsive myotonia	No increased risk over general population
Hyperkalemic periodic paralysis ± myotonia	No increased risk over general population
Myotonic dystrophy type I (Steinert disease)	No increased risk over general population
Myotonic dystrophy type 11	No increased risk over general population
Hypokalemic periodic paralysis	Unclear, may be greater risk than in general population but less risk of MH than in dystrophinopathies
Central core myopathy	MHS
Multi-minicore disease with *RYR1* mutation	MHS
Multi-minicore disease without *RYK1* mutation	MHS less risk of MH than in dystrophinopathies
Nemaline rod myopathy without *RYR1* mutation	No increased risk over general population
Nemaline rod myopathy with *RYR1* mutation	MHS risk of MH not yet determined

* Described in [1,3–5,7].
MHS, malignant hyperthermia susceptibility.

those patients with Duchenne-type muscular dystrophy at increased risk? As previously stated, only a few myopathic conditions can be clearly associated with MH; other myopathies have been associated with MH in the past but have not been clearly linked. Table 45.4 gives a descriptive risk of MH in unusual diseases [174].

Reports have described sudden CA and death in children known to have a muscular dystrophy and attributed those events to fulminant MH. It has become clear, however, that these events are more likely to be the result of rhabdomyolysis and subsequent hyperkalemic CA rather than true MH. The question remains as to whether volatile anesthetics are the cause of the rhabdomyolysis and consequently should be avoided in these patients. Succinylcholine is associated with this phenomenon and should never be used in a patient with a known or suspected dystrophy (or myopathy). In the young boy with Duchenne-type muscular dystrophy, the decision to avoid both succinylcholine and a volatile agent is relatively straightforward, as there are obvious alternatives; however, it is less clear how to approach the child with an undiagnosed myopathy because the alternative, typically propofol, may be contraindicated in children with mitochondrial disorders [13,168,175,176].

Acute management

Successful management of an acute MH episode depends on early recognition and swift application of a treatment protocol that has been well thought out in advance. Figure 45.8 is a poster from the Malignant Hyperthermia Association of the United States that describes the management of fulminant MH [133].

Specific management includes discontinuation of triggering agents and institution of therapy with dantrolene. Non-specific therapy is aimed at the effects of acidosis, fever, rhabdomyolysis, and consequent hyperkalemia, including correction of acidosis with hyperventilation and sodium bicarbonate; and active cooling, maintenance of urine output, and management of hyperkalemia with bicarbonate, glucose, and insulin. Additional antiarrythmic therapies directed against dysrhythmia may be useful; however, rhythm disturbance is almost certainly secondary to hyperkalemia, and therapy should be primarily directed at reducing serum potassium.

First available in the late 1960s as an oral muscle relaxant for use in patients with spasticity, dantrolene was recognized as an effective therapy for MH in pigs by Harrison in 1975 [177] and 2 years later in humans by Austin and Denborough [178]. The drug was of limited value for acute management

given the need to deliver it orally. When solubility problems were resolved, it became available for intravenous use in 1979. Dantrolene acts to inhibit EC coupling in skeletal muscle by inhibiting calcium release at the level of the sarcoplasmic reticulum. It depresses twitch height by more than 70% in humans when given intravenously in a dose of 2.5 mg/kg. Bioavailability of the oral form, once an issue of concern, is very similar to that of the intravenous form [179]. Elimination is by hepatic conversion to an active 5-hydroxy metabolite that is excreted in the urine, with a half-life of approximately 9 h for the parent form and 15 h for the metabolite [180]. Newer formulations are more concentrated and less time intensive to administer rapidly, which is crucial given the importance and proven efficacy of prompt treatment [133]. Dantrolene is highly effective, and when used in sufficient doses early in the course of acute MH, is virtually 100% effective in preventing mortality. The trend in mortality associated with acute MH up to 1993 was described by Strazis and Fox [181]. Mortality declined dramatically in the years immediately after the introduction of dantrolene from more than 60% to less than 10%. Currently, mortality has further declined to less than 5%.

The older preparations of dantrolene contain 20 mg of lyophilized dantrolene and 3000 mg mannitol. Reconstitution with 60 mL sterile water is necessary for each vial. A 2.5 mg/kg initial dantrolene dose requires nine vials for a 70 kg patient; and the drug must be completely dissolved before administration. Anyone who has participated in the preparation of this drug, either for a real MH case, or for a simulation, can attest to how difficult this is to accomplish quickly, and how many team members are required. A new preparation, Ryanodex® (Eagle Pharmaceuticals, Inc., Woodcliff Lake, NJ, USA), is supplied in 20 mL vials containing 250 mg dantrolene sodium and is reconstituted with 5 mL sterile water, dissolving in less than 1 min. The novel formulation includes 125 mg mannitol, 25 mg polysorbate 80, and 4 mg povidone K12 per vial. One provider can reconstitute a 2.5 mg/kg loading dose for a patient weighing up to 100 kg with one vial. Given the emergent nature of treatment of this rapidly evolving hypermetabolic process, it would seem intuitive to utilize the newer preparation when possible.

Preparation and care of the susceptible patient

Identification of the patient at risk and the provision of a safe, non-triggering anesthetic environment are the primary goals for those providing care to people at risk for MH. Patients at risk have been discussed previously and should be managed as if they are known to have MH, regardless of whether they have been tested.

For the patient determined to be at risk, a non-triggering anesthetic should be provided, avoiding the use of volatile anesthetic agents and succinylcholine. The use of regional anesthesia is an excellent option because concerns regarding the safety of amide-type local anesthetics have not been found to carry risk either in animal models or in clinical practice. The anesthesia machine should be prepared per specific manufacturer guidelines, the absorbant changed, and the agent and vaporizers either removed or otherwise rendered inoperable. Activated charcoal filters have decreased the time required to prepare some anesthesia machines; however, preparation time at some sites may require that a clean machine be kept available or that MH-susceptible cases be cared for as the first case on the surgery schedule to avoid delays.

Summary

In summary, MH is a rare pharmacogenetic disorder that is likely to become increasingly rare, given its increased recognition, more frequent use of weak triggering agents, and less frequent use of succinylcholine. Prompt recognition and early treatment with dantrolene should make severe morbidity or mortality extremely rare. As genetic diagnosis becomes increasingly available and sensitive, optimism exists that the disorder will be more easily identified, prevented, and effectively managed in the future.

KEY POINTS: MALIGNANT HYPERTHERMIA

- Malignant hyperthermia is a pharmacogenetic syndrome characterized by a hypermetabolic state of skeletal muscle typically induced by exposure to specific anesthetic agents, including all halogenated volatile anesthetics as well as the depolarizing neuromuscular relaxant succinylcholine
- Treatment of MH includes specific management through discontinuation of triggering agents and administration of dantrolene and non-specific therapy aimed at the reversal of acidosis, fever, rhabdomyolysis, and hyperkalemia, and providing cardiopulmonary support
- Only a few myopathic conditions can be clearly associated with MH: King–Denborough syndrome, Evans myopathy, central core disease, multi-minicore disease, congenital fiber-type disproportion, core–rod myopathy, and centronuclear myopathy
- A new preparation of dantrolene is available that requires only 5 mL sterile water and 1 min to prepare a 2.5 mg/kg loading dose for a patient weighing up to 100 kg

Propofol infusion syndrome

Propofol is an intravenous anesthetic agent used for the induction and maintenance of general anesthesia in children and adults. Because of its rapid onset and offset of action, it is an ideal agent for sedation of mechanically ventilated patients. Developed in 1980, it had been used for a number of years in both adults and children without report of severe adverse events. In 1992, Parke et al [182] reported on the deaths of five children in whom metabolic acidosis and myocardial failure developed after propofol infusion. All these children had upper respiratory tract infections, ranged in age from 4 weeks to 6 years, and were sedated with propofol at a rate ranging between 66 and 178 μg/kg/min (4–10.7 mg/kg/h) for between 66 and 115 h. The constellation of metabolic acidosis, bradyarrhythmia, and heart failure was typical for these patients. The dose range was within those recommended by the British Medical Association at that time: 150–2500 μg/kg/min (9–150 mg/kg/h). Parke was the first to suggest that

propofol infusion, although safe in adults, perhaps should not be used for sedation for children.

In 1998, Bray [183] further characterized this constellation of symptoms as propofol infusion syndrome (PRIS) by the review of information collected from the literature on 18 children who received propofol and had similar adverse effects. The majority of affected patients had respiratory tract infections, although other associations have been reported subsequently by other providers [184]. These other situations were found to occur in young, healthy patients who had sustained head trauma and had received intravenous steroids as well as vasopressors. In Bray's series, the terminal event was myocardial failure, ventricular dysrhythmia, or in some instances, a resistant and progressive bradycardia, which has further been identified as the Brugada syndrome [184]. Postmortem examination commonly reveals a fatty liver and myocardial fiber necrosis, metabolic acidosis is common, and plasma is lipemic. According to Bray [183], there appeared to be a definite association between PRIS and propofol infusions higher than a mean dose of 67 μg/kg/min (4 mg/kg/h) and lasting 48 h or longer.

Although the dose limits suggested by Bray [183] provide guidance, the rapid development of tolerance requires an increased rate of propofol infusion to maintain adequate sedation, and the relatively low dose suggested by Bray is often quickly exceeded. The catecholamine surge, present in acute neurological conditions or produced in various other stress models, may result in sympathetic overactivity with secondary endogenous catecholamine toxicity that may be responsible for decreasing the anesthetic effect of propofol as well as contributing to the direct myocytolytic effects of catecholamines [185].

The mechanism of the myocytotoxic effect of propofol given in prolonged doses has not yet been entirely elucidated. It is known that propofol uncouples oxidative phosphorylation and energy production in the mitochondria, impairs oxygen utilization, and inhibits electron flow along the mitochondrial electron transport chain [186,187]. These cellular effects result in a clinically apparent decrease in ventricular performance. Additionally, in this setting propofol may directly antagonize β-adrenoceptor binding and act directly on calcium channel proteins resulting in diminished cardiac contractility [185].

Cardiac and peripheral muscle necrosis is often evident on postmortem examination. This may be the result of an imbalance of energy supply and demand [185]. Free fatty acids derived from lipolysis of adipose tissues are the most important fuel for both the myocardium and skeletal muscle under fasting conditions [185]. Oxidation within the mitochondria is the key process generating electrons, which are subsequently transferred to the respiratory chain. As propofol can impair the movement of electrons through this chain, the subsequent accumulation of free fatty acids can eventually lead to various grades of myocytolysis. Furthermore, the accumulation of unused free fatty acids has proarrhythmogenic properties that contribute to the overall clinical picture of dysrhythmia and myocardial failure observed in PRIS (Fig. 45.9) [185]. Current experimental data suggest that the respiratory chain inhibition may result in the early, dose-dependent signs of PRIS (cardiac failure, metabolic acidosis, fever, hypotension) while the later, time-dependent signs may be secondary to inhibition of fatty acid oxidation (rhabdomyolusis, hypertriglyceridemia, arrhythmia) [187].

Although PRIS is most commonly observed after a prolonged propofol infusion, there have been some reports of the development of this syndrome after just a few hours of continued propofol infusion in pediatric patients (Table 45.5). Koch et al in 2004 [188] reported the first case of suspected PRIS after short-term infusion of propofol in a child. The patient was a 5-year-old girl admitted to the hospital after endovascular coil embolization of a high-output arteriovenous malformation. Propofol infusion was started at 250 μg/kg/min (15 mg/kg/h). A progressive elevation in serum lactate developed within 6 h of admission, and a diagnosis of PRIS was considered. The lactic acidosis rapidly resolved after propofol infusion was tapered and discontinued, and the child subsequently recovered.

It has been proposed that in patients receiving propofol infusion, frequent monitoring of acid–base status and lactate levels may alert the clinician to early development of PRIS [189]. Veldhoen and colleagues [189] described a 17-year-old boy who sustained multiple skull fractures in a motor vehicle accident. A propofol infusion was initiated to allow continued endotracheal intubation, and over the ensuing hours escalating doses were required to maintain adequate depth of sedation. A maximum of 8 mg/kg/h was administered for 14 h early in the hospital course. On the 4th day, propofol was discontinued as a progressive lactic acidosis was noted. Despite serial measurement of acid–base status and lactate and eventual discontinuation of propofol after lactate was noted to increase, albeit modestly, the child subsequently had CA and eventually died as a result of profound myocardial failure. This was the first report of mortality due to PRIS despite careful monitoring of metabolic parameters and prompt discontinuation of propofol with increased lactate. It should be noted, however, that the child received a continuous infusion of propofol at a dose exceeding the recommended dose of 67 μg/kg/min or 4 mg/kg/h for a duration of no longer than 48 h [189]. Figure 45.10 details this patient's hospital course. It is important to note that PRIS may occur even with moderate doses of propofol (<4 mg/kg/h) or short infusion duration [187].

Some predictors have been identified for mortality in patients with suspected PRIS [190]. Patients with suspected PRIS who died were more likely to be younger than 18 years old, be male, have received propofol for more than 48 h, and have been concomitantly treated with catecholamine therapy. The presence of cardiac symptoms, hypotension, rhabdomyolysis, renal involvement, metabolic acidosis, or dyslipidemia also heralded increased mortality in these patients.

Pediatric patients should not receive infusions of propofol that exceed the recommended dose for more than 48 h [191]. A retrospective study of 142 critically ill children sedated with propfol infusion at doses less than 3 mg/kg/h for less than 24 h found no evidence of PRIS [192]. A retrospective study of more than 200 critically ill children sedated with propofol in the intensive care unit (median average infusion rate 2.7 mg/kg/h (interquartile range, 1.9–3.6 mg/kg/h) and mean infusion duration of 10.3 h (standard deviation, 6.7 h)) did not identify any cases of PRIS and concluded that the use of propofol infusions consistent with current guidelines appears safe although monitoring for adverse effects is still warrented [193]. For those individuals with mitochondrial myopathies or known mitochondrial defects, it is probably prudent to

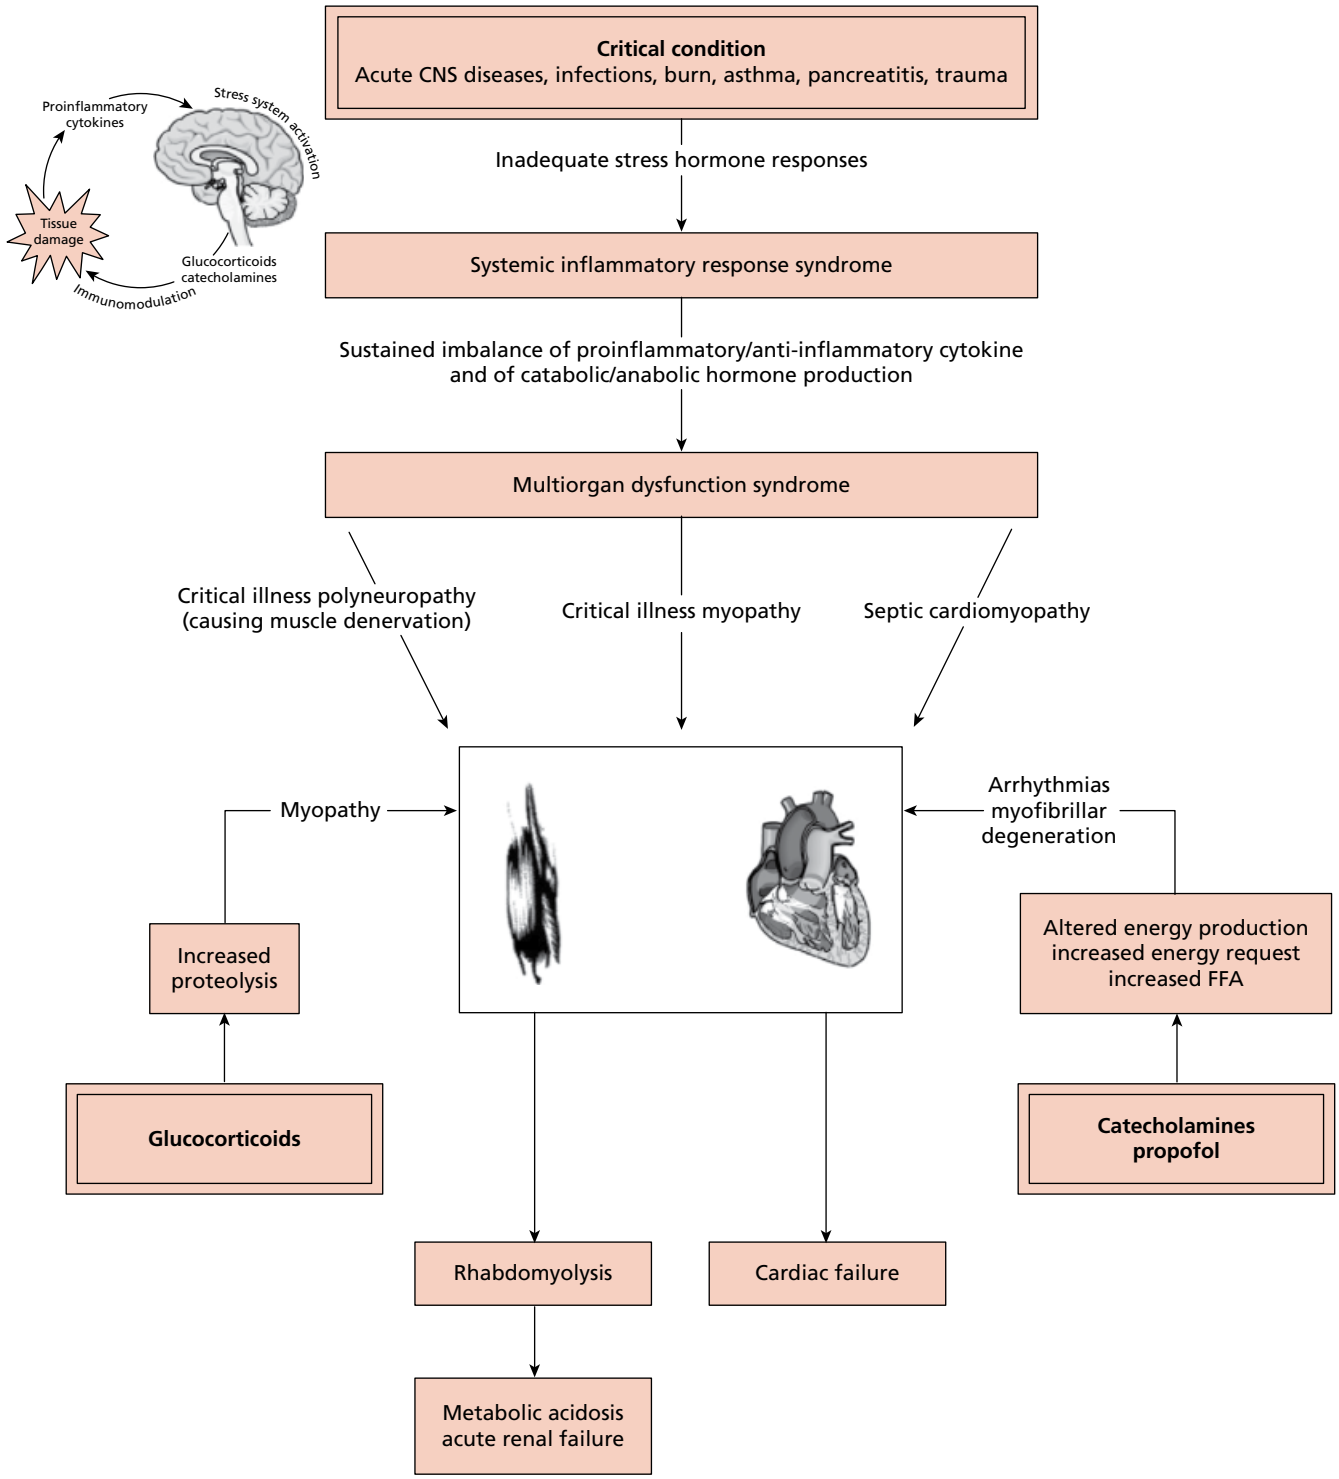

Figure 45.9 Propofol infusion syndrome is a critical illness; cardiac failure and rhabdomyolysis are associated with high-dose propofol, catecholamines, or steroids. CNS, central nervous system; FFA, free fatty acid. *Source:* Reproduced from Vasile et al [185] with permission of Springer Nature.

Table 45.5 Evolution of propofol dose and acid–base status (hours after admission)

		Time after admission (h)						
Dose and status	**Admission**	**2**	**4**	**6**	**8**	**10**	**18**	**24**
Propofol (μg/kg/h)	15	15	15	15	6	6	0	0
pH	7.45	7.38	7.31	7.34	7.33	7.36	7.39	7.37
$PaCO_2$ (mmHg)	33	36	42	36	41	41	40	39

avoid propofol infusions altogether unless there is no viable alternative or to use adjunctive medications to facilitate sedation and allow a lower dose of propofol as infusion. Regardless, it would certainly be recommended to monitor acid–base status as well as lactate level on a regular basis (every 6 h) to minimize the chance for development of PRIS. The development of a metabolic acidosis or rise in lactate without another cause would warrant discontinuation of propofol infusion and administration of an alternative sedating medication. Patients who develop PRIS should be screened for mitochondrial disorder [194].

KEY POINTS: PROPOFOL INFUSION SYNDROME

- PRIS is characterized by dose-related morbidity (cardiac failure, metabolic acidosis, fever, hypotension) and time-dependent morbidity (rhabdomyolusis, hypertriglyceridemia, arrhythmia)
- Propofol uncouples oxidative phosphorylation and energy production in the mitochondria, impairs oxygen utilization, and inhibits electron flow along the mitochondrial electron transport chain
- Predictors of mortality in patients with suspected PRIS include age less than 18 years, male sex, propofol infusion for more than 48 h, and concomitant treatment with catecholamine therapy

Local anesthetic toxicity and intralipid administration

Thousands of doses of local anesthetic medications are administered to pediatric patients every day in hospitals and outpatient surgical centers throughout the world. Local anesthetic medications may act not only as the sole agent for analgesia but also as an important component of an anesthetic technique that uses a combination of both regional and general anesthesia.

Cocaine was the first local anesthetic isolated from coca leaves in the 1860s by Albert Niemann, a German chemist. Cocaine was initially used by Sigmund Freud in 1884 to assist a patient in weaning from morphine. The first clinical use of cocaine for nerve block occurred in 1884 by William Stewart Halsted to create surgical anesthesia. The first modern local anesthetic developed was lidocaine, in the 1940s [195].

Local anesthetics prevent neural transmission through inhibition of fast sodium channels as well as via inhibition of γ-aminobutyric acid in pathways located in the cerebral cortex [196]. Local anesthetics are of either the amide or the ester type and are metabolized via different mechanisms. Local ester anesthetics are metabolized via plasma pseudocholinesterase; local amide anesthetics are metabolized via the liver. It is important to understand that the toxicities of local anesthetics are additive. Therefore, when two local anesthetics are combined, the maximum dose of the local anesthetics must be carefully determined, keeping in mind the overall ratio of each of these medications.

Ever since the first use of cocaine for medicinal purposes, there have been reports of its adverse reactions on the nervous, respiratory, and cardiac systems. In 1885, four publications dealt with serious adverse events, including death. A report by Mayer [197] in 1924 raised medical awareness of the toxic reactions to these medications with a report of 40 fatalities related to local anesthesia.

In pediatric patients, local anesthetic toxicity is relatively rare. Among the largest series that have reviewed complications of regional anesthetics in the pediatric population, Giaufre et al [198] reported a complication rate of four per 10,000 systemic toxic reactions after the performance of epidural injection of local anesthetic. In this series, no systemic toxicity was associated with peripheral nerve blocks.

When neurotoxicity occurs, it typically precedes the more severe cardiotoxicity. In awake patients, tinnitus, a metallic taste in the mouth, and circumoral tingling are frequent initial symptoms. As the blood level of local anesthetics increases, there is progression to motor twitching followed in some by seizures. In those who progress to cardiotoxicity, the manifestations include cardiac arrhythmia and hypotension, with eventual cardiovascular collapse [199]. McClenahan [200] reported the first pediatric death in 1955 after local anesthetic toxicity after the child consumed a dibucaine troche. He described a wide-complex bradycardia unresponsive to conventional treatment with sodium bicarbonate and other medications.

In 2006, Rosenblatt et al [201] reported the first successful use of a 20% lipid emulsion in a human patient during resuscitation after a presumed bupivacaine-related CA. The rationale for the use of lipid emulsion had been introduced by Weinberg et al in 1998 [202] with initial studies in rats and subsequently dogs, demonstrating that lipid infusions both raise the threshold for cardiotoxicity and increase the likehood of survival in rodents receiving a large single intravenous dose of bupivacaine. Ludot et al [203] presented the first case report of successful resuscitation after presumed local anesthetic toxicity in a child. A 13-year-old child received a lumbar plexus block under general anesthetia and subsequently experienced ventricular tachycardia 15 min after the injection of lidocaine and ropivacaine with epinephrine. Plasma levels of local anesthetics were obtained during early resuscitation and indicated local anesthetic toxicity. Within 2 min of intralipid administration, normal sinus rhythm was

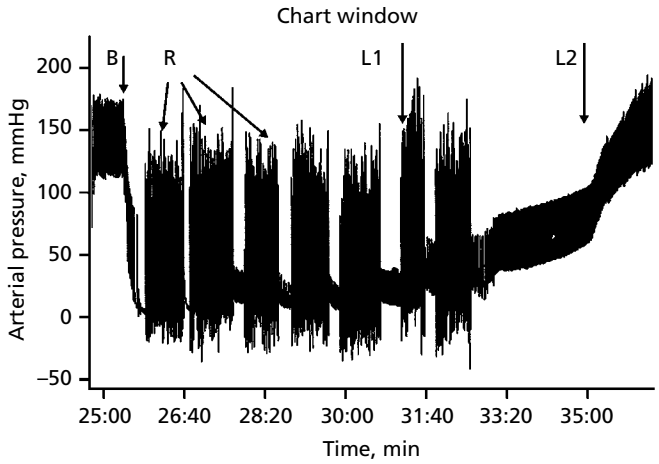

Figure 45.11 Hemodynamic response to lipid infusion. The arterial pressure trace of a rat is shown over approximately 12 min. The arrow at B indicates intravenous injection of bupivacaine 20 mg/kg over 20 s. The arrows at R indicate resuscitation by closed chest compression. The L1 arrow indicates infusion of 30% soybean oil emulsion 5 mL/kg over 10 s. The recovery of the hemodynamic profile occurs after the second lipid bolus, L2 (arrow). *Source:* Reproduced from Weinberg [205] with permission of Wolters Kluwer.

achieved [203]. Experience in animals and humans suggests that intravenous lipid emulsion increases the lethal threshold and decreases mortality after systemic overdose of local anesthetics [204]. This finding represents an important advance in the care of both adults and children, given that CPB has traditionally been the therapy of last resort in adults and children with CA secondary to local anesthetic overdose [205].

Mechanism of action of lipid emulsion

The "lipid sink" theory described by Weinberg suggests that local anesthetic is sequestered in the plasma lipid fraction, thereby isolating tissue from the toxic effect [205]. Lipid may also have a direct inotropic effect on the heart and that effect may contribute positively to its ability to reverse bupivacaine-induced cardiac depression (Fig. 45.11) [205].

Clearly, evidence supports the early use of lipid emulsion in the treatment of local anesthetic toxicity. Rather than wait for progression to a non-productive or unstable rhythm, treatment with lipid emulsion should be initiated as soon as possible. Weinberg suggested that lipid emulsion should be used at the earliest signs of local anesthetic toxicity, for example when the neurological signs and symptoms appear and before the onset of more serious cardiac manifestations [205]. Subsequently, Shah et al [206] reported the successful use of a lipid emulsion in a 40-day-old infant with presumed local anesthetic toxicity after caudal injection.

In 2010, the American Society of Regional Anesthesia and Pain Medicine published guidelines for the prevention and treatment of local anesthetic toxicity. According to Weinberg's recommendations [205], a dose of 1.5 mL/kg of lipid emulsion 20% can be repeated to a maximum dose of 10 mL/kg over the first 30 min [207]. At the point of conversion to sinus rhythm, infusion of lipid emulsion 20%, at a rate of 0.25 mL/kg/min should be continued until hemodynamic recovery. The initiation of intralipid infusion is often needed because the sequelae of local anesthetic systemic toxicity can potentially persist or recur even hours after the initial exposure. Given this potential, monitoring of patients should continue for at least 12 h, particularly if there has been evidence of severe cardiovascular compromise.

While life saving, adverse effects from intravenous lipid emulsion administration have been reported. A recent systematic review identified over 100 studies and found adverse effects associated with intravenous lipid emulsion administration to include acute kidney injury, cardiac arrest, ventilation/perfusion mismatch, acute lung injury, venous thromboembolism, hypersensitivity, fat embolism, fat overload syndrome, pancreatitis, extracorporeal circulation machine circuit obstruction, allergic reaction, and increased susceptibility to infection [208]. Adverse effects appear proportional to total dose received and rate of infusion [208].

The role of more conventional medications used during resuscitation from local anesthetic overdose has been investigated. There is evidence for impairment of lipid-based resuscitation with a single dose of epinephrine of 10 μg/kg or greater. Dose–response trials suggest small epinephrine doses (1–2.5 μg/kg) may be advantageous in terms of rapid recovery; however, higher doses of epinephrine appear to adversely affect both metabolic and hemodynamic recovery profiles. Although experimental animals treated with high-dose epinephrine had earlier return of circulation than the saline-treated or lipid-treated controls, this earlier return of circulation did not translate to sustained hemodynamic stability and, in fact, contributed to their mortality [209]. Likewise, studies in swine that included the use of vasopressin and epinephrine along with lipid administration demonstrated that survival was not improved with this practice [210]. Despite the fact that propofol is formulated in a 10% lipid emulsion, it should not be used as a substitute for lipid administration because a fatal dose of propofol would have to be administered to achieve a therapeutic level of lipid. Propofol also may cause dose-related bradycardia and hypotension and can potentially further impair myocardial contractility in the setting of local anesthetic toxicity [196].

The prevention of local anesthetic systemic toxicity is of utmost importance and is possible via careful choice and dosing of local anesthetics, aspiration prior to injection, dose fractionation, and the use of ultrasound to prevent intravascular injection [211].

Summary

Local anesthetic systemic toxicity, although a rare event, can have devastating consequences. It has been suggested that every facility that administers local anesthetics to patients should assure the rapid availability of lipid emulsion for the treatment of toxicity [201]. Lipid emulsion should be used early in treatment, even before the devastating effects of cardiotoxicity have occurred. As previously described, the initial dose of lipid emulsion 20% is 1.5 mL/kg. This dose could be repeated to a maximum dose of 10 mL/kg in the first 30 min – which has been made easier by new, more concentrated formulations. At the point of return of hemodynamic stability, consideration should be made for initiation of an infusion at the rate of 0.25 mL/kg/min. Because local anesthetic toxicity may recur even after hemodynamic stability, patients should be monitored for at least 12 h if there has been evidence of cardiovascular compromise. In addition, during

resuscitative efforts, attention must be paid to standard cardiopulmonary resuscitation and include provision of adequate oxygenation and ventilation, seizure termination, and maintenance of circulation which may include early initiation of extracorporeal mechanical support. The use of epinephrine in doses higher than 10 μg/kg, administered along with lipid emulsion therapy, may not translate to improved survival and may even contribute to higher mortality. Smaller doses of epinephrine limited to 1–2.5 μg/kg may be tolerated well during resuscitation. Similarly, the addition of vasopressin to this regimen is not recommended, although additional research may be necessary to fully elucidate the effects of more traditional therapy when combined with lipid emulsion therapy.

KEY POINTS: LOCAL ANESTHETIC TOXICITY AND INTRALIPID ADMINISTRATION

- Local anesthetics prevent neural transmission through inhibition of fast sodium channels as well as via inhibition of γ-aminobutyric acid in pathways located in the cerebral cortex
- Lipid emulsion should be used early in treatment, even before the devastating effects of cardiotoxicity have occurred
- Prevention of local anesthetic systemic toxicity is of utmost importance and possible via careful choice and dosing of local anesthetics, aspiration prior to injection, dose fractionation, and use of ultrasound to prevent intravascular injection

Nerve and positioning injuries

The anesthesiologist is primarily responsible for the safe and comfortable positioning of the surgical patient during the operative period. Despite great care and attention, nerve injuries do occur and can lead to temporary, or rarely, permanent disability. Perioperative peripheral neuropathy refers to postoperative signs and symptoms related to peripheral nerve injury (e.g. brachial plexus, sciatic, femoral), manifested by paresthesias, muscle weakness, tingling, or pain.

Few data directly address positioning injuries in children. Clinical practice is therefore primarily dependent on data extrapolated from adult studies to the pediatric population. The incidence of peripheral nerve injuries in pediatric patients appears to be much lower than that among adults although data are limited to a handful of case reports. Morray et al [17], using the ASA Closed Claims database, found that the rate of peripheral nerve injuries in children was only 1% of claims, whereas in adults the figure was 16%. Given that pediatrics represents about 10% of all anesthetics performed, these data tend to confirm the sense that positioning injury is recognized less frequently in children than in adults.

In an adult population, Welch et al [212] evaluated a total of 380,680 anesthetics administered over a 10-year period; only 112 were associated with a nerve injury (0.03%). In that study, nerve injury was defined as a new sensory and/or motor deficit. Nerve injuries from the surgical procedure itself were excluded. This series represents the largest number of consecutive patients ever reviewed for all types of perioperative peripheral nerve injuries. In this study [212], as in others, it was difficult to define nerve injury related to positioning because existing deficits, injuries occurring in the postoperative period, and predisposing conditions make case finding challenging. In that study, by far the most common of the positioning-related injuries was that affecting the ulnar nerve [212]. Table 45.6 is a simplified guide to the recognition of various nerve injuries [213].

Table 45.6 Simplified clinical identification of major peripheral nerve injuries

Nerve	Injury
Arm	
Median nerve	Numbness over the index finger; weakness of abduction of the thumb
Ulnar nerve	Numbness over the little finger; weakness of abduction and/or adduction of the fingers; weakness of flexion at the distal interphalangeal joints of the little and ring fingers if the lesion is at the elbow
Radial nerve	Weakness of extension at the distal interplanalgeal joint of the thumb and of the wrist and finger extensors
Musculocutaneous nerve	Weakness of flexion of the elbow
Circumflex nerve	Weakness of abduction of the shoulder
Brachial plexus	Various combinations of lesions within the median, ulnar, radial, musculocutaneous, and circumflex nerve territories
Leg	
Femoral nerve	Weakness of flexion of the hip; numbness over the thigh
Obturator nerve	Weakness of adduction of the hip
Sciatic nerve	Weakness of ankle dorsiflexion and plantar flexion; weakness of knee flexion, if the lesion is proximal; numbness below the knee
Common peroneal nerve	Weakness of dorsiflexion of the ankle and toes
Tibial nerve	Weakness of plantar flexion of the ankle and toes

The updated practice advisory for the prevention of perioperative peripheral neuropathies published by the ASA in 2011 provides guidance that, although directed primarily at adult patients, can be useful for children as well [214]. Even when the ASA guidelines are followed, injury may not be preventable in all patients secondary to predisposing conditions. Welch et al [212] demonstrated that certain populations may be more likely to have perioperative positioning injuries due to co-morbid conditions. This study reported associations with the following surgical specialties: neurosurgery, cardiac surgery, general surgery, and orthopedic surgery. Medical co-morbid conditions such as hypertension, tobacco use, and diabetes mellitus were also associated with peripheral nerve injuries in the perioperative setting. It is interesting to note that this study [212] did not demonstrate an increased frequency in peripheral nerve injuries in patients maintained in

a prolonged lithotomy position, although it has been shown in previous studies [215] that the lithotomy position for more than 2 h has been a major risk factor for injury. Upper extremity nerve injuries were more common than lower extremity injuries. During this study, three different databases were examined [212]. Sensory deficits were slightly more frequent in one database, whereas motor deficits were more frequent in another, and, not surprisingly, patients with a motor component to their injury were more likely to pursue legal measures.

Ischemia and infarct are mechanisms of localized injury to the peripheral nerves of an anesthetized patient. Winfree and Kline [216] indicated that the disruption of blood supply to the nerves is integral to the mechanism of injury. Thus, it is reasonable to consider that patients with disease states that affect blood flow might have a higher frequency of positioning injuries. Pediatric patients, who are less likely to have some of the above co-morbid conditions, may have a lower frequency of peripheral nerve injuries due to positioning.

Although rare, the potential for nerve injury in children should not be ignored. Careful positioning, special attention to those at greatest risk, and awareness of nerve injury as a cause of postoperative pain and limited mobility, even in the non-verbal or preverbal child, should be maintained.

KEY POINTS: NERVE AND POSITIONING INJURIES

- The anesthesiologist is primarily responsible for safe and comfortable positioning of the surgical patient during the operative period
- Perioperative peripheral neuropathy refers to postoperative signs and symptoms related to peripheral nerve injury manifested by paresthesias, muscle weakness, tingling, or pain
- Although uncommon, the potential for nerve injury in children is present and mostly preventable through careful positioning and care towards those at greatest risk

Perioperative vision loss

In addition to peripheral neuropathy and subsequent neurological deficits, the occurrence of postoperative vision loss (POVL) is of particular concern during the performance of certain procedures. POVL is a devastating but fortunately rare complication most prevalent after cardiac, spine, head and neck, certain orthopedic procedures, and cases performed in the steep Trendelenburg position. POVL can occur after injury at any site in the visual pathway from the cornea to the occipital lobe. POVL can range from transient blurring or loss of vision to permanent bilateral blindness. The exact incidence of POVL is unknown. Estimates of the rate of POVL in the USA by type of surgery ranges between 0.12 for appendectomy to 8.64 for cardiac surgery per 10,000 [217]. The causes of POVL are threefold: ischemic optic neuropathy (including anterior and posterior types), central retinal occlusion, and cortical blindness [218]. A number of factors which may be under the control of the anesthesiologist have been identified as being associated with POVL, including patient positioning, intraoperative hypotension, and blood loss. Patients who had ischemic optic neuropathy had longer periods in the prone position with a larger estimated blood loss compared with those patients with central retinal artery occlusion. The majority of patients with ischemic optic neuropathy had both eyes affected whereas central retinal artery occlusion is almost always unilateral. Recovery of vision is more likely in ischemic optic neuropathy, with 44% of patients recovering their vision compared with 0% recovery in the central retinal artery occlusion group [219]. Etiology of ischemic optic neuropathy is unknown and possibly multifactorial; it is more commonly associated with large blood loss, hypotension, anemia, the prone position, and/or vaso-occlusive disease, although specific etiologies for anterior and posterior ischemic optic neuropathy may differ [220,221]. Conversely, the etiology of central retinal artery occlusion is thought to be caused by direct pressure on the globe from facemasks or cushions when the patient is in the prone position, by emboli, or by low perfusion pressure in the retina [220].

POVL requires urgent ophthalmological consultation for diagnosis and treatment of potentially reversible causes of visual loss. Immediate evaluation should include an assessment of pain, visual deficits, and pupillary light reflex. The best strategy to manage POVL is to make every effort to prevent it. Maintenance of stable hemodynamics, utilization of invasive monitoring (intra-arterial catheter), positioning the head in a neutral or slightly above the level of the heart position, with frequent eye checks should be the goal of an anesthesiologist.

No proven beneficial treatment for POVL related to ischemic optic neuropathy has been identified. It usually consists of attempts to normalize hemodynamics and hemoglobin. Head elevation is of theoretical benefit in cases with significant facial edema such as after prone spinal fusion surgery. High-dose steroids, hyperbaric oxygen, and mannitol have been used without consistent results [222]. Similarly, some conservative measures of uncertain efficacy for central retinal artery occlusion have been tried, including the inhalation of a mixture of 95% oxygen and 5% carbon dioxide (carbogen), anterior chamber paracentesis, and administration of acetazolamide. Intra-arterial thrombolysis is controversial and carries significant risk [223]. POVL is often thought of as being associated with spinal surgery; however, other surgical procedures may be complicated by problems similar to those encountered during prolonged spinal procedures and might also be associated with this complication. Indeed, Lee et al [224] reported on the first case of POVL caused by anterior ischemic optic neuropathy in a pediatric patient who underwent cranial vault reconstruction (Fig. 45.12). Since cranial vault reconstruction is often associated with the possibility of a large volume of blood loss and prolonged surgery often in the prone position, and occasionally the need for controlled hypotension, these conditions increase the chance for ischemic optic neuropathy. The child described by Lee et al [224] had an uneventful anesthetic and immediate postsurgical recovery but was readmitted on postoperative day 6 with bilateral blindness.

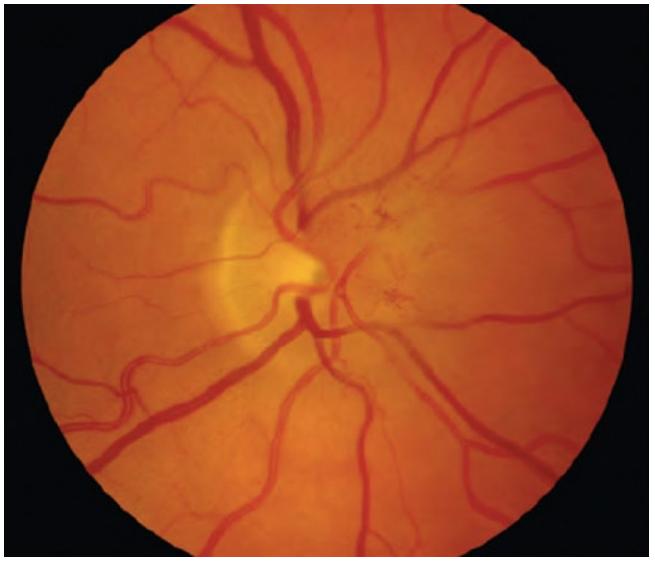

Figure 45.12 Acute (non-arteritic) anterior ischemic optic neuropathy. Blurring of the optic disk margin is from edema. Peripheral hemorrhage is noted superiorly and to the right of the disk. *Source:* Reproduced from Lee [257] with permission of Wolters Kluwer.

KEY POINTS: PERIOPERATIVE VISION LOSS

- POVL is a devastating but fortunately rare complication most prevalent after cardiac, spine, head and neck, certain orthopediac procedures, and cases performed in the steep Trendelenburg position
- POVL can occur after injury at any site in the visual pathway from the cornea to the occipital lobe
- The best strategy to manage POVL is to make every effort to prevent it. Maintenance of stable hemodynamics, utilization of invasive monitoring when indicated, positioning the head in a neutral or slightly above the level of the heart position, with frequent eye checks should be the goal of an anesthesiologist

Anaphylaxis and its treatment

Anaphylactic reactions are immediate, hypersensitivity reactions that are potentially life threatening and are classified according to the World Health Organization as allergic anaphylaxis (immune) rather than non-allergic (anaphylactoid), and that result in the release of mediators from mast cells and basophils [225]. Anaphylaxis is a progressive, potentially fatal, immunoglobulin E (IgE)-mediated reaction associated with histamine release into the systemic circulation. Upon histamine release, hypotension, edema, and hypoxia, even circulatory arrest and death, may occur. To improve survival and outcome, rapid diagnosis and treatment are important. Multiple factors may lead to anaphylaxis (e.g. food allergies, insect stings, drugs); however, up to 20% of patients treated for anaphylaxis have no identifiable cause [226]. This section focuses on drug-induced anaphylaxis in the perioperative period.

Definition

In 2006, the Second Symposium on the Definition and Management of Anaphylaxis recommended the following definition: "Anaphylaxis is a serious allergic reaction that is rapid in onset and may cause death" [227]. Due to the powerful sequelae of histamine release into the systemic circulation, immediate diagnosis and treatment are of utmost importance. Anaphylaxis is due to an IgE-mediated, immediate hypersensitivity reaction, resulting in the immediate release of potent chemical mediators from mast cells and basophils. Histamine is the predominant mediator released, followed by prostaglandin D2, leukotrienes, platelet-activating factor, tryptase, and eosinophil and neutrophil chemotactic factors. In contrast, anaphylactoid reactions are not IgE mediated, do not require previous contact with a substance, and cannot be distinguished clinically from anaphylaxis [225]. The most important organ systems affected by anaphylactic reactions are the cutaneous, respiratory, cardiovascular, and gastrointestinal systems [228].

Epidemiology

The incidence of anaphylactic reactions in the perioperative period ranges from one in 10,000 cases to one in 20,000 cases [229]. Unfortunately, incidence data are often underestimated because of under-reporting. Interestingly, 90% of anaphylactic reactions appear at anesthesia induction. Mortality rates are reported to be between 3% and 9%. Most of the deaths related to anaphylaxis are drug induced, followed by food- and insect sting-related causes. Data regarding pediatric anaphylaxis in the United States vary because of insufficient reporting in the pediatric population and discrepancies in the definition of anaphylaxis. Data from 2004 estimated the incidence of anaphylaxis among children and adolescents to be 10.5 episodes per 100,000 person-years [230], lower than the incidence in the general population.

Overall, in the United States, the lifetime prevalence of anaphylaxis is reported to be 1.6%, while in other industrialized countries it ranges between 0.05% and 2% [231]. The population of the United States seems to have a higher incidence of anaphylaxis compared with that in other countries. Factors such as expansion of diet and increasing use of peanut products in foods have been attributed to this finding. Children and adolescents with atopic conditions are at an increased risk of anaphylaxis. Genetics and racial differences do not seem to play a role; however, any patient who has had an anaphylactic reaction is at increased risk of recurrence. The severity of the previous anaphylactic reaction does not predict the severity of the recurring reaction [228].

In regard to anaphylactic reactions within the perioperative period, non-depolarizing neuromuscular blocking agents (NMBAs) and antibiotics are at the top of the list of offending agents. The incidence of anaphylactic reactions during anesthesia varies widely between counties, ranging from 1:1,200 to 1:20,000 per procedure with substantial geographical variability in different drugs or substances reported [225,232]. While once a common offender of perioperative anaphylaxis, reactions to latex are decreasing as a result of increased awareness and prevention strategies [232].

Death from anaphylaxis is rare, yet lack of reporting and difficulty diagnosing anaphylaxis posthumously with any

specific test contribute to inaccurate numbers related to morbidity and mortality.

Etiology

Although this section is focused on drug-induced anaphylaxis in the perioperative period, there is some relationship between food allergies and drug-induced anaphylaxis. The incidence of anaphylaxis, in particular food-induced anaphylaxis, continues to rise in developed countries, with the greatest impact on those under 5 years [233]. Food is actually the most common cause of anaphylaxis in children, followed by medications, insect stings, blood products, latex, vaccines, and contrast dye [230,234]. While children can outgrow many food allergies (e.g. milk, eggs, soybeans), certain food allergies persist. Foods causing persistent sensitivity include peanuts, tree nuts, and shellfish. These foods are responsible for more severe and near-fatal and fatal anaphylactic reactions [235].

Among drug-induced anaphylactic reactions, allergy to penicillin is the most common [230]. Among individuals with penicillin allergy, 4–10% have cross-reactivity to other penicillin-related drugs [234]. Some medications contain food-related substances to which food-allergic individuals may react. Propofol, marketed as Diprivan (AstraZeneca, Wilmington, DE, USA), is used for sedation and general anesthesia in children and is contraindicated in patients with egg or soy allergy because it contains egg lecithin and soybean oil [236]. While this egg and soy-based lipid solvent is not thought to be allergenic, there may be cross-contamination with egg or soy protein and case reports implicate propofol in some IgE-mediated reactions in some patients with egg and soy allergy; however, confirmatory evidence in many of these case reports is lacking [236]. On the contrary, several studies have shown propofol to be safely used in egg and soy allergic patients [237]. A recent single-center, retrospective, observational analysis of over 1300 esophagogastroduodenoscopies in patients with a clinical history of egg or soy allergy or eosinophlic esophagitis found no difference in compliation rates [236].

Pathophysiology

The IgE-mediated hypersensitivity reaction has been classically used to describe anaphylaxis (Fig. 45.13). The body is introduced to different allergens via different routes like ingestion, skin contact, or intravenous injections or infusions. Only a small amount of allergen exposure is sufficient for cells to react. On initial exposure to an allergen, IgE isotype antibodies are produced and bind to high-affinity FcεRI receptors located in the plasma membrane of tissue mast cells and blood basophils. Lymphocytes, eosinophils, and platelets bind IgE antibodies via low-affinity FcεRII receptors. This initial antigen sensitization is clinically silent.

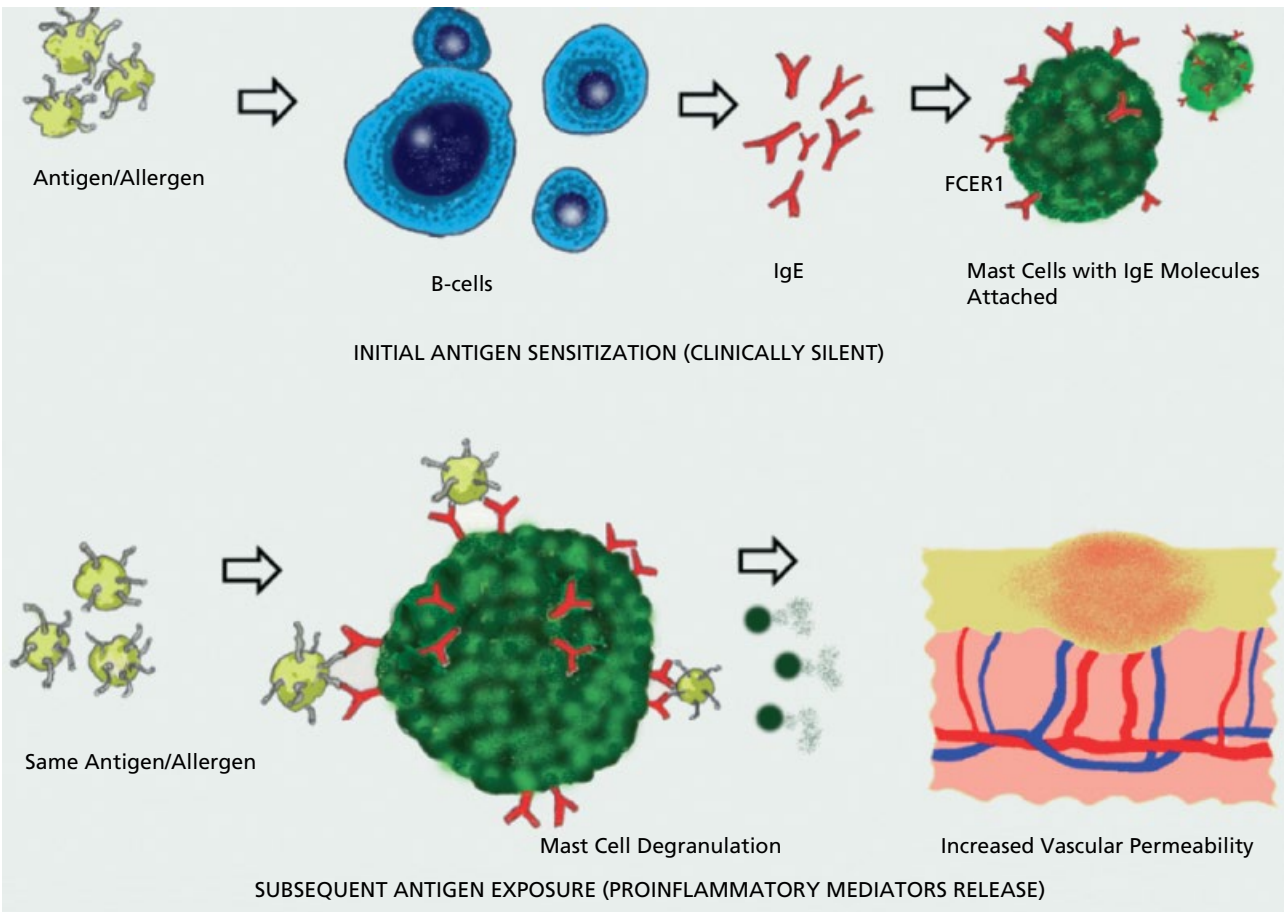

Figure 45.13 Initial antigen sensitization and subsequent antigen exposure in immunoglobulin E (IgE)-mediated allergic reactions. *Source:* Illustration by John Swan II.

On re-exposure, epithelial and endothelial barriers break down. This allows the antigen to come into contact with its specific IgE antibodies. The multimeric allergen cross-links two specific IgE receptors, thereby creating a bridge between two IgEs. The two IgE receptors aggregate and induce a signal transduction cascade releasing systemically preformed biochemical mediators. Histamine is released predominantly from intracellular granules in cells within tissues and blood, followed by neutral proteases (tryptase, chymase) and proteoglycans (heparin). Proinflammatory phospholipid-derived mediators, including prostaglandin D2, leukotrienes, thromboxane A2, and platelet-activating factor, are released soon after. Mast cells then release numerous chemokines and cytokines that initiate recruitment and activation of additional inflammatory cells.

The release of these mediators induces the symptoms of anaphylaxis, i.e. increased vascular permeability with erythema, edema, and pruritus, vasodilation, bronchospasm, and increased smooth muscle tone. Mast cell and basophil activation with subsequent chemical mediator release can also be triggered via activation of the complement system and direct actions on mast cells and basophils; however, the symptoms are indistinguishable from those triggered via IgE.

Timing of reactions

While most anaphylactic reactions occur within minutes of exposure to the offending agent, an additional delayed response is also possible. Delayed reactions may occur up to 72 h after the initial reaction. In addition, inadequate treatment of the initial reaction may predispose individuals to delayed reactions [238]. Route, quantity, and type of antigen do not seem to play a role in delayed reactions. Severity of the initial reaction does not predict the occurrence of a delayed reaction.

Causes of anaphylaxis in the perioperative period

The most common cause of anaphylaxis in the perioperative period is due to NMBAs, with approximately 40–70% of anesthesia-related anaphylaxis thought to be due to NMBAs [226–230,234,235,238–241], followed by antibiotics [242]. Usually, anaphylactic reactions occur shortly after induction, which is especially true for NMBAs and antibiotics, but may occur at any time with all potentially allergenic agents [242]. Latex allergy, which once contributed to a high number of anaphylactic reactions in the perioperative period, is discussed separately in this chapter.

In NMBAs, the quarternary ammonium groups (NH_4^+) on the NMBAs are responsible for the anaphylactic reactions. Quarternary ammonium groups also exist in foods, cosmetics, and drugs. Prior contact with quarternary ammonium groups contained in foods, cosmetics, and drugs may lead to anaphylaxis on subsequent exposure to NMBAs. In addition, NMBAs may trigger mast cell degranulation through activation of nicotinic acetylcholine receptors on cell surfaces [226]. Cross-reactivity between NMBAs occurs in approximately 60–70% of those tested [242].

Antibiotics are also known to cause anaphylaxis, especially in the perioperative period. Specifically β-lactam antibiotics (e.g. penicillins and cephalosporins) and vancomycin seem to trigger anaphylaxis [243]. In regard to vancomycin, direct mast cell activation seems to be the cause. The specificity of skin testing with β-lactams is between 97% and 99%, whereas the sensitivity is about 50% [229].

Anaphylaxis in response to propofol is reported infrequently, whereas anaphylaxis to etomidate and ketamine is extremely rare [240,242]. Anaphylaxis to opioids is very rare as well [240,242].

Anaphylaxis to local anesthetics is uncommon and has decreased in frequency as a result of the reduced use of the ester group of local anesthetics. Most allergic reactions are attributable to the common metabolic product of the ester local anesthetic, para-amino benzoic acid [240,242], which also leads to cross-reactivity among all local anesthetics belonging to the ester group. Allergic reactions to amide local anesthetics remain anecdotal. Ingredients included in local anesthetic solutions such as antioxidants or preservatives, including metabisulfite or parabens, may also elicit allergic or adverse reactions [243]. Cross-reactivity among esters is common, whereas it is rarely seen in the amide group and is absent between esters and amides.

Diagnosis

Because anaphylaxis may progress within minutes to a life-threatening condition, immediate diagnosis is essential. The first line of evidence for the diagnosis of anaphylaxis includes the features and severity of clinical signs as well as the timing between the introduction of a suspected allergen and the onset of symptoms. The amount of resuscitative agents required to treat the occurrence gives insight into the severity of the reaction [242].

Dewachter et al [244] adapted a clinical severity scale from Ring and Messmer [245] to describe perioperative immediate hypersensitivity reactions. Although this scale does not take into account the pathophysiological mechanisms, it is appropriate for grading the clinical severity and guiding the clinical care of immediate reactions [242]. Grades I and II describe cutaneous and cutaneous–mucous signs. Although cutaneous symptoms such as flushing, pruritus, or urticaria may be the first indication of an anaphylactic reaction, these are often missed in the operating room where patients are covered with drapes and blankets. In addition, anesthetized patients cannot verbalize complaints regarding pruritus or nausea. Bronchospasm has been reported to be the first sign of anaphylaxis in the operating room followed by hypotension, hypoxemia, and angioedema, which relates to a grade III reaction [226], followed by CA, which is grade IV. Grades I and II are usually not life-threatening conditions, whereas grades III and IV are emergency situations necessitating prompt resuscitation.

In cases of suspected anaphylaxis, the time of occurrence is important. Appearance of symptoms within minutes of anesthetic induction implicates an intravenous agent. Reactions 15 min or more after induction suggest skin or mucous membrane contact of the offending compounds. Biphasic reactions, with an initial event followed by a second delayed reaction, have been described to occur in 6–23% of patients with

Box 45.3: Clinical criteria for diagnosing anaphylaxis

Anaphylaxis is highly likely when any *one* of the following three criteria are fulfilled:

1. Acute onset of an illness (minutes to several hours) with involvement of the skin, mucosal tissue, or both (e.g. generalized hives, pruritus or flushing, swollen lips–tongue–uvula) *and at least one of the following:*
   a. Respiratory compromise (e.g. dyspnea, wheeze–bronchospasm, stridor, reduced PEF, hypoxemia)
   b. Reduced BP or associated symptoms of end-organ dysfunction (e.g. hypotonia (collapse), syncope, incontinence)
2. Two or more of the following that occur rapidly after exposure *to a likely allergen for that patient* (minutes to several hours):
   a. Involvement of the skin–mucosal tissue (e.g. generalized hives, itch–flush, swollen lips–-tongue–uvula)
   b. Respiratory compromise (e.g. dyspnea, wheeze–bronchospasm, stridor, reduced PEF, hypoxemia)
   c. Reduced BP or associated symptoms (e.g. hypotonia (collapse), syncope, incontinence)
   d. Persistent gastrointestinal tract symptoms (e.g. crampy abdominal pain, vomiting)
3. Reduced BP after exposure to *known allergen for that patient* (minutes to several hours):
   a. Infants and children: low systolic BP (age specific) or greater than 30% decrease in systolic BP*
   b. Adults: systolic BP of less than 90 mmHg or greater than 30% decrease from that person's baseline

* Low systolic BP for children is defined as less than 70 mmHg from 1 month to 1 year; less than (70 mmHg + [2 × age]) from 1 to 10 years; and less than 90 mmHg from 11 to 17 years.

BP, blood pressure; PEF, peak expiratory flow.

anaphylaxis [228]. Delayed reactions can occur up to 72 h after the initial reaction. Insufficient treatment with epinephrine during the initial reaction increases the risk of a delayed reaction.

Box 45.3 shows the clinical criteria for diagnosing anaphylaxis. This table was developed by the participants of the Second Symposium on the Definition and Management of Anaphylaxis, which was thought to capture at least 95% of the cases of anaphylaxis [227]. It is important to notice that the criteria listed refer to patients not undergoing anesthesia at the same time as there is suspicion for an anaphylactic reaction.

The manifestations of anaphylaxis during anesthesia can be different from anaphylaxis not associated with anesthesia, making the diagnosis of perioperative anaphylaxis more challenging. For example, symptoms such as malaise, pruritus, dizziness, and dyspnea can be difficult to ascertain in an unconscious patient. The most commonly reported objective features include pulselessness, ventilation difficulty, decreased end-tidal CO_2, and desaturation [246].

Laboratory tests

During acute management of anaphylaxis, no test is needed to confirm the diagnosis; however, if the diagnosis is uncertain, elevated levels of histamine, serum tryptase, or both may be helpful [228]. Histamine and tryptase are the major components released during mast cell degranulation. While histamine is the major compound released during anaphylaxis, its detection is difficult because of its short plasma half-life of 15–20 min. After a grade I or II reaction, blood samples for histamine measurement should be drawn within 30 min. After severe reactions (grades III and IV), histamine may still be increased 2 h after the reaction. Saturation of the enzymatic metabolism of histamine is the suggested mechanism that allows detection of increased histamine levels for this prolonged period after the reaction [247].

Tryptase is a mast cell neutral serine protease and a preformed enzyme. Two major forms – α-tryptase and β-tryptase – have been identified [240]. While α-tryptase is increased in mastocytosis, pro-β-tryptase serves as a measure of mast cell mass. Mature β-tryptase is preferentially stored in mast cell granules, and when systemically released, reflects mast cell activation with mediator release. Serum tryptase concentrations reach a peak between 15 and 60 min, with a half-life of approximately 2 h [240,242]. In grade I or II reactions, blood samples may be drawn within 15 and 60 min, and within 30 min and 2 h in grade III or IV reactions [242]. An increase of total tryptase concentrations (i.e. the sum of α-tryptase and β-tryptase) is highly suggestive of mast cell activation as seen in anaphylaxis, but its absence does not exclude the diagnosis. Some studies have demonstrated low sensitivity of tryptase levels in the diagnosis of anaphylaxis [240].

As a result of an immediate non-allergic reaction (e.g. histamine release), histamine may be increased, whereas tryptase remains normal. Because histamine and tryptase concentrations correlate with the severity of the allergic reaction, combined histamine and tryptase measurements have been recommended for the diagnosis of immediate reactions, whereas others recommend only tryptase [240,242].

More specific testing should be done in patients who have more than just cutaneous symptoms. Specific IgE testing can be done 2–3 weeks after an anaphylactic reaction. Skin testing is more sensitive than measuring IgE-specific antibodies and remains the gold standard for the detection of IgE-mediated reactions by exposing the mast cells of the skin to the suspected allergen in patients who have had anaphylaxis [229].

Premedication with H1- or H2-receptor antagonists, with corticosteroids, or with a combination of these agents have not been proven to prevent anaphylaxis [242]. Therefore, skin tests allow identification of the offending agent and demonstrate the pathophysiological mechanism of the reaction (allergic versus non-allergic). A 4–6-week delay after the reaction is required to avoid a false-negative test result because of mast cell depletion [242]. After the final test results, patients should be given a detailed report to provide to caregivers prior to future anesthetic exposures.

Management and treatment

The management of patients in whom anaphylaxis develops in the perioperative period is challenging. Most of these patients will have received multiple medications and present with more advanced symptoms, and their

condition progresses faster than in other settings. Anaphylaxis during anesthesia is especially challenging since most of the time the initial symptoms of urticaria or erythema are not observed because the patients are covered by drapes. It is important for all people involved in the care of these patients to help identify the cause so that future exposures can be avoided [226].

Due to its severity, the diagnosis and treatment of anaphylaxis must occur simultaneously. Treatment is directed toward managing the most severe symptoms, including cardiovascular collapse, bronchospasm, and airway edema. Initiation of intravenous epinephrine and other therapies and expeditious interruption of suspected causative agents must go hand in hand. In addition to ventilation with 100% oxygen, volume support and definitive airway managment are required [226]. Patients should be placed supine in the Trendelenburg position, and the surgical procedure abbreviated if possible when anaphylaxis occurs intraoperatively.

The administration of intravenous epinephrine and expansion of intravascular volume are essential to the perioperative management of anaphylaxis [240,242]. Epinephrine's α-agonistic effects reverse vasodilation, while its β-agonist effects treat bronchospasm and the release of inflammatory mediators. Because epinephrine has a short half-life, repeated doses or a continuous infusion may be necessary. There is no absolute contraindication during anaphylaxis for the use of epinephrine, and early administration should be the rule [240,242].

Due to the increased vascular permeability, fluid therapy with crystalloid or colloid solutions should be initiated immediately. Bronchospasm is treated with an inhaled β_2-agonist (albuterol) [240,242]. Given that cardiovascular collapse and bronchospasm occur together, epinephrine remains the first-line therapy as it corrects both cardiovascular disturbances as well as bronchoconstriction through its β_2-adrenergic effects. Intravenous corticosteroids early in the course of therapy are recommended because of their anti-inflammatory effects, although the beneficial effects are delayed at least 4–6 h [242]. Corticosteroids, H1-receptor antagonists, or both are often recommended, with varying success, in the management of anaphylaxis [240,242].

Affected patients are sometimes unresponsive to catecholamines, possibly because of desensitization of adrenergic receptors. The use of arginine vasopressin may be an alternative as its vasoconstrictive effects are mediated by non-adrenergic vascular arginine vasopressin V1 receptors [248].

Summary

Perioperative anaphylaxis is a severe and rapid clinical condition that can lead to mortality even in previously healthy patients. Because of its infrequent presentation and variable clinical presentation, perioperative anaphylaxis may not be diagnosed immediately. The severity of symptoms as well as the rapidity of symptom progression demands prompt and aggressive treatment. The combination of clinical, biochemical, and skin test evidence will identify the responsible agent and allow the patient to avoid these agents in the future.

KEY POINTS: ANAPHYLAXIS AND ITS TREATMENT

- Anaphylactic reactions are immediate, hypersensitivity reactions that are potentially life threatening and are classified according to the World Health Organization as allergic anaphylaxis (immune) rather than non-allergic (anaphylactoid), and thatresult in the release of mediators from mast cells and basophils
- The most common causes of anaphylaxis in the perioperative period are NMBAs
- The clinical manifestation of anaphylaxis during anesthesia can be challenging because initial symptoms of malaise, pruritus, dizziness, and dyspnea can be difficult to ascertain in an unconscious patient. The most commonly reported objective features include pulselessness, ventilation difficulty, decreased end-tidal CO_2, and oxygen desaturation

Latex allergy

Natural rubber latex (NRL) is derived from the rubber tree, *Hevea brasiliensis*, one of over 200 lactifer-type plants belonging to the family Euphorbiaceae [249]. Among numerous compounds released by NRL, the heat-stable proteins retained in NRL are responsible for the adverse events. Although the risks of hypersensitivity as well as anaphylactic reactions to latex are well recognized, the frequency of events have been reduced in the past few years by increased awareness and prevention measures [225,232]. In addition to healthcare workers, children with atopy and spina bifida and those undergoing frequent procedures requiring surgical instrumentation are at increased risk. Among all the products containing NRL in the healthcare environment, surgical gloves made from NRL have the highest prevalence for latex sensitization. Overall, the continued use of latex and the resulting sequelae of allergic reactions impose a high cost in terms of patient risk as well as provider risk and a financial burden to the healthcare system [250].

History

The use of latex items can be tracked back to 1600 BCE in ancient Mesoamerica; however, surgical gloves came into common use in the early 20th century. Descriptions of allergic reactions to NRL appeared in the medical literature by 1927, but the description of an immediate allergic reaction to NRL was not published until 1979. Since 1980, the allergic potential of NRL has been more widely recognized, and different approaches have been taken to study latex sensitivity [251].

Epidemiology

Due to differences in populations studied and methods used to verify sensitization, the reported prevalence of latex allergy in the general population varies widely, ranging from

less than 1% to 6.7% [250]. A French survey obtained between 1989 and 2001 reported that latex was the second highest cause of perioperative accidents, at a rate of 27%. The healthcare environment has the highest incidence of latex sensitivity, ranging form 3% to 17% [252]. Anesthesiologists themselves have a high prevalence of latex senitization [253]. As mentioned above, gloves made from NRL have been associated with the greatest prevalence of sensitization in the hospital setting.

Mechanism of sensitization

Frequent exposure remains the main cause of sensitization. This finding resulted in the recommendation that children undergoing frequent surgical procedures, for example children with spina bifida, should be handled latex-free from the very beginning of their management. As a result of this initiative, these children are automatically listed as being latex sensitive. In addition, children with atopy are at increased risk, especially children with food allergies to tropical fruits such as avocado, kiwi, and banana. Some evidence suggests that genetic profiles may potentiate latex reactions to hevein (HLA-DR phenotypes) [250]. The route of exposure may also play a role. In the case of NRL, skin exposure and inhalation exposure are more common. Skin exposure is of particular importance because it may result in airway hyper-reactivity leading to allergen-induced asthma [254]. Independent of the exposure, patients with latex sensitivity develop increased levels of IgE-specific latex protein. Increased IgE levels are responsible for the symptoms, and IgE levels may increase with increased exposure frequency.

Identification of patients at risk

The identification of patients at risk relies primarily on the history but may be aided by the use of questionnaires developed specifically to aid in identification of these patients. Although some patients initially present with only cutaneous symptoms, cardiovascular symptoms as well as bronchospasm are common clinical features. Cutaneous manifestations are often inapparent as patients in the operating room are typically covered by drapes. As a consequence, the initial manifestation may be increased airway resistance manifested by high airway pressures and wheezing rapidly followed by cardiovascular collapse. Typically, these events occur within 30–60 min after induction [240].

Diagnostic methods

While obtaining a thorough patient history may suggest the diagnosis of latex allergy, specific laboratory tests are needed to confirm the diagnosis. Currently two tests are available: the skin prick test and detection of IgE specific to latex protein (radioallergosorbent test). Skin prick tests are inexpensive, sensitive, and specific; however, they must be performed in the physician's office with appropriate precautions because of the real risk of anaphylaxis. The sensitivity of the measurement of latex-specific IgE is lower than that for the skin prick test, being positive in only 60–90% of sensitized patients [250]. With first exposure, patients produce latex-specific IgE, and the levels increase with each subsequent exposure. Sensitivity of the measurement of latex-specific IgE depends on the number of prior exposures.

Box 45.4: Recommendations for primary prevention of latex allergy (reducing exposure to latex protein to prevent sensitization for latex)

- Bring a latex-free cart into the room
- Use a latex-free reservoir bag, airways, and endotracheal tubes, and laryngeal mask airways
- Use a non-latex breathing circuit with plastic mask and bag
- Ventilator must have non-latex bellows
- Use IV tubing without latex ports; utilize stopcocks if available
- Cover all rubber injection ports on IV bags with tape and label in the following way:
  Do not inject or withdraw fluid through the latex port. Note: pulmonary artery catheters (especially the balloon), central venous catheters, and arterial lines may all contain latex components
- Use non-latex gloves
- Use non-latex tourniquets, electrodes, and examination gloves
- Draw medication directly from opened multidose vials (remove stoppers) if medications are not available in ampoules
- Utilize latex-free syringes, bladder catheter, and nasogastric tubes
- Use stopcocks to inject drugs rather than latex ports
- Minimize mixing/agitating lyophilized drugs in multidose vials with rubber stoppers

IV, intravenous.

Prevention in patients at risk

The first line of prevention is identification of children at risk. Creation of a latex-free or latex-sensitive environment within the perioperative area is desirable and encouraged. Complete avoidance of latex products prevents severe anaphylactic reactions. Indeed, De Queiroz et al [250] reported that since the creation in one institution of a latex-free environment in all operating rooms and perioperative areas in 2002, no latex anaphylactic reactions have occurred after more than 25,000 procedures over a period of 5 years.

A latex-free protocol should include a checklist on how to manage children with latex allergy in every department involved in the care of children. Arrangements for a latex-free environment need to be made not only for the operating room but also for the recovery room and postoperative period. Communication between the different care teams (anesthesiologist, surgeon, nurses) is crucial. In the operating room, there should be a cart with latex-free equipment readily available to be used in these patients. Box 45.4 summarizes the recommendations for the prevention of latex allergy [250].

Aerosolized latex allergen from previous cases requires at least 90 min to clear. The recommendation is to schedule elective procedures as first cases since levels of aerosolized latex allergens are at the lowest level then. Otherwise, a time gap of 90 min should be allowed to lower latex allergen levels between patients [250].

Pre-emptive use of medication to reduce allergic reactions is controversial. Although there have been recommendations to use medications such as diphenhydramine, cimetidine, and prednisone prophylactically, the current opinion is not to do so. In addition, premedication is not necessarily successful in preventing latex anaphylaxis and might even mask the initial immune response [250].

In children where latex exposure can not be completely avoided, desensitization may be an option. Sublingual, subcutaneous, or percutaneous desensitization may improve cutaneous reactions as well as improve rhinitis and asthma.

Prevention: complete avoidance

Complete avoidance of latex in the perioperative care areas is the most effective way to prevent sensitization to latex. The American College of Allergy, Asthma, and Immunology released recommendations to avoid latex material in healthcare institutions [255]. Indeed, since children at risk are better identified, the incidence of latex allergy has markedly decreased. There are numerous reports of reduction of latex sensitization with the implementation of a latex-free perioperative environment. In addition, avoidance of latex can reduce latex-specific IgE in these patients and the progression of symptoms.

Although latex is ubiquitous in medical equipment and devices, manufacturing of single-use latex-free items has improved tremendously. In addition, there is more emphasis by manufacturers on labeling items to identify potential latex content. To maintain a latex-free perioperative environment requires continuous meticulous effort by all healthcare workers involved as well as continuous education among healthcare staff. After all, anaphylactic reactions to latex are most commonly encountered in the perioperative period.

KEY POINTS: LATEX ALLERGY

- The risks of anaphylactic reactions to latex are well recognized; however, the frequency of events have been reduced in the past few years by increased awareness and prevention measures
- Complete avoidance of latex in the perioperative care areas is the most effective way to prevent sensitization to latex
- Children undergoing frequent surgical procedures (spina bifida, bladder exstrophy) should be handled latex free from the very beginning of their management

CASE STUDY

An otherwise healthy, 6-month-old, 7.5 kg male underwent combined general and caudal anesthesia for a distal hypospadias repair. After placement of standard monitors, an inhalation induction was accomplished with sevoflurane and oxygen, a 22 G peripheral IV was inserted, and tracheal intubation was accomplished with a 3.5 mm cuffed endotracheal tube, without muscle relaxants after a 1.5 mg/kg bolus of propofol. The patient was turned to the right lateral decubitus position, and after confirming normal anatomy of the sacral region by inspection and palpation, the area was prepped with 2% chlorhexidine solution. Using sterile technique, a 22 G angiocatheter was placed in the caudal space on the second attempt without ultrasound, using palpation technique. A noticeable loss of resistance was encountered when the needle pierced the sacrococcygeal ligament. The catheter was advanced to its hub, and 7.5 mL of 0.25% plain bupivacaine was injected in divided doses of 1–2 mL each. After gentle aspiration there was no blood or cerebrospinal fluid in the tubing of the T-piece.

Approximately 5 minutes after the caudal injection and during surgical preparation of the operative field, the electrocardiogram (ECG) changed to a wide-complex bradycardia, the end-tidal CO2 decreased from 35 to 6 mmHg, and the noninvasive blood pressure reading was not obtainable. Pulses were not palpable. There were no cutaneous changes, and ventilation volumes and pressures were unchanged. The anesthesiologist suspected local anesthetic systemic toxicity (LAST), and directed the anesthesia fellow to begin chest compressions, and the circulating nurse to call for additional help. Sevoflurane was discontinued, FiO2 increased to 1.0, and the anesthesiologist directed the circulating nurse to bring the 20% intralipid and the resuscitation cart just outside the operating room. She also consulted the cognitive aid cards attached to the anesthesia machine to ensure that no treatment strategies were omitted (Society for Pediatric Anesthesia; https://www.pedsanesthesia.org/critical-events-checklist/).

Subsequently 20% intralipid, 1.5 mL/kg, was injected into the peripheral IV over 1 minute, and repeated every 3 minutes, four times for a total of 7.5 mL/kg. High-quality chest compressions, with a firm backboard underneath the patient, were continued, and epinephrine, 7.5 µg IV, was injected every 5 minutes for a total of three doses. Because there was no return of spontaneous circulation after 5 minutes, the extracorporeal membrane oxygenation (ECMO) team and surgeon were called stat to the operating room.

After the fifth dose of intralipid and 15 minutes of chest compressions, the cardiac rhythm improved to sinus rhythm at 100 bpm, the end-tidal CO2 increased to 24 mmHg, pulses became palpable, and the noninvasive blood pressure registered at 55/42 mmHg. Point-of-care ultrasound was used to image the heart via the subcostal four-chamber view and revealed a poorly contracting left ventricle with no pericardial effusion. A low-dose infusion of epinephrine was started at 0.02 µg/kg/min via a second peripheral IV. A 22 G right radial arterial line was placed with ultrasound guidance, and revealed an arterial pressure of 60/43 mmHg; arterial blood gas was pH 7.15, PaCO2 35 mmHg, PaO2 325 mmHg on FiO2 1.0, and base deficit was −15. Electrolytes, ionized calcium, and glucose were normal, and lactate was 10.5 mmol/L. Sodium bicarbonate 15 mEq was infused over 10 minutes.

An infusion of 20% intralipid was started at 0.25 mL/kg/min, and a 4 Fr double-lumen 8 cm right internal jugular central catheter was inserted using ultrasound guidance. Initial central venous pressure was 14 mmHg, and the infusions were changed to the central line. Blood pressure improved to 84/52 mmHg, heart rate increased to 125 bpm with normal sinus rhythm, and a normal pattern on multilead ECG was recorded from the physiologic monitor. Left ventricular contractility improved on repeat ultrasound examination. A urinary catheter was placed, and when the patient exhibited some spontaneous movement of the extremities (without evidence of clinical seizures), midazolam 0.05 mg IV was administered for sedation, and repeated twice. The patient was transported to the pediatric ICU and a full comprehensive report was given to the ICU team. Mechanical ventilation, intralipid, and epinephrine infusions were continued for 12 hours, and, with no indication of the signs of LAST recurring, the infusions were discontinued. The patient was extubated 2 hours later. He was neurologically intact and was discharged to the surgical ward the next day, and discharged home 48 hours later, with no neurologic or cardiac symptoms, and a normal echocardiogram and ECG on the day of discharge. The anesthesiologist met with the patient's parents each day to explain the LAST event, answer their questions and address their concerns. The patient was scheduled for elective hypospadias repair in 6 weeks, after follow-up with his pediatrician.

This case illustrates the rapid diagnosis and treatment of a rare event, LAST, including the fact that an intravascular injection was not suspected, during divided injections of the local anesthetic. An epinephrine-containing test dose was not used in this case; this practice is often ineffective in infants. Ultrasound guidance for caudal anesthetic placement was also not used; ultrasound can visualize the local anesthetic solution being deposited in the sacral canal and theoretically could determine that this injection was not in the correct location (see Chapter 20). After ruling out anaphylaxis, LAST was quickly diagnosed and high-quality CPR was initiated (see Chapter 13). Defibrillation was not used because the cardiac rhythm was not ventricular fibrillation or pulseless ventricular tachycardia. 20% intralipid, which was available immediately with the resuscitation cart in the operating room, was quickly obtained and injected, and repeated every 3 minutes until return of sinus rhythm and spontaneous circulation; an infusion started and maintained for 12 hours to prevent recurrence of LAST. A lower dose of epinephrine, 1 µg/kg instead of the standard 10 µg/kg, was used during resuscitation because of evidence that the latter may be harmful in LAST. Cognitive aids were readily available in the operating room and consulted so that proper treatment for this rare but potentially devastating complication could be given. The ECMO team was called early in the resuscitation, although not needed. Point-of-care ultrasound was used to image the heart and rapidly obtain invasive vascular access. The patient was transferred to pediatric ICU for ongoing care and monitoring and made a complete recovery. The anesthesiologist kept in close touch with the parents and was able to thoroughly explain the adverse event experienced by their child.

CHAPTER 46

Impact of Pediatric Surgery and Anesthesia on Brain Development

Introduction

The ability to pharmacologically render patients insensible to noxious stimulation using general anesthetics and sedatives represents one of the greatest discoveries in medicine. Undoubtedly, life-threatening conditions are mitigated every day by surgical interventions that can only be performed due to the meticulous administration of modern anesthetic drugs and advanced physiological monitoring. While the exact molecular mechanisms by which general anesthetics provide immobility, analgesia, and amnesia remain under investigation, most are thought to provide their physiological effects in the central nervous system by either potentiating neuronal activity at γ-aminobutyrate acid (GABA) receptors, by inhibiting N-methyl-D-aspartate (NMDA) glutamate receptors, or by a combination of the two.

Worldwide, every year, millions of children are exposed to $GABA_A$-agonists or NMDA-antagonists to ablate the stress response to noxious stimulation and to mitigate potential, stress-related morbidity during painful procedures and imaging studies. However, recent findings in laboratory animals have demonstrated structural brain abnormalities, such as widespread brain cell death and alterations in dendritic architecture immediately following exposure to these drugs early in life. Moreover, several animal studies have also observed lasting neurocognitive impairment into adulthood. These preclinical findings have led to significant concerns among pediatric anesthesiologists, government agencies, and the public. Given the potentially serious consequences of long-term neurological sequelae following an otherwise uneventful surgical procedure early in life, this chapter presents the pediatric anesthesiologist with an overview of this rapidly emerging field of research by summarizing the currently available data from animal models as well as human clinical studies. These findings will be moderated by a review of the neuroprotective effects of anesthetic drugs. Moreover, the impact of other perioperative events, such as pain, stress, inflammation, hypoxia-ischemia, co-morbidities, and genetic predisposition, on long-term neurological function will be discussed. Finally, the reader will be introduced to the phenomenon's putative mechanisms and to the currently proposed ameliorating strategies.

Historical perspective

General anesthetics have been widely used for more than 170 years and are administered to millions of children every year [1]. Prior to the 1980s, general anesthetics were routinely withheld from hemodynamically unstable premature and term neonates. The rationale for this practice was to avoid further hemodynamic deterioration in surgical neonates who were perceived to be unable to tolerate the myocardial depressant effects of the then utilized anesthetic drugs. However, the denial of adequate doses of anesthetics or analgesics in these patients ignored the fact that the neonatal central nervous system is capable of sensing pain and mounting a stress response during surgical stimulation, even in premature infants [2]. Studies by Robinson and Anand demonstrated that opioid administration was able to blunt physiological responses to surgical stress without compromising hemodynamic stability and substantially reduced perioperative morbidity in critically ill neonates [3–5]. These developments, along with technological advances in hemodynamic monitoring and mechanical ventilation, have resulted in the current humane practice of administering anesthetics and analgesics even to the most critically ill neonates during and after surgery.

Gregory's Pediatric Anesthesia, Sixth Edition. Edited by Dean B. Andropoulos and George A. Gregory.

Nociception and stress in the neonate

Neonatal animal models testing the effects of stressful conditions and exposure to recurrent painful stimulation have demonstrated widespread neuronal cell death and adverse neurological outcomes as a result from these deleterious conditions [6]. Both somatic as well as visceral noxious stimulation of the developing brain appear to alter processing of nociceptive inputs in adulthood. Thus, neonatal injury can subsequently be associated with either hyperalgesia or hypoalgesia, depending upon the type and severity of injury and the sensory modality tested [7]. In addition to altered pain processing, repetitive or persistent pain in the neonatal period may result in changes in brain development, widespread alterations in animal behavior, cognitive function, and in subsequent increased vulnerability to stress and anxiety disorders or chronic pain syndromes [6,8,9]. Specifically, inflammatory pain associated with repeated injection of complete Freund's adjuvant in rat pups resulted in hyperalgesia and lasting changes in nociceptive circuitry of the adult dorsal horn [10]. Rat pups receiving repeated formalin injections into the paw developed subsequent generalized thermal hypoalgesia [7]. Moreover, early adverse emotional experiences induced long-lasting age-, brain region-, and neuronal subgroup-specific imbalances of the inhibitory nervous system [11], disrupted development of the nociceptive system, and caused long-term behavioral changes [12] as well as leading to persistent learning impairment [13]. Repetitive painful stimulation in neonatal animals has also been shown to lead to decreased pain thresholds and increased anxiety later in life [8,14,15]. In addition to alterations of the central nervous system, repetitive painful skin lacerations have also been found to lead to long-term, local sensory hyperinnervation [16]. Therefore, fetuses and neonates subjected to pain and stresses associated with painful procedures may be at risk for long-term adverse outcomes.

The pre-emptive administration of analgesics and sedatives, such as morphine or ketamine, in this context, has been found to ameliorate the deleterious effects of neonatal pain in animals [6,13,15]. Importantly, painful stimulation in turn obviated adult behavioral impairment due to neonatally administered morphine [13].

Similar to these animal studies, clinical reports have demonstrated that neonates and infants respond to perioperative stress and painful stimulation with increases in catecholamines, cortisol, β-endorphins, insulin, glucagon, and growth hormone [17–19]. Some of these markers, such as cortisol, can remain elevated for more than a year, potentially due to cumulative stress related to multiple painful procedures early in life [20]. The administration of potent anesthetics, opioid analgesics, and regional anesthesia has been shown to inhibit intraoperative stress and to improve postoperative outcome [4,18,21] by reducing the incidence of sepsis, disseminated intravascular coagulation, and overall mortality [5]. Even less invasive procedures, such as circumcisions, when performed without analgesia, can exaggerate pain responses later in life [22]. In contrast, topical or regional anesthesia for circumcision not only blunted the immediate humoral stress response [23], but also obviated long-term hyperalgesia [22].

In premature neonates, an association has been observed between painful stimulations early in life and subsequent diminished cognition and motor function [24]. Cognitive and motor development was compared after 1 year of age between children born at less than 32 weeks' gestational age, without significant neonatal brain injury or major sensorineural impairment, and full-term controls. Results demonstrated that the number of skin-breaking procedures from birth to term (including heel sticks, intramuscular injections, chest tube placements, and central line insertions) predicted lower subsequent cognitive and motor development, as assessed using the Bayley Scales of Infant Development II. Importantly, after controlling for severity of illness and days on intravenous morphine or dexamethasone, gestational age at birth was not significantly associated with cognitive or motor outcome. These findings suggest that repetitive, pain-related stressful experiences and not prematurity per se were responsible for poor neurodevelopmental outcome [24]. While this study did not examine the effects of anesthetic or analgesic administration during painful stimulation on subsequent outcome, a small, retrospective study suggested improved outcome following anesthetic exposure during painful stimulation. In that study, painful stimulation during the reduction of herniated bowel without anesthesia in infants suffering from gastroschisis tended to more frequently lead to serious adverse events, such as bowel ischemia, need for total parenteral nutrition, and unplanned reoperation than in infants undergoing the same procedure with general anesthesia [25]. However, despite the fact that large numbers of painful and stressful procedures are being performed in vulnerable neonates, available data indicate that the majority of these are still not accompanied by analgesia [26].

KEY POINTS: NOCICEPTION AND STRESS IN THE NEONATE

- Data from animal and human studies suggest that pain-related stress early in life, especially when experienced repeatedly, is deleterious to the developing nervous system
- Sedatives and analgesics may alleviate many of the degenerative effects
- Pain in children still remains undertreated

Developmental anesthetic-induced neurotoxicity

Concerns regarding potentially deleterious effects of general anesthetics on neurological function were first raised after more than a century of their routine clinical use. Prolonged personality changes, such as night terrors, bed wetting, and increased fear responses, were observed in young children following the administration of vinyl ether, cyclopropane, or ethylchloride for otolaryngological surgery [27]. However, these symptoms were interpreted as psychological sequelae resulting from patients' anxiety during anesthesia induction and hospitalization. Approximately two decades later the focus of research into potentially deleterious effects of anesthetics shifted to prolonged occupational exposure of female healthcare workers [28–31]. Chronic exposure of pregnant rats to subanesthetic doses of halothane during their entire

pregnancy led to delayed synapse formation and behavioral abnormalities in their offspring. It took almost another two decades until initial studies were carried out examining anesthetic exposure early in postnatal life, more closely representing pediatric anesthesia practice. In these groundbreaking studies, widespread neuronal degeneration was observed following prolonged ketamine exposure in neonatal rat pups [32]. The researchers likened this phenomenon to abnormalities observed in children suffering from fetal alcohol syndrome caused by maternal ingestion of ethanol, a combined $GABA_A$-agonist/NMDA-antagonist [33–35]. Accordingly, these findings were followed up by using a combination of the $GABA_A$-agonist midazolam, the combined $GABA_A$-agonist and NMDA-antagonist isoflurane, and the NMDA-antagonist nitrous oxide. A 6 h exposure to this drug combination triggered widespread immediate brain cell death in newborn rodents as well as a long-term diminution in neuronal density, altered synaptic function, and impaired neurocognitive function in adult animals exposed as neonates [36,37]. Dramatic acute alterations in brain architecture as well as long-term cognitive impairment have now been confirmed for all routinely used general anesthetics by numerous laboratories in several immature animal models (reviewed in [38]).

However, a causative link between any immediate structural abnormalities and long-term cognitive impairment has yet to be made. The potentially serious implications of potential long-term cognitive deficits following exposure to sedatives or anesthetic early in life compelled the United States Food and Drug Administration (FDA) to issue a warning in December of 2016 (updated in April 2017), stating that exposure to anesthetics "for lengthy periods of time or over multiple surgeries or procedures may negatively affect brain development in children younger than 3 years". At the same time, the FDA acknowledged that "general anesthetic and sedation drugs are necessary for patients, including young children and pregnant women, who require surgery or other painful and stressful procedures" (https://www.fda.gov/Drugs/DrugSafety/ucm554634.htm; accessed May 2019).

Experimental evidence for anesthetic neurotoxicity

To date, more than 500 animal studies have investigated the effects of all clinically utilized sedatives and anesthetics on brain structure and function in immature animal species, including chicks, mice, rats, guinea pigs, swine, sheep, and rhesus monkeys (Fig. 46.1). The repeatedly observed structural abnormalities and/or functional impairment have been termed "anesthetic neurotoxicity" and resulted in an exponential rise in published scientific reports and reviews [38]. While the exact molecular mechanisms by which anesthetics provide their therapeutic effects remain incompletely delineated, two main putative targets include the glutamatergic NMDA and GABA receptors, which also have become the focus of research into this phenomenon. Table 46.1 presents published studies of non-human primates, and human neuronal cultures, after anesthetic exposure.

NMDA-antagonists

Glutamate represents the most ubiquitous excitatory neurotransmitter in the mammalian central nervous system. Clinically utilized anesthetics and sedatives that provide their hypnotic effects predominantly by inhibition of the NMDA-type glutamate receptor include ketamine and nitrous oxide [39], as well as the less frequently clinically utilized noble gas xenon [40]. Pioneering animal studies carried out 20 years ago demonstrated widespread degeneration of brain cells in newborn rat pups following the repeated administration of ketamine [32]. These findings have subsequently been replicated and expanded upon by several other laboratories [38,41].

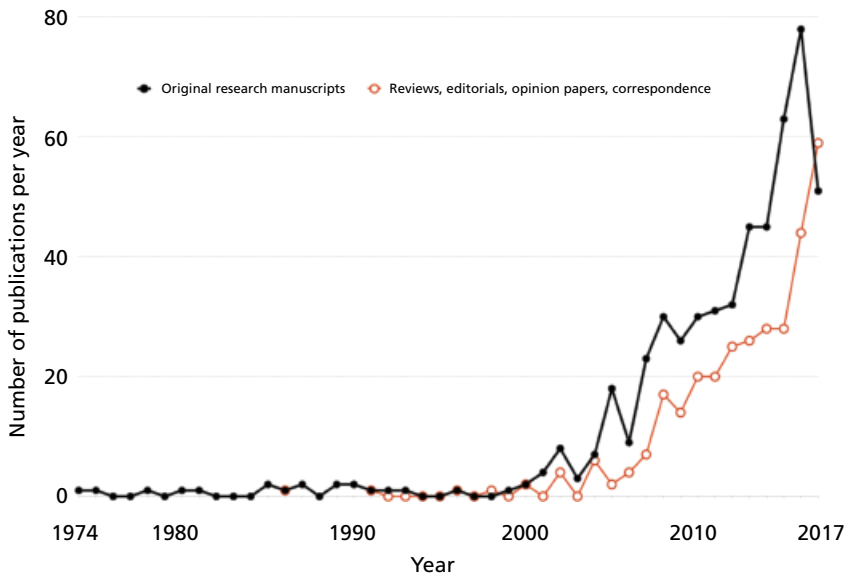

Figure 46.1 Increase in number of animal research articles investigating the effects of anesthetic exposure on the developing brain and commentaries over the past 43 years. The number of annually published original *in vivo* and *in vitro* animal studies (black filled circles) as well as review articles, editorial views, commentaries, opinion papers, and correspondence on this topic (open red circles) are shown from 1974 until October 2017, as identified in a literature search using PubMed and Scopus databases, as well as personal records. The body of literature has expanded into one of the most intensely researched fields in anesthesiology, increasing from two articles published in 2000 to approximately 80 articles in 2016. *Source*: Reproduced from Lin et al [38] with permission of Elsevier.

Table 46.1 Preclinical studies in non-human primates and human neuronal cultures into brain structural and functional effects of anesthetic exposure

Anesthetic agent	Dose and duration	Species, age	Pathology	Reference
Dexmedetomidine or ketamine	3 or 30 μg/kg dexmedetomidine followed by 3 or 30 μg/kg/h for 2 h, or 20 mg/kg ketamine IM, followed by 20–50 mg/kg/h for 12 h	*Macaca fascicularis*, E120	Marked neurode generation in frontal cortex following ketamine, but not after either low- or high-dose dexmedetomidine	Koo et al [294]
Isoflurane	1.6% for 5 h	*Macaca mulatta*, P5	Increase in neocortical apoptotic cell death	Brambrink et al [67]
Isoflurane, N_2O or isoflurane + N_2O	1%, 70%, or 1% + 70% for 8 h	*Macaca mulatta*, P5	Significant neuronal cell death in frontal cortex, temporal gyrus, and hippocampus following anesthetic combination, but not after isoflurane or N_2O alone	Zou et al [295]
Isoflurane	0.7–1% for 5 h	*Macaca mulatta*, P5–6	Widespread apoptotic cell death of neurons and oligodendrocytes	Brambrink et al [68]
Isoflurane	Propofol 2 mg/kg followed by isoflurane for 5 h to provide intermediate surgical plane of anesthesia to dam	*Macaca mulatta*, E120	Neuroapoptosis, most prominent in cerebellum, caudate, putamen, amygdala, and cortex; diffuse distribution of oligodendrocyte death across white matter	Creeley et al [118]
Isoflurane + lithium	1.5–3% for 5 h to maintain surgical plane of anesthesia	*Macaca mulatta*, P5–7	Increased neuronal and oligodendrocyte degeneration, ameliorated by lithium co-administration	Noguchi et al [139]
Isoflurane	Titrated to maintain a surgical plane of anesthesia for 5 h once, or three times 3 days apart	*Macaca mulatta*, P6 or P6, P9, and P12	No abnormalities following single exposure, but following triple exposure deficits are observed in motor reflexes at 1 month and increased anxiety at 12 months	Coleman et al [69]
Isoflurane	Surgical plane of anesthesia for 3 h	*Macaca mulatta*, P6	Widespread oligodendrocyte and neuronal apoptosis in white matter and in cortex, caudate, putamen, and thalamus, respectively	Noguchi et al [66]
Isoflurane	1.3–2.5% to maintain surgical plane of anesthesia for 5 h	*Macaca mulatta*, P20 or P40	Diffuse neuronal and oligodendrocyte cell death	Schenning et al [70]
Isoflurane	2% for 3 or 6 h	Human neuroglioma cells	Caspase-3 activation, ROS accumulation, reduction in cellular ATP, attenuated by hydrogen-rich saline	Li et al [296]
Ketamine	1–20 μM for 2–24 h	*Macaca mulatta* forebrain neuron culture	Increased DNA fragmentation and decreased mitochondrial function after higher doses for longer periods of time	Wang et al [52]
Ketamine	20–50 mg/kg/h for 24 h	*Macaca mulatta*, E122, P5, or P35	Increased neurodegeneration in two younger age groups, ketamine plasma levels higher than in humans	Slikker et al [43]
Ketamine	20–50 mg/kg/h for 24 h	*Macaca mulatta*, P5–6	Impairment in motivation and cognitive performance in Operant Test Battery starting at 10 months and continuing until 3.5 years of age	Paule et al [45]
Ketamine	20–50 mg/kg/h for 3–25 h	*Macaca mulatta*, P5 or P6	Neuronal degeneration only in neocortex following 9 h exposure or longer, no degeneration in deeper brain areas	Zou et al [44]
Ketamine	10 mg/kg followed by 10–85 mg/kg/h for 5 h (fetus), or 20 mg/kg followed by 20–50 mg/kg/h for 5 h (neonate)	*Macaca mulatta*, E120 or P6	Neuronal cell death following exposure; 2.2 times greater during fetal versus neonatal exposure	Brambrink et al [297]
Ketamine	100 μM for 24 h	Human neurons derived from stem cells	Increased apoptosis and caspase-3 expression	Bai et al [298]
Morphine	1–100 μM for 5 days	Human fetal microglial, astrocyte, and neuronal cultures	Progressive increase in apoptosis in neurons after 2-day exposure, or microglia after 3 days, but not in astrocytes	Hu et al [299]
Propofol	7–10 mg/kg followed by 350–450 μg/kg/min for 5 h (fetus), or 3 mg/kg followed by 300–400 μg/kg/min for 5 h (neonate)	*Macaca mulatta*, E120 or P6	Widespread neuronal and oligodendrocyte cell death, particularly subcortical and caudal in fetus and neocortical and caudal brain regions in neonates	Creeley et al [74]
Sevoflurane	Dose adjusted according to calibrated pain stimulus for three 4 h exposures	*Macaca mulatta*, P6–10, P20–24, and P34–38	Starting at 6 months of age, increased anxiety in human intruder test	Raper et al [63]
Sevoflurane	Dose adjusted between 2% and 2.6% to provide surgical plane of anesthesia for 5 h	*Macaca fascicularis*, P6	No abnormalities in behavioral (3–7 months) and cognitive assessment (7 months), or brain protein analysis (10 months)	Zhou et al [300]

Table 46.1 (Continued)

Anesthetic agent	Dose and duration	Species, age	Pathology	Reference
Sevoflurane + L-carnitine	2.5% for 8 h	*Macaca mulatta*, P5-6	Increased neuronal degeneration in frontal cortex. Temporary increased uptake of ^{18}F-FEPPA tracer on PET in frontal and temporal lobes, attenuated by co-administration of L-carnitine	Zhang et al [301]
Sevoflurane	Dose adjusted according to calibrated pain stimulus for three 4 h exposures	*Macaca mulatta*, P6–10, P20–24, and P34–38	No difference in visual recognition memory tested at 6–10 months of age, but deficit observed at 12–18 and 24–30 months old	Alvarado et al [65]

ATP, adenosine triphosphate; E, embryic age in days; IM, intramuscular; P, postnatal day; PET, positron emission tomography; ROS, reactive oxygen species

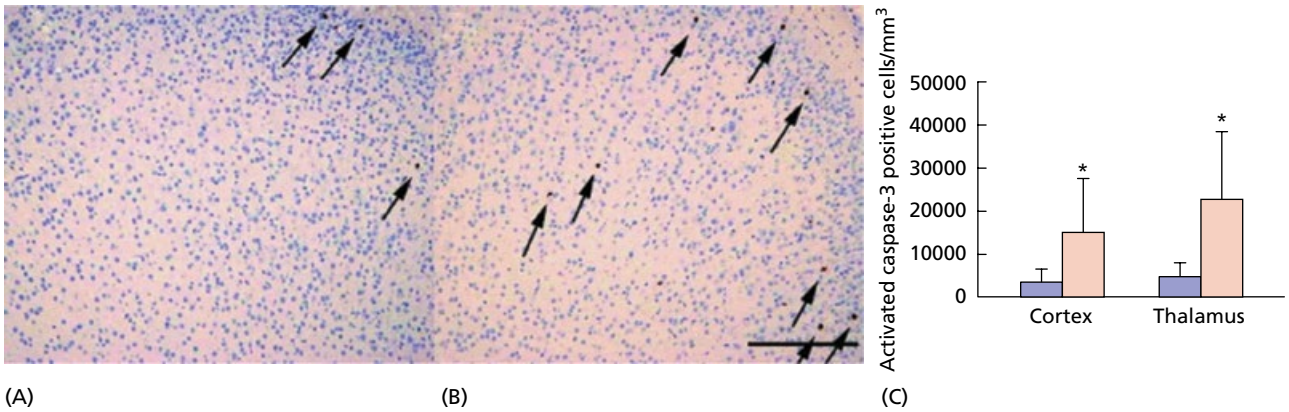

Figure 46.2 Ketamine induces caspase-3 activation *in vivo*. Immunohistochemistry with antibody to cleaved caspase-3 on cortical sections from P7 rat pups receiving either saline (A) or ketamine 20 mg/kg every 90 min for 6 h (B) (scale bar = 200 μm). (C) Quantitation of activated caspase-3-immunoreactive cells in P7 cortex and thalamus. Data are presented as mean ± standard deviation; * $p < 0.05$ compared to saline. *Source*: Courtesy of the Soriano laboratory.

Most studies have demonstrated an increase in cleaved caspase-3 expression, leading to apoptotic cell death. While this was not observed following a single ketamine dose of up to 75 mg/kg in young rodents, multiple doses of up to 75 mg/kg of ketamine led to widespread neuronal cell death [42]. Disturbingly, a similar dose-dependent increase in ketamine-induced neurodegeneration also occurs in non-human primates [43,44]. In these studies, a ketamine infusion (20–50 mg/kg/h for 24 h) significantly increased neuronal cell death in the superficial cortex of prenatal (gestational age 122 days when administered to the mother) or neonatal (5-day-old) rhesus monkeys. A 3 h exposure did not lead to increased neurodegeneration in neonates and even the 24 h infusion failed to cause cortical neuronal degeneration in older, 35-day-old animals. Alarmingly, however, newborn monkeys exposed to the 24 h ketamine infusion and tested with an operant test battery (OTB) starting at 7 months of age, exhibited lasting cognitive and motivational deficits, compared with unexposed peers [45]. In small rodents, a single ketamine exposure of 50 mg/kg in newborn mice led to subsequent abnormal behavior as well as impaired learning and memory acquisition in adolescence [46]; however, in another study, no gross neurobehavioral abnormalities were observed 7 days after neonatal administration of up to 40 mg/kg, albeit formal tests of learning were not performed [47]. Moreover, adult rats that were injected as neonates with relatively small doses of ketamine (5 mg/kg) once a day for 4 days performed as well as their unexposed peers in subsequent learning and memory tasks [6]. Concomitant administration of GABA-mimetic drugs, such as midazolam, thiopental, or propofol, a common practice during clinical anesthesia and sedation, significantly exacerbated the deleterious effects of ketamine [48,49].

In order to better understand the underlying mechanisms, ketamine neurotoxicity has also been studied using several *in vitro* preparations from neonatal rodents and rhesus monkeys [50–52]. When cultured in ketamine for 6 h or longer, primary cortical cells from both species underwent neurodegeneration, whereas shorter exposure times did not cause this effect. However, lower concentrations of ketamine have been shown to decrease dendritic arborization in differentiated neurons in culture [53]. Microscopic images of primary neurons exposed to ketamine demonstrate a reduction in neurite length and the number of branching points (Fig. 46.2). It currently remains unclear whether the large doses of all injectable anesthetics, including ketamine, required in small animals can be directly compared with the lower doses used in clinical practice (further discussed later as part of interspecies comparison). It should further be noted that studies in small rodents suggest differential susceptibility among species, as neonatal mice are vulnerable to lower doses of ketamine and propofol than those found to be deleterious in rats [48,54].

Less information is available regarding the effects of the NMDA-antagonists nitrous oxide or xenon on brain development. Whereas nitrous oxide by itself, even under hyperbaric

conditions, did not seem to increase neuronal cell death [36,55], xenon showed differential effects, being deleterious in one study [56] and not in another [55]. The two compounds, however, differed in their effects when co-administered with isoflurane; nitrous oxide exacerbated isoflurane-induced neurotoxicity [36,37,55,57], whereas xenon alleviated some of isoflurane's cytotoxic effects [55,56].

$GABA_A$-agonists

Gamma-aminobutyrate acid represents the main inhibitory neurotransmitter in the adult central nervous system, while it has excitatory properties in the developing brain [58]. To date, the exact impact of this developmental switch on the deleterious effects of anesthetics observed in the immature brain remains unresolved. Several positive modulators of the $GABA_A$ receptor are commonly used as anesthetics or sedatives in young children, and animal studies have demonstrated the brain structure-altering effects of exposure to all of these compounds during early brain development, including propofol, clonazepam, diazepam, midazolam, thiopental, pentobarbital, chloral hydrate, isoflurane, sevoflurane, halothane, and enflurane (Table 46.1).

Several studies have originated in the Jevtovic-Todorovic laboratory, examining the combined administration of the $GABA_A$-agonist midazolam, the mixed $GABA_A$-agonist and NMDA-antagonist isoflurane, and the NMDA-antagonist nitrous oxide. A 6 h exposure to this drug combination caused a widespread, dramatic increase in the rate of brain cell degeneration in newborn animals shortly following the exposure [36,59–61]. In addition to the immediate deleterious effects on brain structure, long-term abnormalities in spatial learning tasks, altered hippocampal synaptic function, and decreased neuronal cell density were observed in adult rats exposed to the anesthetic combination as neonates [36,37]. The most frequently utilized inhaled anesthetic in pediatric anesthesia, sevoflurane, has also repeatedly been shown to induce neuroapoptosis in neonatal animals and to lead to learning deficits, emotional abnormalities, and altered social behavior [62–65]. The most extensively studied inhalational anesthetic is isoflurane, which has been found to lead to widespread neuronal cell death immediately following prolonged exposures in immature small rodents (Fig. 46.3) and to subsequent cognitive abnormalities in young adulthood. Neuronal or oligodendrocyte death have also been reported in neonatal rhesus monkeys immediately following exposure to clinically relevant doses (0.75–1.5%) of isoflurane for as little as 3 h [66], and have also been found to impair long-term motor and behavioral development [67–70]. While initial studies focused on the very immature rodent brain in the 1st week of life, more recent work has demonstrated isoflurane-induced neuroapoptosis even during prolonged exposure in young animals, specifically in brain regions with ongoing neurogenesis [71]. Moreover, disruption of dendritic architecture has also been observed in small rodents that were older than 2 weeks during exposures to inhaled anesthetics and propofol [72,73]. Propofol, which represents a relatively specific $GABA_A$-agonist, has been shown to induce neuroapoptosis in small rodents and non-human primates [74–77].

Other anesthetics and sedatives

Recently, the α2-agonist dexmedetomidine has gained more prominence in pediatric sedation practice. The Sanders group has examined dexmedetomidine's effects on the developing brain and has found it to be devoid of neurotoxic effects and to ameliorate isoflurane's deleterious consequences on neonatal brain structure and adult learning [57]. More recent data in newborn rats supported the notion that dexmedetomidine caused significantly less neuronal injury than sevoflurane [78,79], while providing a lighter plane of anesthesia compared with the inhaled anesthetic. Another rodent study suggested that dexmedetomidine may induce apoptotic cell death in different brain regions than those affected by ketamine [80]. A dose-ranging study of dexmedetomidine reported that only at cumulative doses likely to be supratherapeutic was neuroapoptosis increased in rat pups; at doses approximating clinical doses in humans there was not an increased level of neurodegeneration [81].

Opioid analgesics

Opioid analgesics are another class of drugs commonly administered to young children before, during, and after surgery, often in conjunction with anesthetics and sedatives [81,82]. Since opioids can reduce dose requirements for anesthetics and sedatives, their co-administration could lead to lower anesthetic requirements and thereby potentially mitigate anesthesia-induced cytotoxicity. However, several animal studies have suggested that opioid exposure may also have harmful effects in the developing brain (Table 46.1). Moreover, opioid co-administration can enhance cell death of

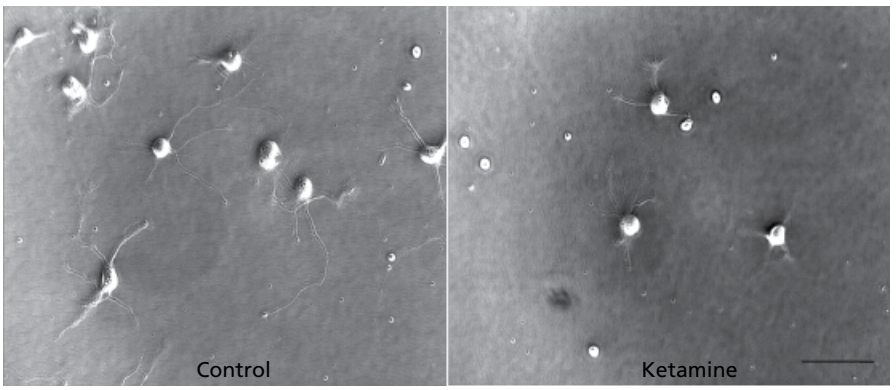

Figure 46.3 Ketamine stunted neurite arborization and branching points in primary neurons (scale bar = 100 μM). *Source*: Courtesy of the Soriano laboratory.

immature brain cells triggered by other apoptosis-inducing drugs [83]. Specifically, chronic perinatal exposure to morphine, fentanyl, or methadone has been shown to induce acute neuronal degeneration in the neonatal animal brain [84], to alter brain opioid receptor density [85–87], and to disrupt nerve growth factor expression as well as dopaminergic, noradrenergic, serotonergic, and cholinergic activity [88,89]. Conversely, Vutskits et al demonstrated that single morphine injections of 1 or 10 mg/kg at 7 or 15 days of age did not induce neuronal cell death in the cerebral cortex of rat pups and that nine daily administrations starting at either of these time points did not impair dendritic arbor differentiation or excitatory synaptogenesis [90]. However, other groups have shown that perinatal opioid administration can cause long-lasting desensitization to opioid analgesia in adult animals [91] and can induce long-term behavioral changes, cognitive deficits, and learning impairment extending into adulthood [13,92–96]. Conversely, as discussed previously, analgesics have also been found to diminish the deleterious effects of painful stimulation early in life.

Putative mechanisms of drug-induced neurotoxicity

The exact mechanisms of deleterious effects induced during exposure in the developing brain to anesthetics, sedatives, and analgesics remain unresolved. Elucidating these mechanisms will be essential for assessing the relevance of toxicity for pediatric anesthesia and neonatal critical care medicine and for devising mitigating therapies, if necessary. Complicating this important line of research is the fact that the phenotype of the phenomenon labeled "anesthetic neurotoxicity" is not well described. While reductions in trophic factors [60,97], synaptic and dendritic aberrations [72,98], impaired neuronal [32], glial [99], and oligodendrocyte viability [68], as well as cognitive abnormalities all seem to be part of the spectrum of anesthetic effects in the developing brain, it remains unclear whether they are part of a dose- and exposure time-dependent continuum. For example with lower doses and shorter exposures leading to trophic factor, synaptic, and dendritic alterations that culminate in cellular death when a certain toxic threshold is surpassed, or whether they represent separate phenomena.

The currently prevailing hypothesis suggests that exposure to $GABA_A$-receptor agonists and/or NMDA-receptor antagonists causes abnormal neuronal inhibition, triggering structural abnormalities in susceptible neurons, which can then lead to adult learning impairment and decreased neuronal density [36,37,100]. Apoptosis, or programmed cell death, represents an inherent, energy-consuming process, which is highly conserved among species and culminates in self-destruction and the elimination of cells that are functionally redundant or potentially detrimental to the organism, utilizing a cascade of enzymes called caspases [101]. As such, apoptotic cell death is an integral part of normal organ development, as demonstrated by the embryonal cell death of mesenchymal tissue between the digits of the hands and feet, as well as during ablation of tail tissue as part of tadpole metamorphosis in amphibians. During normal brain development, neurons are produced in excess and up to 50–70% are eliminated, be it in rodents, primates, or humans [102,103]. This physiological apoptotic cell death establishes proper central nervous system structure and function, and any disruption of this process will lead to massive brain malformation and intrauterine demise [104]. However, apoptotic cell death can also be triggered by pathological insults, such as hypoxia and ischemia [105]. It currently remains unknown whether anesthesia-induced cell death hastens physiological neuroapoptosis.

$GABA_A$-receptor stimulation results in decreased neuronal activity in the mature brain, however it causes excitation in developing neurons [58] which complicates the hypothesis of neuronal silencing as the underlying trigger of neuronal apoptosis. Moreover, the neurotoxic effects of sevoflurane have been associated with excitatory properties and episodes of epileptic seizures in newborn rats [106]. Isoflurane has also been shown to cause excessive Ca^{2+} release from the endoplasmic reticulum via overactivation of inositol 1,4,5-trisphosphate receptors (InsP3Rs) in neonatal rats *in vivo* and *in vitro* [107]. A similar mechanism may be linked to the production of Alzheimer-associated increases in β-amyloid protein levels [108]. Moreover, while xenon and hypothermia cause neuronal inhibition, they do not appear to exacerbate isoflurane-induced neuronal cell death, as expected by their cumulative effects on neuronal inhibition, but rather significantly reduce it [55,56,109].

An alternative mechanistic model proposes that prolonged NMDA receptor blockade by anesthetics upregulates the glutamate receptor NR1 subunit, in turn facilitating pathological calcium entry into the neuron, leading to excitotoxicity and nuclear translocation of nuclear factor κB (NFκB) [43]. However, attempting to link the NMDA receptor to the neurotoxic effect, two *in vitro* preparations have returned conflicting results. When comparing ketamine and S(+)-ketamine, the apoptosis-inducing effect was only marginally stereospecific in one study [110], suggesting that the toxic effect was unlikely to be mediated via the NMDA receptor, whereas in a separate study, ketamine's effects were blocked by glutamate receptor NR1-subunit antisense, suggesting that the NMDA receptor was underlying ketamine's apoptotic-inducing properties [50]. Similar questions regarding the causative role of inhibition of the GABA receptor in anesthesia-induced neurotoxicity have been raised by finding that co-administration of the $GABA_A$ receptor-antagonist gabazine was unable to attenuate isoflurane-induced neuroapoptosis [57]. Decreases in neuronal activity induced by anesthetics may therefore be less important than the disruption of the neuronal balance of excitation and inhibition, as demonstrated by a study in 15 day-old mice [72,73]. While simultaneous blockade of excitatory and inhibitory activity with tetrodotoxin in these animals did not lead to structural changes, as would be expected for a causative relationship between neuronal inhibition and structural damage, the administration of either $GABA_A$-agonistic or NMDA-antagonistic compounds did alter synaptogenesis [72].

Exciting work into the cellular mechanism of anesthesia-induced neuronal cell death has highlighted reductions in synaptic tissue plasminogen activation (tPA) release and increases in proBDNF/$p75^{NTR}$-mediated apoptosis following isoflurane exposure in newborn mice. Another presumptive mechanism of anesthetic neurotoxicity involves intracellular signaling by protein kinases. Straiko and colleagues reported that ketamine and propofol individually suppressed phosphorylation of extracellular signal-regulated protein kinase

and serine/threonine-specific protein kinase 473 ($pAkt^{473}$) in neonatal mice [76]. Moreover, experimental models of neurodegeneration have implicated re-entry of postmitotic neurons into the cell cycle, leading to cell death. Accordingly, a study by one of the authors demonstrated that ketamine induces aberrant cell cycle re-entry, leading to apoptotic cell death in the developing rat brain [111].

It remains unclear whether the overall cell death observed immediately following exposure is predictive of subsequent cognitive outcomes. Even widespread neuronal degeneration in neonatal animals immediately following exposure to isoflurane, sevoflurane, or midazolam does not always culminate in long-term cognitive impairment (Fig. 46.4) [112–114]. Substantial brain cell death during exposure may not always lead to long-term diminution in neuronal density [112,114]. And attenuating neuronal cell death during neonatal exposure, such as by inhibiting the p75 neurotrophin receptor, does not inevitably salvage cognitive impairment in adulthood [115]. Moreover, hypercarbia – oftentimes observed during prolonged anesthetic exposure in spontaneously breathing small rodents [112,116,117] – has been found to induce neuronal cell death by itself without anesthetic exposure, while not being linked to long-term neurocognitive impairment [117]. Combined, these findings suggest that the amount of overall neuronal cell death may not be crucial for cognitive outcomes, but do not exclude that certain subgroups of neurons or alterations in brain structure as part of the repair mechanisms triggered by the neonatal injury may be linked to long-term neurocognitive impairment. Importantly, despite the limitations of small rodent models, the injury pattern observed in monitored, intubated, and mechanically ventilated non-human primates are qualitatively similar to those in spontaneously breathing small rodents [67,118], suggesting that newborn mice and rats can still serve as economical models of research into the anesthetic effects in the developing brain.

Multiple laboratories have demonstrated prolonged cellular effects of anesthetic exposure beyond neuronal death, albeit with somewhat conflicting results. Alterations in synaptic plasticity in neonatal animals include a decrease in synaptic density following anesthetic exposure [98]. In slightly older, postnatal day 15 mice, however, anesthetic exposure increased the density of dendritic spines [72,73,119]. These contradicting observations may indicate an age-dependent difference in the effects of anesthetics on dendritic morphology.

These findings might be explained by anesthetic vulnerabilities of specific neuronal populations, as suggested by studies originating in the laboratory of one of the authors. Dentate granule cells were shown to be susceptible to isoflurane-induced cell death during the late progenitor and immature neuronal stage, but not as immature progenitors or mature neurons, irrespective of the age of the animal [120]. Accordingly, while many brain regions containing immature neurons were vulnerable to degeneration during exposures in the neonatal period, this vulnerability only extended to brain regions with ongoing neurogenesis in adulthood [71]. These findings suggest that different brain regions may be maximally susceptible at different stages of development and different ages and explains the immense vulnerability of the immature brain by the greater number of immature neurons at this stage. As an extension, however, these findings suggest that human vulnerability may extend beyond the neonatal or toddler stage into older childhood or even young adulthood for brain regions serving as neurogenic niches, such as the dentate gyrus and subventricular zone. However, which of the immediate structural abnormalities are causatively linked to long-term neurological dysfunction remains unresolved and represents an important obstacle in translational research efforts into devising mitigating strategies and safer anesthetic regimens. Clearly, additional laboratory research into the mechanism of the anesthetics' structural effects in the developing brain is urgently needed.

Gender differences

Several animal studies have investigated potential sex differences in the structural effects of anesthetic exposure on the developing brain. A study of isoflurane in neonatal rats observed increased neuronal cell death in several brain regions following a 4 h exposure without differences between sexes [121]. However, subsequent learning and social behavior was only impaired in male rats, but not females, suggesting that male animals were more susceptible to behavioral consequences of the exposure. Similarly, studies of 6 h neonatal sevoflurane or 5 h propofol exposures observed neurobehavioral and endocrine abnormalities only in adult male, but not female, rats [122,123]. A third group similarly found a greater detriment of a brief postnatal isoflurane exposure on cognitive performance in adult male rats, compared with their female littermates [124]. However, motor activity was only increased in adult female mice exposed to ketamine *in utero*, but not their male counterparts [125]. Conversely, female rats were more vulnerable to adult cognitive impairment in spatial learning tasks following a neonatal isoflurane-based anesthetic [126]. Similarly, brain structural degeneration following ketamine exposure was more pronounced in neonatal female rats than in male rats [127]. Accordingly, it is currently unclear whether these differences in sex-related outcomes are due to differences in species, age of exposure, or specific to the drug combination.

KEY POINTS: EXPERIMENTAL EVIDENCE FOR ANESTHETIC NEUROTOXICITY

- All commonly utilized anesthetics can alter developing brain structure following prolonged exposures
- Comparison studies of the respective toxic potencies of different anesthetics are difficult to perform and have yielded no conclusive results
- A variety of compounds have been tested to alleviate the deleterious effects, but it is premature to recommend their use in clinical practice
- The immediate structural surrogate of long-term cognitive impairment has yet to be conclusively identified
- Currently, the most viable option is to reduce doses and exposure times of the implicated drugs

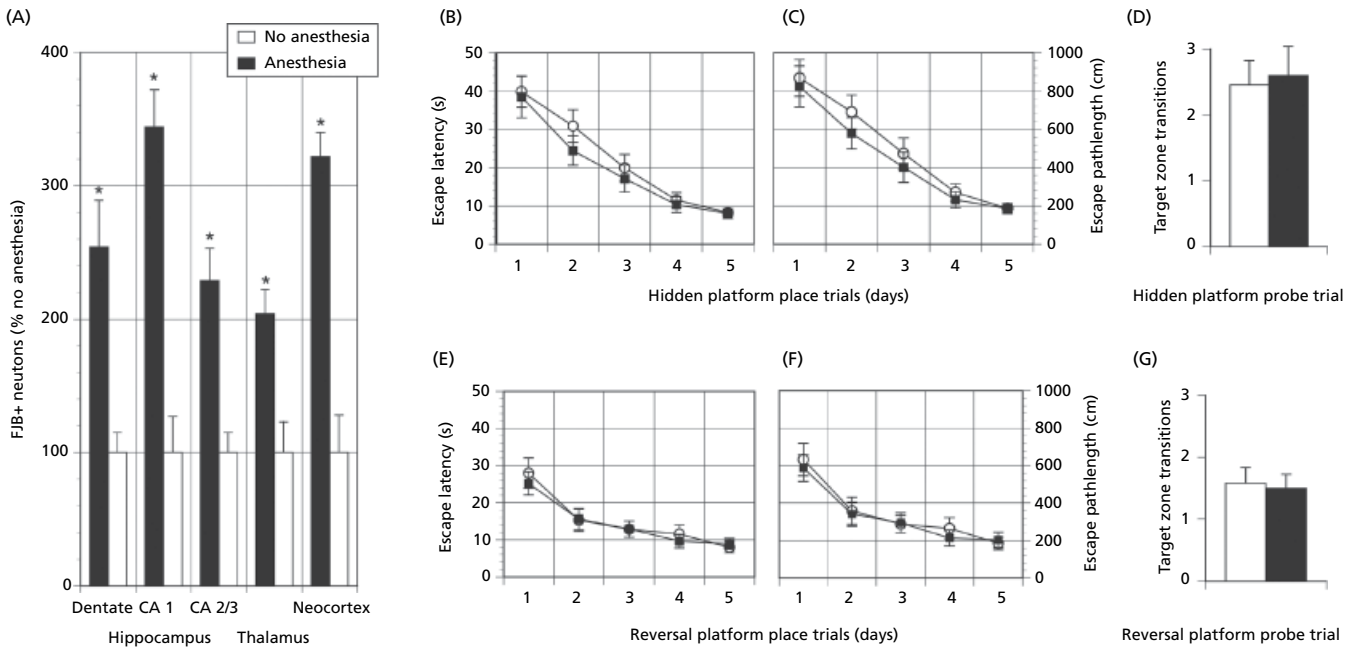

Figure 46.4 (A) Neonatal isoflurane exposure significantly increases the number of dead or dying neurons in the neonatal mouse brain. Columns represent mean number of brain cells staining positive for the cell death marker Fluoro-Jade B (FJB+) for each brain region 2 h following a 6 h exposure to 0.6 MAC of isoflurane (anesthesia, black bars) compared with littermates fasted for 6 h (no anesthesia, white bars). (B–G) However, neuronal cell death in neonatal mice immediately following isoflurane exposure does not inevitably result in impairment in spatial learning and memory in adulthood. Morris water maze place and probe trials in adult mice previously exposed as neonates to 6 h of fasting (no anesthesia, open circles) or to 0.6 MAC isoflurane (anesthesia, black squares) using a hidden platform (B–D) or a more difficult reversal platform paradigm (E–G). Both groups significantly improved over the 5-day trial period and performed equally well in the memory retention tasks. Data are shown as mean ± SEM; n = 8-26 for each group; * $p < 0.05$. *Source*: Reproduced from Loepke et al [112] with permission of Wolters Kluwer.

Safer anesthetic techniques and potential mitigating strategies

While human applicability of the structural effects of prolonged anesthetic exposure seen in animals have not been confirmed, an important translational question directed at animal research is whether any anesthetic can be identified that affords less toxicity than others and might therefore be recommended for clinical research and anesthesia practice. While several studies have addressed this question, no clear consensus has been reached thus far: Comparing inhaled anesthetics with each other, one study in newborn mice identified sevoflurane as causing less neuronal cell death following a 6 h exposure, compared with isoflurane, while no differences in long-term cognitive performance were observed between the two anesthetic regimens [128]. Another mouse study demonstrated sevoflurane and isoflurane to cause comparable degrees of injury following a 6 h exposure, but no long-term dysfunction, while identifying desflurane as more injurious to brain structure immediately following exposure and to cause subsequent cognitive function [129]. In a comparison study using immature rats, Vutskits and co-workers demonstrated differing results of increased dendritic spine density in prefrontal cortex following isoflurane or sevoflurane after only 1 h of exposure, while requiring 2 h of desflurane exposure to demonstrated the same effect [73]. In a different study, a 4 h neonatal isoflurane exposure yielded deficits in both short-term and early long-term memory function in adulthood, whereas sevoflurane exposure only led to early long-term memory abnormalities [130]. While nitrous oxide by itself does not cause neuronal degeneration [36], its administration in newborn animals exacerbates cognitive abnormalities caused by isoflurane or sevoflurane in adulthood [36,131]. Finally, work performed by the Loepke laboratory observed similar degrees of neurodegeneration and caspase-3 expression immediately following a 6 h anesthetic exposure to equipotent doses of 0.6 MAC (minimum alveolar concentration) of all three commonly used inhaled anesthetics, desflurane, isoflurane, and sevoflurane (Figs 46.5 and 46.6) [132].

Combined, these comparative studies suggest that there currently does not exist consistent enough evidence from animal studies to recommend one inhaled anesthetic agent over another for clinical practice. Moreover, while it is much more difficult to compare injectable and inhalational anesthetics with each other in small rodents, separate studies in non-human primates indicate that neuronal cell death is qualitatively comparable between rhesus monkeys exposed to 5 h of propofol or isoflurane [118], albeit quantitative analyses have yet to be performed.

Since all currently utilized general anesthetics as well as many analgesics elicit structure modifying and function -altering

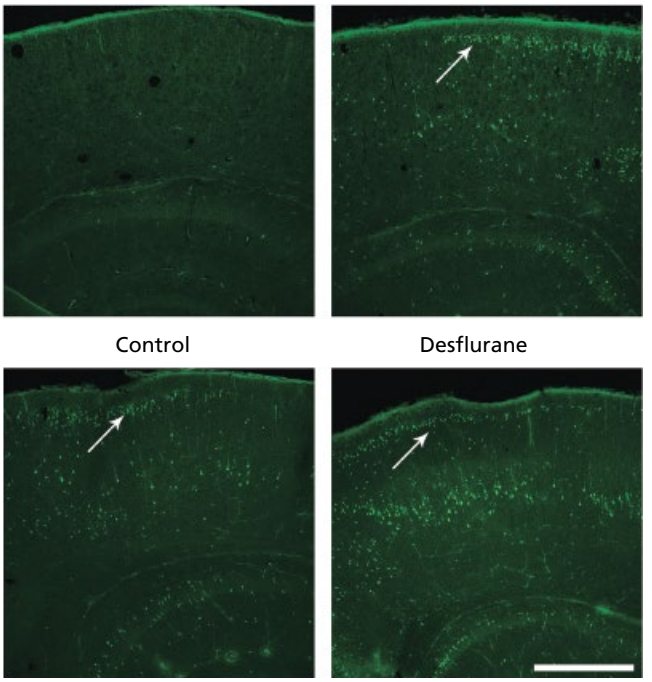

Figure 46.6 Six-hour exposure to desflurane, isoflurane, or sevoflurane similarly increases apoptotic cell death in neonatal mice, compared with fasted, unanesthetized littermates (control). Representative, low-magnification photomicrographs of coronal brain sections, obtained with laser confocal microscopy, demonstrate the pattern of apoptotic neuronal cell death. Brain sections from 7–8-day-old mouse pups were stained for the apoptotic cell death marker activated caspase-3 (bright green) following a 6 h exposure to room air (control), or 0.6 MAC desflurane, isoflurane, or sevoflurane, respectively. Arrows mark clusters of dying neurons in neocortical layers II/III (scale bar = 500 μm). *Source*: Reproduced from Istaphanous et al [132] with permission of Wolters Kluwer.

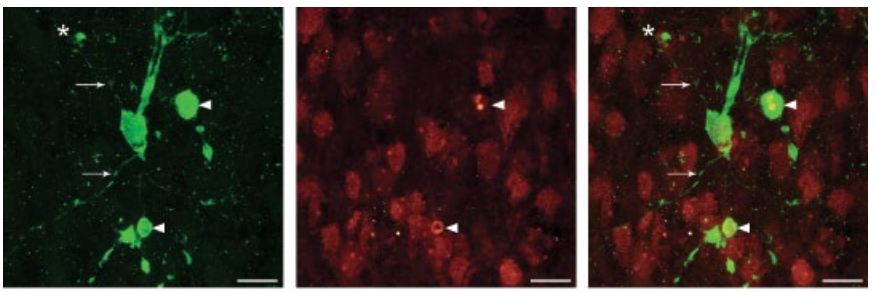

Figure 46.5 Representative, high-power magnification photomicrograph, obtained with laser confocal microscopy, demonstrating co-localization of the apoptotic cell death marker activated caspase-3 (green) and the postmitotic neuronal marker NeuN (red) in the neocortex. The brain section was obtained from a 7-day-old mouse pup following a 6 h exposure to 0.6 MAC of isoflurane, depicting a 9 μm image stack stained for activated caspase-3 (left) and NeuN-stained single optical sections through each cell body, for clarity (middle). Apoptotic neurons, indicated by co-localization of caspase-3 and NeuN in the merged image on the right, demonstrate degenerative changes, such as dendritic atrophy (arrows), dendritic beading (*), and pyknotic neurons (arrowheads), and are surrounded by unaffected neurons (scale bars = 10 μm). *Source*: Reproduced from Istaphanous et al [132] with permission of Wolters Kluwer.

responses in the immature animal brain, alternative anesthetic techniques should be investigated. However, inadequate alleviation of pain and distress may equally trigger neurodegenerative effects. It is therefore imperative to ensure adequate pain relief and to compare equianesthetic states. Decreasing anesthetic doses by combining several deleterious anesthetics may not obviate neurotoxicity according to animal studies, but may rather exacerbate it [36]. Accordingly, several animal studies have now investigated the use of alternative anesthetic techniques and mitigating compounds. Dexmedetomidine represents a promising drug for study as it lacks modulation of NMDA and GABA receptors, which have been implicated in facilitating the toxic effects. Accordingly, when administered as a single drug, dexmedetomidine does not seem to exhibit the same degree of toxicity in small rodents as commonly utilized general anesthetics [78–80,133]. Dexmedetomidine has also been shown to protect from ketamine-induced structural and cognitive abnormalities [134], as well as from the apoptosis-inducing effects of isoflurane [135]. However, none of these studies confirmed comparable levels of sedation.

In a novel approach, two research groups recently conducted a collectively planned study that was performed in parallel in two separate animal laboratories, utilizing the respective methodologies, to address the differential effects of prolonged exposures to sevoflurane, dexmedetomidine, and their combination on level of sedation and brain structure in newborn rodents [78,79]. Both studies confirmed that sevoflurane caused a higher degree of neuronal apoptosis in a variety of brain regions, but also created a deeper plane of anesthesia and reduction in response to painful stimulation, compared with dexmedetomidine alone. Interestingly, however, the findings differed substantially in regard to dexmedetomidine's protective effects, as one study demonstrated diminished neuronal degeneration when a low dose of dexmedetomidine was added to sevoflurane [78], while the other study did not find any neuroprotection [79]. These diverging results, probably due to subtle methodological differences including physiological derangements such as hypoxemia, raise important points regarding the need for confirmation of findings by different research laboratories.

Similar to dexmedetomidine, the noble gas xenon was found to be devoid of toxicity and to protect from isoflurane-induced neuroapoptosis in newborn rats [55,136], whereas some neurotoxic effects were found in two other *in vivo* and *in vitro* studies [56,137]. Lithium co-administration has been utilized as a protective strategy in animal studies as it has been found to alleviate neurodegeneration caused by propofol or ketamine in neonatal mice [76], sevoflurane in neonatal rats [138], as well as isoflurane in non-human primates [139]. Interestingly, even brief preconditioning with isoflurane has been demonstrated to protect from subsequent longer isoflurane exposure [140,141]. Whole-body hypothermia to 24°C has been proposed to reduce isoflurane-induced neuroapoptosis in neonatal mice [109,142]. Moreover, bumetanide has been found to alleviate sevoflurane's neurotoxic effects by inhibiting the Na-K-Cl membrane transport protein NKCC1 [106].

Naturally occurring hormones, such as estradiol [60,143] and melatonin [61], have been successfully tested in *in vivo* and *in vitro* preparations to reduce neuronal injury caused by prolonged exposure to midazolam, isoflurane, and nitrous oxide or to ketamine. Head and co-workers have demonstrated that the administration of tPA or plasmin, or pharmacological inhibition of the neurotrophic receptor $p75^{NTR}$, reduced the neurotoxic effects of isoflurane in neonatal mice [98]. However, more recent data by the same research group showed that inhibition of the p75 receptor, which was successful in reducing immediate neuroapoptosis, was ineffective in preventing cognitive abnormalities in adulthood following neonatal isoflurane exposure [115]. Carbon monoxide and hydrogen gas have been used with varying degrees of success to protect from isoflurane- and sevoflurane-induced structural and cognitive impairment [144–146].

A variety of antioxidants have been tested and found to alleviate several of the structural effects of anesthetic exposure in immature animals, including vitamin C [147,148], L-carnitine [149,150], coenzyme Q10 [64], and resveratrol [151]. Moreover, the mitochondrial stabilizer pramipexole has successfully protected against anesthesia-induced long-term cognitive impairment in female rats [126].

Implementation of these strategies employed in animals into pediatric anesthesia management appears premature, especially since human applicability of this phenomenon remains controversial and the safety of some of the proposed therapies has not been tested in young children. Estradiol, for example, may not be a feasible adjuvant prior to puberty or in boys, lithium has been labeled as harmful for the human fetus [152] and may cause neurocognitive impairment in young children [153,154], and hypothermia of 24°C may only be feasible in procedures involving hypothermic cardiopulmonary bypass, but not during routine pediatric anesthesia or intensive care. While xenon's scarcity renders it a very expensive treatment, dexmedetomidine may be a valid option as a single agent for light sedation or as an adjuvant for reducing doses of "toxic" general anesthetics.

Interspecies comparison

While abundant experimental evidence is available in developing animals implicating anesthetics and sedatives in triggering immediate brain structural alterations and long-term neurocognitive impairment, the relevance of these findings for clinical practice remains unclear. Unlike animal studies, the administration of anesthetics and analgesics in clinical pediatric medicine almost always coincides with significant noxious stimulation, such as during painful procedures and surgical operations. In this setting, some animal models have demonstrated analgesics or sedatives as preventing pain-induced neurotoxicity [6,13], while painful stimulation reduced anesthetic neurotoxicity [155]. Others have found an exacerbation of anesthetic neurotoxicity by concomitant noxious stimulation [156], while yet another group did not find any interaction between pain and anesthesia-induced cell death [157]. Differences exist between the metabolic and respiratory effects of anesthetic exposure in small rodent species and those in humans, such as extensive hypercarbia, metabolic acidosis, and hypoglycemia observed in some animals [112,116,117]. Exposure to clinical doses of anesthetics for only 2–4 h can be lethal in a substantial number of small rodents [112,117]. Moreover, doses needed for injectable anesthetics to cause neuronal degeneration in animals are significantly higher than those used in clinical practice. Animal studies have shown toxic doses for ketamine to be 10 times higher

and doses for propofol to be up to 20–30 times higher than clinically used doses, using a weight-based comparison. Accordingly, plasma concentrations of neurotoxic doses for ketamine, as measured in small rodents and monkeys, were approximately 3–10 times higher than those observed during clinical human practice [43,158]. Some of these discrepancies might be related to differences in body size and whole-body metabolic rates among species, resulting in higher weight-based dose requirements for smaller animals compared with larger animals [159]. However, even with allometric scaling to account for differences in body size [160], toxic doses in animal studies still remain higher than clinically used doses for several of the anesthetics (Table 46.2).

While these aspects limit the immediate applicability of results obtained in small rodents to clinical pediatric anesthesia practice, no obvious biological tenet exists categorically exempting humans from the structural abnormalities observed in animals. Importantly, the pattern of neuronal degeneration immediately following anesthetic exposure is qualitatively similar in small rodents and in intubated and mechanically ventilated non-human primates, suggesting that the more economical and ethically acceptable small animal models still have utility in providing important data to further advance the field.

A critically important finding from animal studies is the observed age window of vulnerability. Prolonged exposure to ketamine or isoflurane inflicts significant damage in developing cortical neurons of rodents aged 5–7 days, or in monkeys during the 3rd trimester or aged 6 days or younger, but not in older animals (Fig. 46.7) [32,34,43,59]. Given these findings of a narrow window of degenerative effects observed in the neoortex, it is imperative to identify the corresponding developmental state of the human brain, in order to predict the age range for possible susceptibility in humans. Previously, simple estimations of brain cell numbers and degree of myelination oversimplified the brain maturational state of the 7-day-old rat to span from the last trimester of pregnancy all the way to the third year of life [100,161,162]. Using a more contemporary neuroinformatics approach, the period of maximum cortical neurotoxic susceptibility in rats and monkeys more closely equates to the human 3rd trimester of pregnancy and 5 months of age, respectively (calculator available at http://www.translatingtime.net (accessed May 2019)) [163]. While it is difficult to translate developmental stages in small animals to humans, these comparisons would suggest that the susceptibility of cortical neurons could potentially be most pertinent in premature neonates, for example during fetal surgery, or in neonatal intensive care, and to a lesser extent during pediatric anesthesia in older children [164]. Importantly, more recent work by one of the authors' group discovered differential windows of vulnerability for different brain regions and anesthesia-induced neuroapoptosis in mice to extend into young adulthood for brain regions with ongoing neurogenesis [71]. These windows of vulnerability paralleled the naturally occurring, developmental cell death, suggesting that anesthetics might interfere with neurogenesis during a specific time of neuronal development during a late progenitor/immature neuron state [120]. Extrapolated to children undergoing prolonged or repeated anesthetic exposures, this may suggest that various neurological domains and cognitive abilities, such as language, motor skills, or executive function, may be particular vulnerable when they are being actively developed and supported by increased neurogenesis. If correct, however, this would substantially extend the window of

Table 46.2 Interspecies comparison of toxic and non-deleterious doses for injectable anesthetics (with references)

	Mouse	Rat	Monkey	Human
Toxic ketamine dose	20–40 or 50 mg/kg [46,48]	14–17 mg/kg/h for 11 h [32,42,158]	20–50 mg/kg/h for 24 h in 5-day-old [43,44]	
Estimated equivalent human dose	1.6–3.3 or 4.1 mg/kg	2.3–2.7 mg/kg/h for 11 h	6.5–16 mg/kg/h for 24 h	
Safe ketamine dose	10 mg/kg [48]	75 mg/kg or 17 mg/kg/h for 6 h [42]	20–50 mg/kg/h for 24 h in 35-day-old [43]	
Estimated equivalent human dose	0.8 mg/kg	12.2 mg/kg or 2.7 mg/kg/h for 6 h	6.5–16 mg/kg/h for 24 h	
				0.5–2 mg/kg or 0.1–1.2 mg/kg/h
Toxic propofol dose	60 mg/kg [49]	25 mg/kg [302]		
Estimated equivalent human dose	4.9 mg/kg	4 mg/kg		
Safe propofol dose	10 mg/kg [49]	n.s.		
Estimated equivalent human dose	0.8 mg/kg			
				2–3 mg/kg
Toxic diazepam dose	n.s.	10–30 mg/kg [34,303]		
Estimated equivalent human dose		1.6–4.9 mg/kg		
Safe diazepam dose	5 mg/kg [46]	5 mg/kg [303]		
Estimated equivalent human dose	0.4 mg/kg	0.8 mg/kg		
				0.1 mg/kg
Toxic midazolam dose	9 mg/kg [48]	n.s.		
Estimated equivalent human dose	0.7 mg/kg			
Safe midazolam dose	n.s.	9 mg/kg [36]		
Estimated equivalent human dose		1.5 mg/kg		
				0.1 mg/kg

n.s., not specified.

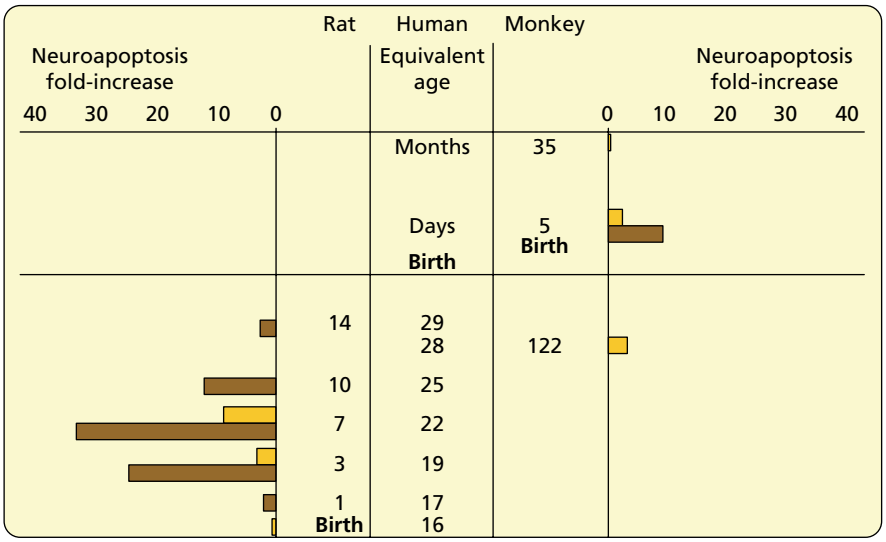

Figure 46.7 Quantification and developmental timing of anesthesia-induced neuroapoptosis. Brown bars signify a relative increase in neuroapotosis compared with physiological apoptosis (fold-increase) following an isoflurane-based anesthetic. Yellow bars signify ketamine exposure. Ages indicate postnatal days for rats (left), embryological and postnatal days for rhesus monkeys (right), and estimated equivalent gestational weeks in humans (center). Data are derived from references [32,43,60,67] and the human developmental equivalency are estimated using reference [163]. *Source*: Reproduced from Istaphanous et al [368].

susceptibility, potentially into adolescence or adulthood, and could explain the difficulties encountered in clinical studies using a wide age range of participants to identify a specifically affected neurological phenotype following anesthetic exposures in children.

KEY POINTS: INTERSPECIES COMPARISON

- Brain regional vulnerability to structural abnormalities is dependent on the age during exposure
- Emerging research suggests this to be linked to the maturational stage of developing brain cells
- This would suggest that the window of vulnerability could potentially extend beyond early childhood into adolescence or young adulthood

Clinical evidence for anesthetic neurotoxicity

While neurotoxic properties of anesthetics are well documented in developing animals, explicit clinical evidence for specific neurological abnormalities in children following anesthetic exposure is much harder to attain. Obvious ethical concerns preclude randomization of young children to undergo painful procedures with or without anesthesia and analgesia. Moreover, prolonged anesthetic exposures cannot be justified without any surgical or diagnostic indication. Hence, possible clinical evidence for the neurological effects of anesthetics and sedatives in young children has mostly been gathered from case reports of inadvertent overdoses, postoperative behavioral studies, epidemiological analyses, or from studies into long-term neurological outcome in children suffering from disorders requiring the administration of anesthetics and sedatives during life-saving surgery and intensive care at a very young age [38,41].

Postoperative behavioral abnormalities

While many studies investigating behavioral changes immediately postoperatively list the specific anesthetic drugs used, and usually involve healthy patient cohorts, their neurological assessment historically only consisted of short-term, parent-reported behavioral questionnaires or observations (Table 46.3). Only more recently have studies emerged utilizing standardized cognitive assessment tools. It has long been known that surgery and anesthesia in young children can lead to prolonged behavioral abnormalities [27,165–174]. Reported behavioral abnormalities, such as attention seeking, crying, temper tantrums, sleep disturbance, and anxiety occur in up to 50% of children early after anesthesia, and diminish significantly during the first postoperative month. These symptoms have repeatedly been associated with younger patient age, severity of postoperative pain, and lack of sedation prior to induction of anesthesia [27,167,169,172,174]. While the phenomenon's exact mechanism remains unknown, psychological factors, rather than structural brain abnormalities, are generally believed to be the underlying etiology [165,166,175]. Importantly, the administration of a benzodiazepine prior to general anesthesia did not exacerbate postoperative behavioral abnormalities, as expected for a cytotoxic etiology, but rather significantly reduced abnormal behavioral symptoms postoperatively [176]. However, since most postoperative behavioral studies rely on parental assessment of the child, no continuing professional observations and long-term neurocognitive assessments were incorporated in any of the behavioral studies. Therefore, the permanence of these neurological abnormalities remains uncertain.

Table 46.3 Behavioral or cognitive assessment following anesthetic exposure in early childhood*

Anesthetic agent	Dose or duration	Study design	Number of subjects	Age during exposure	Neurological sequelae on exam	Duration of symptoms and outcome	Reference
Midazolam (plus fentanyl)	0.07–0.94 mg/kg/h for up to 38 days	Case–control	45	0.03–19.2 years	After discontinuation of sedation, poor social interaction, decreased visual attentiveness, dystonic postures, and choreoathetosis in 11%	No sequelae 4 weeks after discontinuation	Bergman et al [304]
Midazolam (plus pentobarbital)	1–17 days	Retrospective cohort study	40	0.5–14 years	After discontinuation of sedation, agitation, anxiety, muscle twitching, sweating, tremor in 35%. Midazolam dose of >60 mg/kg strongly associated with symptoms	Symptoms abolished by pentobarbital treatment	Fonsmark et al [305]
Midazolam (plus opioid)	1.5–4 mg/h for 10 days	Case series	6	1–6 years	Multifocal myoclonus, dystonia, chorea, facial grimacing, tongue thrusting without seizure activity on EEG. Chemotherapy for CNS malignancies, MRI abnormalities	3–7 days	Khan et al [306]
Midazolam (plus morphine)	0.025–0.72 mg/kg/h for 1–18 days	Cohort study	53	6 days to 11 years	After discontinuation, prolonged sedation for up to 1 week in 8%. Disorientation, hallucinations, and behavioral abnormalities in up to 11%	0.13–7 days	Hughes et al [307]
Midazolam (plus opioid)	0–0.014 mg/kg/min for 4–18 days	Cohort study	15	6 weeks to 2.3 years	After discontinuation, sleeplessness, tremors, agitation, movement disorder in up to 50%. Symptoms occured as late as 6 days after start of taper	3 days	Franck et al [308]
Lorazepam (plus opioid)	0.1–0.4 mg/kg/h for 11–30 days	Prospective, open-label study	29	0.2–3 years	During taper, 24% experienced agitation, irritability, abnormal movements, or hallucinations	Not specified	Dominguez et al [309]
Pentobarbital (plus midazolam)	1–17 days	Retrospective cohort study	40	0.5–14 years	After discontinuation of sedation, agitation, anxiety, muscle twitching, sweating, tremor in 35%. Pentobarbital >25 mg/kg associated with symptoms	Symptoms abolished by pentobarbital treatment	Fonsmark et al [305]
Pentobarbital (plus benzodiazepines and opioids)	1–5 mg/kg/h for 0.6–49 days	Case series	8	0.4–7 years	During sedation, one patient (12.5%) experienced choreiform movements with athetoid features, ataxia, facial twitching. Also received mathadone and phenobarbital	1 week	Yanay et al [310]
Pentobarbital	1–4 mg/kg/h for 4–28 days	Case series	6	0.17–1.4 years	None reported	Not applicable	Tobias et al [311]
Phenobarbital (plus phenytoin)	20–1800 mg/day in mother	Case–control	172	Fetal exposure	Greater need for special education, learning difficulties, lower intelligence (WAIS), decreased attention on D-2, but not CPT test in adults after fetal exposure versus controls. No difference in memory tasks (DS, ALT)	Not applicable	Dessens et al [312]
Phenobarbital	2.5–50 mg for 1–540 days	Cross sectional, case–control	28	Neonate	No difference in Kaufman-ABC intelligence and D-2 tests between 8- and 14-year-old children following neonatal treatment with phenobarbital and "best friend" controls	Not applicable	Gerstner et al [313]
Ketamine	13–56 mg/kg	Case series	18	0.07–7 years	After inadvertent overdose, prolonged sedation and respiratory depression	Sedation for 3–24 h, no neurological sequelae on follow-up, where available	Green et al [314]

Propofol	200 mg/h for 48h *in utero*	Case report	1	Premature neonate 33 weeks GA	Prolonged sedation, no other neurological sequelae reported	12 h	Bacon et al [315]
Propofol	10.9 mg/kg/h for 11 days	Case report	1	23 months	Restlessness, muscle twitching limbs, functional blindness	Motor function impaired for 2 weeks, blindness for 33 days	Lanigan et al [316]
Propofol	Median infusion 2.7 mg/kg/h for >24 h	Case series	20	Median age 3.3 years	No neurological sequelae	Not applicable	Macrae and James [317]
Propofol	6–18 mg/kg/h for 2–4 days	Case report	2	2.5 and 4 years	Muscle weakness, twitching	9–18 days, full recovery	Trotter et al [318]
Propofol	10 mg/kg/h for 54 min	Case report	1	6 years	Seizure, ataxia, hallucinations starting 44 h after discontinuation of propofol	5 days, recovered without overt long-term sequelae	Bendiksen et al [319]
Isoflurane	13–497 MAC-hours	Cohort study	10	0.06–19 years	Agitation, non-purposeful movement in 50% of patients; all received >70 MAC-hours isoflurane, plus benzodiazepines and opioids	Symptoms responded to treatment advocated for opioid withdrawal	Arnold et al [320]
Isoflurane	0.25–1.5% for 1–76 h	Case series, case–control	12	0.5–10 years	Transient ataxia, agitation, hallucinations, and confusion after isoflurane administration >24 h; no symptoms after benzodiazepines or isoflurane <15 h	Normal follow-up exam 4–6 weeks after discharge	Kelsall et al [321]
Isoflurane	81 MAC-hours	Case report	1	2.5 years	Self-limiting, fine tremor in patient with myasthenia	46 h	McBeth et al [322]
Isoflurane	0.4–0.9% for 6–8 days	Case series	3	4–11 years	Temporary involuntary movements, myoclonia, brief seizures, and ataxia	Resolution of symptoms within 4–5 days	Sackey et al [323]
Isoflurane (plus midazolam and morphine)	0.5–1% for 4 days	Case report	1	7 years	Disorientation, hallucinations, agitation, seizure	5 days; reportedly normal behavior	Hughes et al [324]
Sevoflurane	8% during induction	Prospective study	20	1.1–8.4 years	Seizure-like movement and epileptiform EEG in 10%, no neurological exam	Not applicable	Conreux et al [325]
Sevoflurane	8% during induction	Prospective study	31	2–12 years	Epileptiform discharge in 88% with controlled ventilation and 20% with spontaneous breathing. No neurological exam	Not applicable	Vakkuri et al [326]
Sevoflurane	7% during induction	Prospective, randomized trial	45	2–12 years	No seizure activity on induction. Neurological exam not performed	Not applicable	Constant et al [327]
Sevoflurane	2% after IV thiopental	Prospective study	30	3–8 years	No epileptiform EEG activity. Neurological exam not performed	Not applicable	Nieminen et al [328]
Sevoflurane	Dose not specified	Meta-analysis of prospective studies in one center	791	3.3±2.1 to 6.9±2.4 years	increased "maladaptive" behavior in children, who were younger, and whose parents were more anxious on induction	Assessment up to 14 days postoperatively	Kain et al [172]
Sevoflurane or halothane	2–4% for 22±17 min/ 1–2% for 22±15 min	Prospective, randomized trial	120	3.3±2.6 to 4±2.9 years	Negative behavioral changes, such as temper tantrums, loss of appetite, or sleep disturbance in 38% for up to 30 days; no difference between sevoflurane or halothane	Assessment up to 30 days postoperatively	Keaney et al [171]
Sevoflurane or halothane	Doses not specified; outpatient surgery	Double-blinded, randomized, controlled trial	102	3–10 years	PHBQ: no difference between both anesthetics in regard to postoperative anxiety, sleep or appetite disturbance, strength, and energy	Up to 1 week postoperatively	Kain et al [173]

(*Continued*)

Table 46.3 (Continued)

Anesthetic agent	Dose or duration	Study design	Number of subjects	Age during exposure	Neurological sequelae on exam	Duration of symptoms and outcome	Reference
Pentobarbital, scopolamine, ether, nitrous oxide, and/or cyclopropane	Doses not specified; otolaryngological surgery	Survey study	612	2 to >12 years	Parental assessment: Negative behavioral changes, such as night terrors, temper tantrums, fears, and bed wetting most prevalent in under 3-year group (57%) compared with older group (8%)	Questionnaires mailed to parents 2 months postoperatively	Eckenhoff [27]
Pentobarbital, scopolamine, morphine, and ether or nitrous oxide	Doses not specified; otolaryngological, dental, or ophthalmological surgery	Survey, case–control	290	1–15 years	No differences in psychological upset after anesthesia, surgery, and hospitalization compared with siblings or healthy controls	Interview administered to patient's mother 2 weeks postoperatively	Davenport and Werry [329]
Halothane or ketamine	Dose not specified; scheduled and emergency surgery	Prospective randomized study, survey	103	1–12 years	Parental assessment: fear of strangers, sleep disturbance, nightmares, or bed wetting in 38% under 4 years versus 16% in 4-year-olds and over	Parental assessment 1 month postoperatively	Modvig et al [166]
Thiopental, halothane, or methohexital induction, and halothane and nitrous oxide maintenance	Methohexital 15 mg/kg PR, otherwise not specified; routine day-case ENT surgery	Survey study	86	2–10 years	PHBQ: problematic behavioral changes in 51% at 1 day and 34% at 1 month postoperatively. Temper tantrums tended to be more common following stormy induction versus calm induction of anesthesia	Questionnaires given to parents to report behavior 1 day, 1 week, and 1 month postoperatively	Kotiemi et al [168]
Thiopental or propofol, isoflurane, or halothane or enflurane. Midazolam or diazepam premed	Doses not specified; ENT or ophthalmological procedures with mean anesthesia time of 32.8±17.9 min	Multicenter survey	551	0.3–13.4 years	PHBQ: behavioral problems in 47% on day of surgery, 9% after 4 weeks, including attention seeking, crying, temper tantrums, sleep problems, and anxiety	Questionnaires given to parents to report behavior up to 4 weeks postoperatively	Kotiemi et al [169,170]
Halothane/nitrous oxide	Dose not specified; elective minor head and neck surgery	Survey study	122	1–8 years	Parental assessment: behavioral abnormalities in up to 88% of children awake during induction and 58% of children asleep during induction	Questionnaires mailed to parents within 1st postoperative month	Meyers and Muravchick [167]
Predominantly halothane, nitrous oxide, ketamine, and/or thiopental	Doses not specified, stratified by number of exposures for mostly ENT and general surgery	Retrospective, epidemiological study	5357	0–4 years	Review of medical and educational records demonstrate a doubling of the risk of learning disabilities following two or more surgical procedures with anesthesia for more than a combined 2 h, compared with no or one exposure	Review of educational records several years after anesthetic exposure	Wilder et al [211]
Predominantly sodium thiopental, nitrous oxide, and halothane	Doses not specified, general or regional anesthesia for cesarean delivery versus spontaneous vaginal birth	Retrospective review of records	5320	Perinatal	The incidence of learning disabilities was similar among children delivered vaginally without anesthesia and via cesarean section with general anesthesia, but lower following cesarean section with regional anesthesia	Review of school records	Sprung et al [210]

No data	No data	Epidemiological case–control study	5050	0–3 years	Doubling of presence of diagnostic codes for developmental problems in children also carrying a billing code for inguinal hernia repair prior to 3 years of age, compared with those who did not carry this billing code	Presence of diagnostic codes for developmental or behavioral disorder, mental retardation, autism, and language or speech problems	DiMaggio et al [206]
No data	No data	Review of data from monozygotic twin pairs from Young Netherlands Twin Register	1143	0–3 years	Educational scores lower in concordant twin pairs exposed to anesthesia compared with unexposed pairs. However, no difference in educational achievement comparing both twins in discordantly exposed pairs	Educational achievement (Cito test administered at age 12 years) and Connor Teacher Rating Scale	Bartels et al [286]
No data	No data	Sibling case–control study	10,450	0–3 years	Risk for developmental or behavioral disorder increased to 2.9 (95%CI: 2.5, 3.1) following two operations to 4 (95%CI: 3.5, 4.5) following three operations	Diagnosis of developmental or behavioral disorder, as assessed with billing codes	DiMaggio et al [330]
No data	No data	Matched cohort study	1050	0–2 years	Multiple exposures increased risk for learning disabilities by 2.1 (95%CI: 1.3, 3.5) but not need for educational intervention for emotion/behavior	Diagnosis of learning disability, after adjustment for health status	Flick et al [214]
No data	No data	Matched cohort study	4684	Perinatal	Not increased by neuraxial labor analgesia (adjusted OR 1.05, 95%CI: 0.9, 1.3)	Diagnosis of learning disability	Flick et al [331]
Benzodiazepines, chloral hydrate, opioids, ketamine, volatile anesthetics	Cumulative and daily	Prospective follow-up study	95	Neonatal complex heart surgery	No association between sedation/analgesia variables and behavioral or cognitive outcomes at 18–24 months	Bayley II/III, ABAS-GAC, and LDS	Garcia Guerra et al [199]
Benzodiazepines, chloral hydrate, opioids, ketamine, volatile anesthetics	Cumulative and daily	Prospective follow-up study	91	Infant complex heart surgery	Association between days on chloral hydrate and lower performance IQ, cumulative benzodiazepine dose associated with lower VMI scores at 54±5 months	WPPSI II, VMI-V, ABAS-GAC	Garcia Guerra et al [200]
No data	No data	Nationwide case–control study	17,264	Infant inguinal hernia repair	No difference in scores between exposed and unexposed, after adjustment for confounders; rates of non-attainment higher in exposed	Academic achievement in compulsory 9th grade exam and teacher rating	Hansen et al [220]
No data	No data	Nationwide case–control study	17,264	Pyloromyotomy <3 months	No difference in scores between exposed and unexposed, after adjustment for confounders; rates of non-attainment higher in exposed	Academic achievement in compulsory 9th grade exam and teacher rating	Hansen et al [221]
No data	No data	Nationwide case–control study	15,655	Cholesteatoma removal <15 years	No difference in scores between exposed and unexposed, except for lower grades in first foreign language following repeat exposure; rates of non-attainment higher in exposed	Academic achievement in compulsory 9th grade exam and teacher rating	Djurhuus et al [332]

(*Continued*)

Table 46.3 (Continued)

Anesthetic agent	Dose or duration	Study design	Number of subjects	Age during exposure	Neurological sequelae on exam	Duration of symptoms and outcome	Reference
Nitrous oxide, halothane, thiopental, isoflurane, morphine, sevoflurane, and/or fentanyl	Duration ranging from 0.8 to 3.8 h	Retrospective observational study	58	Infant surgery for inguinal hernia repair, orchidopexy, pyloromyotomy, or circumcision	No difference in academic achievement, but higher proportion scored below the 5th percentile; duration of anesthesia correlated negatively with scores	Statewide academic achievement test scores (Iowa Tests of Basic Skills and of Educational Development)	Block et al [333]
No data	No data	Case–control study	208	Surgery in premature infants born at <30 weeks GA	Compared with non-surgical group, smaller brain and deep gray matter volumes, greater white matter injury in infants exposed at term; PDI and MDI similar after adjustment for confounders	Volumetric analysis of MRI at term, Bayley-II at age 2 years	Filan et al [334]
No data	No data	Birth cohort case–control study	2608	Surgery < 3 years of age	Higher risk of language and abstract reasoning deficits at age 10 years, after adjustment for demographics	CELF, CPM	Ing et al [335]
No data	No data	Case–control study	5357	Surgery <2 years of age	Multiple, but not single, exposures associated with increased risk of ADHD, after adjustment for cofounders	Review of records for clinical diagnosis of ADHD and at least one form of supporting evidence	Sprung et al [215]
No data	Mean duration 51 min	Prospective longitudinal study	21	Strabismus surgery between 5 and 10 years of age	No difference in pre- and postoperative performance, except for diminished hand-eye coordination in patients with decreased stereoacuity	Kaufman-ABCadministered prior to and 4 weeks after surgery	Yang et al [336]
Sevoflurane, thiopental, or propofol	30–120 min surgeries	Case–control study	100	Infant surgery	No difference in aggregate score, but 4.5 times higher odds ratio for diagnosis of learning disability following exposure	Singapore primary school leaving examination at 12 years of age	Bong et al [337]
No data	No data	Prospective follow-up study	27	Neonatal laparotomy for bowel obstruction	Abnormal motor function and attention, no other cognitive domains affected	Movement-ABC, abbreviated WISC-III, TEA-Ch, visuomotor integration part of NEPSY-II, and AVLT	Elsinga et al [338]
Sevoflurane, fentanyl	Mean anesthesia time 67±10 min	Prospective longitudinal study	72	Strabismus surgery between 4 and 7 years of age	No adverse effects on cognitive function observed	WPPSI III prior to, 1 month, and 6 months following operation	Fan et al [339]
Opioids, benzodiazepines, volatile anesthetics	4.4±3.1 MAC-hours during 2–4 exposures	Prospective observational study	59	Infant repair of complex congenital heart lesions	Higher volatile anesthetic exposure associated with lower cognitive scores	Bayley-III at 1 year	Andropoulos et al [201]

No data	No data	Case–control study	781	Surgery <3 years of age	Increased risk for measured language deficits and ICD-9-identified disorders, but no change in academic achievement	CELF, mental, behavioral, neurodevelopmental disorders per ICD-9 codes, academic achievement scores	Ing et al [340]
No data	No data	Case–control study	2,868	Surgery between 3 and 10 years of age	Higher risk for motor deficit following exposure between 3 and 5 years of age	CELF, Raven's Colored Matrices, Peabody Picture Vocabulary Test, MAND, CBCL	Ing et al [341]
No data	No data	Case–control study	16,465	Surgery <3 years of age	No difference between diagnosis of ADHD between exposed and unexposed	ICD-9-CM code 314.01 for diagnosis of ADHD >3 years	Ko et al [342]
No data	No data	Case–control study	20,788	Surgery <2 years of age	No difference between diagnosis of autistic disorder between exposed and unexposed	Diagnosis of autism according to ICD-9-CM code 299.00	Ko et al [343]
Propofol, nitrous oxide, sevoflurane, isoflurane, or halothane	Median anesthetic dose 203 MAC-minutes (two outliers of <60 MAC-minutes)	Case–control study	28	Infant, mostly urological surgery	Recognition memory impairment, no difference in IQ	WASI, recognition memory task tested at 6–11 years of age	Stratmann et al [344]
Spinal anesthesia	Mean duration of surgery 40±13 min	Retrospective observational study	265	Infant surgery for circumcision, pyloromyotomy, or inguinal hernia repair with spinal anesthesia <5 years	Decrease in reading and mathematics scores in exposed group; no correlation with duration of surgery	New Standards Reference Examination achievement and New England Common Assessment Program Examination tests	Williams et al [345]
Ketamine 8 mg/kg IM	1–3 exposures	Observational study	49	1–3 laser excisions of facial growth in 3–22-month-olds	Diminished MDI following third exposure	Bayley-II	Yan et al [346]
Etomidate followed by propofol (5–10 μg/kg/min) or sevoflurane (1–3%)	No data	Prospective, longitudinal study	60	Inguinal hernia repair at 7–13 years of age	Transient memory impairment observed in propofol exposed patients 7 days postoperatively, but not following sevoflurane exposure	Wechsler Memory Scale preoperatively, and 7 days or 3 months postoperatively	Yin et al [347]
Halothane, nitrous oxide, sevoflurane	0.2–3.8 MAC-hours	Matched case–control study	53	Surgery <4 years of age, mostly ENT	Impaired listening comprehension and diminished performance IQ, associated with diminished gray matter density in occipital cortex and cerebellum	WISC/WAIS, OWLS, MRI between 5 and 18 years	Backeljauw et al [348]
No data	No data	Nationwide case–control study	536,673	Perinatal for cesarean section	Increased risk for development of autism following cesarean section with general anesthesia compared with regional anesthesia or vaginal birth	ICD-9-CM code 299.0 for diagnosis of autism during mean follow-up of 4.3 years	Chien et al [349]

(*Continued*)

Table 46.3 (Continued)

Anesthetic agent	Dose or duration	Study design	Number of subjects	Age during exposure	Neurological sequelae on exam	Duration of symptoms and outcome	Reference
Halothane ± nitrous oxide ± thiopental	Duration 65–317 min cumulative duration	Matched case–control study	30	Surgery <2 years	Activation differences with unexposed subjects in cerebellum, cingulate gyrus, and paracentral lobule during tests of response inhibition	Blood oxygen-dependent fMRI at 10–17 years of age	Taghon et al [350]
							Clausen et al [351]
Sevoflurane versus neuraxial anesthesia	Duration 41–70 min (median 54 min)	Randomized controlled trial	532	Infant inguinal hernia repair	No difference in cognitive performance between general and regional anesthesia	Bayley-III at 2 years	Davidson et al [226]
Desflurane, halothane, isoflurane, and/or sevoflurane	0–35.3 MAC-hours cumulative	Retrospective observational study	96	Infant surgeries for HLHS or variants	Inverse correlation between MAC-hours and full-scale and verbal IQ scores	WPPSI III between 4 and 5 years of age	Diaz et al [352]
No data	Mean neonatal duration of 145 min (95% CI: 115, 175 min) and cumulative period of 268 min	Ambidirectional case–control study	40	Neonatal surgery for gastrointestinal malformations	Diminished mental development index due to impaired verbal abilities	Bayley-II	Doberschuetz et al [353]
No data	No data	Retrospective matched cohort study	18,056	Surgery <4 years	Single exposure between 2 and 4, but not between 0 and 2 years, associated with deficits	EDI assessment at 5 years of age	Graham et al [223]
No data	No data	Population-based cohort study	188,557	Surgery <4 years	Early developmental vulnerability following first exposure after 2nd birthday, but not if exposure occurred before age 2	EDI assessment age 5–6 years	O'Leary et al [222]
No data	Range from 20 to 240 min (median 80 min)	Ambidirectional sibling-matched cohort study	210	Inguinal hernia repair <3 years	No difference in mean IQ scores compared with sibling control	NEPSY-II at 8–15 years	Sun et al [228]
Morphine	Median cumulative dose of 1905 mg/kg	Prospective cohort study	136	Very preterm neonates (24–32 weeks GA)	Decrease in cerebellar volume, diminished cognitive and motor outcomes associated with cumulative morphine dose	Peabody Developmental Motor Scales, Bayley-III, serial MRI scans	Zwicker et al [354]
No data	Cumulative duration of anesthesia ranged from 0.8 to 22.4 h	Retrospective cohort study	87	Cleft lip and/or palate repair before 7 years of age	Diminished verbal IQ and higher frontal lobe volume associated with number of surgeries with anesthesia	WISC-III or WAIS-III, brain MRI	Conrad et al [355]
Propofol, isoflurane or sevoflurane, fentanyl, sufentanil, or alfentanil	No data	Retrospective cohort study	3441	Surgery with anesthesia before age 5 years	Lower IQ scores in exposed group	Snijders Oomen Niet-verbale intelligentie test – Revisie	De Heer et al [356]
No data	No data	Nationwide cohort study	196,773	Surgery before age 4 years	Less than 1% school grades in exposed children, compared with unexposed	School grades at age 16 years, IQ test at military conscription at age 18 years	Glatz et al [224]

No data	No data	Retrospective cohort study	1036	Surgery before age 3 years	Increased frequency of learning disabilities and attention-deficit/hyperactivity disorder, decreased academic achievement following multiple, but not single, exposures. Decreased reading and language achievement following single exposure	Medical and school records review	Hu et al [216]
Nitrous oxide, halothane, isoflurane, or enflurane, as well as thiopental, propofol, or benzodiazepines	No data	Population-based cohort study	1622	Anesthesia with volatile agents before age 3 years	Lower total and expressive language scores following exposures exceeding 35 min, but not following shorter durations	CELF, CPM	Ing et al [357]
No data	No data	Retrospective matched cohort study	230,958	Single anesthetic exposure before age 5 years	Increased risk of diagnoses for mental disorder, developmental delay, and ADHD, without effect of age when exposure occurred	Presence of ICD-9 coded mental disorder diagnosis	Ing et al [209]
No data	Exposure duration 124±137 min	Ambidirectional case–control study	31	Infant surgery for circumcision, pyloromyotomy, inguinal hernia, orchidopexy, or tympanostomy	Decreased whole-brain white matter volume and diminished white matter integrity in several regions	Structural MRI in boys at age 12–15 years	Block et al [358]

Neurological outcomes in critically ill neonates

Previously critically ill neonates represent a patient population historically closely followed with standardized neurodevelopmental tests. Many of these patients underwent surgical procedures involving general anesthesia early in life, such as for ligation of the patent ductus arteriosus, repair of esophageal atresia, inguinal hernia repair, neurosurgical operations, laparotomies, or tracheotomies [177–186]. However, none of these studies were designed to study the long-term effects of anesthetic exposure and, accordingly, they consistently fail to specify the exact anesthetic agents used and oftentimes involve several potent confounders, such as severe prematurity, prolonged ventilator support, considerable pain and distress, significant co-morbidities, and latent episodes of hypoxia or hypoxia-ischemia, and frequently include major surgical procedures with potentially significant postoperative inflammatory response (Table 46.4). In this context, long-term neurodevelopmental impairment, such as a reduction in IQ, increased incidence of cerebral palsy, deafness, or blindness have frequently been observed [180–184,186]. Coexisting disease and congenital abnormalities were associated with worse neurological outcomes [178,183]. In an attempt to at least partly control for severity of illness, several case–control studies compared neurodevelopmental outcome in survivors of surgical operations for necrotizing enterocolitis and patent ductus arteriosus with those receiving medical management alone. When compared with age-matched controls or medically treated patients in the same cohort, several investigators noticed an impairment in neurocognitive function in surgically treated survivors of laparotomy or thoracotomy [180–182,184,186], while others were unable to find these differences [177,179,185]. However, it remains difficult to separate the effects of neonatal stress and surgery from the effects of the anesthetics. Moreover, study designs did not include randomized controlled trials, but were rather designed as cohort studies or case–control studies. It therefore seems conceivable that, due to selection bias, some of the extremely premature neonates that needed surgery had more concomitant illnesses and were therefore sicker than their matched controls. This notion is underscored by the fact that some of the studies identified longer periods of hypotension, more common use of inotropic support, and longer periods of total parenteral nutrition in the postsurgical patients [180,182]. Accordingly, a prospective randomized trial of 117 preterm infants with necrotizing enterocolitis who were assigned to either laparotomy or to peritoneal drainage without surgery did not find any difference in patient survival and early outcomes [187].

Another patient population that has been followed for evaluation of long-term neurocognitive development following surgical procedures early in life are neonates and infants undergoing congenital heart surgery, such as for hypoplastic left heart syndrome, transposition of the great arteries, or tetralogy of Fallot [188–198]. This patient population frequently requires repeated or prolonged anesthetic exposures, and neurocognitive impairment has been documented in many of these patients when compared with population norms [188–196,198] or with 'best friend' control subjects [197]. However, in these studies the anesthetic regimen was frequently not specified and confounding factors included preoperative neurological lesions, pre-existing or perioperative hypoxia and hypotension, as well as chronic postoperative hypoxemia in many of these patients. Interestingly, in the largest trial, the Boston Circulatory Arrest Trial with patient follow-up for 8 years after arterial switch operation, many outcome measures in a battery of neurodevelopmental tests were within normal population limits, despite major corrective cardiac surgery with anesthesia in the neonatal period [196]. In an important preliminary report in this population, Garcia Guerra et al studied 95 survivors of neonatal open heart surgery with normal chromosomes [199]. They calculated the cumulative dose, dose per day, and number of days each patient received opioids, benzodiazepines, ketamine, and chloral hydrate in the intensive care unit. At 18–24 months, none of the sedation variables was associated with poor performance on the Bayley Scales of Infant Development, or other tests of adaptive behavior and vocabulary [199]. However, a follow-up at 4 years of age uncovered exposure to chloral hydrate to be associated with lower performance IQ, and higher cumulative benzodiazepine doses to be associated with visual motor abnormalities [200]. While the intraoperative exposure to anesthetic gases and other drugs were not recorded in that study, a retrospective review of neonates with complex congenital heart disease undergoing corrective surgery at Texas Children's Hospital identified higher exposure to volatile anesthetics to be associated with lower cognitive Bayley III scores at 12 months of age [201].

Several case–control studies have also attempted to address the neurocognitive implications of prenatal anesthetic exposure *in utero* [202–205]. Abnormal neurological activity observed in neonates early after delivery included increased motor tone and decreased interaction [205], visual test abnormalities [203], and motor weakness [202]. Interestingly, the incidence of early neurological abnormalities following cesarean section did not differ between neonates exposed to general anesthesia, including thiopental and nitrous oxide, or to maternal epidural analgesia using lidocaine 2]. In a small, 4-year follow-up after prenatal exposure to anesthetics for dental procedures [203], children demonstrated decreased intelligence scores compared with unexposed controls, but demonstrated similar performance on tests of their vocabulary [204]. However, anesthetic exposure was not quantified, spanned from the 1st to the 3rd trimester of pregnancy, and consisted of such diverse agents as methohexital, sodium thiopental, lidocaine, and carbocaine.

KEY POINTS: COHORT STUDY EVIDENCE FOR ANESTHETIC NEUROTOXICITY

- Several cohort studies in premature and term neonates undergoing major surgical operations involving general anesthesia demonstrate neurodevelopmental impairment later in life, however none of these studies specified the anesthetic technique utilized
- The effects of concomitant disease and the impact of the surgical procedure cannot be separated from the effects of anesthesia

Table 46.4 Outcomes studies following major surgery in neonates and infants

Study design	Study group	Control group	Number of subjects	Age during exposure	Age during neurological assessment	Neurological assessment tool*	Neurological sequelae in study group	Reference
Case–control study	PDA ligation, inguinal hernia repair, GI surgery, neurosurgery, tracheotomy	No surgical intervention	221	First hospitalization for <27 weeks PCA, ELBW	5 years	Neurological examination, WPPSI-R	Increased incidence of cerebral palsy, blindness, deafness, WPPSI-R >3 SD below mean	Victorian Infant Collaborative Study Group [181]
Case series	Repair esophageal atresia	None, comparison with general population	36	Neonatal	10.2 years	WISC-RN, ADQC, CBCL, TRF	10% reduction in IQ; special education five times as frequent; subgroup without major associated congenital anomalies had normal IQ	Bouman et al [183]
Case series	Repair esophageal atresia	None, comparison with general population	34	Neonatal	12.7 years	WISC, HFT, Rohrschach Test	No statistical difference in IQ compared with age- and gender-matched general population	Lindahl et al [177]
Cohort study, case–control study	PDA ligation	Indomethacin treatment	340	84% neonatal (25–29 weeks PCA), ELBW	18 months	Neurological examination, BSID2	Increase in cerebral palsy, cognitive delay, hearing loss, bilateral blindness	Kabra et al [186]
Cohort study, case–control study	Laparotomy	Peritoneal drain placement	3725	Neonatal, ELBW	18–22 months	Neurological examination, BSID2	Blinded assessor: higher frequency of cerebral palsy and lower BSID2; no difference between medically treated patients with or without NEC	Hintz et al [184]
Case–control study	Laparotomy	Peritoneal drain placement	78	29 weeks PCA, ELBW	18–22 months post-term	Neurological examination, BSID2	Less neurodevelopmental impairment and lower mortality	Blakely et al [185]
Case–control study	NEC	No NEC	802	30 weeks PCA, VLBW	20 months post-term	SBIS, BSID	No blinded assessor: no significant difference in BSID scores; impairment more prevalent in survivors of most severe form of NEC, however not stratified by surgical or medical management	Walsh et al [178]
Case–control study	NEC requiring laparotomy	No NEC or NEC managed medically	115	26–27 weeks PCA, VLBW	12 months, 3 years, and 5 years PCA	GMDS, SBIS	No blinded assessor: higher incidence of neurodevelopmental impairment; use of inotropes and TPN dependence more prevalent after laparotomy	Tobiansky et al [180]
Case–control study	NEC requiring laparotomy	Gestational age and birthweight matched controls	30	26 weeks PCA, ELBW	5 and 7 years	GMDS, SBIS, CBCL, Peabody tests	No blinded assessor: NDI in 70% of survivors of NEC versus 25% in age-matched controls. NDI after laparotomy for NEC 66.6% versus 9.1% after NEC managed medically. Hypotension requiring inotropes more prevalent after laparotomy	Chacko et al [182]
Case–control study	NEC requiring laparotomy	NEC managed medically	18	Neonatal, VLBW	8 and 15 months post-term, 24 months	BSID, INFANIB, DDST	Assessor not blinded: higher prevalence of motor delays early after surgery; no differences detected at 2 years of age	Simon et al [179]

(*Continued*)

Table 46.4 (Continued)

Study design	Study group	Control group	Number of subjects	Age during exposure	Age during neurological assessment	Neurological assessment tool*	Neurological sequelae in study group	Reference
Prospective, randomized trial	ASO with DHCA	ASO with LF-CPB or general population	155	Neonatal	1, 2.5, 4, and 8 years	WISC-III, WIAT, TRF, CBCL, WCST, TOVA, Mayo Test for Apraxia of Speech, Goldman–Fristoe Test of Articulation	Lower full-scale IQ, Perceptual Organization, and Freedom from Distractability scores, WIAT reading and mathematics composites, Memory Screening Index, WCST, and TOVA scores. Most differences were <1 SD	Bellinger et al [190,192,196]
Cohort study	Open heart surgery	None	59	Neonatal	≥2 years	SBIS or BSID	Cerebral palsy in 22%, mean IQ 90, but highly dependent on type of congenital heart disease	Miller et al [188,189]
Case series	ASO	None, comparison with general population	60	Neonatal	3–14 years	Kiphard and Schilling Body Coordination Test, Kaufman Assessment Battery for Children, Oral and Speech Motor Control Test, Nayo Test of Speech and Oral Apraxia	Assessor not blinded: increased prevalence of neurological impairment (27%), speech impairment (40%), motor dysfunction, and language impairment; no difference in intelligence	Hövels-Gürich et al [198,359]
Case–control study	ASO with limited DHCA	"Best friend" control group or general population	148	0–118 (median 9) days	9.1±2.9 years	WPPSI-R or WISC-III, CBCL, Movement-ABC	Lower IQ than control, but still above general population mean; higher prevalence of behavioral, language expression, and comprehension problems	Karl et al [197]
Case series	Open heart surgery	None, comparison with general population	98	Infancy	1–3 years	PDMS, GMDS	Blinded assessor: abnormal neurological exam in 41%, motor delay in 42%, and global developmental delay in 23%	Limperopoulos et al [360]
Case series	HLHS	None, comparison with general population	28	Several procedures as neonates and early childhood	8.6±2.1 years	WISC-III, WJPB, VMI, CELF-R, CBCL	Assessor not blinded: prevalence of mental retardation 18% and borderline IQ in 36%. Learning disability in over 14% of survivors. Performance IQ scores lower than verbal IQ scores	Mahle et al [194]
Cohort study, case–control study	Intrauterine exposure to nitrous oxide	No intrauterine exposure	159	Prenatal: 3rd trimester	5 days postnatally	Prechtl's Neurological and Brazelton's Behavioral Assessments	Weaker habituation to sound, stronger muscular tension and resistance to cuddle, fewer smiles	Eishima [205]
Case–control study	General or local anesthetics	No anesthetic exposure	39	Prenatal: 1st to 3rd trimester	0.8–6 days postnatally	Measurement of visual pattern preference	Prolongation of visual pattern preference	Blair et al [203]
Case–control study	General or local anesthetics	No anesthetic exposure	14	Prenatal: 1st to 3rd trimester	4±0.08 years	PPVT, vocabulary parts of WPPSI and SBIS	Lower PPVT IQ scores, no differences in WPPSI or SBIS	Hollenbeck et al [204]

Prospective, case–control study	Thiopental, nitrous oxide for general anesthesia	Lidocaine 1.5% for epidural analgesia	30	Perinatal for cesarean section	1–7 days	Neurological assessment as per Prechtl and Beintema	Blinded assessor: abnormal neurological activity for up to 7 days in 47%, regardless of group assignment	Hollmen et al [202]
Cohort study	Elective procedures that required anesthesia		340	2–13 years	Up to 2 weeks after exposure	PHBQ, CBCL	Behavioral abnormalities in 34%, especially if age <5 years, postoperative pain or nausea, anxiety during induction, post-tonsillectomy, previous hospitalizations	Karling et al [361,362]
Survey study	General anesthesia for general surgery, ENT, gastroenterology, plastics surgery, orthopedics	None, some sibling controls	1027	3–12 years	3 and 30 days postanesthesia	PHBQ	Behavioral changes in 24% on day 3 after surgery, 16% on day 30, including anxiety and regression, apathy or withdrawal, and separation anxiety	Stargatt et al [174]
Prospective poulation-based study	Prolonged sedation and/or analgesia for intensive care	No exposure to sedation or analgesia	1345	Neonatal: premature infants born 22–32 weeks PCA	Up to 5 years	MPC of Kaufman Assessment Battery for Children	No difference in disability after adjustment for severity of illness (not powered to identify cognitive group differences <10%)	Rozé et al [217]
Retrospective cohort study	General anesthesia for urological procedures	None, comparison with general population	243	0–6 years	Several years after surgery	CBCL/4-18	Incidence of behavioral disturbances higher in children operated on <2 years of age, compared with >2 years	Kalkman et al [218]
Prospective, longitudinal study	General anesthesia, intensive care for correction of congenital anomalies	None, comparison with general population	101	Neonatal period	Up to 2 years	BSID, MDI	Normal mental development, but impaired growth and delayed psychomotor development	Gischler et al [363]
Prospective, longitudinal case–control study	General anesthesia, intensive care, ventilator support following major emergency abdominal surgeries	Healthy controls and neonates requiring intensive medical care	19	Neonatal period	Up to 11 years	GMDS, Reynell Developmental Language Scales, British Picture Vocabulary Scales, Wallin B pegboard, compulsory national curriculum examinations	Continued impaired performance in previously critically ill patients requiring prolonged care, with significant improvements in medical group, but not surgical patients, especially following multiple procedures	Ludman et al [364–367]

* Test and assessment abbreviations: ADQC, Abbreviated Depression Questionnaire for Children Self-Assessment; BSID, Bayley Scales of Infant Development; CBCL, Achenbach Child Behavior Checklist Parental Assessment; CELF-R, Clinical Evaluation of Language Fundamentals – Revised; DDST, Denver Developmental Screening Test; GMDS, Griffiths Mental Development Scales; HFT, human figure drawing; INFANIB, Infant Neurological International Battery; MDI, Bayley Mental Development Index; Movement-ABC, Movement Assessment Battery for Children; MPC, Mental Composite Score of the Kaufman Assessment Battery for Children; PDMS, Peabody Developmental Motor Scales; PHBQ, Vernon Post Hospitalization Behavior Questionnaire; PPVT, Peabody Picture Vocabulary Test; SBIS, Stanford–Binet Intelligence Scales; TOVA, Test of Variables of Attention; TRF, teacher's report form; VMI, Developmental Test of Visual Motor Integration; WCST, Wisconsin Card Sorting Test of Problem Solving; WIAT, Wechsler Individual Achievement Test; WISC, Wechsler Intelligence Scales for ChildrenWJPB, Woodcock–Johnson Psychoeducational Battery; WPPSI, Wechsler Preschool and Primary Scales for Intelligence.

ASO, arterial switch operation; DHCA, deep hypothermic circulatory arrest; ELBW, extremely low birthweight (<1000 g); ENT, ear, nose, and throat; GI, gastrointestinal; HLHS, hypoplastic left heart syndrome; LF-CPB, low-flow cardiopulmonary bypass; NDI, neurodevelopmental impairment; NEC, necrotizing enterocolitis; PCA, postconceptual age; PDA, patent ductus arteriosus; SD, standard deviation; TPN, total parenteral nutrition; VLBW, very low birthweight (≤1500 g).

Focused epidemiological studies

Several research groups have utilized retrospective reviews of large-scale epidemiological datasets to investigate neurodevelopmental outcome following surgery and anesthesia early in life (see Table 46.3). One of these studies used billing codes to identify a birth cohort of children in the New York State Medicaid database who underwent inguinal hernia repair during the first 3 years of life and compared these patients with a sample of more than 5000 age-matched children without the same billing code [206]. After controlling for gender and birth-related complications, such as low birthweight, children who carried an ICD-9 (*International Classification of Disease*, 9th edition) procedure code for inguinal hernia repair were more than twice as likely than their age-matched peers without this procedural code to also possess diagnostic codes for developmental or behavioral disorders. Interestingly, highlighting the importance of co-morbidities in retrospective datasets, surgical patients were more likely to carry secondary diagnoses, including congenital anomalies of the central nervous system (10% of patients), birthweight less than 2500 g (32%), or perinatal hypoxia (17%) and were also more likely to be male and African-American. Accordingly, as the authors correctly pointed out, health and medical care utilization as well as the frequency of mental illness differ in this vulnerable Medicaid study group from the general population [207,208], significantly complicating the generalization of these findings to all patients undergoing surgery with anesthesia. A follow-up analysis of both the New York and Texas Medicaid database by the same group reaffirmed an increased rate of mental disorder, developmental delays, and attention deficit disorder in children undoing surgery before 5 years of age. However, the incidence of these disorders was equivalent if the surgery occurred before or after 2 years of age, thereby negating the practice of delaying surgery to reduce the potential of adverse neurocognitive deficits [209].

Epidemiological studies in more heterogeneous patient populations investigated the effects of anesthetic exposure either during cesarean delivery or for pediatric surgery prior to age 4 years on subsequent learning abilities [210,211]. After adjusting for gestational age, sex, birthweight, and American Society of Anesthesiologist (ASA) physical status, children who underwent multiple surgical procedures with general anesthesia prior to age 4 were found to be at increased risk for learning disabilities (35% of children), while children who only underwent one operation with anesthesia did not differ from unexposed children (21% learning disabilities) [211]. While listing the anesthetic regimen as predominantly halothane, nitrous oxide, and ketamine, the study was not powered to specifically analyze learning disabilities according to anesthetic drug. The important confounding influence of co-morbidities in this patient cohort was highlighted by the fact that almost half the previously anesthetized patients diagnosed with developmental disability had suffered from serous otitis media prior to age 4 years, a controversial predictor of neurocognitive disabilities, whereas only one-third of children without learning disabilities had experienced chronic ear infections [212,213]. However, a more definitive analysis including the unanesthetized children will be needed to assess this potential association.

In a second retrospective review, the same research group collected school and health data from almost 5000 children born via vaginal delivery and compared them to almost 200 neonates delivered via cesarean section with either general anesthesia, consisting predominantly of sodium thiopental, halothane, and nitrous oxide, or with about 300 children undergoing cesarean delivery with regional anesthesia [210]. The overall rate of potential learning disability was found to be 26% in this study population and did not differ between those children delivered with or without anesthesia. This finding could not have been easily predicted, because neonates in the general anesthesia group experienced lower birthweights, lower gestational age, and lower Apgar scores. In addition, their delivery was more commonly complicated by hemorrhage and eclampsia/pre-eclampsia, and was more frequently performed due to an emergency indication. Importantly, other risk factors independent from anesthetic exposure, such as male gender and mother's educational status, were strongly correlated with subsequent learning impairment. Children born to mothers with only some high school education were three times more likely to acquire learning disabilities than children from mothers with college education, suggesting powerful genetic and/or socioeconomic confounders. Interestingly, babies born with regional anesthesia were less likely to be diagnosed with a later learning disability than those born vaginally without anesthesia, most likely because their parents also tended to be better educated. Subsequent reports from this research group demonstrated that a pattern of repeated episodes of surgery and anesthesia were risk factors for an increased hazards ratio for learning disabilities [214] and attention deficit hyperactivity disorder (ADHD) [215]. It should be noted that these reports were based on patient cohorts from 1976 to 1982, thereby reflecting anesthesia practices from that period. A recent reanalysis of similar cohorts from 1996 to 2000 confirmed a similar hazards ratio for learning disabilities and ADHD with current anesthesia management techniques [216].

In a pilot study, Kalkman et al tried to control for the fact that a causal relationship between the requirement for surgery and subsequent behavioral and learning impairment independent of anesthetic exposure may impact neurodevelopment [217]. They examined behavioral outcome following similar urological procedures, performed either before or after 2 years of age. In this small retrospective study involving fewer than 300 patients, parental evaluations of their children's competencies and behavioral/emotional issues were based on a combination of the child's activities, social relationships, and performance in school. There was a non-significant trend towards a relationship between timing of surgery and the risk for developing behavioral problems, even after adjusting for confounders such as parental education, number of total anesthetic exposures, gestational age, and birthweight. However, the authors correctly point out in their discussion that the indication for the surgery or the timing of the procedure may not be entirely independent of factors that could have also influenced neurobehavioral development, such as co-morbidities. In other words, the decision to operate on a child prior to age 2 years could depend on the severity of symptoms resulting from the anatomical anomaly, which in turn may influence neurobehavioral development independent of anesthetic exposure.

Arguably the most vulnerable group of patients potentially susceptible to the effects of prolonged exposure to anesthetics and sedatives during an immature state of brain developmental is not otherwise healthy pediatric patients undergoing brief, elective surgical procedures, but rather premature infants requiring neonatal intensive care [164]. In this particularly vulnerable patient population, Rozé and co-workers employed a prospective, population-based study approach to evaluate the effects of prolonged sedation and analgesia on long-term neurological outcome, as measured by a validated neurocognitive assessment tool [218]. A birth cohort of preterm infants born prior to 33 weeks' gestational age, who were subjected to mechanical ventilation and/or surgery, were examined at 5 years of age using the Kaufman Assessment Battery for Children. While 74% of those treated with sedatives and/or analgesics for less than 7 days or not at all showed no disabilities, only 58% of those treated for more than 7 days were deemed without disability. However, after adjustment for significant confounders, such as birthweight, malformations, complications of pregnancy, characteristics of the delivering hospital, neonatal complications, need for surgery, and postnatal administration of corticosteroids, this association no longer remained statistically significant. While the study did not have the power to detect differences in disability of less than 10%, the long exposure times suggest that effect sizes during comparably briefer surgical anesthesia would be expected to be even smaller.

Big data analyses

Countries that have uniform educational assessment tools applied to a homogenous population afford a unique opportunity to compare the impact of a surgical intervention with concurrent anesthesia in naïve and surgical pediatric patients (see Table 46.3). Utilizing the Danish birth registry, Hansen and co-workers interrogated a database of all 45,000 children who underwent surgical operations in Denmark from 1977 to 1990 before 1 year of age, comparing the academic achievement of exposed children with that of the general Danish population. This was accomplished by linking a nationwide demographic database with a national hospital discharge registry and compulsory school completion test scores. While this approach is limited by the retrospective nature of an epidemiological methodology and the relatively outdated anesthetic methods, the large size of the cohort will help to control for many of the confounders discussed in this review [219]. In three separate reports, this approach resulted in a comparison of children who underwent either an inguinal herniorrhaphy, pyloromyotomy, or cleft palate repairs as infants with age-matched controls. No statistically significant differences were found between the exposed and non-exposed children after adjusting for known confounders [220,221].

Subsequent cohort studies in substantially larger surgical populations from Canada and Sweden revealed that exposure to surgery and anesthesia at age greater 2–4 years increased the odds ratio of cognitive deficits [222–224]. Scrutiny of the these large datasets reveal a lower percentage in academic achievement scores for toddlers undergoing ear, nose, and throat surgery [224]. This finding suggests that early derangements in hearing and speech may have an impact on subsequent cognitive domains assessed by school performance [225].

Prospective clinical investigations

Two high-profile multicenter clinical trials, the GAS and PANDA trials, have recently published their findings (see Table 46.3). The GAS trial is a randomized controlled trial that provided strong evidence that 1 h of anesthesia exposure in infancy does not result in neurological deficit as measurable at 2 years of age [226]. The subsequent 5-year assessment was consistent with the 2-year assessement [227]. However, assessments at both 2 and 5 years of age are insensitive in predicting long-term cognitive outcomes, so the trial does not rule out an effect on higher exectutive function, cognition, and memory. Moreover, the relatively brief exposure time of approximately 1 h does not allow for the assessment of dose–response relationships.

The PANDA study prospectively examined the impact of inguinal hernia surgery prior to 3 years of age on an extensive battery of neurocognitive tests [228]. When compared with a sibling cohort naïve to surgery and general anesthesia, no significant differences in these neurocognitive domains were detected. Due to the relatively brief surgical time, these findings are limited to less than 2 h of anesthetic exposure, which nonetheless represent the length of the typical pediatric surgical procedure. Furthermore, the measured outcome does not distinguish the respective impacts of surgery and anesthesia. Accordingly, both of these negative studies examined the impact of a relatively short exposure to general anesthesia and surgery, which does not exclude effects of prolonged exposures, and, importantly, are consistent with the lack of toxicity and neurobehavioral deficits observed in laboratory animals after short exposures to anesthetics.

The Mayo Anesthesia Safety in Kids (MASK) study performed a battery of neuropsychological tests on two age groups of subjects: 8–12 years and 15–19 years, who had general anesthesia before age 3 years from 1994 to 2007. There were 250 subjects in each age group: 150 with a single anesthetic exposure and 100 with two or more exposures. The control group of 250 unexposed subjects in each age group was propensity matched (attempting to reduce confounding by matching co-variates for characteristics such as age, prematurity, parental education, gender, etc.) [229]. A primary analysis failed to demonstrate deficits in general intelligence [229]. However, a secondary analysis of a subset of multiply exposed patients revealed a pattern of deficits in several neuropsychological tests [230]. The OTB has been shown to detect deficits in non-human primates exposed to ketamine [231]. The patient cohorts in the MASK study were also tested with the OTB and a primary analysis did not detect a difference in scores between the control and exposed groups [232].

KEY POINTS: EPIDEMIOLOGICAL, BIG DATA, AND PROSPECTIVE CLINICAL STUDIES

- Epidemiological studies into the long-term effects of anesthesia for surgery in early childhood are equivocal
- Early outcomes of the only prospective study using a 1 h exposure did not find any effects in addition to those of surgery performed with regional anesthesia
- Prolonged or repeated exposures, as well as long-term cognitive outcomes, require further research

Confounders and anesthetic protection

The presence of powerful, confounding perioperative factors in infants and children undergoing surgery and anesthesia and the lack thereof in animal studies represents a serious limitation of directly applying findings of preclinical studies to humans. Given the overwhelming evidence for pharmacological interference with the normal development of the central nervous system and the lack of anesthetics devoid of cytotoxic effects, one could be tempted to limit the use of suspect medications during medical interventions early in life. However, preclinical and human studies, as outlined earlier, have clearly demonstrated the increased morbidity and developmental abnormalities in animals and children exposed to unmitigated pain and stress. In this deleterious context, anesthetics have demonstrated protective abilities. Similarly, anesthetics may help alleviate the harmful effects from other perioperative stressors, such as inflammation and hypoxia-ischemia.

Inflammatory response

Following physical trauma or surgery, in addition to painful stimulation, neurological impairment of infants may also be related to long-term effects of the inflammatory response to the trauma or due to subsequent bacterial infections. Inflammation plays a major role in the evolution of cerebral injury after cerebral ischemia and traumatic brain injury. Within hours, transcription factors are activated locally in brain tissue and upregulate proinflammatory genes, including the cytokines, tumor necrosis factor α (TNF-α), interleukin 1b (IL-1b), and chemokines such as IL-8, interferon-inducible protein 10, monocyte chemoattractant protein 1, and fractalkine [233]. The production of these inflammatory cytokines promotes the transmigration of the inflammatory cells in the brain parenchyma. Experimental studies in animal models of focal ischemic stroke have suggested that leucocytes play an important role in the development of secondary injury after acute central nervous system injury [234].

In animal studies, local neonatal inflammation has led to excessive hyperalgesia in adulthood [235]. Chronic persistent inflammation experienced early during development is capable of altering behavior and sensitivity to pain later in life, especially in response to recurrent inflammatory events [236]. Systemic infection, as demonstrated in a mouse model of neonatal injection of live bacteria, leads to sustained increases in microglial activation in the brain [237]. In these animals, cytokine levels are exaggerated following an immune challenge in adulthood, which can lead to impairment in memory function [237]. Injection of lipopolysaccharides during a critical postnatal period can affect adult sensation and pain responses [238] and may also cause long-lasting increases in seizure susceptibility [239].

Several injectable and inhaled anesthetics have been found to modulate immune function. Inhaled anesthetics, such as isoflurane and sevoflurane, were shown to interfere with the leukocyte-mediated immune response, which may lead to immunosuppression following surgical procedures [240]. Ketamine and propofol have also been shown to play a role in modulating inflammatory or immune system function [241,242]. However, postoperative immune function may be influenced by dose and timing of the anesthetic drugs, pain, psychological state, perioperative blood loss, or hypothermia [243]. Similarly, opioid analgesics such as morphine have been found to suppress natural killer cell activity, inflammatory cytokine production, and mitogen-induced lymphocyte proliferation [244–246]. However, this response is modulated by the presence or absence of noxious stimulation and the type of opioid used.

Importantly, in an adult mouse endotoxemia model, isoflurane anesthesia immediately following the injection of a lethal dose of *Escherichia coli* lipopolysaccharide dramatically improved survival by 300% compared with unanesthetized animals [247]. In these animals, the administration of isoflurane, pentobarbital, or ketamine/xylazine attenuated serum levels of the inflammatory markers TNF-α, IL-10, and IL-6. These findings suggest that anesthetic administration during endotoxemia may not only improve survival, but also lead to attenuation of the inflammatory process.

In children, abdominal surgery can lead to significant increases in blood levels of the cytokines C-reactive protein and iIL-6 [248,249], which have been linked to increased complication rates in adult patients [250]. Moreover, invasive surgery in children has also shown to depress the patients' immune system [248,251]. Neuromotor abnormalities 6 months following open heart surgery have been correlated with plasma levels of IL-6 that were measured immediately postoperatively [252]. These findings justify further investigations into the long-term effects of anesthetics on cytokine levels and their potential for improved outcome.

Hypoxia and hypoxia-ischemia

Due to the brain's limited ischemia tolerance, even relatively brief episodes of inadequate supply of oxygen or nutrients can lead to long-term neurological impairment in critically ill children, irrespective of anesthetic exposure. Several patient populations at increased risk for neurological sequelae, such as infants with congenital heart disease and premature neonates undergoing surgical procedures, have been studied regarding their long-term neurodevelopmental outcome. Many of these studies demonstrate neurobehavioral abnormalities, motor deficiencies, and decreased intelligence in many of these patients [181,195,253–255]. However, none of these studies describe the anesthetic and sedative regimens utilized or discuss their impact on subsequent neurological outcome. Conversely, neonatal animal models have repeatedly confirmed the protective properties of anesthetics when administered during episodes of brain hypoxia-ischemia [256–262]. These findings in immature animals suggest that critically ill human neonates could potentially also benefit from these protective properties during clinical scenarios of neurological injury.

KEY POINTS: CONFOUNDERS AND ANESTHETIC PROTECTION

- Perioperative stressors and pain have been found to have deleterious effects on the developing brain
- Anesthetics might protect from these deleterious effects, further complicating research into anesthetic neurotoxicity

Co-morbidities and environmental factors

Even patients who do not suffer from life-threatening illnesses may have co-morbidities or be exposed to environmental factors outside of the perioperative period that may act as confounders for neurodevelopmental outcome.

Chronic otitis media

Relatively subtle medical problems, such as chronic otitis media, have been implicated in causing neurological impairment. While this effect is controversial and the exact mechanism unresolved, some studies suggest impairment in language development, literacy, and school performance following chronic otitis media with persistent middle ear effusions before the age of 3 years, while others were unable to find this association [212,213,263–266]. A recent epidemiological review of anesthetic exposure in young children suggested a trend towards an association between serous otitis media prior to the age of 4 and subsequent learning disabilities [211].

Chronic airway obstruction

In contrast to the contentious effects of chronic otitis media, the deleterious consequences of sleep disordered breathing on neurocognition are well documented. Children with obstructive sleep apnea may face behavioral abnormalities, lower intelligence, and diminished academic performance when compared with children with normal breathing patterns [267–269]. In these patients, surgical correction of the obstruction through adenotonsillectomy, which involves exposure to anesthetics, results in improved quality of life, behavior, and cognitive function [270]. Interestingly, even children with a pre-existing neurological condition, such as children with ADHD, demonstrated improved attention and decreased hyperactivity following surgical correction of mild sleep disordered breathing, despite the obligatory exposure to surgery and anesthesia [271].

Environmental factors

Environmental factors and exposures outside of the operating room can significantly interfere with normal brain development in humans. *In utero*, environmental compounds that may negatively influence subsequent neurocognition include such diverse substances as pesticides [272], methyl mercury, manganese, lead, and polychlorinated biphenyls [273]. Fetal exposure to prescription medications have also been found to lead to subsequent neurological sequelae, such as drugs for the treatment of acne [274], antihypertensives [275], and anticoagulants [276]. Prenatal exposure to alcohol and cocaine can impair children's speech, language, hearing, and cognitive development [277]. Intrauterine exposure to antiepileptic drugs, which share many pharmacodynamic properties with anesthetics, have been linked to brain structural abnormalities in young adults [278].

Other "environmental" factors known to affect learning and behavior in children are not as easily measured by subjective standards. Socioeconomic aspects related to family dynamics, neighborhoods, and school environments all contribute to development and learning in children. In this context, factors negatively influencing neurodevelopment include economic deprivation, minority and/or immigrant status, exposure to violence, and chronic poverty [279]. Even when providing a strong community and positive family support, differences in school quality, and negative encounters with teachers and/or peers, can dramatically affect development and learning outcomes [279]. Moreover, negative influences on neurocognition have also been suggested by recreational activities, such as prolonged television viewing or video game play [280–282]. Due to this myriad of confounders, studies into the potential detrimental effects of anesthetic exposures need to take these socioeconomic and environmental influences into account.

Genetic predisposition

Genetic composition can also affect neurodevelopment, even to a greater degree than environmental confounders. Close relationships have been demonstrated between genetic factors and cognitive abilities, including reading and mathematics skills and intelligence [283]. Moreover, genetic predisposition can influence the effects of environmental stressors and vice versa [284]. A compelling example of this is the co-mingling of genetic mutations in infants with congenital heart defects, extracardiac congenital anomalies, and neurodevelopmental disabilities [285]. This provocative finding suggests that patients undergoing corrections of congenital defects and anomalies may be predisposed to subsequent neurodevelopmental disorders regardless of the surgical or anesthetic interventions.

Investigating the effects of anesthetic exposure on learning abilities in young children with an emphasis on genetic predisposition, a twin study found no causal relationship between anesthetic exposure and cognitive impairment [286]. A review of data from more than 1000 monozygotic twin pairs in the Netherlands Twin Registry demonstrated that, while children exposed to an anesthetic prior to age 3 years scored significantly lower on educational achievement tests and experienced more cognitive problems than children not exposed to anesthesia, cognitive performance of the unexposed co-twin did not differ from that of the exposed twin [286]. While not addressing the effects of multiple exposures, no evidence for a causal relationship between anesthesia administration and later learning-related outcomes was found, but rather, the data supported the notion that anesthetic exposure prior to 3 years of age represented a marker for subsequent learning problems, regardless of exposure to anesthetics.

Ongoing and future research

Whereas animal studies seem to unequivocally demonstrate deleterious brain structural changes immediately following anesthetic exposure, long-term neurological abnormalities are not universally demonstrated. Moreover, human epidemiological studies examining developmental outcomes have returned ambiguous results. The immense impact of potential neurotoxicity induced by anesthetics and sedatives on child health necessitates significant future research efforts into this phenomenon. These efforts must include both preclinical studies investigating the exact structural changes, underlying molecular mechanisms, and affected neuronal and glial cell populations, as well as carefully designed clinical studies

delineating human susceptibility, while taking into full account the above-mentioned perioperative confounding variables. Given the public health impact of the potential neurotoxic effect of anesthetic drugs in pediatric patients, the US FDA and the International Anesthesia Research Society created a public–private partnership called SmartTots to support clinical investigators in this area. This collaboration has provided funding for ongoing research studies (e.g. the GAS and PANDA studies). Additional funding sources are required to promote discovery in and improve safety of pediatric anesthesia in young children.

Summary

In conclusion, in animals, neonatal exposure to all commonly used general anesthetics causes widespread neurodegeneration in a dose- and duration-dependent fashion, alters brain architecture, and can lead to long-term neurological impairment into adulthood. The phenomenon's exact underlying mechanism has not yet been determined, but does not seem to be entirely explained by anesthetic-induced neuronal inhibition and most likely affects several signaling pathways. Importantly, while cortical structural alterations are most pronounced during stages of brain development equivalent to the preterm and infant human brain, other brain regions are affected at a later stage and may be vulnerable throughout life in areas of ongoing neurogenesis. While the relevance of these preclinical findings for pediatric anesthesia is still unclear, in an overabundance of caution, the US FDA has released a warning regarding the prolonged and repeated use of anaesthetic and sedative drugs in patients aged 3 years and under. Emerging human epidemiological studies do not exclude anesthetics as a factor for impaired learning and neurodevelopment observed following surgical procedures. However, thus far, neurological sequelae observed in retrospective epidemiological studies seem sporadic and do not affect all exposed individuals to the same degree, suggesting a potential genetic or other influence on this association. Moreover, epidemiological studies cannot establish causality or distinguish between the differential effects of surgery and anesthesia on neurological outcome. Therefore, further well-designed preclinical and clinical studies are needed to determine the phenomenon's mechanisms, assess its clinical relevance, and devise mitigating strategies. The only randomized controlled trial in the field suggests that a 1 h sevoflurane exposure for inguinal hernia repair in infancy has little to no effect on neurocognitive function at 2 and 5 years of age [227,287]. Moreover, given the serious consequences of unopposed pain for the developing brain, there are at present no recommendations to alter current anesthetic practices [288]. However, clinicians are encouraged to keep abreast of scientific developments in the field.

KEY POINTS: SUMMARY

- All currently used general anesthetics have been found to be neurotoxic in neonatal animal studies
- The phenomenon's clinical relevance is unknown
- Lack of causative association between immediate structural abnormalities and long-term cognitive impairment observed in animals limit translation to humans
- Pain and stress in unanesthetized, immature animals and humans similarly cause brain structural and functional abnormalities, further complicating recommendations for clinical practice
- Additional studies in animals and humans are needed before recommending changes to current anesthetic and sedation management

CASE STUDY

A 2.5-year-old boy has a perimembranous ventricular septal defect (VSD) where the right coronary leaflet of the aortic valve prolapses into the defect and has started to cause mild aortic insufficiency (AI). His cardiologist is recommending repair in the next several months to prevent progression of the AI. The boy is otherwise healthy, developmentally normal, and has had one brief general anesthetic at age 18 months for myringotomy and tubes, which he tolerated well. The boy's parents have read the US FDA warning about prolonged (>3 h) or repeated anesthetics in children less than 3 years of age, and possible long-term effects on brain development, including "deficits in cognition, learning, and behavior" [289]. They have contacted you to ask whether they should have the surgery and anesthesia now, or wait until after their child's 3rd birthday. They also have read that dexmedetomidine might be a drug that does not cause brain damage in animals and want to know if he should have it added to the anesthetic.

Your response addresses two major concers: timing of the surgery and the type of anesthetic utilized for the surgery. Firstly, the risks and benefits of proceeding with the cardiac surgery should be weighed against the theoretical "toxic" effect of the prolonged anesthetic exposure. Three factors appear to induce anesthetic-induced neurotoxicity in laboratory models: (1) developmental/age susceptibility; (2) high dose of the anesthetic; and (3) prolonged duration of exposure. However, aberrations in neurobehavior have yet to be linked to equivalent measures in humans, because current clinical investigations have been equivocal. Delaying the surgical repair of this cardiac lesion has significant impact on both the physiological and neurological development of the infant. Furthermore, non-anesthetic drug related events have direct impact on morbidity. The APRICOT study of over 30,000 anesthetics in 261 hospitals in 33 European countries revealed a 5.2% incidence of severe critical perioperative respiratory or cardiac events,

with a 10–15% incidents in infants and neonates [290]. On the other hand, a study of near-infrared cerebral oximetry in 453 infants under the age of 6 months undergoing non-cardiac surgery revealed a very low incidence (2%) of significant cerebral oxygen desaturation, with these periods so brief that they were extremely unlikely to cause any long-term effect [291]. Finally, in the GAS study noted earlier, the relative risk of significant hypotension was 2.8 times greater with sevoflurane general anesthesia than with spinal anesthesia [292]. However, neurodevelopmental outcomes were not different between the groups [226,227]. Although additional data are needed, it seems less likely that physiological derangement is a significant explanation for anesthetic neurotoxicity.

Although preclinical reports demonstrate that specific anesthetic drug classes, GABA receptor agonists and NMDA receptor antagonists, are neurotoxic and lead to neurocognitive deficits, clinical investigations have also been inconclusive. Dexmedetomidine has been shown to mitigate isoflurane-induced neurotoxicity and is less toxic as a sole anesthetic in rodents [57,78,217]. An ongoing multicenter human randomized controlled trial comparing dexmedetomindine to sevoflurane on neurocognitive outcomes is underway [293].

Introduction

Simulation has become a well-established part of the medical armamentarium, across most healthcare disciplines and venues. Why has this approach to teaching, evaluation, and research become so popular in medicine? What does it have to offer us in improving the delivery of pediatric anesthesia care to patients? How can we harness it to improve training paradigms, systems of care, and perhaps patient outcomes?

There are many types of simulation, using many types of equipment and facilities, but all can be neatly described as a creation of an artificial environment that replicates a real-world situation to achieve a particular objective (Fig. 47.1). In recreating a critical event after the fact, the objective may be the ability to better understand factors that lead to the undesirable outcome. In developing a crisis scenario for an imaginary patient, it may be the training of a new resident in the management of the medical events portrayed. The set of possible goals is as infinite as the human imagination.

In today's world of shrinking budgets, limited hours for trainees, and dispersal of patients from the inpatient to the outpatient setting, the degree of exposure to a wide variety of patients and critical situations for our trainees in medicine has decreased steadily. The challenge, to ensure that residents and students have the basic tools required to react appropriately to crisis situations or to diagnose rare illnesses, has increased. Private payers, the government, and the public are scrutinizing the medical system, demanding improved patient safety, a decrease in medical errors, and a means of measuring the training and performance of medical practitioners and integrated teams.

Using simulation, we can focus training hours for residents, nurses, staff, and students to elicit the maximum exposure to the specific types of patients and events deemed critical for complete well-rounded training in any particular field. Skills required by the US Accreditation Council for Graduate Medical Education (ACGME) in communication, professionalism, patient care, and medical knowledge can be practiced and tested. Teams can be drilled on critical actions, helping to ensure they will act together in appropriate ways when a real situation presents itself. Potentially harmful issues in the care environments can be identified which can result in changing processes, protocols, and equipment, prior to exposing our patients to imperfect systems. We can even research the effects of different protocols, equipment, environments, and staffing patterns to understand how they affect performance.

It is clear that simulation in medicine is here to stay. Putting it to good use will ultimately benefit not only patients, but improve professional mastery as well. This chapter will explore the many guises of simulation, several of the ways in which it is applied, and many of the applications and current state of simulation use in pediatric anesthesia. It will present a theoretical case of implementation of a simulation program, highlighting the challenges and possible solutions, hopefully assisting the reader in spreading the use of simulation to their own institution.

History of simulation

Development in aviation

Aviation is often used as a metaphor for the practice of anesthesia. Both require a high degree of vigilance, attention to detail, and periods of relative inactivity interspersed with critical moments when the need to react quickly and effectively is mandatory to avoid poor outcomes. In both fields, lives are at risk if mistakes happen or if practitioners are unable to respond appropriately. Thus, it is helpful to understand the evolution of simulation in the aviation field and to understand how those methods have been adapted to the anesthesia environment (Fig. 47.2).

Figure 47.3 The Link Trainer built by Edwin Link for flight simulation. *Source:* https://commons.wikimedia.org/wiki/File:LinkTrainerSeymourIndiana.jpg (public domain).

In aviation, simulation in the form of mocked up aircraft controls was used as early as the manufacturing of the first aircraft, between 1920 and 1927. A more sophisticated, pneumatically driven flight simulator was invented by Edwin Link in 1929 (Fig. 47.3) [1]. Improvements have been made over time, with the modern computer-assisted simulators including high-fidelity computer graphics to create the illusion of the real world outside the cockpit [2]. These simulators are routinely used for both the training of new pilots and the review of crisis situations for experienced pilots. However, not all aviation simulators are for flight training, some focus on the physical aspects of surviving in worst case scenarios. In the military, dunker training, a simulated crash of an aircraft into water, is routinely used as a method both to train recruits in the appropriate reactions to survive such a crash and to weed out individuals who do not have the necessary skills and mental focus to respond appropriately in such a situation (Fig. 47.4). Army flight surgeon training includes a day of simulated water exercises, with long bouts in a pool in full flight gear, jumps from high boards into water, and escape from a simulated "downed helicopter" which flips underwater (personal experience, 1988, Army Aviation Medicine Course, Ft. Rucker, AL, USA). Other centers have developed similar training for private and commercial use.

Team training in aviation began in earnest after a series of crashes in the 1970s that were clearly not related to technical or equipment failures. One of the most famous was the Tenerife Airport disaster that occurred in 1977, involving two jet airliners that crashed on the runway at take-off, killing 583 people in all. Review of the crashes clearly demonstrated multiple failures including problems with communication and teamwork [3]. Crew resource management training, teaching crews to work together through a crisis in a simulated environment, was developed as a method to reduce the system and communication errors inherent in these complex environments [4].

Beginnings in medicine and anesthesia

Just as in aviation, simulation in medicine started with simple task trainers and moved to complex high-fidelity simulation environments. Patient simulation was first explored in medicine by Asmund S. Laerdal, with Peter Safar and James Elam, who created a mannequin, Resusci® Anne, for the training of mouth-to-mouth resuscitation (Fig. 47.5) [5]. She was introduced as the first patient simulator in 1960, her face based on the death mask of a young girl pulled from the River Seine at the turn of the century [6]. These first simulation systems were simple and generally task oriented, looking to teach individuals medical skills. High-fidelity patient simulation with the replication of a real-world environment using interactive mannequins, was introduced to anesthesia in 1967 with the Sim One Anesthesiological Simulator by Denson and Abrahamson [7]. Dave Gaba created the Virtual Anesthesiology Training Simulation System in 1986 as the first center-based, high-fidelity anesthesia simulator environment, allowing a full range of individual and team training, and research into the uses of simulation and the assessment of human performance [8].

In aviation, it took a series of disasters to stimulate the use of simulation and the birth of crew resource management training. In medicine, the widespread use of simulation was stimulated after a pivotal report from the Institutes of Medicine was released in 2000 that shocked the medical world. It publically exposed the high degree of medical error that routinely occured in the USA, stating that between 44,000 and 98,000 patients die in US hospitals due to avoidable medical errors each year. The report went on to recommend team training based on both aviation's crew resource management programs and simulation-based education and training in medicine, as a means to create a safer healthcare environment [9]. The widespread acceptance of these techniques and perceived utility in developing and maintaining critical skills is

Figure 47.4 Dunker training for aviation skills – Apache Modular Egress Training Simulator (Apache METS®) by Survival Systems, Inc.

exemplified by the approach taken by Harvard's malpractice insurance carrier, which offers a discounted insurance rate for staff who receive simulation training. This has resulted in all anesthesia faculty at Boston Children's Hospital participating in regular simulation training [10]. This approach has since been taken by other malpractice carriers.

Creating a simulation educational approach

The following situation will serve as an example of how a simulation program might develop in your own institution, with stem questions throughout the remainder of the chapter guiding you through the key areas that would be needed to plan and establish a program to support your own pediatric anesthesia clinical and educational goals.

You are an active member of your Pediatric Anesthesiology Quality Improvement Committee. At the last meeting, it was reported that your department has averaged one cardiac arrest per month for the last 6 months. You also recall that several people involved in these cases have found that the events appeared very chaotic and disorganized. In addition, it seemed that many of the people were unfamiliar with the use of the defibrillator. Most people you ask about previous resuscitations report that most of the issues seem to be related to problems in teamwork and communication (but usually not knowledge). You would like to find a proactive way to improve the response in future cardiac arrests.

You have been asked by the chief of pediatric anesthesiology to develop educational training sessions to target these issues. The hospital recently purchased several medical simulation manikins, and while you have no experience in medical simulation, you believe that it may be a useful modality for your project. You then meet with the simulation medical director, from the hospital-based simulation center, to explore this option. You have several questions to help you develop a better understanding of medical simulation and decide whether this is the right tool for your educational project.

Uses of simulation

Stem question:

- How and where can medical simulation be used, and does it have benefits over other educational tools, such as a case-based discussion?

As the need for simulation in medicine has grown, its use has moved from specialized simulation centers into actual patient care areas, such as hospitals and clinics. It has also progressed from a focus on single medical specialties, to involving all levels of healthcare professionals and disciplines, often working together. In the following section, the application of simulation to education, research, team training, professional evaluation, continuing medical education (CME), and systems evaluation will be reviewed.

Education

Medical schools are now using simulation as a regular part of their curricula, responding in part to the ethical dilemma of allowing novice students to learn techniques for the first time on real patients. From part-task trainers, which allow students to place IV lines or stitches, to standardized patient actors who teach students how to approach a patient, communicate, and perform a physical exam, simulation has become an integral part of medical student education. Five factors have been cited by Issenberg and Gaba as contributing to the increased use of simulation in medical school curricula: "a. problems with clinical teaching, b. new technologies for diagnosis and management, c. assessing professional competence, d. medical errors, patient safety and team training, and e. the role of deliberate practice" [11].

This trend toward simulation-based training has not been restricted to medical students. The continued shrinking of residency training hours is a worldwide trend [12]. In the USA, it is limited by the ACGME to 80 h per week, with strict rules about rest time between shifts [13]. While this may appear to be enough time to expose residents to the myriads of cases required, the restrictions have been felt across all medical disciplines and reflected in residency programs looking for ways in which to accelerate learning apart from the usual "apprenticeship" model currently practiced [14–19]. More and more, simulation is being used to fill the gap.

In anesthesia training, these tools have been used for many years. The operating room (OR) represents a unique environment in medicine. It is full of complicated technology requiring rapid responses, often coordinated among multiple team members when changes in patient status occur. Most medical students have very minimal exposure to this environment prior to residency training. This creates a strong impetus for simulation's use in anesthesia education for development of trainees' skills, both in basic understanding of the equipment and in responding to critical events as part of a team [3,14]. At Stanford, as for many other programs, training for anesthesia residents includes regular simulation training with an increase in the difficulty level of scenarios presented at each level of training. Trainees may spend a day in the simulation center, running through a series of simulation scenarios and debriefing sessions, examining their own performance and that of their peers in a formative review format [15]. *In situ* training, with shortened, focused simulation events, is also becoming more common (Fig. 47.6).

Trying to understand human performance factors, which are critical in achieving positive outcomes in crisis situations, has been a widely appreciated practice since it became a focus in evaluating a series of severe accidents in the aviation industry in the 1970s. These critical human performance factors have been heavily studied and described [16]. Recognizing their importance to a wide variety of situations in medicine, many of the factors are also listed as required competencies for all medical residents by the ACGME [17]. Gaba has also described a set of skills that correlate with successful performance during a simulated anesthesia crisis (anesthesia crisis resource management or ACRM) [18]. Many of these human performance skills, described as non-technical skills by Flin and colleagues in *Safety at the Sharp End: a Guide to Non-Technical Skills* are also noted as essential for effective team work during a crisis within multiple industries [3]. The concurrency in the description of these skills is evident in the listing of some of the factors from these three systems: ACGME, ACRM, and non-technical team skills (Table 47.1). They all have aspects of human behavior and communication as key components, in order for the team to work together well during complex situations. Because of simulation's unique ability to bring team members together to actively work through a scenario, these communication and teamwork skills can be practiced and reviewed in a way not possible using other learning methods, such as table-top case-based discussions. Medical simulation courses, such as the ACRM course based on aviation's crew resource management principles, are geared to help teach these critical human performance factors (see section "Team training and ACRM principles") [11,19]. Simulation, with debriefing sessions focused on these non-technical skills, can help improve overall competency while raising the awareness of these critical teamwork skills [20].

Figure 47.6 *In situ* simulation training with anesthesia resident.

Table 47.1 Comparison of non-technical and team skill characteristics from three systems: non-technical team skills as described by Flin et al, ACRM performance goals, and ACGME trainees' performance criteria

Non-technical skills	Behaviors	ACRM key points	Behaviors	ACGME competency areas*	Interpretation: demonstrated behaviors for anesthesia residents at Stanford University
Situation awareness	• Gathering information • Interpreting information • Anticipating future states	Maintain situational awareness	• Anticipate and plan • Maintain vigilance • Know the environment • Assign team member to monitor patient if involved in task	Systems-based practice Patient care	• Acts to deliver anesthesia services efficiently • Able to call on system resources/providers to improve care • Gathers adequate preoperative information and recommends appropriate diagnostic steps/consults if preparation is inadequate
Communication	• Sending information clearly and concisely • Including context and intent during information exchange • Receiving information, especially by listening • Identifying and addressing barriers to communication	Communicate effectively	• Clearly state requests and commands • Avoid statements into "thin air" • Close communication loop • Foster open exchange between team members • Deal with conflict: what is right for patient not who is right	Interpersonal and communication skills	• Listens effectively, allows patients/families to ask questions. • Leader in the healthcare team • Explains procedures and anesthesia plans appropriately for consent • Creates sound relationship with patient
Teamwork Leadership	• Supporting others • Solving conflicts • Exchanging information • Coordinating activities • Using authority • Maintaining standards • Planning and prioritizing • Managing workload and resources	Take an appropriate leadership role	• Ensure the team knows who is in charge • Prioritize and assign tasks • Make decisions • Elicit participation • Be assertive while respectful	Professionalism	• Takes responsibility and is appropriately self-confident • Respectful, courteous and compassionate • Adheres to professional ethics and respects patient privacy
Decision making	• Defining problem • Considering Options • Selecting and implementing option • Outcome review	Utilize all available resources	• All team members • Equipment • Cognitive aids • External Resources: call for help	Patient care	• Carries out safe and rational anesthetic after proper selection of drugs/techniques and responds appropriately to changes in anesthetic course
Managing stress Coping with fatigue	• Identifying symptoms of stress • Recognizing effects of stress • Implementing coping strategies • Identifying symptoms of fatigue • Recognizing effects of fatigue • Implementing coping strategies	Distribute the workload	• Assign tasks appropriately to skill of individual • Delegate manual tasks unless particular skills required; • Scan for overload or fatigue of team members	Patient care	• Possesses appropriate technical skills in airway management (mask, ETT, LMA, FOB) and vascular access (IV, CVP/PA, arterial line)

* Only includes the subset of ACRM and ACGME areas for which there was some correlation with the other system behaviors noted.
ACGME, Accreditation Council for Graduate Medical Education; ACRM, anesthesia crisis resource management; CVP, central venous pressure; ETT, endotracheal tube; FOB, fiberoptic bronchoscope; IV, intravenous; LMA, laryngeal mask airway; PA, pulmonary artery.

Most anesthesia residents may spend very little time in pediatric anesthesia training: often just 2–4 months during their 3 years of residency. The approach to patients and families, the method of preoperative sedation and preparation, the induction techniques, and the types of crisis that occur in pediatrics are very different to those in adult anesthesia. This limited clinical time, along with the extensive behavioral knowledge set required, creates an ideal situation for the application of simulation training to enhance the rapid acquisition of this specialized skill set.

The reasons that simulation functions as an effective tool within medical education has been studied, but with some inconsistent results. Issenberg et al searched the literature to identify the key factors of simulation noted to be associated with effective learning [11]. Listed in Table 47.2, the most common element seen in 47% of the journal articles they reviewed was "providing feedback." During high-fidelity patient simulation this is usually done during a debriefing session that immediately follows the simulated scenario. Effective debriefing engages the learners to make an introspective review of the scenario events, soliciting input from all participants. Other common factors include "repetitive practice," cited in 39% of journal articles, and "curriculum integration" in 25%. These two factors require a standardized design to scenario development, which allows for repetition and inclusion in standard curriculum, for consistent objectives and goals [21].

Table 47.2 Factors associated with effective learning

Factor	Relative frequency of citations in reviewed articles	Description
Providing feedback	15.6	Educational feedback
Repetitive practice	13	Repeated practice of behavior
Curriculum integration	8.3	Integration of simulation-based exercises into the standard medical school or postgraduate educational curriculum
Range of difficulty	4.6	Range of task difficulty level
Multiple learning strategies	3.3	Adaptability of high-fidelity simulations to multiple learning strategies
Capture clinical variation	3.3	Capture a wide variety of clinical conditions
Controlled environment	3	Controlled environment where learners can make, detect, and correct errors without adverse consequences
Individual learning	3	Reproducible, standardized, educational experiences where learners are active participants, not passive bystanders
Defined Outcomes	2	Clearly stated goals with tangible outcome measures, appropriate to level of training
Simulator validity	1	Degree of realism

Templates have been designed to facilitate standardization of scenario development and consistency in repeated use of single scenarios [22] (see later in this chapter).

Performance of these types of dynamic, interactive, and interpersonal human performance skills is difficult to observe and evaluate in the normal testing situation. Simulation provides a venue to demonstrate or practice these skills, allowing feedback on effectiveness of leadership, communication, and decision-making abilities [23,24]. The use of simulation for the evaluation of performance of trainees has long been an area of considerable interest [25]. While it has been difficult to convincingly link performance measurements in simulated environments to real clinical situations, tools are beginning to be developed that demonstrate improved reliability and validity [26,27]. Finally, another factor driving the increased use of simulation in medical education is the perceived effectiveness of the learning method itself. By using high-fidelity patient simulation, the learner becomes immersed in the educational domain, participating actively in the learning environment rather than passively absorbing information as in a traditional lecture. This type of performance learning has been shown to be more effective for adult learners, and information is retained at a higher rate than information imparted from passive learning sessions [28,29]. The evocation of emotional responses also improves the learning process, increasing retention as well [30]. Simulation provides just such a learning environment.

Research

Simulation's applicability to research is beginning to be fully realized. From answering basic questions in human performance to teasing out ways to improve protocols, techniques, systems, and equipment, simulation can be used not only for training but to answer multiple questions regarding several types of issues within the healthcare system.

Research in human factors and performance is facilitated with the use of simulation. This has been a particularly fruitful area of investigation, because of the ability to recreate relatively uniform circumstances for testing with more than one practitioner group [31]. Theoretically, questions regarding practice performance can be answered, which otherwise might demand an approach using retroactive reviews of multiple charts, thereby including many uncontrolled assumptions. Investigations have been conducted into human interactions with the environment, fatigue, and response to the stressors inherent in caring for patients during a crisis [32,33]. Looking at the effectiveness of flight crew coordination and the ability to perform to task would be difficult or impossible without the use of a high-fidelity simulated environment in which to create a crisis scenario and elicit a team response [34].

Finally, not only has high-fidelity patient simulation facilitated obtaining answers to many primary research questions, it has also been used by researchers to improve the effectiveness of their clinical trials. Problems in protocol design, procedures, and data collection tools can be exposed prior to the beginning of the trial, saving time and decreasing costs. Simulation can also be utilized to train evaluators and coordinators, helping decrease errors at the start of the trial and ensuring better compliance with trial rules [35,36].

Team training and ACRM principles

Stem question:

- What is crisis resource management?

Anesthesia crisis resource management refers to a system of appropriate team and individual responses to a crisis in a patient under anesthesia. This system is based on principles and techniques derived in aviation: crew resource management. Training in these techniques teaches crews to work together through an aviation crisis in a simulated environment, and was developed as a method to reduce the system and communication errors inherent in the complex aviation environment [37–40]. The primary goal of crisis management is to detect problems early in its evolution, then mobilize an appropriate response in order to prevent an adverse outcome.

Many of the keys to ACRM revolve around maintenance of situation awareness and effective dynamic decision making. Leadership ability and communication among team members is essential, as is the effective use of all available resources. Figure 47.7, an example of a cognitive aid, includes the behaviors that are associated with an improved team response to crisis as taught in ACRM [23].

One of the mechanisms that helps create an effective team is the concept of the "shared mental model," that is the mutually agreed upon set of knowledge and processes used to explain or predict events to achieve certain goals safely and effectively [41,42]. While team training began in the military in the 1950s and 1960s, team training based on the shared mental model concept was first instituted in the 1990s [26]. Crew resource management, used in aviation for many years, works with shared mental models, including a variety of training methods, including simulation, to teach appropriate team skills. These teamwork functions are fleshed out from work that focused on the macrocognitive skill sets required to achieve effective team management of complex tasks [43]. Included are leadership and communication skills such as those outlined in Table 47.1, and others such as adaptability, back-up behavior, mutual trust, and team orientation. Simulation is an effective tool to create a situation in which these skills can be teased out and practiced [44].

Professional evaluation

The ability to grade performance in medicine has long been fraught with difficulty. Testing paradigms that focus on the ability to regurgitate medical knowledge in board examinations ignores the multiple skill sets known to impact performance in real patient care situations, including communication and professional skills, and ability to work in an acute crisis situation within a team structure. Across healthcare disciplines, simulation has been adopted for training and assessment because of its ability to provide the opportunity for learners to demonstrate these critical skill sets [44]. Both standardized patients and mannequin-based simulation activities have been used for summative assessment, and in some cases, are necessary certification and licensure requirements [45,46].

Various simulation modalities, ranging from partial task trainers and mannequins to computer-based case

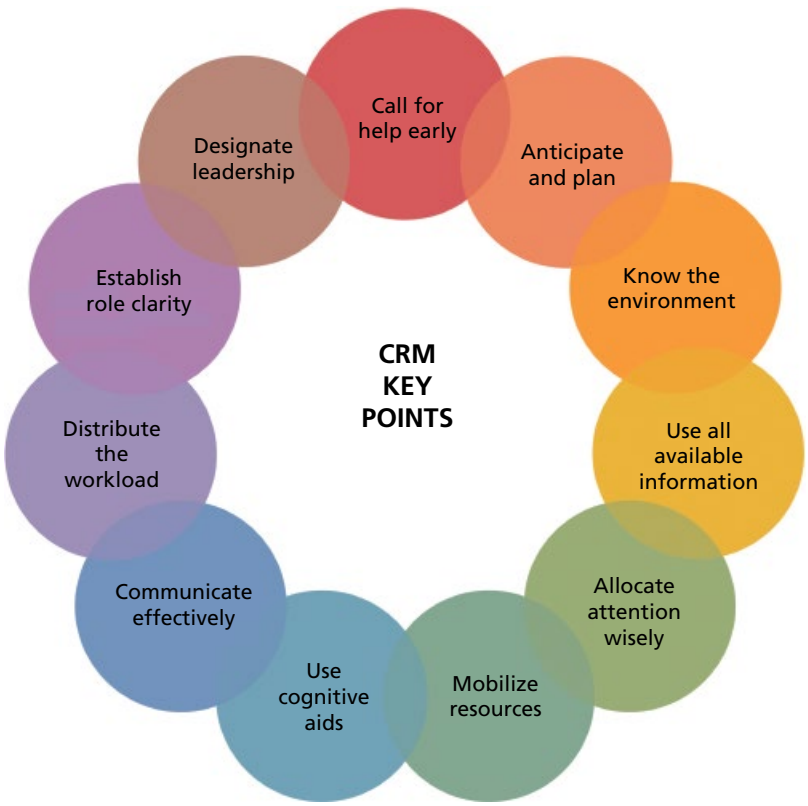

Figure 47.7 Cognitive aid used in the Center for Immersive and Simulation-Based Learning (CISL) at Stanford, crisis resource management (CRM) course. *Source:* © 2008 Diagram by S. management scenarios have been adopted for professional assessment in anesthesiology [47]. Using simulation, particular situations can be recreated for the testing of competence. For limited situations, experts come together to develop checklists, which can be tested for reliability and validity, permitting "credentialing" for that particular situation [37,48, 49]. Broadening evaluation in order to comment on a practitioner's ability to practice is fraught with difficulty due to the lack of a widely accepted assessment tool [50]. Despite these challenges, this model is already in place in some countries, and is being used to allow professional accreditation, such as passing of board certification exams [51]. Testing systems are being investigated and developed for residency training in several fields, including anesthesia [52].

While not being used for evaluation, the American Board of Anesthesiology (ABA) has medical simulation exposure as part of the optional requirements within the Maintenance of Certification in Anesthesiology 2.0® Part 4: improvement in medical practice section for board recertification [53]. According to the ABA, simulation activities performed at an endorsed center provides "Simulation that realistically replicates clinical scenarios that participants can work through in a manner similar to what they may experience in clinical practice." In addition, in 2018 the ABA added Objective Structured Clinical Examinations (OSCEs) to the Applied Examinations. The ABA OSCE-type examinations will focus on demonstrating technical and communication skills during several perioperative situations. The robust active learning component within medical simulation makes this an excellent tool to prepare learners for these types of examinations [53].

Systems evaluation

Simulation methods have been used to evaluate the effectiveness of hospital systems, allowing targeting of systematic threats. Team responses to disasters in which multiple patients arriving in the emergency department can be evaluated, as can the ability to respond in a timely and appropriate way to hospital emergency codes [46,54]. The ability to respond to crisis in the use of extracorporeal membrane oxygenation for neonates can also now be evaluated (Fig. 47.8) [55]. Simulation has been used to review new spaces prior to being used for patient care, ensuring adequate equipment, space, workflow, and familiarization of staff with the environment [56]. Prior to opening the new operating rooms at Lucile Packard Children's Hospital in Palo Alto at Stanford University, simulations of the complex information technology systems were created to assist with scheduling of surgical cases and recording of surgical care in nursing and anesthesia documentation. The simulations, which also tested the ability to perform the anticipated surgical cases, were completed prior to using the new OR suites. All surgical services were scheduled for a simulation session in which a test case was scheduled, all required team members were present, and all equipment and supplies were reviewed to ensure no significant faults remained prior to scheduling the first patient. Issues revealed included critical equipment that was discovered to be missing, process and policy problems that interfered with effective communications, and poor patient flow. These problems were then addressed proactively, eliminating their possible impact on actual patients (Fig. 47.9).

KEY POINTS: USES OF SIMULATION

- With limited hours for standard teaching curriculum and exposure to patients, simulation can fill a large teaching gap at both the medical school and resident level, with ability to target specific learner groups, patient types, procedures, and disease states
- Team training is particularly well suited to a simulated model, enabling practice of crisis resource management skills, assessment of team skill abilities, and enhancement of integrated teamwork
- Simulation can be used for evaluation of everything from the systems affecting the patient care, to the abilities of the team members in responding effectively together, to individual abilities to integrate knowledge and performance in the delivery of care
- Research into human factors and environments of care affecting performance is extremely effective using simulation

Types of simulation

Stem question:

- What type of educational activities should I plan?

Part-task trainers

The performance of procedures requires technical skills that rely on mechanical dexterity. An understanding of the basic mechanical steps can be acquired with the use of part-task trainers; this trainer is typically a portion of the whole patient that represents some part of a patient or physical reality. For instance, a mock arm, with tubing representing vessels, can be used to practice the steps required for starting an IV. A mannequin head, with tongue, pharynx, glottis, larynx, and trachea, can be used to practice mask ventilation and intubation. These trainers can be as simple as a block of gelatin encompassing a target for practice doing ultrasound-guided regional blocks to sophisticated computer-driven sensor-laden systems for the practice of laparoscopic surgical manipulations [57,58]. Complex haptic devices are being developed that meld computer-based virtual simulation and hands-on control of devices [59,60].

Just as adult simulation high-tech mannequins have "evolved" to smaller pediatric models, part-task trainers are now being created to simulate pediatric patients. Limbs for vascular access, "intubateable" neonatal heads, and ultrasound-guided central vascular access trainers are just some of the items that are currently available. Figures 47.10–47.14 represent some of the current pediatric task trainers and simulated infant parts being marketed. As interest in these products has grown, the variety and scale of available models has increased significantly.

Computer-based simulation systems

Sophisticated computer programs have been written to enable practice of various anesthesia tasks and medical crisis scenarios in a virtual format. These types of systems have the advantage of being available at any time to allow learners the chance to practice whenever they have the time (Fig. 47.15) [61,62]. Using the input of large amounts of data, from systems such as magnetic resonance imagining (MRI) and models of human anatomy, based on various patients' idiosyncrasies, this technology can finally be realized and used to provide learners with the type of variety that will be presented to them in practice [63,64]. Some internet-based systems, based on avatars, facilitate multiple users coming together in a virtual world to act as team members in various clinical scenarios. This keeps facility and material costs down, but relies on scheduling participants appropriately, having multiple access ports available, and a teacher/facilitator to guide the action [65].

Other systems allow for a melding of simulated transparency of functions in real time, enabling a deeper understanding of both mechanical anesthesia systems and simulated patient physiology [66]. Taking virtual systems and task trainers and combining them with a full-scale simulator allows for another viewpoint on increasing the perceived reality of the scenario depicted [67,68]. Currently, the American Society of Anesthesiologists (ASA) has partnered with CAE Healthcare to develop a virtual, anesthesiology-based CME product.

The existing product information currently has no timeline for release and suggests that the product will focus on adult perioperative scenarios [69].

High-fidelity patient simulation

High-fidelity patient simulation refers to simulation scenarios that closely replicate real patients and clinical situations usually using interactive mannequins as the simulated patient, making it easier for participants to believe in the reality of the situation depicted, and thus to apply realistic responses. In any high-fidelity simulation, a learning or evaluative goal is selected, and a scenario is developed to create the opportunity for the goal to be achieved. Using a simulated environment and tools, such as the high-tech mannequins that both simulate a patient's responses to interventions and allow varying degrees of interaction with the participants, the scenario is played out. Expert facilitators in various roles encourage the participants to react to the cues supplied for the scenario and supply real-time feedback supporting the scenario as it unfolds.

High-tech mannequins

High-tech mannequins have been developed by several companies for use in medical simulation. These mannequins are made to represent patients of varying ages, from neonates to adults, and come equipped with mechanical and electrical parts to produce various effects from coughing and wheezing to hypotension and cyanosis (Figs 47.16 and 47.17). Heart tones, chest wall motion, palpable pulses, and closure of the airway can all be mimicked. Interventions are possible including bag–mask ventilation, intubation, IV line placement, defibrillation, and in some cases chest tube insertion or cricothyrotomy. A vital signs monitor shows the patient's current status and can be manipulated by a technician in response to interventions by the simulation participants.)

Figure 47.17 Premature simulator. *Source:* Courtesy of Laerdal Medical.

Some simulation systems include software that has been created to provide automatic realistic responses to interventions including chest compressions, ventilation, and medication administration. Table 47.3 provides a review of the features

Table 47.3 High-fidelity pediatric simulators are available in premature, neonatal, infant, toddler, and small child sizes from various manufacturers with a variety of features*

Basic features	Advanced features
Airway/respiratory	
Ability to perform positive pressure mask ventilation	Exhaled carbon dioxide measured synchronized with breath sounds
Ability to perform tracheal intubation	Internal air compressor
Right/left mainstem bronchi for differential ventilation/intubation	Ability to perform tracheostomy
Spontaneous breathing	Chest needle decompression detection
Nasal intubation	Chest tube insertion with fluid output
Laryngospasm	Measurable pulse oximeter with actual patient monitors
Blockage of airway, right or left	Ability to ventilate with dynamic airway pressure monitor
Retrograde intubation	
Tongue edema	
Pharyngeal edema	
Lung sounds	
Cardiovascular	
Ability to perform chest compressions	Improved defibrillation and pacing
Heart sounds	Measure BP with actual patient cuff and hear Korotkoff sounds
Carotid and radial pulses	Measurement of compressions and ventilations
Palpable brachial and femoral pulses	Femoral access sites
Interosseous access	Subcutaneous injections
Peripheral venous access sites with drains and flashback	
Ability for catheter placement in umbilical vessels	
IM injections	
Neurological	
Seizure-like movement	Adjustable fontanelle
Vocal sounds	Eyes that blink with variable pupil size
Muscle tone in limbs	
Gastrointestinal/urological	
Ability to place OG/NG tubes	Bladder fillable and able to place Foley catheter
Auscultate bowel sounds	Enema administration
Gastric distension with esophageal intubation	
Other	
Color change with conditions (cyanosis)	Tearing and secretions for ears, eyes, and mouth
Replaceable parts	Ability to track some administered medications
	Washable/reusable parts

* Not all features are available in every model and different manufacturers choose different features to highlight. Premature models have constraints in types and number of features due to size. Most manufacturers charge more for advanced features.
BP, blood pressure; IM, intramuscular; NG, nasogastric; OG, orogastic.

currently available in common pediatric mannequins. Many of the mannequins have common features that allow for basic interactions to control the airway and respirations. Some mannequins provide the ability to perform a variety of invasive interventions. The "consumable" parts, skin and bone, etc., often need to be replaced after a certain number of uses. Setting some rules of engagement for learners with the mannequins before beginning the simulation can allow for near-realistic performance while protecting the unnecessary replacement of mannequin parts. Warranties are often available for purchase, enabling protection of this considerable investment.

Standardized patient actors

When interpersonal and communication skills were made one of the core competencies by the ACGME, the central importance of clear and effective communication in medicine was emphasized. Team communication is very important and can be practiced during simulated scenarios involving mannequins, but effective communication with a patient or family member cannot be simulated well with these tools. Thus, standardized patient actors are frequently being used in many simulated situations in both medical schools and other educational venues (Fig. 47.18) [70]. Using patient actors allows learners to interact with a "patient" or "family member" capable of evoking convincing emotions by improvising and adjusting their response based on the learner's responses. This type of high-fidelity simulation can also create complex and subtle interactions, with the ability to practice the most basic features of medicine: effective history taking or developing a caring and empathetic approach. Videotaping of the interactions for review during debriefing also helps the learner see how they come across to others and the non-verbal communication cues they may be using unknowingly.

This type of simulation has now been incorporated into the United States Medical Licensing Examination® for medical students, in step 2 of the exams. Students must effectively interact with trained patient actors to obtain a history and physical examination, thereby demonstrating not only technical medical knowledge but also the effective communication and interactive skills critical to becoming a physician [44,71]. In addition, the ABA added an additional OSCE-type examination, which is required as part of getting the initial board certification in anesthesiology.

Figure 47.18 Confederate actor playing the role of mother of a simulated infant in a medical student training exercise.

Figure 47.19 A hybrid simulation combines an infant simulator with a standardized patient as the mother to assist in obstetrics simulation at Stanford Children's Hospital.

Hybrid simulation

Hybrid simulations refer to the combination of any two types of simulation, whether it involves the use of a part-task trainer combined with a mannequin, or a patient actor and a simulated body part that can be manipulated by the participant to treat the simulated situation (Fig. 47.19). For instance, a part-task trainer arm can be attached to a patient actor's arm, and used to start an IV line, or a delivery task trainer can be combined with a patient actor for simulating an infant delivery. The patient actor can then provide active and realistic responses to the participant as they attempt to provide the indicated procedural care. This combination of task training and communication with the "patient," such as suturing of a wound or injection of a local anesthetic, creates a much more instructive and meaningful situation for the learner and allows a substantially greater understanding by an evaluator of the participant's skill set and patient management style. The tasks that are performed on patients never happen in a vacuum. Learning to deal with the patient's reactions to the procedures performed is critical for effective patient care. This hybrid model allows the integration of these components for a much more realistic and effective training scenario [72].

KEY POINTS: TYPES OF SIMULATION

- There are many types of simulation, all of which serve specific learning goals, including part-task trainers, standardized patient actors, computer-based simulation, virtual reality simulation, and high-fidelity simulation
- High-fidelity simulation attempts to create as real an experience as possible using interactive patient mannequins that exhibit multiple "physical" signs, can be manipulated in realistic ways, such as intubation, and can respond to learner manipulations
- Hybrid simulation uses combinations of simulation methods, such as part-task trainers with standardized patient actors, to enhance the learner's ability to interact in a realistic manner throughout the scenario in all performance domains

Organizing and running high-fidelity simulation sessions

Stem questions:

- What are the common challenges when using medical simulation?
- What type(s) of learners should attend the session?
- How can an effective educational activity using medical simulation be designed?
- What type of orientation should a learner have prior to using medical simulation?

Elements of high-fidelity patient simulation

Preparation

Prior to starting a simulation scenario, the participants should be familiarized with the simulation environment, the tools to be used, and the roles they will play – elements critical in enabling a positive learning experience. Just as important is ensuring that all learners understand the goals of the exercise and how their performance will be assessed. Some essential points to cover include: goals of the session, who will be participating, who will be facilitating, and how to engage and behave in the environment.

When the simulation scenario is focused on formative, rather than summative, assessment, removing any sense of threat from the session will help ensure a positive learning frame of mind. Many simulation centers ask the participants to sign a consent that emphasizes the importance of keeping the elements of the session, both the scenario and the performance of individuals, confidential. This can help decrease the concern that an "inadequate" performance will be talked about after the event. In these types of learning sessions, participants are told that there is no penalty for "failing" in a crisis simulation, allowing them to take risks in their interactions and actions during the scenario, that will enable their learning.

The scenario

A scenario is created, somewhat like a storyboard for a movie, which sets the framework for the simulation session. It is based on both the goals and the anticipated participants. Content experts are critical in designing a realistic and relevant simulation scenario. No matter what framework is set for the situation, the particular participants during the session will bring their own experience and knowledge base to the interpretation of the scenario, and will often react in unexpected ways. Thus, content experts are key during the running of the scenario as well, allowing credible manipulation of patient vital signs and reactions to any actions made by the participants.

Debriefing

Stem questions:

- What is the purpose of the debriefing portion?
- What are the key elements of an effective debriefing session?
- Are there any risks inherent in running simulations and debriefing?

Arguably, the greatest learning from a simulation session occurs during the final section, called the debriefing. Debriefing has its roots in the military and aviation, where a group leader brings the unit together after an event or mission to review outcomes, both positive and negative, and to develop some lessons learned to apply to the next mission. Similarly, in medical simulations, this part of the session allows the team to discuss what occurred during the scenario and to develop an understanding of how the crisis or situation unfolded (Fig. 47.20). The goals of a debriefing session may vary, but in ACRM, the technique is used to allow members of the team a chance to review their own performance, to evaluate the team's performance, to understand the drivers in the crisis, and to learn some general principles in crisis management that they may then use more effectively during future critical events [35,73].

Facilitated debriefing is the key to reaching your learning goals from a simulation scenario. During a critical event, attention is intensely focused on managing the crisis and completing necessary tasks. It is only in the later analysis, that an understanding of all the factors impacting on the outcome can be evaluated. This then leads to learning from the event, its management, and any failures that occurred. A facilitator is important in guiding the debriefing and framing the learning points. Ideally, the facilitator encourages reflective analysis, leading the participants in the crisis through the event, eliciting their own reactions to occurrences, thus assisting them in developing their own analyses. Material covered in a group discussion is much more likely to be retained than that passively obtained in a lecture-type presentation. In addition, when participants provide their own insights and observations, they feel that their input has been heard and they have more of a stake in the discussion, and a sense that their ideas become part of the conclusion. These conclusions then become more acceptable and believable to the participants. Facilitating a debriefing well takes time and practice. Table 47.4 includes actions that help create a positive learning session and several that can hinder the ability of the group to develop their own conclusions.

Debriefing sessions are most effective when the team members guide their own discussion based on their own observations, using the facilitator to initiate the discussion by setting the objectives and assist in leading the discussion minimally.

Figure 47.20 *In situ* team debrief after simulation in Stanford Children's Hospital recovery room.

Table 47.4 Debriefing "dos" and "don'ts" – factors that can facilitate or detract from the effectiveness of the debriefing portion of a simulation session

Thing to do	Things to avoid
Set expectations for crew participation	Don't lecture
Engage the team to facilitate achieving those expectations	Don't provide your own analysis before it is "discovered" by the team's analysis
Cover all critical topics	Don't give impression that your observations are the most important
Balance the discussion: draw in quiet participants	Limit interruptions of team discussion
Cover teaching points to be made – integrate into discussion at appropriate times	Don't create the sense of an interrogation
Discuss positive actions and how they impacted outcome	Avoid a rigid agenda
Consider using visual cues to track major discussion points	Don't cut sessions short when outcomes are positive

Teams that have not previously participated in this type of analysis or group discussion will require much more guidance on the part of the facilitator.

Starting the debriefing session with an introduction that outlines the expectations for the session, and the ways in which the team members will participate, allows creation of the proper framework for the learning session. Setting a format will then help the team develop an agenda for the session. The facilitator should be sure that all critical items are included in the agenda. Using the basic principles of ACRM to frame the analysis and evaluation can help deflect difficult feelings related to any perceptions of individual inadequate performance among participants. Finally, the lessons learned from the session should be explicitly reviewed and generalized if possible.

Some of the techniques that encourage active team member participation and in-depth analysis of events are the following: (1) ask questions – what, why, and how; (2) engage all team members in the discussion; (3) re-word questions instead of answering – allow the team to answer the questions; and (4) allow pauses and silence to encourage thoughtful analysis and time for answers.

In summary, debriefing creates the opportunity for members of a team involved in a crisis situation to reflect on their performance, review the elements that were active during the crisis, analyze how these factors impacted the outcome, and develop some lessons to be carried away and used in future situations. In addition, basic concepts useful in approaching any crisis can be emphasized during the debriefing, allowing a review of important skills that can then enhance participants' performance over a wider set of circumstances.

Creating scenarios

Stem questions:

- How does one go about creating a scenario?
- What factors should be included to be sure of capture learning for all team members effectively?
- How can the utility of crew resource management learning for the perioperative teams be demonstrated?

The first step in creating a scenario is defining the participants who will be taking part and the learning goals to be set. The resources available to run the simulation must also be considered: from location of the simulation to equipment, to staffing and facilitators. The particular clinical situation can then be set. A simple story line for the scenario, identifying roles to be played by both participants and facilitators/confederates, an outline of the basic clinical situation, the crisis to be dealt with, and the key patient characteristics that will orient the participants to the situation at hand, are all key elements to include. It is helpful to try and anticipate the types of reactions from the participants and map out the likely patient responses, vital signs, etc., to those actions. A map is therefore

Critical Steps in Scenario

Patient State	Physiologic Parameter: no atropine	Physiologic Parameter: atropine	Time	Step Required	Time Occurred: Hour/min
Awake	HR 120 BP 90/50 RR 25 SpO2 99%	HR 120 BP 90/50 RR 25 SpO2 99%	t = –x	Step 1 WHO Pediatric Checklist	
Induction	HR 140 BP 80/40 RR 35 SpO2 100%	HR 140 BP 80/40 RR 35 SpO2 100%	t = 0	Monitors Placed	
Laryngospasm	HR 160 BP 100/60 RR 0 SpO2 95	HR 160 BP 100/60 RR 0 SpO2 95	t = 1	CPAP, alert nurse have issue	
Apnea	HR 160 BP 70/40 RR 0 SpO2 90	HR 160 BP 70/40 RR 0 SpO2 90	t = 2	Ask for IV/IM drugs	
Unable to Mask	HR 120 BP 70/40 RR 0 SpO2 80	HR 160 BP 70/40 RR 0 SpO2 80	t = 3	call for Help, initiate emergency protocol	
Unable to Mask	HR 100 BP 65/35 RR 0 SpO2 70	HR 130 BP 65/35 RR 0 SpO2 70	t = 4	Attempt intubation X 2

Figure 47.21 Example of template used for planning and running vital signs responses during high-fidelity patient simulation.

created that helps the technician running the mannequin and attached monitor to set the proper circumstances as the scenario plays out (Fig. 47.21).

Development of the scenario relies on content experts for the clinical situation being portrayed to ensure realistic patient responses in a relevant context. In addition, running of the scenario must include confederate facilitators who are experts, allowing the team to modify scenario responses spontaneously based on the actions of the participants. Thus one of the challenges in creating scenarios that are generally applicable to a wide range of practitioners, particularly for evaluative purposes, is the ability to translate the expertise of one group to the expectations of another. Consensus must be developed around scenarios and performance goals.

Creating the environment: where simulations are run

Medical simulation training has traditionally occurred in simulation centers. These centers were designed to recreate specific patient environments such as operating rooms. They were often built with viewing rooms and debriefing conference rooms, allowing postevent reviews of audiovideo sources from the scenario and discussing the trainees' performance [74]. Many large academic centers now include a separate simulation center for education, incorporating multidisciplinary approaches and allowing for training of medical personnel at all levels of training and practice. From Stanford University, where simulation use in anesthesia training was first developed, to Duke University in North Carolina, to the

Figure 47.22 Three-dimensional model of a simulation center – the Medicine Company Simulation Center, designed by Paul Lukez Architecture. *Source:* Courtesy of Paul Lukez Architecture.

University of Florida in Jacksonville and many more, these centers are now an integral part of the fabric of medical education [75,76]. The use of some of these centers is not limited to physician education, but includes nursing education as well, partially in response to increased limits of access to patients during their training. Private free-standing centers are also beginning to be seen, a response to the growing demand by hospitals and physicians for reproducible, reliable training and testing. Many hospital systems are also developing their own simulation centers to target specific populations not necessarily addressed in other systems. Several free-standing pediatric hospitals have developed their own simulation centers (Fig. 47.22).

Taking simulations to the various areas in which actual patient care is provided is called *in situ* simulation and allows a unique ability to test not only the areas for process and equipment deficiencies, but also to see how the teams work in their usual environment. This helps create a highly realistic milieu for training and eliminates many confounders that otherwise inhibit the normal responses of participants. However, the ability to recreate the positive features available in full-blown simulation centers, including audiovideo capture and playback of scenarios, could be a technical challenge. By using a mobile audiovisual cart, simulation can be used in any work environment without giving up the video-facilitated debriefing used in analyzing center-based simulation scenarios. After experimenting with several prototypes, a system was developed and first demonstrated at the 2006 Society for Pediatric Anesthesia Annual Winter Meeting by the Stanford Pediatric Anesthesia group (Fig. 47.23) [77]. Commercial mobile audiovideo systems are now also available and have been used with positive results at other centers [77]. However, *in situ* simulation for pediatric anesthesia also has a set of challenges that must be considered including competition with actual patient care, confidentiality issues, and perhaps parents/families present in the training vicinity.

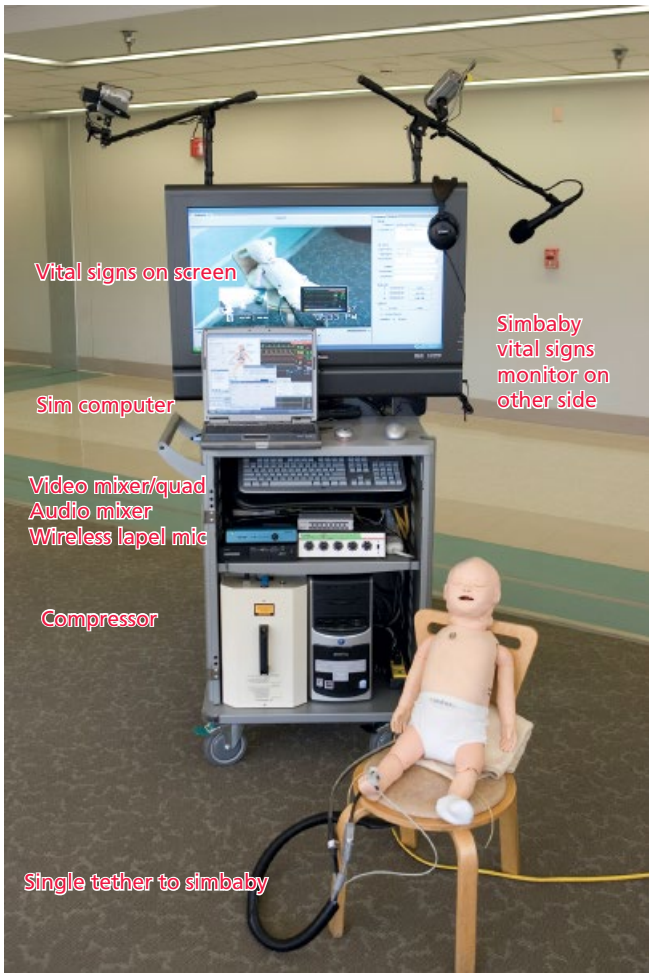

Figure 47.23 *In situ* simulation cart developed at Lucile Packard Children's Hospital. It includes mechanical elements for a high-fidelity simulator with audiovisual system to record and display multiple video and audio channels.

Facilitation: running a scenario

Prior to starting the scenario, the participants must be briefed on the basic setting, helping them to set the proper mental framework in which to play out the scenario. Specific roles are assigned to each participant, allowing them to take part in the scenario as part of the care team. For instance, when the goal is improving medical management of a rare medical crisis in the OR, the learners may be assigned the role of the anesthesiologist, a member of a code team, or a second anesthesiologist responder. However, if the goal is to develop an understanding of team dynamics in the OR, participants may be asked to assume other roles within the team, such as the scrub-tech, which would allow them a different perspective on events as they unfold during the crisis. Alternatively, a group of learners may be summoned "emergently" to a simulated situation with one of the objectives to see how the group assigns leadership and other team roles.

Teaching facilitators will take other roles in the clinical team, such as the surgeon or circulating nurse, playing the parts as the scenario unfolds to help present the appropriate cues for the learner; these roles played by the faculty instructors are termed "confederates." The confederates feed information to the learners at appropriate times, guiding the understanding of the situation for participants or constraining their actions if needed.

A technician is typically required to run the computer that controls the mannequin throughout the scenario, allowing realistic "patient" responses to the actions from the participants. Communication between the confederates within the scenario and the technician controlling the mannequin is important to ensure the mannequin responses are made in an appropriate and timely manner.

An expert facilitator manages the flow of the scenario throughout, perhaps answering queries from the participants when environmental cues are unclear, and providing additional information about the situation, which align with the objectives initially developed for the scenario.

KEY POINTS: ORGANIZING AND RUNNING HIGH-FIDELITY SIMULATION SESSIONS

- Running high-fidelity simulations well takes preparation of the space, the equipment, the facilitators, and the learners
- The simulation environment is key in realizing the learning goals, and can have a great impact on the ability to complete the simulations as planned: simulation centers tend to have regular, well-scheduled sessions while *in situ* simulations may need to happen "on-the-fly" when clinical space becomes available
- Debriefing is the key step in facilitating the full acquisition of lessons learned for participants; ideally it will elicit responses of self-reflection from learners guided by a facilitator ensuring the learning goals are discussed
- Both the creation of the scenario and the running of the simulation activity require content experts to ensure patient parameters are realistically set, reactions to participant actions are within clinically normal bounds, and the background scenario story makes medical sense to the learner group

Pediatric anesthesia simulation

Applications of pediatric anesthesia simulations

Simulation scenarios focused on pediatric anesthesia care can be created to serve many purposes: basic training of medical students or anesthesia residents, advanced training for pediatric anesthesia fellows, and refresher training for non-pediatric anesthesiologists, pediatric anesthesiologists, or perhaps non-anesthesia providers who might be called to sedate or resuscitate a pediatric patient. With the continuing trend to centralize the surgical care of pediatric patients to large pediatric centers, anesthesiologists in community hospitals are exposed to fewer and fewer pediatric patients [78]. This could increase the demand for simulations related to pediatric care in order to maintain a sense of confidence in caring for these patients. Common crisis scenarios, that depict relatively common and potentially critical events, could help in this setting.

Current uses and activities: pediatric anesthesia simulation centers and activities

Centers offering simulation experiences in pediatric anesthesia have multiplied over the last decade. Academic centers across the country have developed pediatric-focused groups, allowing training of fellows and residents, OR teams, and support personnel. Fellowship training in pediatric anesthesiology includes simulation to varying degrees. With the gradual decline in numbers of cases of neonatal emergency surgery in the past decade, some centers are beginning to develop scenarios targeted at exposing fellows in pediatric anesthesiology to these rare cases critical to becoming competent consultants in pediatric anesthesia. Medical simulation can be effectively utilized in many capacities to fulfill learning gaps, conduct research, and promote a culture of safety [79].

Factors in creating pediatric-specific anesthesia simulations

There are six major factors that affect the types of anesthesia simulations that are created for pediatrics versus adults: anatomy, psychology, physiology, procedural locations, types of surgery required, and parental involvement. The first relates simply to the size of the patients: children come in a large variety of sizes as a normal function of growth and development. This requires a whole different range of equipment, including mannequins specialized for the appearance of infants and small children. The second factor is that children present psychological challenges in IV access, cooperation, and the desire to avoid trauma. Therefore, they are frequently anesthetized using an inhalational mask induction, without IV access in place. The third factor relates to the propensity for children to exhibit rapid reactions and decompensation based on their physiology, such as rapid hypoxemia following laryngospasm because of low functional residual capacity and high metabolic rate. These reactions present challenges in management, unique to pediatric anesthesia. The fourth factor is the relatively wide variety of locations in which anesthetics are administered to children routinely,

Box 47.1: List of pediatric anesthesia simulation scenarios used at Cincinnati Children's Medical Center

- Supraventricular tachycardia
- Ventricular tachycardia arrest
- VFIB arrest
- Hemorrhage shock
- Cardiogenic shock
- Pulseless electrical activity (no CPR initially)
- Hypovolemia – basic (ECMO)
- Septic shock
- Meningococcal disease
- Anaphylaxis
- Child diabetic ketoacidosis
- Status asthmaticus
- Spontaneous pneumothorax
- Airway trach crisis
- FBOA arrest
- Laryngospasm-induced pulmonary edema
- Pneumothorax (ECMO)
- Respiratory failure
- Fentanyl reaction
- Ketamine reaction
- Opiate ingestion
- Calcium channel blocker overdose
- Malignant hyperthermia (PACU specific)
- TCA overdose
- Hypertensive encephalopathy
- Seizures
- Child burn victim
- Smoke inhalation
- Near drowning
- Head injury requiring RSI
- Child gunshot wound
- Pediatric blunt trauma
- Infant blunt trauma
- Infant multiple trauma
- Head injury requiring RSI – complication
- Infant heat illness

CPR, cardiopulmonary resuscitation; ECMO, extracorporeal membrane oxygenation; FBOA, foreign body obstructing the airway; PACU, postanesthesia care unit; RSI, rapid sequence intubation; TCA, tricyclic antidepressant; VFIB, ventricular fibrillation.

because of their inability to cooperate with procedures or remain still such as for diagnostic imaging. The limited equipment and support systems available in these diverse locations create opportunities for interesting scenarios. The fifth factor pertains to the types of surgery required by infants, which are often rare but require a high skill and focused knowledge set to manage well. Finally, the sixth factor acknowledges the parents' relation to and role in their children's lives: they have the legal authority for their children and extremely strong emotional bonds. This relationship creates some unique situations ideal for simulation learning. See Box 47.1 for examples of scenarios created at the Cincinnati Children's Medical Center (personal communication, Paul Samuels).

The early patient simulation mannequins were developed with the adult model in mind. This not only targeted the vast majority of medical care delivered, but the larger mannequin provided more space for the mechanical and electrical components needed to create the various desired physical effects. With advances in computer technology and the miniaturization of components, smaller high-tech mannequins have become possible. Selection of the most appropriate equipment for the learning objectives of the session will promote engagement of the learners into the scenario [80]. Several companies now offer pediatric, newborn, and even premature newborn size mannequins with a wide range of realistic physical effects and interactive capabilities. Table 46.3 lists some of the various mannequins, the modeled age range, and the simulated qualities available for each as an example of how far this technology has come. For instance, the newborn simulator by Guamard not only delivers heart tones, breath sounds,

Figure 47.24 Guamard's Super Tory neonatal simulator – wireless with "dynamic lung compliance" to allow for realistic ventilator support. *Source:* Courtesy of Gaumard Medical.

peripheral pulses, and patient phonation, but will exhibit chest wall motion with either spontaneous or positive pressure ventilation, increased peak inspiratory pressures with various pathological conditions being simulated, and random rapid motion of the extremities to simulate a seizure. Advances in wireless signaling allow this mannequin to be picked up and moved without any cables, allowing for an increased degree of realism and flexibility in creating scenarios, during which an infant might normally be moved from one location to another in a caregiver's arms (Fig. 47.24).

Scenarios based on infants can only be realistically created using these appropriately sized mannequins. Everything in the environment is then appropriately sized as well, engaging the participant learner to more easily "suspend disbelief" and react to the crisis. Indeed, sizing of equipment and materials such as authentic laryngoscopes and endotracheal tubes is one of the key elements in effectively working in any pediatric milieu. For applications in either learning or checking for proficiency, this size barrier was essential to overcome before pediatric scenarios were possible.

Anatomy, psychology, and physiology affect another fundamental aspect of pediatric anesthesia, which is the induction technique. Pediatric patients have small veins, often masked by copious subcutaneous tissue, making IV access difficult. They do not have the ability to understand the circumstances bringing them to medical care, nor to cooperate and follow directions. These characteristics create a situation in which the child can become agitated and combative when attempting an IV start while awake. In addition, their physiology, including a high metabolic rate, heart rate, and respiratory rate, combine to ensure rapid uptake of inhaled anesthetic agents, allowing for rapid induction using a mask technique. For these reasons, inhalation induction is commonly the method of choice when anesthetizing small children. Because there is no IV access for drug delivery yet available, this also creates some unique circumstances in which life-threatening reactions that are difficult to treat can occur during induction. Pediatric scenarios dealing with laryngospasm, bronchospasm, desaturation, bradycardia, and hypotension during induction are both realistic and rich in teasing out both technical and non-technical skills for debriefing and learning.

Figure 47.25 *In situ* simulation in computer tomography scanner with infant simulator.

A practiced pediatric anesthesiologist becomes facile at the critical steps involved in these types of situations, and working through these reactions and steps in simulation scenarios, with anesthesiologists that do not care for children every day or trainees, is extremely useful.

The basic physiology in children is fundamentally different to that of adults in many ways, as noted earlier. In neonates, particularly if born prematurely, the airway reflexes are physiologically immature, creating the propensity for apnea, laryngospasm, and bronchospasm, at times with no clear stimulation. Desaturation occurs very rapidly due to the limited functional residual capacity and rapid metabolic rate. Bradycardia is a common sequela of desaturation and, as opposed to adults, is commonly accompanied by significant hypotension due to the fixed ejection fraction of the still developing heart. These combined circumstances allow for a varied set of crisis to deal with in simulated scenarios, often simply manipulating the patient's vital signs to create very realistic sequences. Also, the crisis can be attributed to minor triggers in healthy patients without major pathology, enabling a quick, rich scenario with full recovery of the patient which creates a sense of positive engagement and reinforcement for the learners.

When designing pediatric anesthetic scenarios, the full range of hospital locations can be utilized. Unlike the adult population, children often require anesthesia for painless imaging studies and minimally invasive procedures (Fig. 47.25). As a result, it is common to anesthetize pediatric patients in various venues, such as MRI suites, radiotherapy rooms, endoscopic suites, and dental offices. Scenarios based on some of these remote locations can take advantage of the variable constellation of equipment available, unfamiliar personnel on hand, and unique environmental concerns. For example, one common scenario involves anesthetizing patients in the MRI suite, which requires special precautions around the magnetic field. Resuscitation cannot occur within the magnet, so the simulated patient must be removed to an adjacent location for treatment. In these remote locations, the availability of back-up support or help in the event of a crisis is likely to be markedly different. A focus on the system requirements in these locations during debriefing of these scenarios can open the participants' minds to the depth of safeguards that have been put in place in their usual work environment and what might in fact be lacking.

Figure 47.26 Simulaid Neonatal Wound kit including gastroschisis and omphalocele wounds. *Source:* Courtesy of Simulaid.

Pediatric patients undergo many types of surgery and procedures that are not performed in adults. Some of these operations are becoming rarer. Thus it can be more difficult to acquire the skills needed to successfully navigate the appropriate anesthetic and the ability to develop an understanding of the physiological aberrations that are commonly seen. Emergent operations in neonates such as tracheoesophageal fistula repair, congenital diaphragmatic hernia repair, and omphalocele and gastroschisis repair are becoming less and less frequent (Fig. 47.26). This, coupled with the increasing

use of thoracoscopic and laparoscopic surgical approaches, which adds additional challenges to the anesthetic management, creates an ideal circumstance for the use of simulation training. Simulation scenarios created to mimic these rare operations can be used equally for fellow trainees and for maintenance of skill in senior faculty. Using high-fidelity simulation can be extremely useful to improve interdisciplinary communication and coordination, key to successful management of these types of cases. Debriefing topics could include communication related to sharing the airway with the otolaryngologist during direct laryngoscopy and bronchoscopy, or the decision to intermittently ventilate both lungs in single-lung ventilation cases, forcing a pause in the surgery for stabilization of the patient.

Finally, since children are minors, and unable to consent for their medical care without an adult or legal guardian, working with the patient's caregivers is a normal part of every pediatric anesthetic plan. Parents must be interviewed for a preoperative evaluation, counseled for consent to be obtained, and at times be present during induction. Their own anxieties in facing the procedure or surgery for their child are often extreme and can impact the behavior of the child. Scenarios that incorporate a parental presence component not only add a great deal of realism to pediatric simulations but can be used to create the crisis or circumstance that is the scenario's learning objective. Whether this is effective communication before, during, or after an event, or successfully disengaging a parent as a crisis begins to unfold, there is much to work with. Scenarios are often derived from the real-world experiences of faculty members. One example involves a parent-present induction in which the parent became panicked as the child went into laryngospasm on induction and fled with the baby from the OR. This prompted a scenario with the parent present in the OR with their infant at induction. The patient developed laryngospasm and hypotension, and the parent moved to "protect" their child. This forced our participant learner to effectively communicate with the parent, engage the team members for assistance in managing the crisis, and direct a team member to assist the parent out of the room, all while beginning effective management of the patient.

Pediatric-specific anesthesia simulation equipment

An essential element of high-fidelity patient simulation is the creation of a realistic environment with appropriate equipment and props. Pediatric anesthesia simulations had to await the production of mannequins sized to approximate pediatric age ranges. In 1999, METI (Medical Education Technologies Inc., Sarasota, FL, USA; acquired by CAE Healthcare in 2011) was the first to develop and introduce a pediatric mannequin known as the PediaSIM®. This mannequin was approximately the size of a 5–7-year-old child. Challenges in developing components small enough to fit in the smaller size of an infant mannequin delayed introduction of an infant mannequin for many years. In 2005, both Laerdal Medical (Stavanger, Norway) and METI brought infant mannequins to the market [78]. There are many features, and the availability of connected vital sign monitors, allowing for the creation of complex and realistic scenarios. Now other companies, such as Gaumard Scientific (Miami FL, USA), have created infant and neonatal models (Fig. 47.27). See Table 47.3 for a listing of many of the features available in current mannequin systems.

Figure 47.27 Extreme premature simulator mannequin being examined with attempts at resuscitation. *Source:* Courtesy of Medical X.

Creating pediatric anesthesia scenarios

While some scenarios may be available from a variety of sources, such as the *Journal of the Society for Simulation in Health Care*, the Society for Pediatric Anesthesia Simulation Interest Group, or the Managing Emergencies Paediatric Anesthesia site, most people will most likely want to create simulation scenarios that suit their own particular needs. After choosing the participant group, the first step in creating a scenario is to decide upon the learning or evaluative goals. Goals can be based on general team dynamics, focusing on some of the ACGME core areas or ACRM team skills, or on medical knowledge areas required for the learner group, such as the proper medications for induction of a critically ill infant, or on technical skills, such as effective bag–mask ventilation or compressions in cardiopulmonary resuscitation, or any combination of the above. The target learner group should have a needs assessment that drives the choice of goals.

Once the goals have been decided, the setting for the scenario must be chosen to support them. Available resources, including personnel, time, equipment, or supplies, will play a large role in where and when the scenario can be run. And these in turn will affect the specific scenario elements choosen. For example, the number of facilitators might influence the ability to run a team crisis scenario versus an individual medical knowledge and skills learning opportunity. And the mannequin at hand would dictate the ability to run scenarios based on the appropriate matching age ranges.

Various templates have been used to prompt inclusion and organization of all the diverse elements required to create a scenario for high-fidelity patient simulation. All templates include the basic premise for the scenario to be acted out with a description of the patient's condition, the procedure or circumstance in which the patient is found, and the sequence of events that is planned to occur. This plan is created to specifically test the skills and teamwork of the participants in the scenario, targeting the particular learning goals. The roles for facilitators and participants must also be carefully delineated. The supporting equipment required, either to create a realistic

environment or for use in responding appropriately to the scenario, must be listed. Expected reactions to the script and the typical physiological responses are planned as well, so that any actions taken by the participants will have realistic responses. Figure 47.28 depicts a typical short template for a scenario, listing all critical elements required. A longer format adds detail to each element or includes references to support reactions depicted in various steps of the scenario. A vital signs "map" for the technician, to help guide them through the expected physiological reactions to different steps in the scenario, can also be included (see Fig. 47.21). Learning objectives are explicitly spelled out to ensure their inclusion during the debriefing section of the simulation.

KEY POINTS: PEDIATRIC ANESTHESIA SIMULATION

- Numerous applications are achievable using medical simulation in pediatric anesthesia including procedural training, complex medical scenario sessions, crisis management/teamwork performance training, and managing professional issues
- Many different learner groups can participate in pediatric anesthesia medical simulation activities including physicians in training, attending physicians (both anesthesiologists and surgeons), nurse anesthetists, nurses, and ancillary staff
- Developing pediatric anesthesia medical simulation scenarios requires a deliberate process with particular attention paid to the identification of the key learning objectives for the session
- Learning objectives can be achieved in a variety of venues with modification of equipment, simulation methods, and teaching approach

Measuring the effectiveness of simulation learning

Stem questions:

- How will you know if the medical simulation sessions were effective?
- How will you use this information to make future improvements to the medical simulation sessions?

Educators want to understand the true impact of providing medical simulation activities. However, demonstrating a true relationship from the simulated venue to an actual medical environment is challenging [81]. This is relevant from a program development perspective since simulation education is relatively resource intensive, and when team training is involved, it requires a great deal of coordination and preplanning to ensure all team members are present and well prepared. Exposing whole clinical units to regular educational sessions is both time and cost prohibitive. In contrast, simulation-related activities are advantageous due to their emphasis on using active learning formats [82]. Measuring general patient outcomes for relatively rare events therefore is unlikely to show a direct correlation to the specific training of the units' teams. However, when smaller groups, such as code teams, are deployed to assist with resuscitation management in entire hospitals, focused training is possible. Knight et al demonstrated an improvement in patient survival to discharge and in code team adherence to standard operating performance variables for patients who suffered cardiopulmonary arrest after a simulation-based resuscitation team training program was implemented [83]. While exciting in concept, it is not possible to completely attribute causality to the training program.

How then should the effectiveness of the simulated training sessions be measured? Three approaches have been used extensively in the past: review of participant survey data, pre-and post-training teamwork scoring, and comparison of pre- and post-training timed/measured actions in well-protocoled procedures and processes, such as pediatric advanced life support (PALS) or advanced cardiac life support (ACLS). Questionnaires for self-assessment and/or knowledge-based tests are often used to gauge the educational effectiveness of the simulation sessions. These are usually administered prior to the educational intervention, immediately postintervention, and perhaps again at some future interval to determine the sustainability or longevity of the educational outcomes as well as improvements in knowledge and/or psychomotor skills.

Evaluation tools utilized in medical simulation to determine the effectiveness of training typically incorporate one, if not several, of the four levels in the Kirkpatrick model [84]. The most common Kirkpatrick levels utilized within medical simulation include level 1 (reaction) and level 2 (learning). Attainment of level 1 could be achieved by surveying the learner group regarding their reactions to training, while level 2 could be achieved by measuring the knowledge of each learner by the administration of a post-test. The ideal goal within the medical simulation community would be to demonstrate evidence at Kirkpatrick level 4 (results). Kirkpatrick level 4 would include exhibiting targeted effects (e.g. patient outcomes) as a direct result from receiving medical simulation training. Establishing this degree of direct outcomes becomes significantly challenging and very complex to substantiate.

Medical simulation participants often report an improved sense of confidence and comfort in working through communication-based scenarios and crisis resource management scenarios after receiving focused training. Indeed, when high-fidelity simulation is used for teams in high-acuity settings, such as intensive care units, operating rooms, and emergency departments, participants often report being confronted with a similar actual situation post-training which provides a feeling that the simulation training has primed their abilities to respond more effectively [85,86]. In addition, common qualities from simulated crisis resource management training may be extrapolated for use in the future by the learners (e.g. leadership skills and duties related to specific role assignments).

Most frequently, the teamwork scoring is achieved as part of a series of simulation educational events, in which a researcher watches live or taped simulation scenarios and uses a standard scoring system to grade various teamwork skills, such as closed-loop communication, clear designation of a code leader, and effective delegation of tasks. Using the Clinical Teamwork Scale, Gilfoyle et al demonstrated clear gains in teamwork effectiveness, and in effectiveness of

Case Title (**Not to be read to participants**)	**Management of Anaphylaxis in Patient with Congenital Cardiac Disease for Hernia Repair: inaccurate paperwork causes confusion about allergies, and wrong med given** ***NOTE: scenario is preliminary for follow up scenario in which the "hot seat" anesthesiologist must disclose the events to the patient's mother***		
Patient Information	**Name Baby Sim Packard**	**Age 13 m**	**Gender Male**
MRN (will be changed)	**Weight 14 kg**	**Height 90 cm**	**Race Caucasian**

Case Presentation (**To be read to participants**)	**13 month old boy, scheduled for Hernia Repair one week after difficult reduction of incarcerated hernia**	
Past medical/surgical/family history	**Original surgery planned for day of hernia reduction but patient with Down's Syndrome, h/o AV Canal repair with small PFO, mild PHN, therefore surgery delayed for cardiac consult, now one week later, consult states patient is stable with no active cardiac symptoms and OK for surgery, "avoid hypotension and hypoxia"; URI and OM 2 weeks prior, no other medical history, family history negative for problems with anesthetics**	
Diagnostic Tools	**ASA monitors**	
Narrative Case Description (describe how the case unfolds, including major patient trends and consequences of interventions)	**Patient in the OR and already induced when "hot seat" participant comes in to take over care - original anesthesiologist acutely severely ill (chest pain, presyncopal); patient is stable at the time of handoff, immediately after intubation; surgeon is impatient to begin, draping completed and surgeon asks for antibiotics, which are already drawn up (Cefazolin), antibiotics given by hot-seat participant, surgeon states that patient moves with incision and anesthetic deepened, shortly thereafter desaturation and hypotension occur. Congenital Cardiac Disease, causes confusion about immediate diagnosis in OR, "red herring"/complicating factor. Wheezing, increased PIP's, and hives appear within next few minutes. Anaphylaxis treatment ensues, with patient not responding completely, requiring pressors/remain intubated, transfer to ICU for observation and treatment; the primary circulating nurse is not in the room at "time-out" to relay new allergy information to team, she presents this information when clear that allergic reaction is occurring and asks what antibiotic was given, this information does not correlate with information on anesthesia preop assessment form. Surgery cancelled with incision already made, transfer to ICU. Surgeon states will go speak with mother while team takes patient to ICU.**	
Clinical Diagnosis and "Correct" Treatment	**1. Recognize signs and symptoms of anaphylaxis.** **2. Understand likely manifestations of congenital heart condition.** **3. Manage ventilation, hypotension.** **4. Initiate post-op care plan.**	
Educational Objectives (with references to core competencies when applicable)	**1. Understand the importance of timeout procedures** **2. Increase understanding of Congenital Cardiac Condition** **3. Review of Anaphylaxis manifestations and treatments.** **4. Understand critical behaviors for effective team performance in ACRM, leadership and communication in a crisis situation (Communication & system based practice)**	
3-5 Teaching/Debriefing Points (include references)	**Proper Steps for Timeout (WHO Checklist?)** **Paperwork/System problems with mixed information** **Team Roles in Crisis Management - anaphylaxis** **Sorting out differential diagnosis in patient with congenital heart disease**	
Staffing (roles - participants needed to reenact case)	**Simulation Facilitator (run computer)** **Circulating Nurse** **Surgeon** **Hand-off anesthesiologist (becomes computer facilitator)**	
Learners (med students, residents, etc.)	**Participants: SPA attendees,**	**1. Hot Seat** **2. First Responder** **3. Scrub Tech** **4. 2nd circulating nurse**
Props needed	**SimBaby, Anesthesia Machine, IV poles/sets, IV materials/supplies, syringes and needles for sim meds, airway equipment, suction, defibrillator (?), stethoscopes, drapes/surgical instruments**	
Timing	**Scenario: 20 minutes** **Debriefing: 20 minutes**	

Figure 47.28 Example of a template used to capture and organize the critical elements in a scenario, from a short description of the basic clinical situation being depicted, to the staffing and equipment needs and the learning goals and objectives. *Source:* Adapted from the Duke University Simulation Scenario Development Template available at http://simcenter.duke.edu/support.html and the Scenario Preparation and Script by P. Dieckmann and M. Rall, TuPASS Germany, published in the IMSH 2008 Instructor Training Course manual.

Table 47.5 Example of a performance checklist for timed elements in a lost airway crisis scenario for team training, giving the anesthesiologist's performance parameters (part of Stanford Children's Hospital operating room team training)

Anesthesiologist performance parameters	Maximum points	Not done	Done/delayed	Done within time limit
1. Participate in checklist/timeout	10	0	5	10
2. Recognize difficulty in masking with apnea	5	0	2	5
3. Apply CPAP/oral airway	5	0	2	5
4. Communicate to team: having difficulty with patient's airway	5	0	2	5
5. Call for help	20	0	10	20
6. Limit DL attempts to two (will be unable to intubate)	5	0	n/a	5
7. Attempt placement of LMA (will be unable to achieve ventilation)	5	0	2	5
8. Alert surgeon that surgical airway may be required	10	0	5	10
9. Start CPR – direct team	5	0	2	5
10. Stop all anesthetics and attempt to awaken patient	10	0	5	10
11. Ensure IV line started	5	0	2	5
12. Alert surgeon that surgical airway may be required	10	0	5	10
13. Ask for cricothyrotomy kit to be brought to room	5	0	2	5

resuscitation using the Clinical Performance Tool after a full-day simulation-based training program for multidisciplinary teams [87–89]. Effectiveness of clinical performance scoring requires observation of simulated or real events by a person thoroughly trained in the key components of the standard protocol and the designated learning objectives for the simulation scenario. Typically, an evaluation tool with key elements, many of which are time sensitive, is used to frame the scoring (Table 47.5). For simulated events this is relatively straightforward to execute, but with unanticipated events in real clinical environments, a predetermined process for ensuring trained observers are present is significantly challenging to consistently provide.

Evaluations for medical simulation activities can be achieved in several capacities. Evaluations can be formative or summative. Formative evaluations are utilized to focus on improving future performance and may consist of generalized comments or observations; these findings may then be utilized to promote discussion during debriefing sessions. Summative evaluations are primarily utilized to assign various types of scores to previous performance. These scores can be related to a wide variety of characteristics such as individual performance, team performance, team characteristics, medical knowledge, psychomotor skills, and professional attributes. The scores can be assigned to individual actions (e.g. a list of the 10 steps in the placement of a central venous catheter) and/or as part of a global overall rating [90,91]. Scores can be assigned for a single simulation scenario or as part of a series of scenarios contained within a long-term course [92]. The scores from summative evaluations can also be used for several purposes such as providing certification in PALS as well as for research projects.

Analysis of evaluation data is another critical component of maintaining an effective and sustainable simulation program. The simulation educator should be open and willing to receiving ongoing feedback regarding their simulation activities from several sources. Review and reflection of learner evaluation data should become a required and automatic process to identify areas for improvement. The review of learner evaluation data will allow valuable insight from the learners' perspective. In addition, postcourse debriefings that occur with the simulation instructors and support staff will provide further critical information from another perspective. All viewpoints can be utilized to make meaningful adjustments in the educational activity to make it as effective as possible.

Effectiveness of the medical simulation activity can and should be determined in several ways. Learner evaluations bring one perspective while instructor interpretations add a different layer of insights. In addition, adherence to the original learning objectives is another consideration. Accordance with pre-established standards or guidelines (e.g. PALS) can also provide additional guidance on educational effectiveness. Finally, long-term learner satisfaction, and perhaps performance change, is another overarching goal to seek. Improvements to future simulation sessions may be adapted to reflect changes in several elements including learning objectives, learner levels or backgrounds, advances in technology, and changes in medical knowledge.

KEY POINTS: MEASURING THE EFFECTIVENESS OF SIMULATION LEARNING

- Simulation educators should attempt to determine the true impact of providing medical simulation activities, despite the challenges in extrapolating to patient care and educational outcomes
- The most common evaluation tools utilized in medical simulation to determine the effectiveness of simulation training are learner surveys and performance checklists for both individuals and teams
- Evaluation tools utilized in medical simulation commonly assess several categories of performance including medical knowledge, psychomotor skills, and team performance

Summary

Medical simulation has become a standard in medical education among medical schools and resident training, used for research, systems evaluations, and human performance evaluation. With the development of pediatric-sized equipment, the use of simulation has been expanded within the area of pediatric anesthesia, with multiple and varied applications. It seems clear that these tools will continue to be developed and extend within medicine to improve education and ultimately patient care.

CHAPTER 48

Databases, Registries, and Outcome Research in Pediatric Anesthesia

Joseph Cravero
Harvard Medical School, Boston, MA, USA

Introduction

The use of data aggregation for the purposes of detecting trends, factor associations, or prediction of future outcomes – sometimes referred to as "Big Data" analysis – is part of everyday life. One need look no further than opening an internet browser to find customized advertisements that have been chosen for you based on your previous browsing history and analysis of purchases by individuals with similar histories. Similarly, sports executives, particularly in baseball, use large datasets of previous performance to predict the likely future outcomes of individual match-ups. It is hardly surprising then that the same kind of database creation and analysis has been applied to medicine, including pediatric anesthesia.

Large data analysis of healthcare outcomes is nothing new. There are numerous national registries in the United States including those from the National Surgical Quality Improvement Program (NSQIP) [1–3], the Society of Thoracic Surgeons (STS) National Database [4,5], and the Closed Claims Registry that has long been utilized by anesthesiologists [6,7]. Similarly large data analysis has long been available in Britain through data developed by the National Health Service [8] and by even larger collaboratives throughout Europe [9]. While the specialty of anesthesia has taken some time to adopt large data as a primary analysis tool, the current environment has accelerated this trend to a fever pitch. The (almost) universal adoption of the electronic medical record and intraoperative record, the collection of almost infinite amounts of perioperative data has become both low cost and relatively simple. The creation of multi-institutional data-sharing collaboratives has expanded the scope of data gathering even further [10,11]. The result is data aggregation that is larger than could ever have been imagined 20 years ago.

The growth of database outcomes research in pediatric anesthesia is further spurred by the ethical, financial, and regulatory pressure to optimize patient care and outcomes. Large data analysis is optimally suited to allow evaluation of various outcomes of interest and associations between care factors and outcomes. While randomized controlled trials (RCTs) remain the standard by which all studies of health outcomes are judged, the current financial/funding environment has made execution of these trials more difficult than ever. RCTs are expensive to perform and often difficult to approve on ethical grounds. In addition, it is simply impossible to study all of the different aspects of pediatric anesthesia practice with RCTs. Finally, there is evidence that well-conducted large data observational trials provide similar findings when compared to controlled trials that investigate the same outcomes [12,13].

This chapter reviews a variety of registries and large data studies relating to anesthesia and pediatric anesthesia. In addition it highlights the advantages, contributions, and pitfalls of large data studies.

Outcome research from data registries

Why large data analysis?

Outcomes analysis is essential to healthcare quality improvement efforts. Pediatric anesthesia faces unique challenges when analyzing outcomes, since it involves a one-time point of care interaction where work flow precludes detailed

Gregory's Pediatric Anesthesia, Sixth Edition. Edited by Dean B. Andropoulos and George A. Gregory.

feedback to caregivers. In addition, pediatric outcome evaluations must take into account the patient's age, development, and underlying illness when attempting to establish benchmarks. The deployment of "Big Data," including preoperative, operative, and postoperative data, offers an opportunity to create datasets large and inclusive enough to offer useful information on the nature and rate of the most pressing outcomes of interest. Consider the fact that at any large pediatric hospital there are at least 10 different ways in which an anesthesiologist may provide care – using varying methods for airway management, maintenance of anesthesia (e.g. total intravenous anesthesia versus volatile anesthetic), and extubation/recovery choices. The care delivered is driven by personal experience and "choice" of the provider based on their understanding of a very confusing body of evidence. In fact, there is little evidence base for many of the options that face anesthesiologists daily. Conversely, other areas of commerce and industry that involve similar levels of risk and complexity do not allow such a free-form process. In order to continuously improve outcomes, anesthesiologists need to evaluate care delivery with respect to patient-centered perioperative outcomes, quality improvement, resource utilization, risk-adjusted outcomes, and clinical prediction modeling. These concepts are completely in line with the concept of "perioperative surgical home" (see Chapter 15) wherein anesthesiologists evaluate patient-centered outcomes in creating safe and efficient systems of care for operative patients.

As mentioned, RCTs are particularly difficult to accomplish in perioperative children. Instead, over the last 10 years there has been an explosion in the use of observational registry research (databases) to evaluate outcomes of surgery and anesthesiology. For perioperative children, many treatments and exposures cannot be randomized due to ethical issues. For instance no one can randomize groups to an exposure to a major surgery versus no surgery. Many institutions are likewise convinced that their specific method of delivering analgesia for children after surgery is the best and do not believe it is appropriate to expose patients to other alternatives. In light of this, databases created from multiple institutions serve as the next best mechanism for evaluating quality outcomes in children undergoing tests or surgeries. Aggregated outcomes from institutions using different methodologies for accomplishing the same care can be compared in an effort to simulate a randomized trial [14]. Furthermore, the availability of large amounts of data from geographically diverse sources has made large registry data the primary source for health services research in anesthesia (which primarily evaluates cost versus outcome).

Considering the data

Well-conducted large data studies result in risk stratification that correlates with RCTs [12,15], although they tend to overestimate treatment effect. In spite of this, it is reasonable to utilize data from large observational trials to help direct clinical care. The adoption of huge data resources now available from electronic medical record (EMRs) for this purpose, has proven to be the primary source for this outcome analysis. However, data collected for the purposes of clinical care is not always reliable for use as "research data." These issues become amplified when tens or hundreds of institutions are involved in data collection. For instance, what is meant when a clinician states that "laryngospasm" occurred during a case [16]? Different clinicians might have very different ideas as to what constitutes this clinical entity, causing data from varying centers to have different meanings. In light of this, when considering data from observational studies, it is critical that clear definitions for outcomes are agreed upon by those gathering data. Large data reports from clinical interactions are most accurate when considering major adverse events (e.g. death or intensive care unit (ICU) admission) which are impossible to ignore (and are less subject to interpretation). In this way, they are much more likely to be captured accurately than minor events that do not result in a change in patient status.

Large data registries and collaboratives are most helpful when they focus on outcomes that are "meaningful." Appropriate outcomes for analysis are often not clear. For instance, many studies of anesthesia or sedation techniques report the frequency of minor oxygen desaturations as an outcome [17]. Unfortunately, events such as these are of uncertain importance, since brief oxygen desaturation has little or no impact on the patient's overall health or outcome. These outcomes would be important only if the frequency of these finding correlated with more concerning adverse events, but this connection is almost never made. On the other hand, severe prolonged oxygen desaturation events (such as those associated with unexpected tracheal reintubation, ICU admissions, etc.) are much more important and deserve careful consideration.

Retrospective and prospective cohort studies

The most common use of large registry data is for retrospective cohort studies or case–control studies. These methodologies are ideal for studying rare problems or patient factors that are not modifiable. Retrospective cohort studies examine the outcomes related to a specific disease or intervention over a prolonged period and (usually) involve a particularly large total population [6]. A report of the outcomes of hypoplastic left heart patients undergoing non-cardiac surgery would be in this category. On the other hand, a case–control study would identify two cohorts, one having the characteristic of interest and the other *not* having that characteristic. These studies then look at the outcomes of these two cohorts with respect to a given intervention or exposure in a retrospective manner. An example of this kind of study would be the assessment of pain after tonsillectomy (the characteristic) with respect to various exposures (age, race, surgical approach, anesthetic management).

Large data registries are also used to perform prospective cohort studies. In these cases cohorts that are similar, except for having a specific exposure, are compared in a prospective manner. Such studies are preferable to retrospective analyses because outcomes of interest can be specifically defined and followed in a predefined manner that is not possible in a retrospective design. Studies from the Pediatric Regional Anesthesia Network (PRAN) or other such collaboratives fit into this study design type.

Large data quality improvement and research efforts can be broadly divided into three groups: (1) those with tens or hundreds of investigators/institutions collecting data on literally

millions of patient interactions where a huge number of patient encounters can be evaluated, but the density and quality of data is relatively low; (2) more circumscribed collection efforts that aggregate data from a single or smaller number of institutions (20 or fewer) using a more detailed and specific data collection strategy; and (3) very comprehensive data collection from single institution that include copious data on a relatively smaller number of patients. The trade-off for these strategies is clear, the larger data collection efforts allow information to be collected on issues that have very low frequency and are usually accurate in their estimate of outcome frequencies. Unfortunately very large national sources such as the US Centers for Medicare and Medicaid Services (CMS) database usually only contain primarily basic demographic information, billing codes, hospitalization duration data, and mortality data. Very large data collection also occurs at the expense of data quality and detail. When the total number of sites involved is very large, there is inevitable variability in recording accuracy.

KEY POINTS: OUTCOME RESEARCH FROM DATA REGISTRIES

- "Big Data" from the now ubiquitous anesthesia electronic medical record offers an opportunity to create datasets to offer useful information on the nature and rate of the most pressing perioperative outcomes of interest
- Randomized controlled trials are difficult to accomplish and expensive; over the last 10 years there has been an explosion in observational registry research (databases) to evaluate outcomes of surgery and anesthesiology
- The most common use of large registry data is for retrospective cohort studies or case–control studies

"Big Data" in anesthesia research

There are innumerable examples of EMR collaboration to produce large data collaborations in the field of anesthesiology. The Anesthesia Quality Institute (AQI) was founded in 2008 with a vision of improving anesthesia quality and safety in the clinical care of patients undergoing anesthesia. In order to meet these goals, the AQI created the National Anesthesia Clinical Outcomes Registry (NACOR) in 2010 – it was then, and continues to be, the largest and perhaps the most ambitious data-gathering organization in anesthesia [10,18,19] (information available at http://aqihq.org). NACOR is designed to automatically capture electronic data specific to anesthesia cases. Data are gathered from billing systems, hospital electronic healthcare records, and anesthesia information management systems. The database is intended to serve several purposes. First and foremost, it functions as a quality improvement tool for all centers that participate. Data are initially entered and go through a portal that performs validation checks and feedback. Once this step is completed, the data can be sent to a central data repository to undergo processing and analysis. This registry aggregates data from hundreds of institutions that house literally tens of millions of patient encounters for review. NACOR then feeds back information in the form of reports to member organizations that allows benchmarking of provider factors and outcomes. From its conception, data collection for this effort goes on "in the background" of day-to-day clinical activity – invisible to the care providers [20]. Data on all types of factors or outcomes can be collected and analyzed, from the frequency of adverse events to the age of patients undergoing surgery at a given institution. The convenience of this type of data collection is undeniable and has garnered excitement from clinical researchers around the globe (Fig. 48.1).

Data are also shared with the CMS as the organization is a qualified clinical data registry as well as a qualified registry within that organization. The NACOR Qualified Registry includes 31 merit-based incentive payment system measures. Data from centers can be automatically shared with the CMS to allow reimbursement for performance that meets specific criteria. NACOR reports on 26 Physician Quality Reporting System metrics and 19 American Society of Anesthesiology (ASA) Quality Clinical Data Registry metrics. These metrics include items such as perioperative mortality and the use of combination therapy for the prevention of perioperative nausea and vomiting.

Data collected through NACOR's efforts have also been used for research purposes. Reports from the AQI have addressed broad and (at times) controversial issues involved in anesthesia practice. Papers have been published on multiple topics, including the variability in choices of anesthesia for patients undergoing total knee arthroplasty [21]. In this report over 100,000 knee replacements were analyzed and the percentage having surgery under regional (11%), neuraxial (31%), and general (58%) anesthesia were reported. A more recent report delineated the frequency of neuraxial anesthesia for caesarian delivery [22]. This study looked at almost 220,000 caesarian deliveries and found that general anesthesia was used in just 5.8% of elective cases and 14.6% of emergency cases. These manuscripts point out the power of a database such as NACOR to investigate operative and anesthetic demographics and trends in anesthesia delivery.

Other reports from the NACOR database have tracked differences in care-based payer mix, as noted by Flood et al who investigated labor analgesia duration at various sites around the United States [23]. These data are also very helpful for defining demographic trends in anesthesia delivery – such as the delivery of neuroanesthesia [24]. To date there have been no research reports on issues of pediatric anesthesia from this group, but helpful population-level data may exist in this database and reports of anesthetic outcomes and performance of providers caring for children will doubtless be forthcoming.

Data collected and analyzed for NACOR to date have largely involved population health and are intended to be analyzed at this level. To address the need for some level of individual patient data, the AQI created the Anesthesia Incident Reporting System (AIRS). This system is intended to collect information on specific adverse events reported from a large number of institutions and for subsequent incident analysis. A subspecialty module for pediatric anesthesia exists in AIRS; however, the overall purpose and methodologies involved have been largely taken on by the Wake Up Safe initiative outlined later in this chapter.

The Multicenter Perioperative Outcomes Group (MPOG) is another large data-gathering organization in the field of

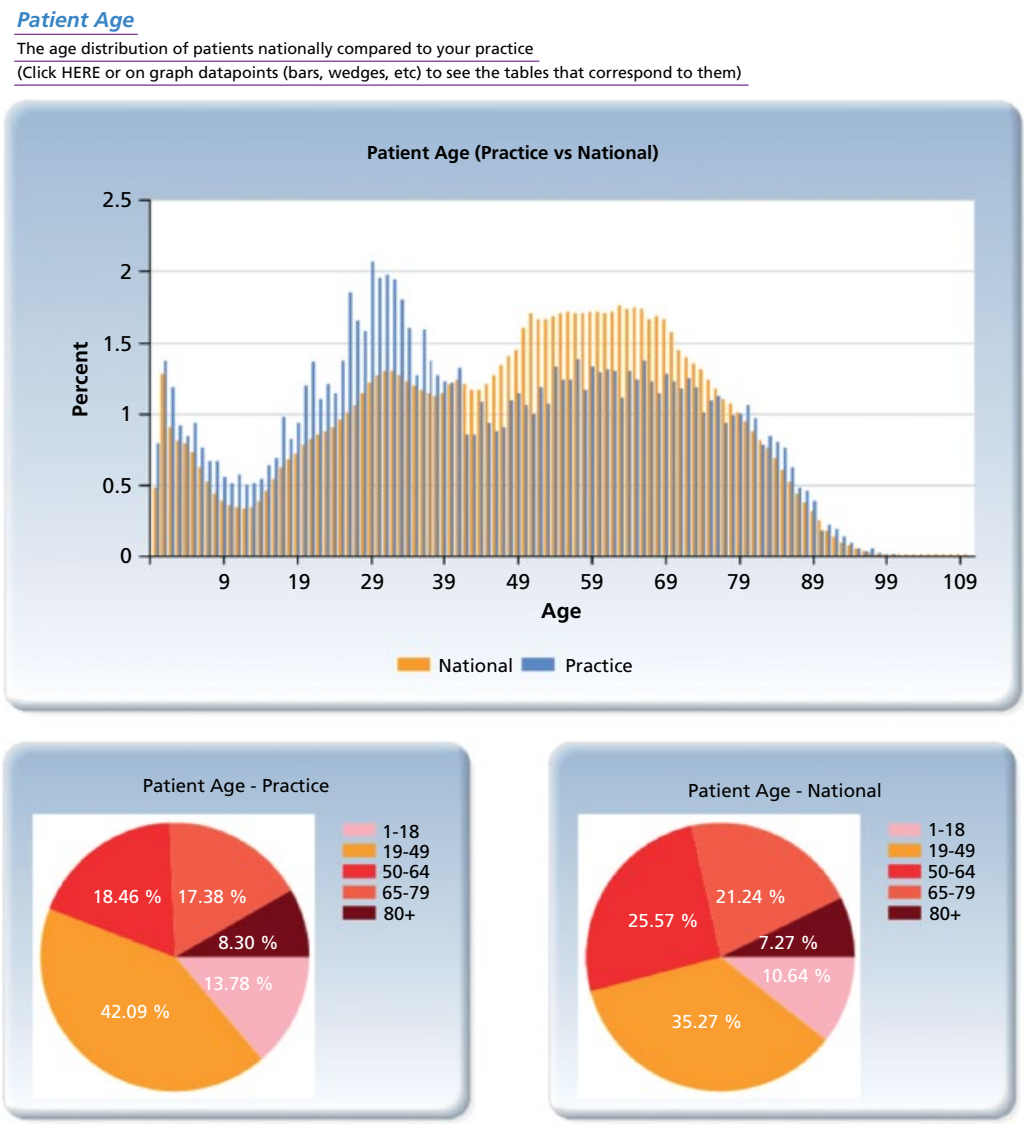

Figure 48.1 Example of data from the National Anesthesia Clinical Outcomes Registry (NACOR) database on the age of patients undergoing surgery. *Source*: Data from Anesthesia Quality Institute, http://aqihq.org.

anesthesiology. This data collective was initiated in 2008 with the mission to develop policies, procedures, and the infrastructure required for collaborative outcomes research in anesthesiology. This group now has 58 participating medical centers in the United States and Europe and has accumulated millions of patient encounters that include patient outcomes and administrative outcomes. Members have published multiple manuscripts in highly regarded peer-reviewed journals and have presented work at numerous national meetings. This group has also created a performance improvement arm (Anesthesiology Performance Improvement and Reporting Exchange) that is partially funded by Blue Cross Blue Shield of Michigan and is based on the data infrastructure of MPOG. This group utilizes the clinical and administrative data to analyze the relationship between patient factors, surgical procedures, anesthesia techniques, and perioperative outcomes.

To aid in establishing improved practices, MPOG members have published on topical issues, such as the rate of hematoma formation after neuraxial anesthesia in parturients, and has related these rates to platelet counts – showing that the rate of hematoma formation is increased with decreasing platelet counts [25,26]. Other low-frequency events have been evaluated and reported – including the success of tracheal intubation rescue techniques after failed direct laryngoscopy in adults [27]. This study documented the high frequency of use and high success rate of videolaryngoscopy techniques. MPOG has also produced publications on the nature of anesthesia practice in general including the relationships between anesthesia pump alarm settings and the infusion rates that are routinely utilized [28], the use of lung protective strategies for intraoperative ventilation [29], and the incidence and predictors of difficult mask ventilation [30].

In its first publication concerning pediatric anesthesia, MPOG analyzed oscillometric blood pressure values from the EMRs in 116,362 ASA physical status (PS) 1 and 2 pediatric cases from 10 institutions [31]. This paper reported normative blood pressure ranges during the postinduction and surgical phases (Fig. 48.2). Reading it, one is struck by how low the normative blood pressure ranges under anesthesia are in patients with no or minimal co-morbities who have good outcomes. For example, from birth through 3 months, the mean arterial pressure corresponding to 2 standard deviations

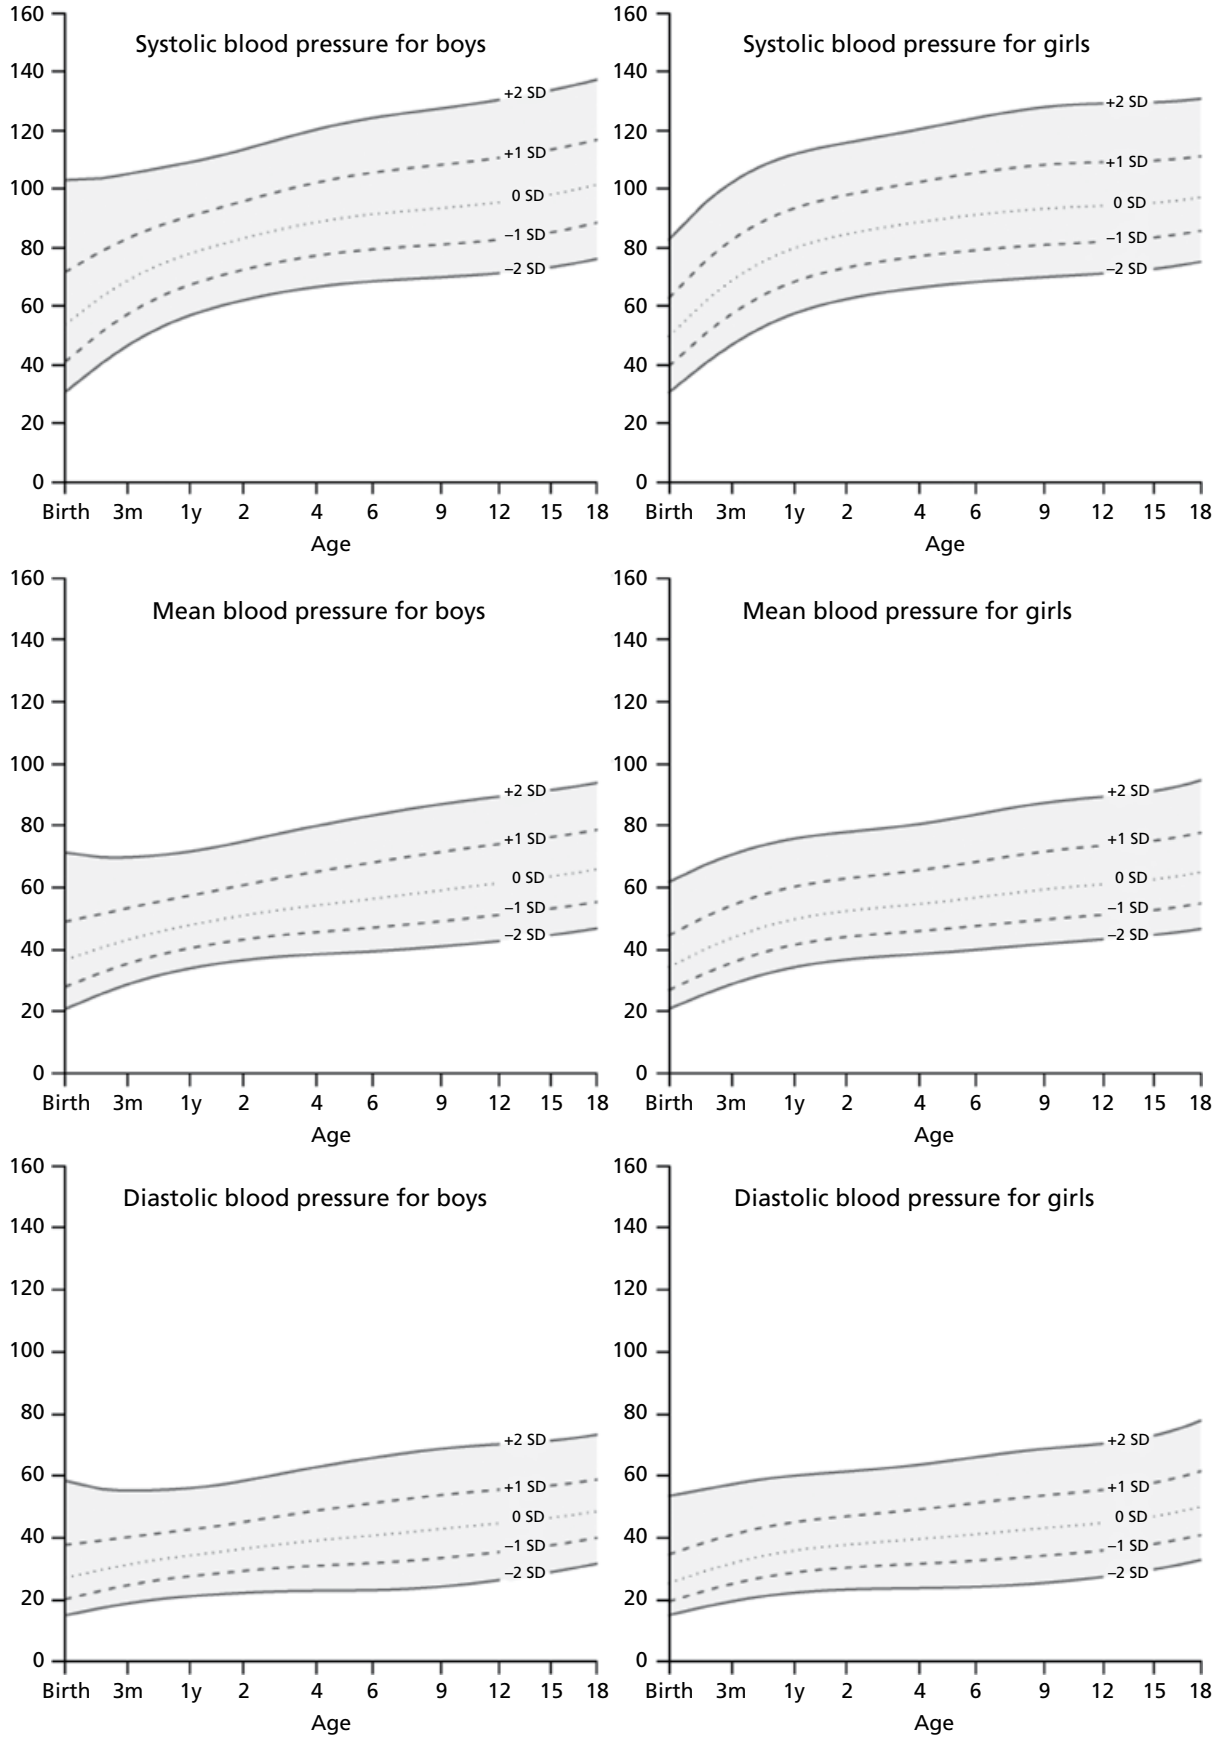

Figure 48.2 Normative oscillometric blood pressure ranges for 116,362 patients from the Multicenter Perioperative Outcomes Group (MPOG) registry during the surgical phase of the anesthetic in relation to age. Source: Reproduced from rde Graaff et al [31] with permission of Wolters Kluwer.

below the 50th percentile is 18–22 mmHg. This is an example of how a large dataset could be used to establish norms for blood pressure in daily clinical care, and develop tools for clinical care and research to rapidly screen blood pressure values for defining hypo- and hypertension.

Both the AQI/NACOR and MPOG data initiatives have helped describe anesthesia practice and correlate outcomes with specific patient characteristics or anesthesia techniques. The power of large data aggregation is clear. The data analyzed by these organizations could not be aggregated by a single institution or small group of institutions. On the other hand, data gathered by large numbers of geographically diverse centers is very difficult to audit and assure consistency or reporting. Analysis is limited to clearly definable outcomes that are not ambiguous or do not lend themselves to interpretation. Still, while observational large data collaboratives are limited in their detail and accuracy, their ability to describe practice patterns and general outcome parameters has the potential to revolutionize the practice of anesthesia in the future. These efforts have just started to define pediatric- specific practice parameters, and active pediatric work groups exist in these organizations and should increasingly bring the power of these large data collaboratives to pediatric anesthesia [32].

KEY POINTS: "BIG DATA" IN ANESTHESIA RESEARCH

- The Anesthesia Quality Institute created the National Anesthesia Clinical Outcomes Registry to automatically capture electronic data specific to anesthesia cases
- Quality assurance and research can be conducted from this databse, and the millions of anesthetic cases constitute a rich source for data mining on a myriad of questions of anesthetic practice and outcomes
- The Multicenter Perioperative Outcomes Group (MPOG) is a consortium of 58 institutions in the USA and Europe collecting data directly from anesthesia EMRs that has allowed detailed analyses of anesthetic practice and outcomes. Their first pediatric publication established blood pressure norms in pediatric patients

Databases and registries specific to pediatric anesthesia

Pediatric Regional Anesthesia Network

The PRAN was organized in 2007 as a consortium of six institutions in the United States where pediatric regional anesthesia was regularly performed. Their goal was to collect prospective data for multicenter collaborative research projects concerning pediatric regional anesthesia. This group now involves 22 centers and has close to 150,000 patient encounters in the database and is growing daily. The original members established guidelines for data collection and auditing of the data and developed online data entry methodology. The first report from this group was published in 2012 and outlined the outcomes of almost 15,000 regional anesthesia encounters in children, including a large number of neuraxial blocks (particularly caudal blocks) as well as peripheral nerve blocks (Table 48.1) [33]. This report described in general terms the techniques used for regional anesthesia in children and the adverse event rates in this cohort – which represented the largest such collection of regional anesthesia cases in children ever studied. The most notable findings included the fact that there were no deaths or long-term complications, and that the vast majority of blocks were placed while the patients were sedated or anesthetized. They also noted the fact that ultrasound guidance was almost universally used in the placement of these blocks. This information has served to

Table 48.1 Pediatric Regional Anesthesia Network (PRAN) summary of single injection blocks and adverse event rates in 14,917 regional blocks

reinforce (with data) the generally accepted practice of placing major conductive nerve blocks while patients are under general anesthesia or deep sedation.

Over the last several years, the PRAN has continued to produce reports on the safety of pediatric regional anesthesia. Papers cataloging the adverse event rates associated with interscalene blocks [34], caudal blocks, continuous peripheral nerve catheters, transversus abdominis plane blocks [35], and neuraxial catheters in neonates [36] have been published. In every case, the collaborative has shown that the incidence of serious complications with these blocks is low, even though in some cases (such as neuraxial catheters in neonates) the risk of minor adverse events could be significant (13%). Perhaps more importantly, the PRAN has helped clinicians understand the nature of pediatric regional anesthesia practice by providing insights into the frequency of nerve block application.

The PRAN has allowed data to be developed concerning peripheral nerve blocks that would have been impossible to obtain in the absence of a data-sharing collaborative. RCTs involving relatively limited number of patients could not lead to the broad understanding of this practice that this collaborative has developed. The ability to both describe a wide range of practice, and understand the nature and frequency of outcomes that are infrequent, is impossible without this type of data accumulation and analysis. The ongoing work of this group has shaped the practice of pediatric regional anesthesia and will continue to do so going forward.

Pediatric Perioperative Cardiac Arrest registry

The Pediatric Perioperative Cardiac Arrest (POCA) registry was perhaps the earliest registry effort specifically organized to address issues related to pediatric anesthesia and perioperative care. It was developed in 1994 to track anesthesia-related cardiac arrests and deaths in children during the administration of or recovery from anesthesia and to determine the clinical factors and outcomes associated with cardiac arrest in anesthetized pediatric patients. In this case, rather than collect ongoing data on practice from medical records, the organizers sought to enlist centers that would voluntarily and anonymously agree to send standardized information on all perioperative cardiac arrests to the database. A representative from each participating organization also provided annual demographic information for the surgical population. In this way, the POCA registry could provide both analysis of severe adverse events and estimated rates at which these events occurred. Given that this collaborative was started before the era of EMRs, much of the data was collected through painstaking chart review.

In the first report from this collaborative, data was gathered from 63 institutions; 150 cardiac arrests were evaluated that were thought to be related to anesthesia care [37]. The overall rate of arrest was calculated to be approximately 1.5 in 10,000 anesthetics. Cardiovascular depression related to halothane alone or in combination with other medications was found to be responsible for two-thirds of the arrests. Two factors were found to be independently related to arrest – ASA status of 3–5 (odds ratio 12.99) and emergency status (odds ratio of 3.99). Infants younger than 1 year of age accounted for 55% of all anesthesia-related arrests. A subsequent report from this registry tracked arrests occurring in children with underlying cardiac disease [38]. In this case data came from 80 institutions and the authors evaluated the underlying anomalies in those who experienced arrest. Patients with single-ventricle anomalies were most commonly involved, but those with aortic stenosis or cardiomyopathy were found to have the highest mortality rate (62% and 50%, respectively) (Table 48.2).

The outcomes from the POCA registry helped codify risk concerning the rare, but all important, issue of perioperative cardiac arrest in children. These data would have been impossible to accumulate and analyze without the significant effort of all involved. While the outcomes analyzed in this effort are unarguably important, the POCA registry was limited by its ability to only analyze the most critical incidents in pediatric anesthesia practice. Current electronic medical record technology, combined with data-sharing networks, can/should allow investigators to evaluate much more nuanced

precursor events, along with future rates of pediatric perioperative cardiac arrests. Automated data collection makes more comprehensive, real-time, data collection possible and affordable.

Congenital Cardiac Anesthesia Society database

In order to more completely understand the nature of outcomes in anesthesia for children with congenital heart disease, the Congenital Cardiac Anesthesia Society (CCAS) created its own database to collect data on treatment of this population. This registry has the distinction of partnering with a surgical society with overlapping patient interest (the STS) to further the analysis of the care of these children.

There are multiple uses for the data gathered by the CCAS and STS. These organizations used data extraction from their combined database over the years 2010 to 2013 to describe the use of dexmedetomidine in patients undergoing congenital heart disease surgery [39]. Outcomes were analyzed for 12,142 operations of which 3600 (29.6%) received dexmedetomidine. Patients who received the drug were generally of a lower risk profile and (not unexpectedly) had better outcomes (Table 48.3). As such, the report is somewhat limited by selection bias, but shows the power of collaborative efforts between anesthesia and surgical interest groups that will doubtless result in an enormous amount of new and helpful outcome data in the near future.

Wake Up Safe registry

The Quality and Safety Committee of the Society for Pediatric Anesthesia initiated the Wake Up Safe (WUS) registry as a quality improvement effort in 2006. The aim of this collaborative has been to create a registry of serious adverse events in a de-identified manner. The ultimate goal of this group has been to implement change in processes of care that will improve patient safety and quality through analysis of collected adverse events. As with the POCA registry, the WUS effort requires participating centers to submit data on the types and numbers of anesthetics performed in addition to the index events themselves. Analysis of each adverse events is reviewed by three anesthesiologists who were not involved in the event. Root cause analysis is used to identify causal factors [40].

Recently Christensen used data from this collaborative to report on the nature of cardiac arrests occurring in the postanesthesia care unit. The study reported 26 such events and found that 67% were likely preventable. Along with analysis of the errors associated with these events, the authors noted that events of cardiac origin were much more likely to result in permanent harm or death than events of respiratory origin. Another report from this group evaluated medication errors [41]. In this case 32 institutions submitted 276 medication error events. The authors outlined the phase of the medication delivery when these events occurred along with the nature of the error (e.g. wrong dose administration (30%) versus syringe swap (18%) (Table 48.4) and types of medications involved in the errors (Box 48.1). Notably, 80% of the errors actually reached the patient; 50% were thought to result in patient harm; almost all events (97%) were thought to be preventable.

As with the POCA registry, the WUS registry offers the opportunity to evaluate events from a number of institutions. This type of data aggregation and analysis allows evaluation of relative small numbers of events collected from large numbers of cases. The resulting reports (that include contributing factors and possible corrective actions) are not possible from single-center data collection.

Report on pain prevalence and trajectories following pediatric spinal fusion surgery

A very different recently published project involves reports on pain prevalence and trajectories following pediatric spinal fusion surgery [42]. This multicenter registry collected survey information on very specific pain issues in patients undergoing correction of idiopathic scoliosis. In this case the investigators wished to specifically determine the pain prevalence of patients at various points before and after scoliosis surgery. The outcome measure was the Scoliosis Research Society Questionnaire-Version 30, which includes pain, activity, mental health, and self-image scales. Patients were evaluated just prior to surgery and then at 1 and 2 years postsurgery. Thirty five percent of patients reported pain in the moderate to

severe range presurgery and 11% reported pain at 1 year; 15% reported pain at 2 years. Of the different pain trajectories reported, there were significant differences on the self-image, mental health, and age metrics. The authors suggest that identifying factors that predict poor long-term outcomes in children with postsurgical pain may prevent the development of chronic pain into adulthood. Unlike the PRAN database mentioned earlier, this report does not detail the anesthetic management of these patients or any adverse events related to their interventions. A future data registry that includes information on the surgical correction and the anesthetic/pain management of these patients would add important information on potential confounders.

Pediatric Craniofacial Surgery Perioperative Registry

The Pediatric Craniofacial Surgery Perioperative Registry was established by the Pediatric Craniofacial Collaborative Group to promote understanding of the practices and outcomes in children undergoing operative procedures for craniosynostosis. These procedures involve complex cranial vault reconstruction which often is associated with significant blood loss and lengthy operative times. This collaborative is interested in promoting quality improvement through shared data on key aspects of patient management. For their first peer-reviewed publication, data collected from 2012 to 2015 were extracted from the registry, including demographics, perioperative management, length of stay, and blood management [43]. Outcomes analyzed included intraoperative and perioperative transfusion volumes and length of stay data. Adverse events and significant outlier data were analyzed. In all, 1223 cases were analyzed with over 70% being below 24 months of age at the time of their procedure (Table 48.5). The results revealed a very high rate of transfusion (95% for those under 2 years old) and a number of significant adverse events, including cardiac arrest, seizures, unplanned ventilation, and second surgeries. As is the case for many pediatric anesthesia registry efforts, this project allows clinicians to understand the nature of the care provided patients undergoing these procedures as well as some idea of the frequency and nature of adverse events. These kinds of data are impossible to assemble from a single institution's experience and allow some element of benchmarking for those who provide anesthesia for these patients.

Pediatric Sedation Research Consortium

The Pediatric Sedation Research Consortium (PSRC) is a consortium of hospitals and medical centers dedicated to sharing information on sedation in an effort to understand better what works and what does not work for sedation of children. This group is made up of a variety of pediatric specialists from 40 institutions in the United States and Canada. Information includes demographic data, procedure, coexisting illness, provider of sedation, drugs used, monitors, outcomes of the sedation, etc. This database is somewhat unique in that it is a collaboration between anesthesiologists and a variety of other specialists in pediatrics. After more than 10 years, there are almost 500,000 sedation encounters in the database. In September 2006 the first paper from the PSRC describing the types of adverse events and unexpected airway management issues encountered during the first 30,000 sedations collected by this consortium was published in the journal *Pediatrics* [44]. Serious adverse events were rare, but this study described the incidence of airway interventions and other unexpected adverse events (Table 48.6).

The authors suggested that these data help define the critical competencies necessary when providing procedural sedation. These competencies include recognition of apnea, clearing of an airway, airway adjunct insertion, and provision of positive pressure ventilation. A subsequent paper was published in *Anesthesia and Analgesia* in 2009 [16]. This paper discussed data from 49,836 sedation encounters utilizing primarily propofol. Data were evaluated for complications and

effectiveness of sedation. The study outcomes showed a very high rate of success (over 99% completed procedures) with a low rate of serious adverse outcomes. Other papers from this group have included analysis of adverse events between different specialists [45], the use of end-tidal CO_2 monitoring during sedation [46], the association between nil per os status [47] and adverse events, the effect of obesity on adverse event rates [48], sedation provided by pediatricians [49], sedation for gastrointestinal procedures [50], and several others [51–53]. Taken together, the prospective cohort studies from the PSRC have helped investigators describe outcomes of pediatric sedation practice with data. The information provided has the potential to help shape sedation recommendations and guidelines going forward.

Pediatric Difficult Intubation Registry

To address the issues relating to the incidence and nature of difficult intubation in children, the Pediatric Difficult Intubation Registry was formed by 13 children's hospitals in the USA. The group has established standard data collection methods and has successfully established a web-based registry for difficult intubation encounters. As with many of the large data analysis groups mentioned, this collaborative has the advantage of both reporting on the outcomes of interest (adverse events associated with difficult airway management) and on airway management practices as they exist across the participating centers. In one published report, investigators reported on multiple aspects of pediatric airway management involving 1018 difficult pediatric tracheal intubation encounters (Table 48.7) [54]. In children who were proven to have a difficult airway, the first attempt at intubation was by direct laryngoscopy in 46%, followed by fiberoptic bronchoscopy in 28%, and indirect videolaryngoscopy in 18%. Success rates were widely different, ranging from 3% with direct laryngoscopy to 55% with indirect laryngoscopy. The authors also separated "severe" (3%) from "non-severe" (30%) outcomes. They were able to describe patient characteristics that were most likely to be associated with complications – weight less than 10 kg, short submental distance, and more than three direct laryngoscopy attempts prior to trying another method of intubation.

The findings from analysis of this registry are not surprising, but the approach is promising for the future of this effort and others like it. The strict definition of the data elements and outcomes selected allows for consistency in reporting that is not possible without very large data collection efforts that look at broad aspects of pediatric anesthesia practice. Ongoing data collection from the Pediatric Difficult Intubation Group will allow tracking of the frequency and nature of adverse airway events, as well as the evolving nature of airway management as centers shift from direct to indirect laryngoscopic methods for all types of airway management.

APRICOT registry study

The APRICOT (**A**naesthesia **PR**actice **I**n **C**hildren **O**bservational **T**rial) registry study of 31,127 anesthetics in 261 hospitals in 33 European countries consisted of detailed prospective data collection for every anesthetic for patients aged 0–15 years over a 2-week period in 2014 or 2015 in each hospital [55]. The primary outcome was the incidence of perioperative severe critical events requiring immediate intervention. A severe critical event was defined as the occurrence of respiratory, cardiac, allergic, or neurological complications requiring immediate intervention and that led (or could have led) to major disability or death. This study revealed a 5.2% incidence of severe critical perioperative respiratory or cardiac events, with a 10–15% incidence in infants and neonates (Fig. 48.3). This rate of severe events is considered to be high, and the study also revealed a large variability in the practice and outcomes of pediatric anesthesia in Europe. This study could be repeated after targeted education and quality improvement strategies are implemented to assess whether they are associated with lower rates of critical events.

KEY POINTS: DATABASES AND REGISTRIES SPECIFIC TO PEDIATRIC ANESTHESIA

- Registries collect data about specific features of anesthesia of interest, such as regional anesthesia, cardiac arrests, medication errors, craniofacial cases, difficult intubation, etc.
- Databases collect more comprehensive information about every anesthetic in a particular field, regardless of complication rate. Examples are databases of anesthetics for pediatric cardiac patients, or pediatric anesethetics and sedations outside of operating rooms

Pediatric anesthesia data-based outcomes analysis from single institutions

Consideration of large datasets can influence pediatric anesthesia practice in many ways. As outlined in this chapter, studies using this methodology have added greatly to the collected knowledge concerning adverse events (and safety in general) in the areas of practice that each of these efforts is based in. Many individual institutions have ongoing efforts that use large amounts of integrated data from their own practice to establish systems that help evaluate the quality of care by continuously evaluating outcomes. As an example, the system at Boston Children's Hospital continuously integrates data from preoperative assessment, intraoperative care, postanesthesia care unit recovery status, and remote postoperative information into one relational database (Fig. 48.4) [56]. Once data have been consolidated into the application, it is available in numerous output formats, depending on the audience. For this project, two separate strategies can be chosen:

1. Researchers tend to want large amounts of very detailed information relating specific factors/interventions and outcomes that can be presented in tabular form (Fig. 48.5). Relationships are analyzed for statistically significant correlations using well-described methods.
2. Clinicians and administrators desire large amounts of information that indicate trends in care or overall performance. They desire a method of viewing information that makes the trends easy to visualize. For this, the data dashboard has been developed (Fig. 48.6). In this case, data

visualization software allows individuals to choose the surgery, age group, contributing factors, and outcomes they want to analyze.

These two visualizations are made possible through the data export (detailed view for researchers) and data dashboard (feedback clinicians' view). The data export component contains a large number of standard metrics, but also allows for the researcher to specify specific derivations from housed data (e.g. what is the rate of severe pain in patients undergoing tonsillectomy). Alternatively, the data dashboard

displays a subset of aggregated data from the integrated database through the use of standard pie charts. These aggregated data are transferred into a cache, which increases performance when the data are retrieved in the dashboard. The controls on the dashboard allow for clinicians to easily explore different relationships within the data that are of interest to them. Ultimately, all of the data are stored in a database environment that is managed by the hospital database administrators.

The result of this system is an ongoing data collection and reporting strategy that is expected to meet both the research and ongoing quality improvement goals of the department.

KEY POINTS: PEDIATRIC ANESTHESIA DATA-BASED OUTCOMES ANALYSIS FROM SINGLE INSTITUTIONS

- Many individual institutions are now using data from the anesthesia and hospital EMRs to produce reports about outcomes of interest for administrators or clinicians for quality improvement purposes
- Researchers can also harvest very detailed data fields from the EMR and other hospital information systems to address research questions

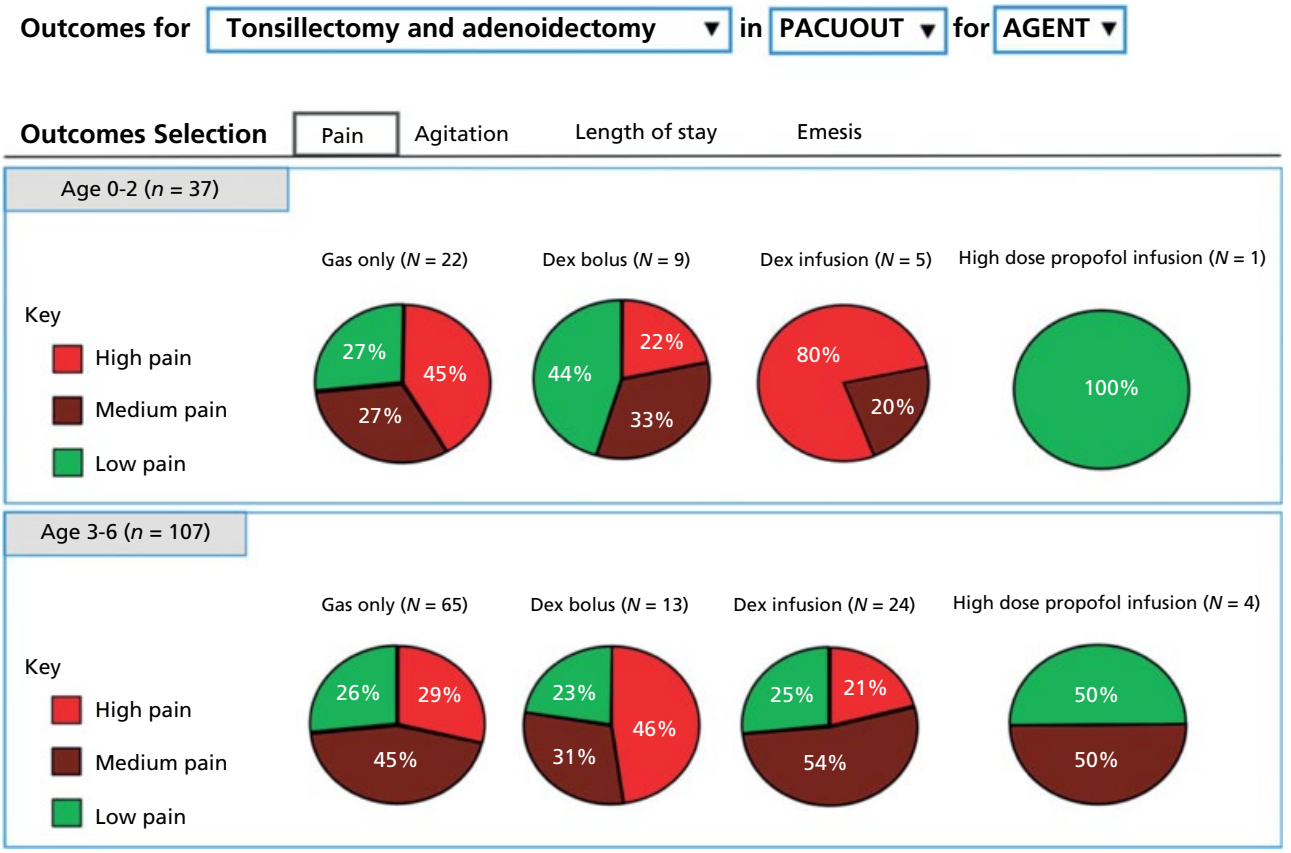

Figure 48.6 Data presentation from the integrated database. The continuously aggregated data include pain outcomes for patients undergoing tonsillectomy and adenoidectomy in the 0–2- and 3–6-year-old age groups. Data are presented based on the type of anesthesia delivered – inhaled agents (only) or inhaled agents with dexmedetomidine. Anesthesia providers choose the surgery, location, age group, and type of outcome they want to view on a daily basis. *Source*: Data from Boston Children's Hospital.

Artificial intelligence and machine learning

The database efforts outlined so far in this chapter are focused on aggregation and analysis of clinical data. The availability of large amounts of data from ubiquitous EMRs has fundamentally changed the manner in which we can evaluate our practice. The next phase of this revolution will take place in the manner in which we process the data that is gathered – through the use of artificial intelligence (AI) and machine learning. AI is revolutionizing the use of large and super-large datasets. This is notable in the way internet search engines and social media companies are utilizing this technology to enhance data processing. For instance, AI is critical to natural language translation and the way in which photos are searched or stored using facial recognition. In its simplest terms, AI allows computer programs to respond to data in a manner that is similar to human intelligence, by learning through experience. All AI is built on machine learning platforms that match input with output data – in large quantities [57]. The application of AI and machine learning to anesthesiology has lagged behind more commercial fields of enterprise, but it is increasing and will continue to revolutionize our field.

Examples of the application of AI and machine learning in anesthesiology can be found in many areas. One of the best examples was described by Lee et al [58] to harness the power of AI in the analysis of total intravenous anesthesia dose–response relationships and the creation of improved closed loop anesthesia algorithms. Because of machine learning techniques, the model used needed no programming of pharmacokinetics or pharmacodynamics, it simply used millions of data points relating dose of drug to bispectral index readings to predict future relationships between infusion rates and bispectral index values. While the performance these investigators were able to describe was better than model-driven pumps, it was still not perfect. Future efforts that would include orders of magnitude more data, could enhance performance and result in performance that is better than ever imagined.

AI will also be helpful in improving the utility of clinical decision support (CDS) software. While CDS tools have been shown to be helpful in reminding anesthesia providers about common tasks (antibiotic administration or blood pressure management), they have been criticized for being generic and ignoring the subtle differences between patients that are inherent in real world applications [59]. Future CDS tools will use machine learning to yield improved predictive analytics. The resultant clinical pathways will be truly "evidence based" since they could be derived from an analysis of huge amounts of data that will be continuously updated and customized for the individual characteristics of the patient who is being treated at any moment [60].

The only logical conclusion from a review of current literature on AI and machine learning is the likelihood of exponential growth in anesthesia and the ultimate evolution

of semi-autonomous anesthesia delivery systems. While this future may seem disconcerting to some, it will (doubtless) lead to increased productivity that could also free up anesthesiologists for more personal patient interactions (such as direct care coordination) that will leverage significant improvements in quality of overall perioperative care and patient satisfaction. Moreover, these developments will only take place through the collaboration of information technologists and clinical scientists who will have to conceive of, and validate, the models that utilize AI in anesthesiology.

Data registry concerns

The current explosion of large data research grows out of the switch from paper to electronic records (also known as EMRs). Electronically collected data are now available on patients concerning both their overall medical history and care and on their operating room data. Data can be included from many geographically or temporally distinct sources into common outcome-oriented databases. This aggregation of data allows investigators to evaluate a total number of patient encounters (or "*n*") that would otherwise be impossible to approach. This chapter has noted some of the most notable data-related research in pediatric anesthesia. There are many advantages to database-centered research. However, there are also many issues that can lead to misinterpretation of the data and undermine appropriate use and conclusions from data registry research [61].

Data mining

In traditional clinical studies, investigators begin with a hypothesis and test its validity by comparing interventions in different cohorts of patients. Studies utilizing data registries, on the other hand, are mostly observational in nature and evaluate outcomes by analyzing the data. There is a temptation to search for interesting associations and then further evaluate data elements that are found to be correlated. This is frequently done without strictly defining a hypothesis for data relationships. When embarking on such a study, it is critical for investigators and clinician readers to remember that the phrase "statistical significance" means a given result is unlikely to have occurred by chance. However, there is a possibility that the relationship is by chance. If one simply searches a large database for cause and effect between enough factors, without a reasoned hypothesis, "significant" relationships will be found, even in data that are unrelated. For instance, if we take $p < 0.05$ as the threshold for significant association, one out of 20 random data associations will appear to be related statistically even though the finding simply occurs by chance.

Many methods attempt to account for this possible error. The simplest and most commonly employed is the Bonferroni correction [62–65]. With the Bonferroni methodology, each additional test requires significance to be reached at $1/n$ times what it would be if one was testing only one hypothesis. For example, if one is trying to relate the rate of lung injury to major surgery in neonates and consider five possible factors in addition to a primary factor (such as postconceptual age), the threshold for significance should be held at $p < 0.05/5$ or 0.01 rather than 0.05 – as it would be for the original comparison.

Data mining is a major problem in database research. When considering outcomes derived from registry research, the analysis should be hypothesis driven and planned before analyzing data.

Quality of data

Data collected in the course of clinical care are not always consistent from one person (or institution) to another. Strict definitions for specific outcomes and metrics must be explained and agreed upon by all participants. If this is not done, data collected can be inconsistent and conclusions inaccurate. Furthermore, data registries should establish a framework of procedures for data quality assurance [66]. The procedures in such a framework exist at the coordinating center level as well as at the centers where the data are collected. Auditing of data is required to prevent insufficient data quality, to detect imperfect data, and to define actions to be taken to correct insufficient data. Data systems that collect information for registries should be designed with automatic data "checks" that prevent the inclusion of spurious data. For instance, it should be impossible to enter data that are an order of magnitude higher or lower than that which is expected. Furthermore values that are at the extreme of the expected values should generate messages to assure this is the intended entry.

In terms of anesthesia for pediatric patients, consider the terms "respiratory distress," "bronchospasm," or "laryngospasm." The exact definition applied to each of these terms can vary greatly from one clinician to another. Do these terms imply change in physiological state or simply the appearance or sound of difficulty with air exchange? For instance, the clinical entity that represents "laryngospasm" might be met by a patient with extreme stridor in one institution yet may require complete obstruction of the airway and oxygen desaturation in another. Unless registries have clearly defined outcome terminology, a great deal of uncertainty will be generated when these outcomes are encountered. Registries that restrict analysis to relatively unambiguous outcomes may largely avoid these issues.

Statistical methodology

The use of multivariable regression with stepwise variable selection can lead to results that are difficult to replicate from one large dataset analysis to another. Regression techniques consider patient characteristics as statistical variables in themselves across a large population. Risk calculations are amended with respect to their cumulative known effect on a given outcome of interest. Newer and more sophisticated methods, including propensity score techniques and mixed effects modeling, are better suited for evaluating treatment effects in large registries with multiple possible confounding factors [67–71]. In the most general sense, these methodologies require investigators to identify populations of patients who share characteristics, such as postconceptual age, presence or absence of neurological compromise, etc., and then consider the effect of one variable uncommon to these cohorts – such as anesthesia exposure or surgical intervention. As mentioned earlier, when considering any of these sophisticated statistical methods, it is important to only consider confounders that are likely to affect final outcomes and have been hypothesized to impact results.

Missing confounders

Outcome researchers can only compensate for those confounders that are known to exist or have been demonstrated in past studies [68,69,71]. Unfortunately, there may be a host of other influences that are not known or have not been identified. As an example, investigators may account for age of a neonate at the time of surgery as a major influence on long-term outcome. On the other hand, it may be impossible to completely understand and codify the social context in which these patients subsequently live after birth, or possible drug use by the patient's mother during gestation – even though these factors may heavily influence the long-term outcome for a given patient. The known factor (age at the time of surgery) will be used as a primary factor in the analysis of outcomes, while the numerous other confounders (e.g. environment and prenatal drug exposure) would go unknown and unappreciated in the analysis. Since the patients in observational registries are not randomized, it is easy for these unknown issues to unevenly influence outcomes in groups that are being considered. Many authors will report the issues that were "controlled" for in their analysis of surgical outcomes as if these represent the complete list of all possible influences. In fact, it is always possible that confounders exist, and caution is advised in considering the possible unknown influences on surgical results.

Confounders versus mediators

In any registry is it important to distinguish between variables that are potentially confounders and those that are mediators. Confounders can affect outcome but are unrelated to the primary factor of interest [68,71], while mediators are actually related to the primary factor and work as mechanisms that change the outcome of interest [70,72]. A mediator, therefore, is necessarily linked to the factor of interest and plays a role in determining the relationship between that attribute or variable and an outcome of interest. Statistically, controlling for known confounders is necessary. On the other hand, adjusting for mediators in the causal pathway can reduce or eliminate real associations. For example, infants of diabetic mothers (IDMs) have multiple abnormalities in the newborn period, one of which is a propensity for hypoglycemia. Hypoglycemia can occur during surgery and injure the patient. If an investigator were to consider the outcomes from neonatal surgery in IDM newborns and control for hypoglycemia, this would underestimate the true impact that birth to a diabetic mother may have on overall risk in this cohort since the hypoglycemia that accompanies IDM status would be lost as a factor. Registry researchers should clearly define confounders versus mediators and only control for those factors that are *not* clearly linked to a fundamental aspect of a patient's state or diagnosis.

Selection and measurement bias

Once again, registries are, by definition, not controlled comparison studies. Selection bias results when the study population is non-randomly selected or distributed from the registry population [73]. For instance, if a study wished to consider the incidence of severe pain after surgery and consider the impact of a specific regional anesthesia intervention versus systemic analgesia, it is very possible that the choice to perform regional versus systemic analgesia could be influenced by the presence of preoperative pain or opioid therapy. If an investigator were to compare the pain outcomes in a surgical cohort, it is quite possible that the distribution of patients into the different intervention cohorts could be biased by the amount of pain or the personality characteristics that were present. Such bias would constitute a selection of patients for each intervention that could easily impact outcomes but would not be apparent to the investigator.

There is a similar issue of bias when comparing data across institutions in large data collaboratives. Fair comparisons require accurate risk adjustment for the types of patients and cases that are performed. In adult medicine there are several of these types of tools including the Risk Quantification Index that was developed as an outgrowth of the NSQIP database [74]. This index is based on assessment of current procedure terminology codes and is transparent in its methods for stratifying risk. Another such risk adjustment strategy was devised in order to compare outcomes from neonatal surgery as described by Lillehei et al in 2012 [75]. For this assessment ICD-9 (*International Classification of Disease*, 9th edition) codes were used to group patients and surgeries into one of four risk categories based on previous data reported on surgical outcomes. The resultant classification scheme was validated in three distinct, large, public health datasets. The specific risk stratification strategy used is less critical than the fact that some effort must be made to understand the data coming from various institutions. The data must be considered in the context of the type of patients that experience care at each location and the inherent bias that is present due to the unequal distribution of complexity.

Interpretation issues

Large observational trials with tens of thousands of patient records will often lead to findings of statistical significance with marginal clinical significance [76]. For example, in a database evaluating 10,000 postoperative pediatric patients, a difference at any one time point of 0.3 units on an observational pain scale (from 0 to 10) will have a p-value of 0.0001. At the same time, many observers might argue that (while the difference is likely real) this does not constitute a difference that would impact clinical care. In fact, the exact same difference would have a p-value of >0.05 in a cohort of 20 patients. Investigators as well as clinicians need to consider clinical versus statistical significance in outcomes that are reported in any study, particularly large data trials. The fact that a given data comparison results in statistical significance must be considered in the context of the clinical importance of the difference described.

There are other methods available to consider the issue of "significance" when evaluating outcome data from large data studies. The calculation of relative risk (RR), numbers needed to treat (NNT), and absolute risk reduction (ARR) [77] all help put the calculations of factor correlation into context. Relative risk is the ratio of the risks for a given outcome in a population of interest (by intervention or demographics) versus that in a control group. It is important to recognize that RR is independent of the prevalence of an outcome and therefore (once again) can be misleading to investigators and clinicians. The

RR may be large, but if the baseline prevalence of an outcome is very low, the clinical significance of the effect may be marginal. For instance, the rate of intensive care admission may be five times higher for infants after a given surgery when compared to adolescents. On the other hand, if the rate of admission for adolescents is 0.001%, then even the much higher RR for infants remains so low it would not likely change care parameters. Measures such as the ARR and NNT vary with the rate of an outcome in a population. The ARR is calculated as the difference in the absolute risk rates between a treated cohort and the controls. In the above example it would be 0.005%. The NNT is the number of patients that need to be treated with a given intervention (or in a given demographic group) in order to see a difference of one adverse outcome. This is numerically equivalent to 1/ARR. Both the NNT and ARR can be viewed as methods for avoiding the problem of overvaluing statistical versus clinical significance in large registry studies.

Any discussion of the clinical significance of outcomes must include the clinical impact of the outcome in question. Anesthetic interventions that lead to a significantly higher survival rate are clearly of greater interest than those that may slightly decrease the length of the postanesthesia unit stay.

Finally, when considering the studies from datasets, it must be emphasized that observational data yield results that can suggest association, but rarely indicate causation [78]. Given all of the pitfalls and weaknesses inherent in this kind of data analysis, it is important not to assume that relationships are causal until they have been proven in more controlled studies. Data that suggest association can be extremely helpful in the investigation of very rare conditions and may help in the design of controlled trials. Clinicians need to keep in mind the limitations (as well as the advantages) of this kind of study and base practice on a careful consideration of all aspects of this category of data but confirm assumptions with the highest quality data available.

KEY POINTS: DATA REGISTRY CONCERNS

- Data mining research without strictly defining a hypothesis in advance is subject to random data associations that appear to be related statistically even though the finding is simply occurs by chance
- Quality of data, including missing data and differing data field definitions among different instutions, render conclusions ambiguous if these problems are not addressed before setting up a database
- Missing confounders, selection and measurement bias, and interpretation issues are additional problems that can be encountered in using data registries for research

Future uses of large registry data and outcomes analysis

In general, statistical science indicates that clinical trials are most valuable when large numbers of patients are studied in order to best understand the presence of treatment effect. Collecting and managing data on very large cohorts of patients has traditionally been done by direct observation and entered into paper case report forms or CRFs. Given the trend toward electronic data capture and analysis that has become part of the daily operations for anesthesia departments, the data required for clinical trials are generally readily available on any operative patient. As such, if the data can be made available to clinical trialists (after institutional review board approval), very few data need to be recorded on traditional CRFs. The cost of research can be radically decreased since the study essentially only needs to include acquisition of consent and patient randomization – all subsequent outcomes are automatically included in the electronic data collection [6]. Furthermore, this kind of a trial fits well with the concept of the Response Adaptive Clinical Trial where the goal is to place more patients in the better treatment based on patient responses already accrued in the trial [79–81]. While this type of trial design was difficult when relatively small cohort trials were being tracked manually, the advent of large data and electronic data capture makes this type of a trial much more practical and (potentially) more acceptable to institutional review boards.

An extension of this automated study design includes "real-time" randomization based on automated decision support technology. Study designs can include an algorithm that identifies patients eligible for study (based on a specific set of characteristics – such as hypotension) and then, in real time, allocates them to one type of treatment or another. Outcomes would then be collected from the intraoperative or postoperative electronic health data. Such studies require a waiver of consent from institutional review boards, but this has proven possible when treatments arms are considered equal and not harmful or possibly beneficial. Such a strategy has already been used to study use of clinical alerts in the management of low blood pressure, low bispectral index, and low minimal alveolar fraction events [82]. Another innovative strategy for outcomes analysis is the alternating intervention trial where a specific intervention is initiated in a set of operating venues and then switched to a different intervention after a specific period of time. The switch can occur back and forth several times with outcome data collected automatically through the electronic record, thus eliminating some of the bias that is inherent in most time-based trials. Such as design has been used to evaluate the effect of inhaled anesthesia agents on hospital stay [82,783].

Summary

Large data registries, regardless of absolute size of origin, are a rapidly growing and evolving source of information for quality improvement and research in the field of anesthesiology. This information revolution will help shape the specialty in the future as the ability to collect and process data improves. It is critical for pediatric anesthesiologists to understand both the advantages and pitfalls of this resource and help apply this technology in ways that will allow us to improve care and outcomes for our patients. While the data management is exciting, the data must be reliably recorded and applications must be done in a manner that makes sense clinically. Far from making the human anesthesiologist irrelevant, the ability to form appropriate questions, understand the nature of the information, and effectively translate the large data results into clinical improvement, will make pediatric anesthesiologists more important than ever in determining the future of pediatric anesthesia care.

Introduction

Over the past few decades, healthcare organizations and providers have implemented electronic health record (EHR) systems for computerized clinical documentation, order entry, and other functions [1]. EHRs enable the collection of patient data in an electronic format that can be explored and analyzed to improve patient care processes, optimize resource allocation and utilization, and facilitate decision making at the clinical and enterprise levels [1]. Furthermore, recent advances in computer and networking technology, patient monitoring systems, and EHRs have enabled hospitals to collect and store a rapidly accumulating volume and variety of patient data [2,3].

Meanwhile, US physicians and healthcare organizations have adopted EHRs at a steady rate, partly due to the US federal government's passage of the Health Information Technology for Economic and Clinical Health Act in 2009, which incentivized the "meaningful use" of EHRs with the goal of improving healthcare quality and efficiency [4–6]. Thus, an increasing number of anesthesiologists and other healthcare professionals interact with EHRs on a daily basis as they provide patient care.

Anesthesia information management systems (AIMS) are either integrated EHR modules or stand-alone software and hardware products that were developed as a means to document electronically the details of a patient's anesthetic and physiological status while under anesthesia. This chapter will define and describe AIMS and some of their features, explore the benefits and drawbacks of AIMS, discuss the various secondary uses for AIMS data, and present future directions of AIMS research, applications, and utilization.

From paper anesthesia records to anesthesia information management systems

While the origin of medical records goes back to the time of Hippocrates in ancient Greece, the use of paper records to document a patient's physiological status during an anesthetic did not occur until the 1890s, when Drs Cushing and Codman devised the famous "ether chart" in 1894 to record a patient's anesthetic course [7,8]. The practice of paper anesthesia record keeping spread quickly afterward, and the paper record remains in widespread use to this day (Fig. 49.1) [9]. However, manual written paper records are often inaccurate, biased, incomplete, and illegible, and they can divert the attention of the anesthesiologist from more important tasks (Fig. 49.2) [10].

There was growing recognition that automated charting of an anesthetic might address the fallibility and inherent "smoothing" in paper records [11]. Thus, in the 1970s and 1980s, as microcomputers became more affordable and widely available, anesthesia providers sought to use the devices for the capture, storage, and retrieval of electronic perioperative data [12]. Initially, computers were used to manually document patients' physiological data in the 1970s, and in the early 1980s computers were first used to record patients' data from physiological monitors in an automated fashion [13]. These efforts were the precursors to the AIMS that originated in the 1980s as simple, computer-based intraoperative record keepers to complement or replace paper documentation of a patient's anesthetic [14].

AIMS have been adopted gradually over the subsequent decades, particularly in academic hospitals. In 2014, 75% of

Gregory's Pediatric Anesthesia, Sixth Edition. Edited by Dean B. Andropoulos and George A. Gregory.

academic anesthesiology departments had installed an AIMS, with an 84% AIMS adoption rate anticipated between 2018 and 2020 [15]. Meanwhile, AIMS have evolved from basic anesthesia record documentation software tools to either a stand-alone software product or a component of a hospital's EHR system coupled with hardware components and physiological device interfaces. Most currently available AIMS offer features that enable anesthesia providers to record, view, and share patient information across the entire perioperative continuum [16]. One of the most significant

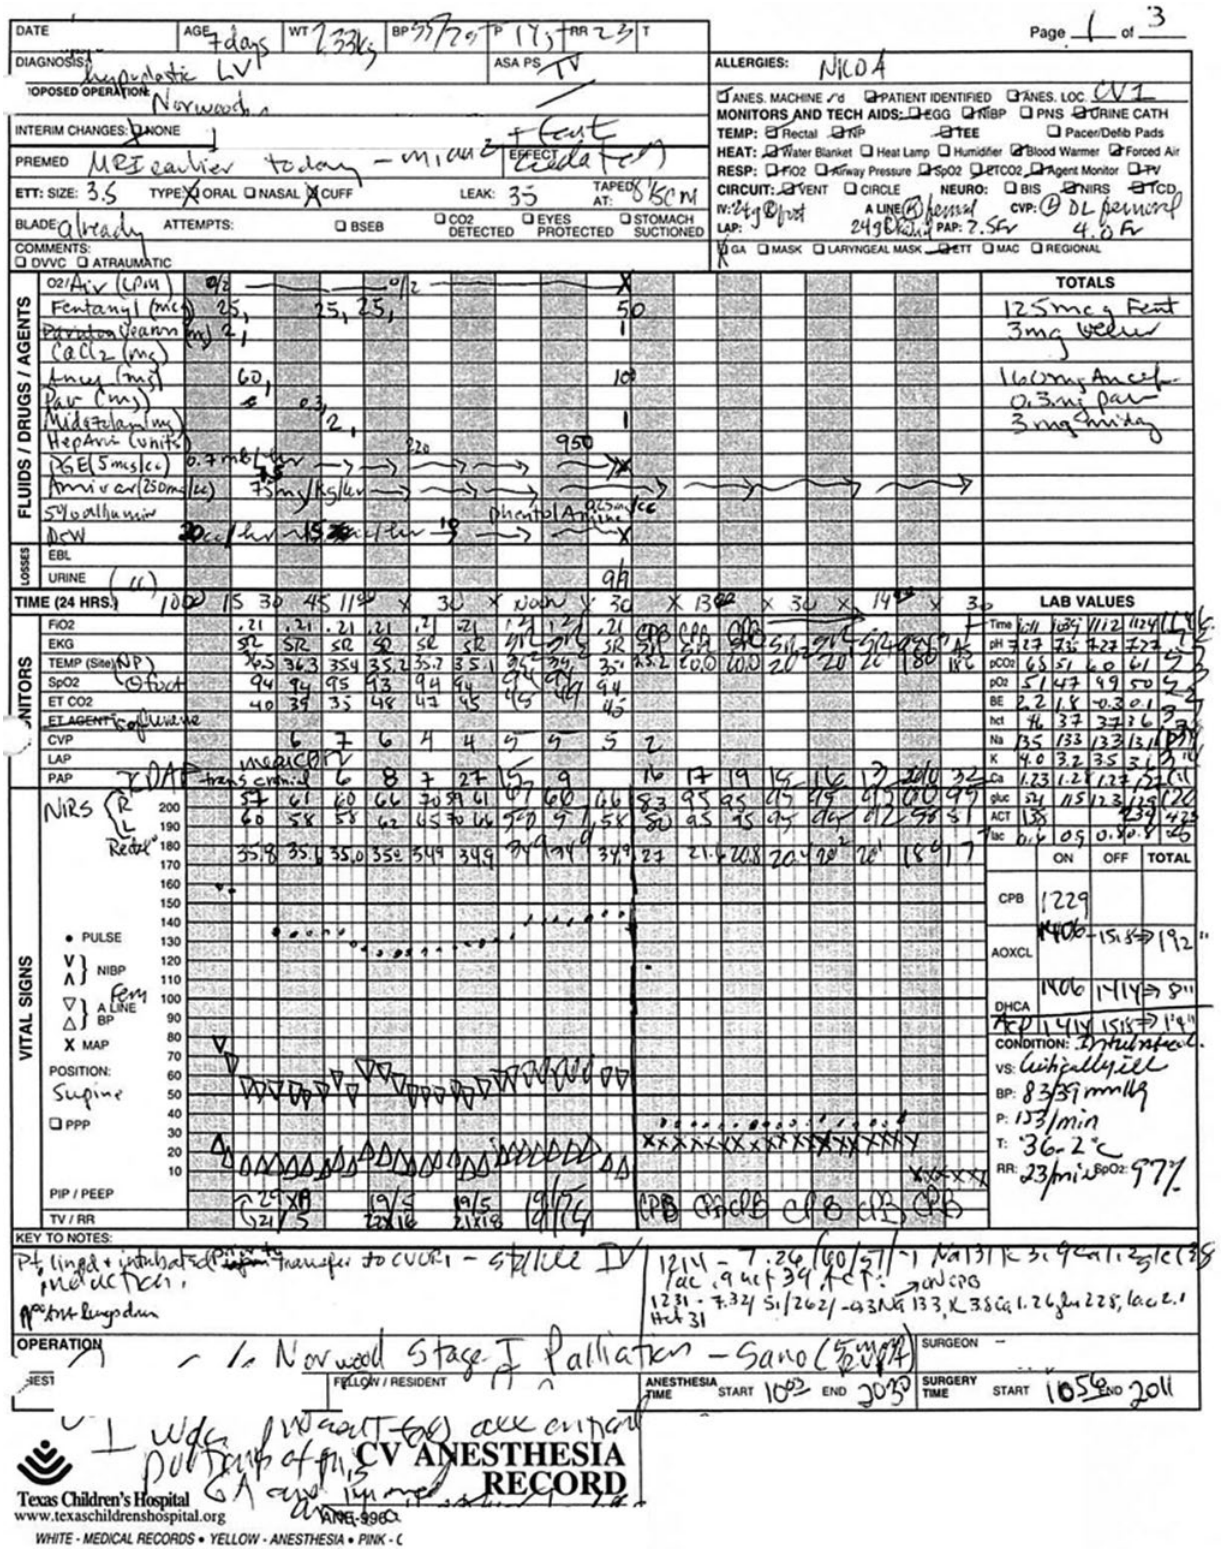

Figure 49.2 Paper anesthetic record completely filled out. *Source*: Reproduced with permission of Dr Andropoulos, chief of the Texas Children's Hospital department.

changes to AIMS over the past several years has been the broad implementation of integrated EHRs such as Cerner (Cerner, Kansas City, MO, USA), Epic (Epic Systems, Verona, WI, USA), and others [17,18]. AIMS are used not only throughout traditional operating room (OR) care (i.e. the preoperative, intraoperative, and postoperative phases), but also throughout the hospital to document acute pain services and the delivery of anesthesia during bedside procedures in intensive care units (ICUs) and the labor and delivery floors [19,20].

KEY POINTS: INTRODUCTION

- AIMs are either integrated EHR modules or stand-alone software and hardware products that document electronically the patient's anesthetic status while under anesthesia, as well as preoperative and postoperative data
- About 75% of academic anesthesiology departments had adopted AIMs by 2014, with an 84% adoption rate anticipated between 2018 and 2020
- Integration of AIMS into broad healthcare EHRs has occurred rapidly over the past several years, and all anesthetic activity, including pain medicine and bedside cases, can now be captured

AIMS software, hardware, and "peopleware"

Most currently available AIMS software offers preoperative patient assessment documentation tools whose features range from rudimentary data entry forms for manually entering free text to comprehensive questionnaires containing richly populated drop-down menus, systems-based assessments, the ability to display patients' photos, and graphical editing tools for annotating images representing patients' dentition and other physical characteristics [18,19]. Entering data into this form enables the creation of a preanesthesia assessment and evaluation note that includes required data elements such as the patient's assigned American Society of Anesthesiologists (ASA) physical status (PS) classification (Fig. 49.3). Stand-alone AIMS that have access to the data within a hospital's EHR and

ROS/MED HX
General: Patient has no history of anesthetic complications (no prior h/o surgery or GA; deny fmhx of GA issues) or fever (no recent illness).
Perinatal: Patient was preterm (36 WGA, prenatal dx of CHD, NICU x 44 days-did not require intubation and remained on CPAP as well as HFNC).
Cardiovascular: Patient has a murmur and hypertension (captopril). Patient has no cyanosis or syncope. Patient has dyspnea at rest. She has no diaphoresis. Patient has a history of congenital heart defect. She has tetralogy of Fallot (large perimembranous VSD, moderate valvar and supravalvar pulmonary stenosis, moderate ASD, mild override of the aorta, small PDA). It is unrepaired. Patient has tricuspid regurgitation (mild). She has congestive heart failure (Lasix). Patient has no decreased myocardial function (mild to moderate RVH). Cardio comments:
-prenatal dx of large perimembranous VSD, moderate valvar and supravalvar pulmonary stenosis, moderate ASD, mild override of the aorta, small PDA
-CHF- Lasix TID
-+ suprasternal and subcostal retractions at rest
Respiratory: Negative respiratory ROS. Patient has no cyanosis or reactive airway disease. The patient does not snore. Patient has dyspnea at rest. The patient did not have a recent URI.
HEENT: Negative HEENT ROS.
Neurological: She has no seizures.She has developmental delays.
Musculoskeletal: She has hypotonia.
Integumentary: Patient does not have a rash.
Gastrointestinal: She has no diarrhea or vomiting. Patient has no esophageal reflux. Patient does not have liver disease. She has hyperbilirubinanemia (s/p phototherapy). She has failure to thrive (NGT feeds).
Genitourinary: She does not have chronic renal disease.
Endocrine/Metabolic: The patient does not have diabetes mellitus. Patient has no hyperthyroidism or hypothyroidism. Endo/other comments:
-NBS- normal per parents.
Syndromes: She has trisomy 21.
Hematological/Lymphatic: Patient does not have bleeding disorder or anemia.
Hematologic/Lymphatic comments:
-deny fmhx of bleeding of clotting issues
Additional ROS/Med Hx Findings:

Procedure: ASD/VSD Closure, PDA ligation, inspection of the PV,

3 mo former 36 wk'er female w/ Trisomy 21 and h/o:
-prenatal dx of large perimembranous VSD, moderate valvar and supravalvar pulmonary stenosis, moderate ASD, mild override of the aorta, small PDA
-CHF- Lasix TID
-+ suprasternal and subcostal retractions at rest

Non-cardiac issues:
-FTT- followed by GI, NGT feeds- EBM with Neosure to 27 kcal 65 ml for 8 feeds, recent visit to GI w/ increased wt gain, so now taking 24kcal Neosure
-chronic nasal congestion- seen by ENT, completed 2 weeks of nasal cipro and receives nasal saline
-s/p phototherapy for hyperbilirubinemia

Allergies: NKA
Meds:
-captopril PO SUSP 1 mg/mL (Compounded - TCH)Give 0.38 mL by mouth 2 times daily for 30 days. 22.8 mL 0
-furosemide PO SOLN 10 mg/mL Give 0.4 mL by mouth 3 times daily for 30 days. 36 mL 0
-multivitamins with iron (POLY-VI-SOL WITH IRON) PO DROP Give 1 mL by mouth daily.
-potassium CHLORide PO SOLN 10% (20 mEq/15 mL) Give 3.2 mL by mouth 2 times daily.

SOCIAL HISTORY: Lives in with biological parents and two elder sisters aged 3 and 7 yrs. Both sisters are healthy.Pet dog, no smoke exposure, no daycare.

Studies:
ECHO
Follow-up study.
Small patent ductus arteriosus with continuous left to right shunting by color doppler(unable to obtain a peak velocity).
There is a prominent anterior ridge seen at the aortic isthmus with no obstruction to flow (image 118); normal color and pulsed wave doppler in the descending and abdominal aorta.
Large perimembranous ventricular septal defect with aortic outlet extension, low-velocity bidirectional shunting (predominantly left to right, with some right to left in diastole). Peak velocity <1.5 meters per second.

Figure 49.3 Portion of a screen image capture of a preoperative evaluation for cardiac surgery in an infant. Text in black font is either imported from other portions of the integrated EMR, copied and pasted, or scripted. Text in red font is entered by the provider. *Source*: Reproduced with permission of Dr Andropoulos, chief of the Texas Children's Hospital department.

AIMS that are a component of a hospital's EHR can retrieve pertinent patient data such as medications, allergies, and procedure information into the preoperative assessment and the intraoperative record [19,21]. Other typical features in preoperative AIMS modules include the ability to peruse a patient's previous anesthesia records, record a review of systems and physical examination, and document an anesthetic assessment and plan [19].

The primary function of every AIMS is the generation of an electronic anesthesia record that captures data in an automated fashion from devices, such as the anesthesia machine and the patient's monitors, and allows the user to manually document a variety of data: administered medications, fluids, and blood products; clinical events such as anesthesia induction, patient positioning, and lines placed; required documentation for billing or regulatory guidelines (e.g. anesthesia start and stop times, procedure notes); and other relevant data that is not captured in automated fashion, such as train-of-four counts [18,19,22]. To accomplish these tasks, AIMS display the anesthesia record in a user interface that the clinician uses to access, review, and edit the record as it is generated.

The intraoperative user interface of most current AIMS consists typically of a grid for vital signs and administered medications that resembles the traditional paper record, with other patient data available in panels surrounding the vital sign grid (Fig. 49.4). The patient data that are displayed varies across AIMS, but data that are typically shown include the patient's name, date of birth, and medical record identifier. Other crucial information such as allergies and recent medications are displayed in some AIMS. Action buttons and drop-down menus are used to access data entry forms to record items such as administered medications and blood products. Procedure notes, such as for regional nerve blocks, can also be entered via the AIMS interface (Fig. 49.5). If the AIMS is a component of an EHR, then the user is often able to access the patient's full EHR record via the software interface.

Most AIMS enable users to document a patient's postoperative status using a computer workstation at the patient's

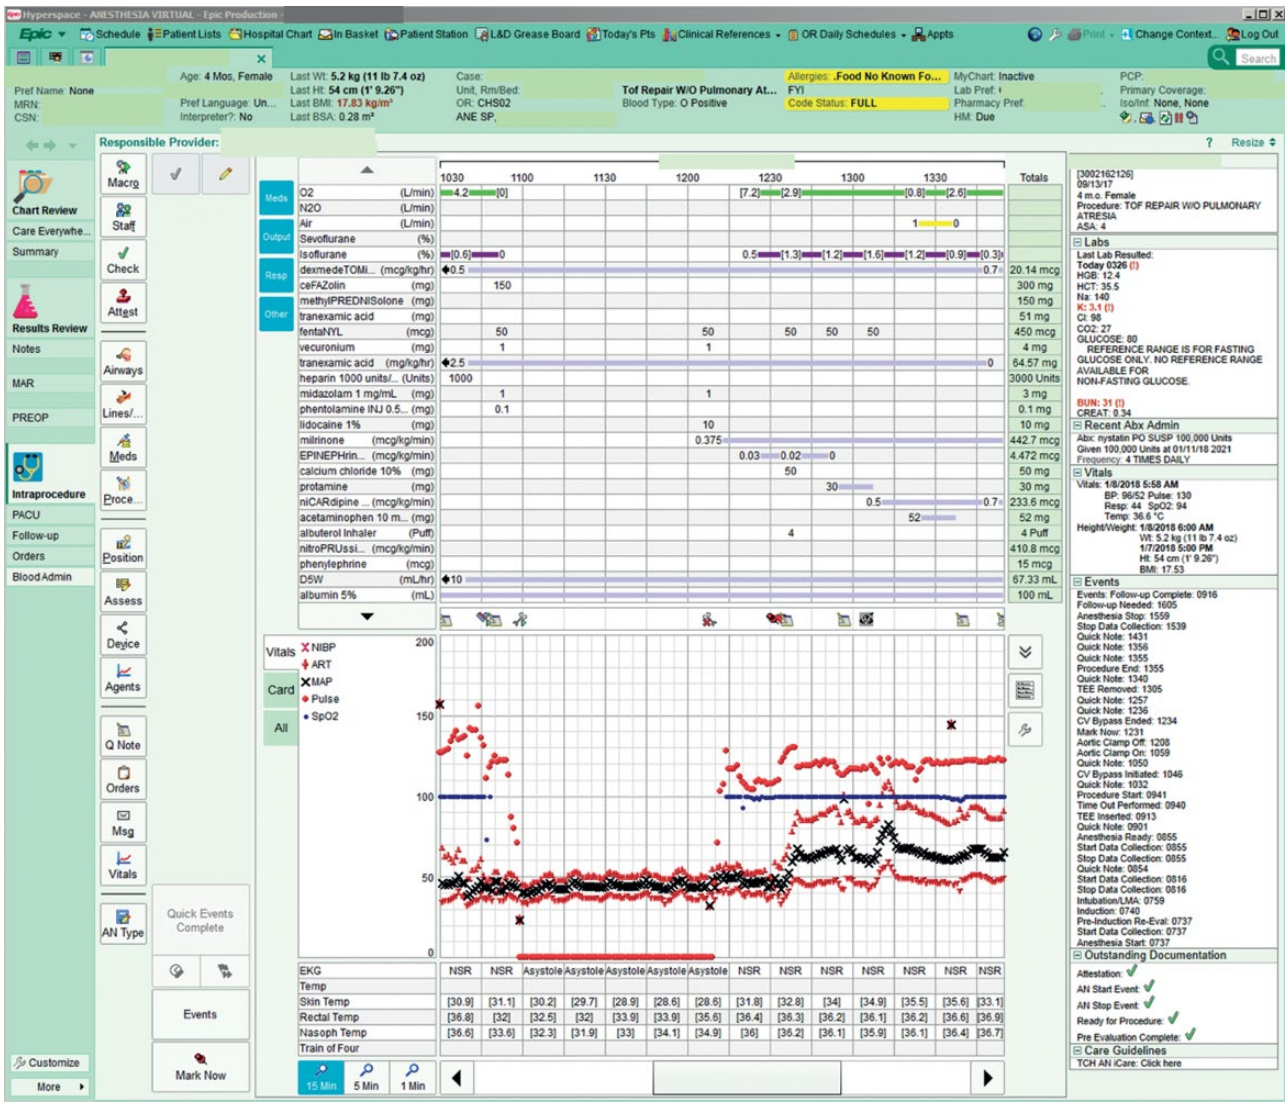

Figure 49.4 Portion of a screen image capture of an intraoperative anesthesia record for a cardiac surgery case in an infant. Even a complex case with multiple medications and interventions can be rendered organized and legible. Other parameters can be accessed by scrolling to other parts of the record or by activating icons along the sides of the screen. This is an example of an AIMS that is part of an integrated system-wide EHR, and the patient's entire medical record can be accessed from this screen. *Source*: Reproduced with permission of Dr Andropoulos, chief of the Texas Children's Hospital department.

Anesthesia Line Placement - Right Internal jugularCVC
Procedure Note

Location
Patient location during procedure: OR
Start time: 1/10/2018 8:30 AM
End time: 1/10/2018 8:45 AM

Staff
Anesthesiologist: **Fellow/Resident:**
Procedure performed by: Fellow/resident

Anesthesia Checklist
Completed: patient identified, IV checked, risks and benefits discussed, monitors and equipment checked, pre-op evaluation, anesthesia consent given and all elements of maximal sterile barrier technique followed

Line/Catheter
Non-tunneled single lumen CVC
Skin Prep: Skin prepped with 2% chlorhexidine

Indications
central pressure monitoring

Sedation/Anesthesia

Procedure
Orientation: Right
Size: 3Fr
Location: Internal jugular
Patient position: Flat
Pre Procedure: Landmarks identified
Ultrasound Guided? Ultrasound guided Sterile gel and sterile probe cover used.
Number of Attempts: 1

Post Procedure
Placement Verification: Guidewire, Blood Return and Ultrasound Ultrasound guidance. All relevant anatomy identified. Needle position visualized. Inadvertent cannulation of adjacent structures avoided. An image was obtained and saved.
Secured with: Clear adhesive and Sutured

Notes

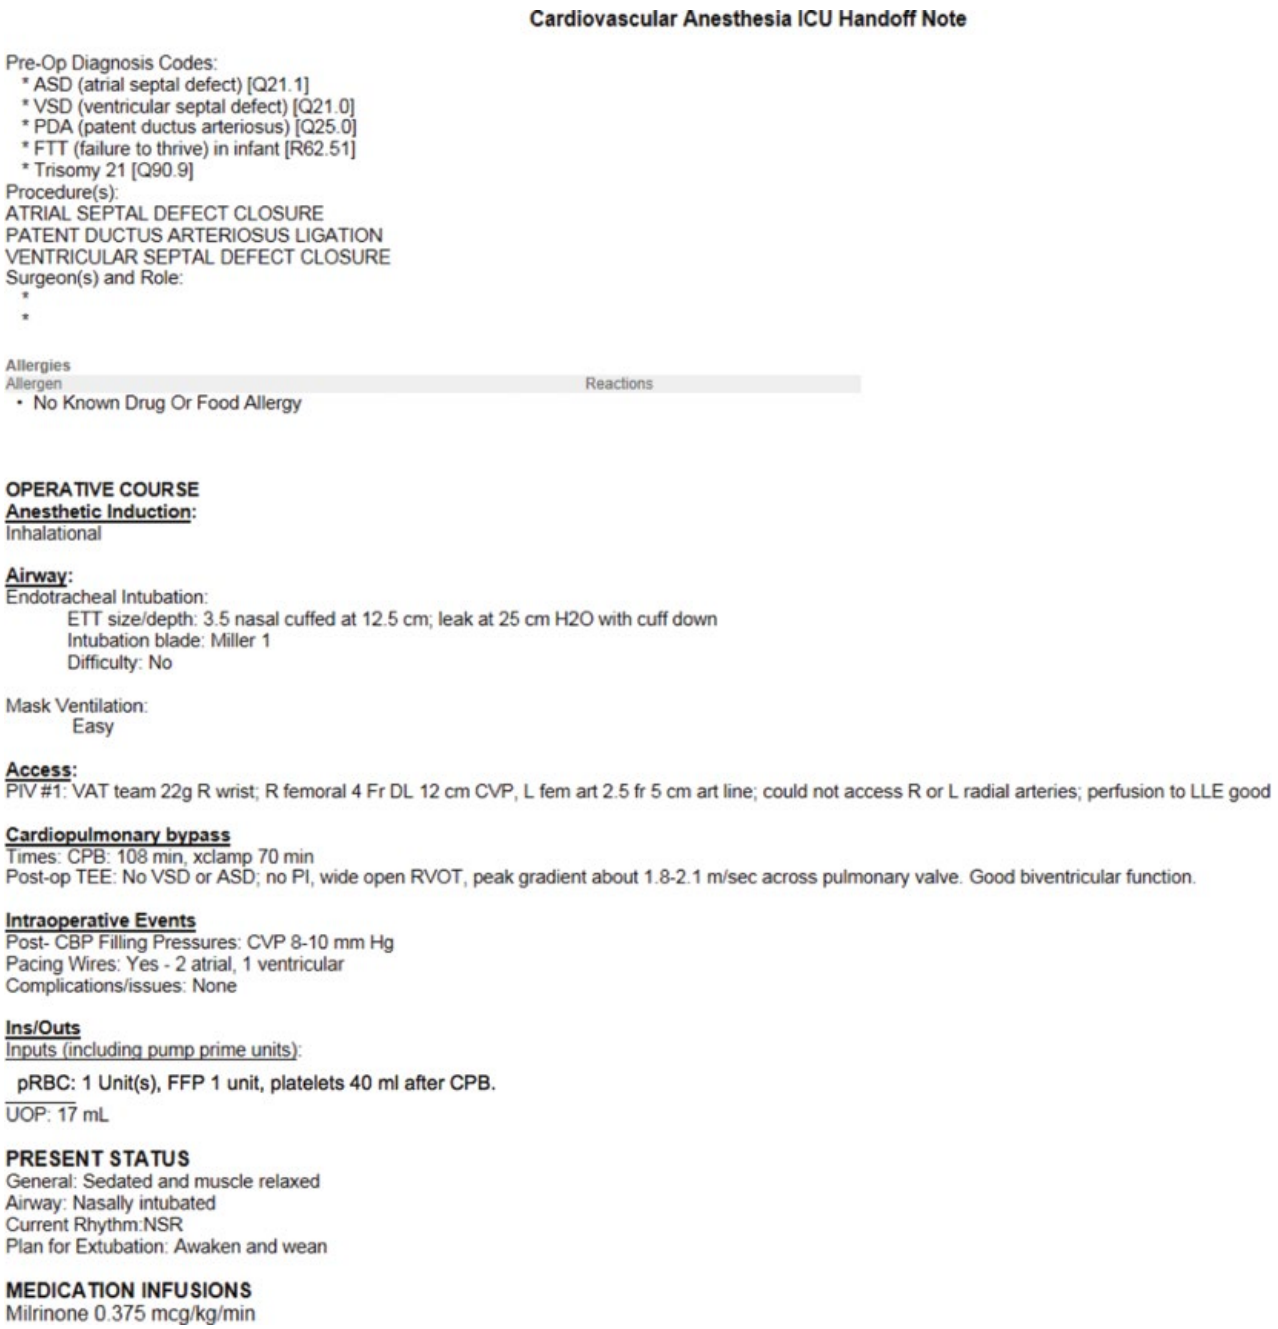
recovery location, such as the postanesthesia care unit (PACU) or ICU. The patient's preoperative and intraoperative data that have been recorded up to that point can be used during the hand-off of patient care to the receiving clinician, and postoperative vital signs can be recorded [19]. A postoperative ICU transfer note can also be documented (Fig. 49.6). Some AIMS can prompt the clinician to enter quality improvement data on relevant perioperative events [23]. Automated documentation checks can trigger notifications via real-time alerts or automated e-mail or text messaging to inform user of any deficiencies that need to be corrected [24].

AIMS hardware components include a computer workstation and mounting equipment and/or a wheeled mobile stand, and might also include vendor-specific devices such as special keyboards, bar code scanners, or syringe pumps [19]. AIMS hardware should meet the hospital's infection control guidelines (i.e. be easy to disinfect) and be durable, ergonomic, water resistant, and usable in multiple environments [19]. The device data flow from the devices to the client and then the server – or first to the server and then the client workstations – depending on the AIMS set-up. Physiological device interfaces are crucial for enabling patient physiological



Cardiovascular Anesthesia ICU Handoff Note

Pre-Op Diagnosis Codes:
* ASD (atrial septal defect) [Q21.1]
* VSD (ventricular septal defect) [Q21.0]
* PDA (patent ductus arteriosus) [Q25.0]
* FTT (failure to thrive) in infant [R62.51]
* Trisomy 21 [Q90.9]

Procedure(s):
ATRIAL SEPTAL DEFECT CLOSURE
PATENT DUCTUS ARTERIOSUS LIGATION
VENTRICULAR SEPTAL DEFECT CLOSURE

monitors, anesthesia machines, ventilators, and other monitors to communicate and record automatically via the AIMS hardware and software.

Thus, AIMS software is installed on AIMS hardware at sites of anesthetic care, such as computers attached to the anesthesia machine in the OR (Fig. 49.7), PACU, or even on mobile workstations in the ICU (Fig. 49.8) [19,20]. The AIMS hardware and software obtains physiological data via interfaces with the monitoring devices. Stand-alone AIMS software on a workstation is typically in the form of a "thick client" that stores the anesthesia data on that workstation; the data are then filed periodically to a central server. With AIMS that are components of EHRs, the software on the workstation is typically a front-end user interface – also called a "thin client" – with most or all of the data filed directly to a central server [18].

Successful AIMS implementations require not only the appropriate hardware and software, but also a substantial investment of time and "peopleware" – that is, clinicians with sufficient expertise within a department to lead the AIMS installation decision-making and implementation processes. The cost of an AIMS implementation will depend on many factors, including its level of sophistication, the hardware and software needed to attain that level of sophistication, and most significantly, the implementation team's time as clinicians are taken from the clinical setting to guide the AIMS implementation efforts through site visits, meetings, and other time-consuming efforts [18]. The personnel and

expertise required for successful basic and advanced AIMS implementation are displayed in Box 49.1.

KEY POINTS: AIMS SOFTWARE, HARDWARE, AND "PEOPLEWARE"

- AIMS software varies but all will at least be able to retrieve data about medications, allergies, and procedure information for the preoperative assessment
- The primary function of every AIMS is to generate an electronic anesthesia record that captures data from the anesthesia machine and patient monitors and allows manual documentation of medications, fluids, and all the other events of a case
- A successful AIMS implementation also requires substantial investment of time and expertise of clinicians to design and implement the system

Box 49.1: People and expertise required within a department for successful implementation of basic and advanced anesthesia information management systems (AIMS)

Minimum requirements for a basic implementation

- One or more physician clinical champions to guide decision-making processes and inform clinical workflow requirements for the AIMS installation team
- Support from biomedical engineering and information technology personnel for the software and hardware interfaces between devices, the AIMS, and the hospital's electronic health record (HER) system

Advanced requirements for a state-of-the-art AIMS implementation within an institution

- Requirements listed in "minimum requirements"
- Data scientists with expertise in visual and advanced analytics for descriptive and predictive AIMS data analytics [35,38]
- Database system administrator to handle AIMS data queries for research and quality improvement
- Physicians with informatics expertise to spearhead clinical decision support and data analytics efforts
- EHR and AIMS programmers for implementing clinical decision support tools
- Project manager

Clinical decision support in AIMS and EHRs

Computer-assisted decision making, or clinical decision support (CDS), has been used widely in EHRs to improve patient care quality and safety [25,26]. Several systematic reviews have described how CDS alerts and tools that are embedded within hospitals' EHRs can improve clinical performance, resource utilization, and patient care [27,28]. CDS tools can provide clinicians with patient-specific assessments or recommendations to assist with making clinical decisions [29]. The critical features for successful CDS systems are often summarized as the five "rights": delivering the right information, to the right person, in the right intervention format, through the right channel, at the right time in workflow [30].

AIMS have similarly incorporated CDS in order to accomplish the same or similar goals, and CDS tools have been increasingly integrated within AIMS to provide clinicians with near real-time alerts and post hoc reports to enhance patient care processes, documentation compliance, and resource utilization [31–33]. There are numerous narrative and systematic reviews of AIMS-based CDS that have described the extent to which CDS tools can impact aspects of clinical performance and patient care, particularly if the CDS is smoothly integrated into clinical workflow and comprised of evidence-based recommendations rather than assessments [4,33–38]. Some examples of AIMS-based CDS include alerts, reminders, and notifications to modify the behavior of anesthesia practitioners with the goal of enhancing various perioperative processes [39]: improving intraoperative glucose monitoring and management [40–42], addressing intraoperative hypothermia [43], restoring suspended alarms after cessation of cardiopulmonary bypass [44], correcting OR location errors [45], improving β-blocker medication compliance, and informing clinicians of the optimal postoperative nausea and vomiting and antibiotic prophylaxis [46,47]. Decision support can also consist of post hoc reports to clinicians to impact many aspects of clinical care and documentation [33].

AIMS: potential benefits and perceived drawbacks

In addition to CDS, AIMS offer many additional benefits. Box 49.2 lists the areas where peer-reviewed literature has supported the positive impact of AIMS on patients, anesthesia departments, and hospital systems [48].

There are several perceived drawbacks to installing and using an AIMS: a reluctance to abandon familiar paper anesthesia record forms, unacceptable or unsustainable costs of installation and maintenance, electronic distraction of anesthesia providers, and medicolegal concerns due to AIMS automatically recording all physiological data, as well as

Box 49.2: Benefits of anesthesia information management systems published in peer-reviewed literature

Improving the safety and quality of patient care
- Automated recording of vital signs offloads cognitive burden, enabling anesthesia providers to focus on the patient
- Provides automatic notification of operating room location errors
- Enables automated drug diversion surveillance systems
- Warns users of potential drug allergy and blood transfusion reactions
- Facilitates implementation of and adherence to departmental protocols (such as perioperative antibiotic prophylaxis administration)
- Provides point-of-care clinical decision support (such as perioperative glucose and insulin management and ventilator management)
- Enables real-time surveillance of patient monitors
- Provides timely clinical feedback via post hoc reports to impact clinicians' behavior

Improved documentation
- Precise, accurate capture of intraoperative data and patients' hemodynamic responses to anesthesia
- Generates high-resolution anesthetic records that are more easily searched, accessed, and used for post hoc analysis than paper records
- Automated, real-time, or near real-time notification of missing or incomplete documentation
- Enhanced legal fortification due to unbiased, precise records
- Facilitates risk management and quality assurance activities

Improved operations management
- Improves billing personnel workflow when reviewing anesthesia records
- Enhances anesthesiology department's administrative role in the perioperative setting
- Facilitates faculty and staff scheduling
- Generates a real-time surgical whiteboard to improve situational awareness and workflow
- Enables operating room modeling for administrative decision support
- Facilitates individual anesthesia provider and departmental performance tracking
- Allows verification of Accreditation Council for Graduate Medical Education case requirements for residents and fellows
- Provides post hoc reports to residents with a log of their anesthesia experiences to guide requests for next day's cases

Improved cost containment and reimbursement
- Accurate accounting of anesthesia supplies and medications
- Decreases costs and utilization of anesthesia medications and supplies
- Facilitates resource management in the operating room
- Enhances anesthesia billing and charge capture
- Increases hospital reimbursement
- Merges financial systems with clinical documentation to improve efficiency

Improved clinical research
- Enables researchers to search for rare events or specific occurrences across a large number of cases
- Helps develop evidence-based medicine guidelines from validated datasets of clinical practice
- Facilitates linking of perioperative data to outcomes data for research (such as the National Surgical Quality Improvement Program)
- Enhances the sharing of data in national and international consortiums (such as the Multicenter Perioperative Outcomes Group or Anesthesia Quality Institute)

Sources: Adapted from Ehrenfeld and Rehman [21], Kadry et al [22], Epstein et al [35], Simpao and Rehman [18], Simpao et al [45], and O'Sullivan et al [54].

hospital, departmental, or clinicians' resistance to changes in established clinical workflow [18,49–51]. However, studies have established that electronic records are more accurate and reliable than paper records [52,53]. AIMS implementations indeed bear significant costs, and the return on investment depends on an institution's financial, billing, and management practices. AIMS can produce a positive net return on investment in four ways: (1) decreased anesthesia medication costs; (2) decreased staffing costs due to more efficient staff scheduling; (3) enhanced charge and billing capture; and (4) increased hospital reimbursement from improvements in hospital coding [54]. As for AIMS distracting anesthesia providers in the OR, studies have reported no significant effect of AIMS on clinicians' vigilance [55–57]. With respect to medicolegal concerns, some have indeed argued that failure to recognize a loss of incoming data into an AIMS may increase medical liability [58]. However, the majority of 24 anesthesia departments reported in a survey that AIMS were useful for risk management, and there were no cases in which AIMS hindered the defense process [59].

Secondary use of AIMS data

Countless clinical research, quality improvement, and collaborative projects across myriad institutions and anesthesia practices have utilized AIMS data [60]. For example, studies have been published using data from multi-institutional AIMS registries such as the Anesthesia Quality Institute's National Anesthesia Clinical Outcomes Registry and the Multicenter Perioperative Outcomes Group [61,62]. It is important to note that collecting vast amounts of data does not necessarily ensure valid, high-quality data, as the quality and reliability of the AIMS data is dependent on the clinicians recording it [63]. Truly valid and reliable perioperative documentation requires clear, consistent definitions of perioperative events and outcomes that can enhance billing, reporting, and clinical decision support processes. However, these definitions vary routinely across and sometimes even within institutions. For instance, a few different events can be considered the "induction of anesthesia," such as administration of a hypnotic, provision of anxiolytics, or start of preoxygenation [18]. Research, administrative, and quality improvement initiatives that are based on AIMS data must factor in any inconsistent definitions as well as other issues such as physiological monitoring artifacts in order to avoid arriving at invalid, faulty conclusions ("garbage in, garbage out") [64,65]. Chapter 48 presents further discussion about using AIMS data for contribution to large national databases and local databases for quality and outcomes projects and research.

AIMS data quality and outcomes

The massive amount of data collected by AIMS can be used for quality and safety initiatives. One approach is visual analytics, a category of computational tools that integrate data analytics with interactive visual interfaces and can be used to navigate and manipulate large data [1]. Parameters of interest, such as medication alerts and the number of times they are over-ridden, can be tracked over time to assess their appropriateness and proper use. Point-and-click functionality allows the user to access the data, often in near real time, for periodic assessment of progress. An example of a quality program to increase reliability of medication alerts is displayed in Figure 49.9 [1]. Intraoperative blood transfusion is another area of pediatric anesthetic practice that has significant variability, and risk and

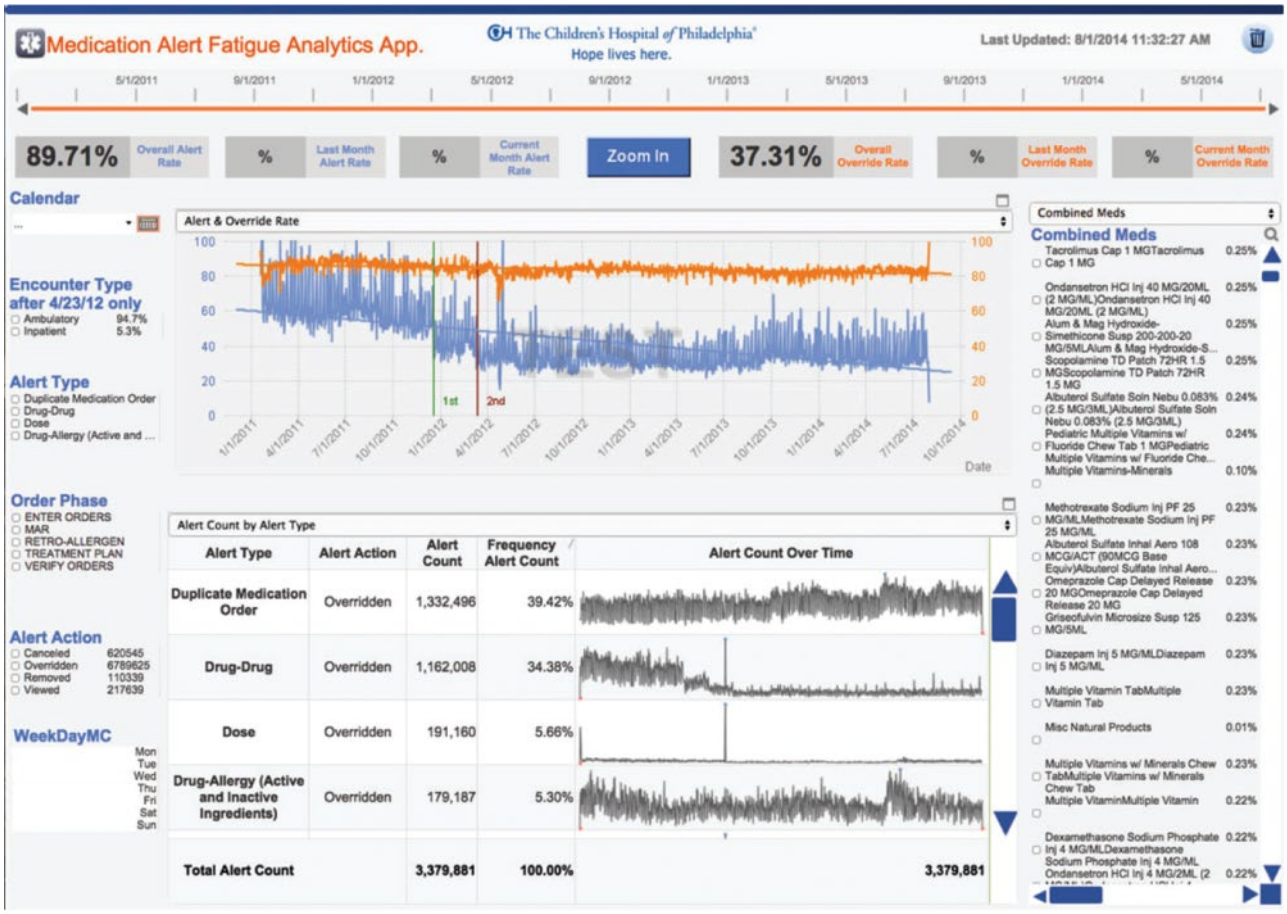

Figure 49.9 Screen image capture of the Children's Hospital of Philadelphia medication alert fatigue visual analytics dashboard. This enables the user to explore electronic health record medication alert data. *Source*: Reproduced from Simpao et al [1] with permission of Elsevier.

cost to the patient and hospital, and the AIMS and EHR can be mined to display contemporaneous data about this important aspect of practice (Fig. 49.10) [1].

Quality and adverse event reporting is another area in which AIMS can facilitate reporting and analysis of adverse events and outcomes. The Children's Hospital of Philadelphia initiated a quality improvement program designed to improve response to, and reporting of, anesthesia emergencies where additional personnel were called to assist in critical events, for example, significant laryngospasm. These events were termed Anesthesia Now! (AN!), and were documented in the AIMS [66]. The purpose of the project was to categorize these emergency events, and then plan programs that targeted their prevention and rapid response. Rates and outcomes could be compared to national data as part of the overall quality improvement program. Of 213 AN! calls, 67% were for airway emergencies, with laryngospasm the leading cause (Table 49.1). Overall prevalence was 1:234, and AN! events were inversely proportional to age and ASA physical status. Critical event response algorithms have been designed and electronically formatted for operating room use as a result of these data. Team response efficacy is being studied using these emergency algorithms and simulation scenarios.

In the USA, data collected for quality and outcomes analysis are legally protected from discovery for malpractice purposes in most states, and so quality and outcomes databases are not considered part of the patients' EHRs. One approach to this issue used by some children's hospitals is an electronic quality improvement reporting screen that appears after the anesthetic and must be filled out before formal closure of the electronic anesthesia record for the case. The data, however, are sent to a separate database and not the EHR for later quality analysis (Fig. 49.11).

KEY POINTS: DECISION SUPPORT, BENEFITS AND DRAWBACKS, AND SECONDARY USE OF AIMS DATA

- Clinical decision support tools such as electronic reminders for antibiotic dosing can improve the processes of delivering appropriate clinical care
- Drawbacks of AIMS include their considerable costs, and reluctance to change well-accepted workflows of paper records
- Advantages include legible and accurate records, and ability to capture a myriad of data related to cost and quality of care
- Secondary use of AIMS data for quality and research does not occur automatically; knowledgeable clinicians working with information technology professionals must work together to determine how to mine these data

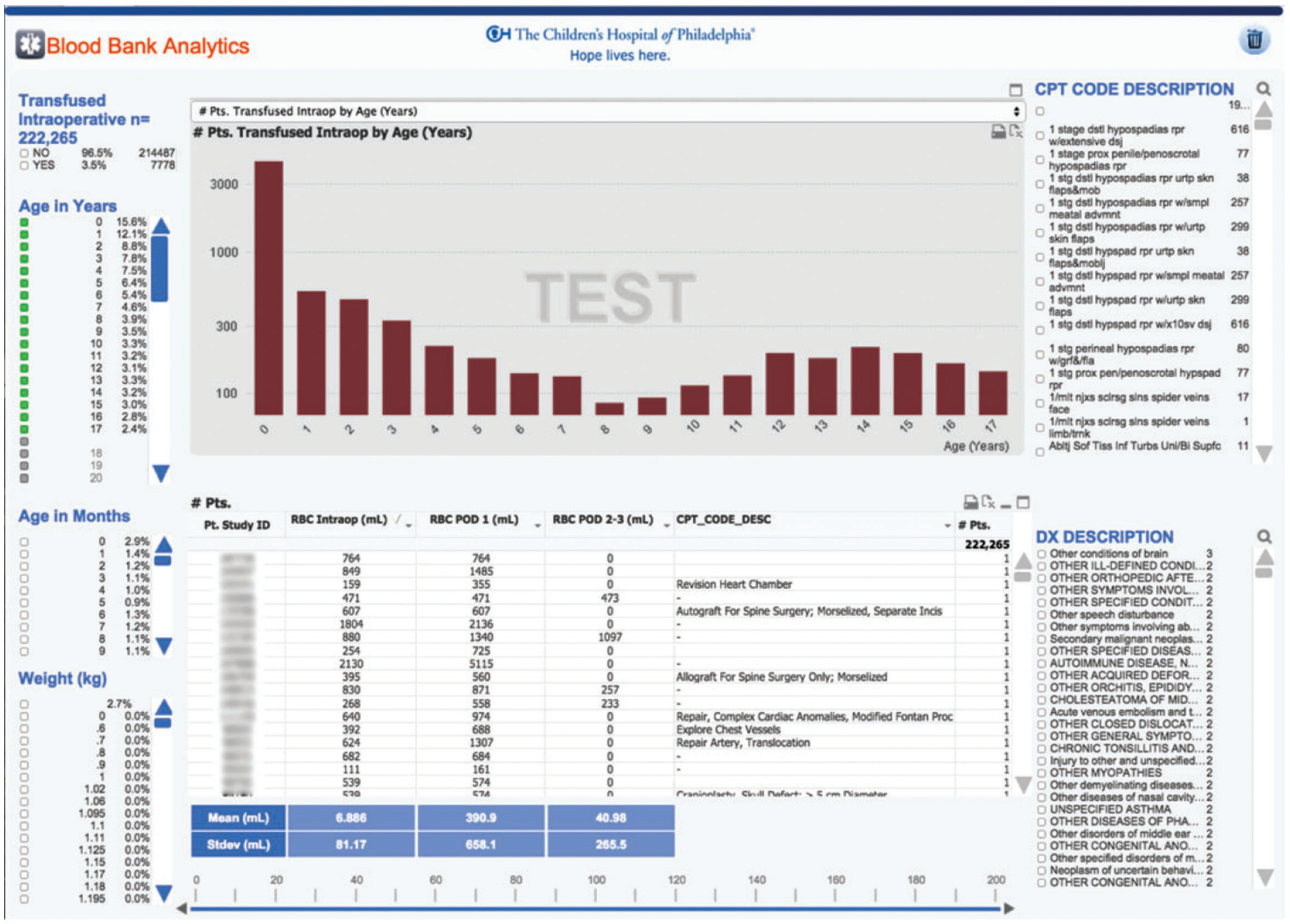

Figure 49.10 Screen image capture of the Children's Hospital of Philadelphia perioperative blood transfusion visual analytics dashboard. Table 49.1 Adverse event classification

Event	*n* (%)
Respiratory	143 (67.1)
Laryngospasm*	63 (29.6)
Bronchospasm*	20 (9.4)
Difficult ventilation	18 (8.5)
Airway obstruction	12 (5.6)
Desaturation	11 (5.2)
Respiratory failure after extubation	11 (5.2)
Breath holding	7 (3.3)
Other	5 (2.3)
Cardiac	23 (10.8)
Bradycardia	11 (5.2)
Arrhythmia	4 (1.9)
Arrest	3 (1.4)
Hypotension	2 (0.9)
Other	3 (1.4)
Accidental extubation	14 (6.6)
Hemorrhage	11 (5.2)
Emesis	10 (4.7)
Difficult airway	4 (1.9)
Anaphylaxis	3 (1.4)
Communication error	3 (1.4)
Air embolism	1 (0.5)
High spinal blockade	1 (0.5)

* There were four cases of combined laryngospasm/bronchospasm included in each.

AIMS and pediatric anesthesia research

With the appropriate analytical tools and programs, the anesthesia electronic record has been mined for a number of research reports that have documented a number of important pediatric anesthetic practices, or characteristics and outcomes of particular patient groups. One such example assessed the significantly higher incidence of bradycardia and hypotension during sevoflurane induction in patients with Down syndrome than in patients without Down syndrome. Data were analyzed for the induction period from 8 years of AIMS records, and bradycardia and hypotension was present in 57% of the 209 patients with Down syndrome versus 12% of the 268 control patients without (odds ratio 9.56, 95%CI 6.06–15.09), and this was independent of the presence of congenital heart disease, age, sevoflurane concentration, or cyanosis [67].

The potential for pediatric anesthesia research within the anesthesia EHR is great, and is just beginning to be realized. With the considerable expense, time, and complexity of prospective clinical trials in pediatrics, the data already residing in the AIMS can be utilized to construct a "trial within a database" on a number of clinical questions including superiority of one drug versus another, or outcomes of different anesthetic approaches. It must be emphasized that AIMS in general are excellent clinical documentation systems, but are not

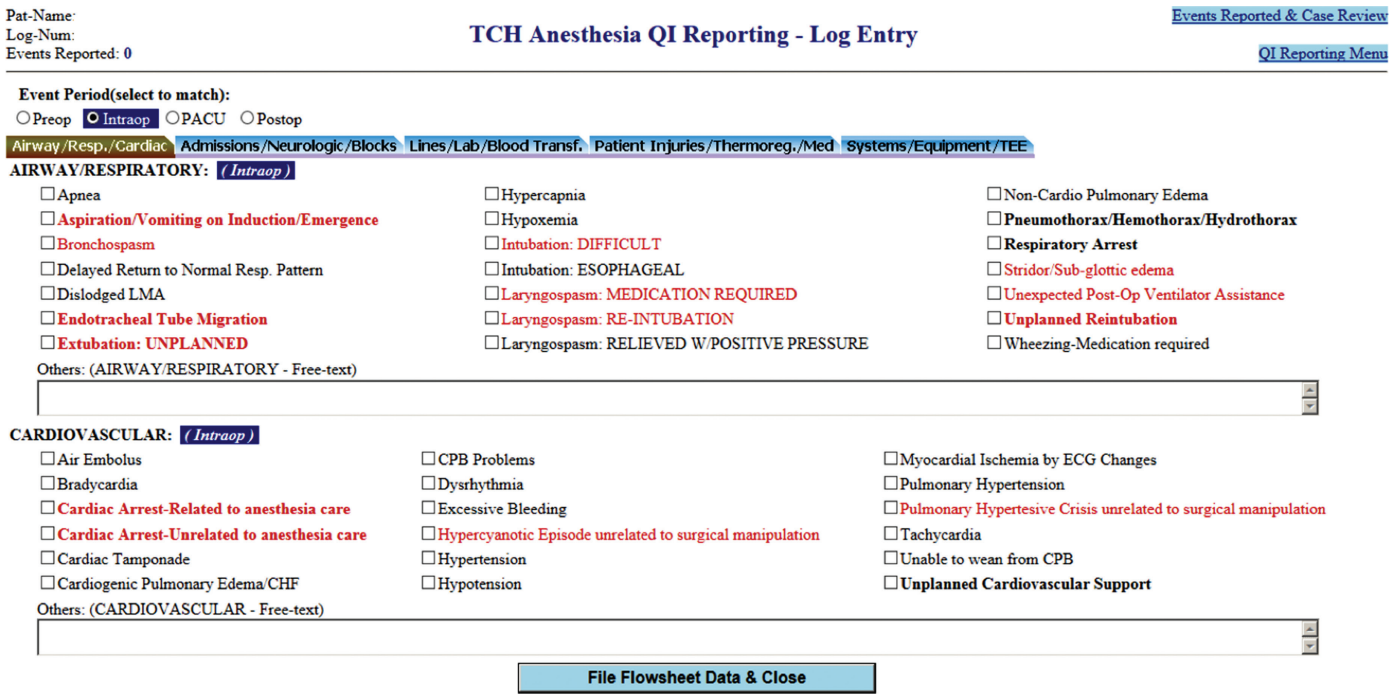

Figure 49.11 Screen image capture of a mandatory quality improvement screen documenting adverse events before closure of the anesthesia record. The data are not part of the medical record, and are sent to a separate, legally protected quality and outcomes database. *Source*: Reproduced with permission of Dr Andropoulos, chief of the Texas Children's Hospital department.

commonly equipped with the analytical programs that are able to perform the data mining described above for quality and research purposes. Significant informatics expertise, coupled with clinical and research knowledge and experience, is required to write meaningful programs or utilize sophisticated software applications to extract and analyze these complex datasets.

Future directions

In the future, AIMS should improve in terms of user interface and either interoperability with or functionality within EHRs. Useful AIMS functionality on portable devices such as tablet computers and smartphones in the perioperative period should continue to expand (Fig. 49.12) [68]. As new hospitals adopt EHRs, integrated AIMS should also become more widely available, and automated data capture will be feasible from a continually growing array of devices, such as barcode medication labeling systems and "smart" medication infusion pumps [18,69,70].

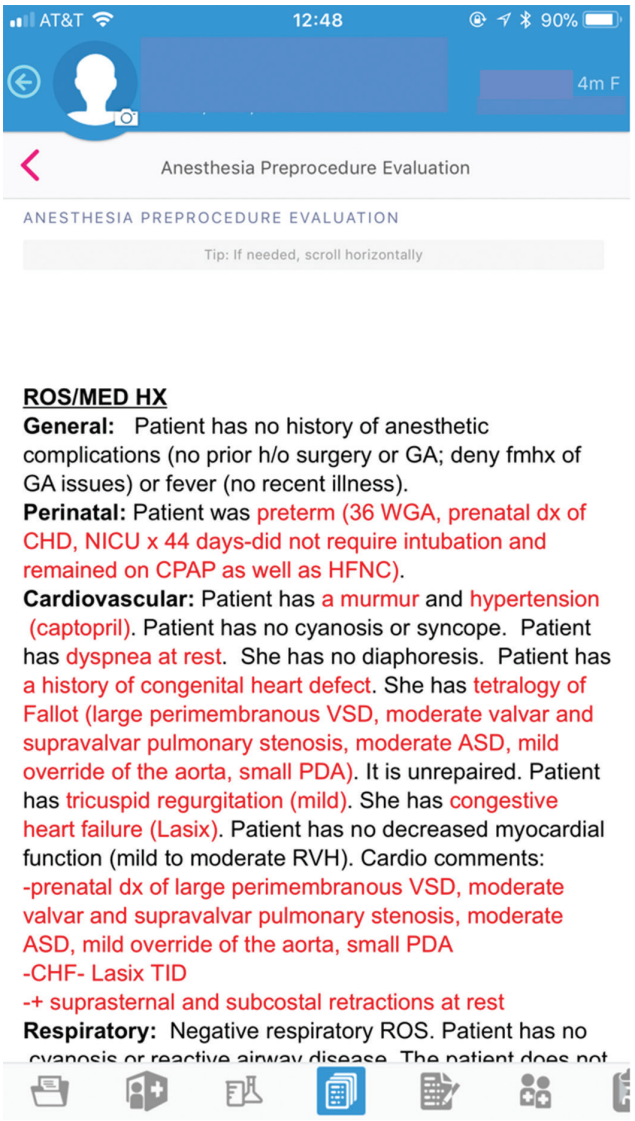

Figure 49.12 Screen image capture of a smartphone remote EHR access application that allows viewing of the medical record from a cellular phone or tablet, with proper access credentials. *Source*: Reproduced with permission of Dr Andropoulos, chief of the Texas Children's Hospital department.

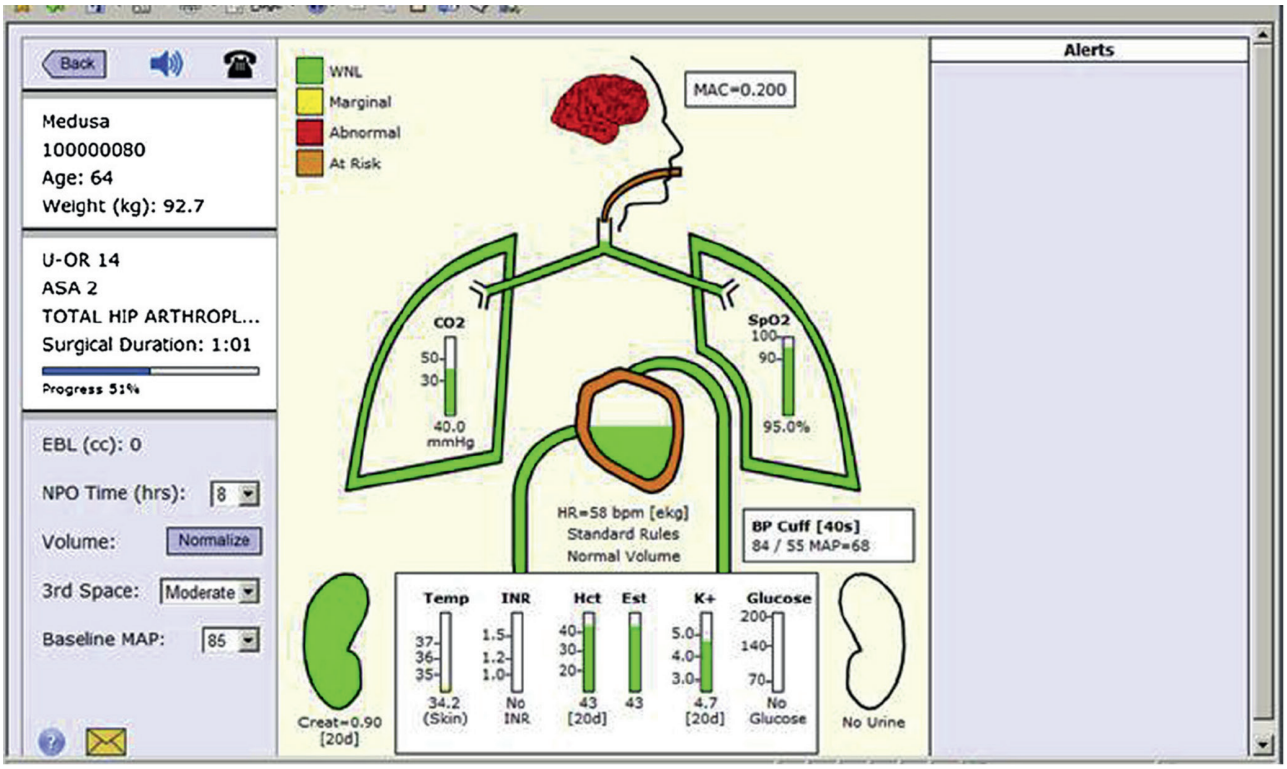
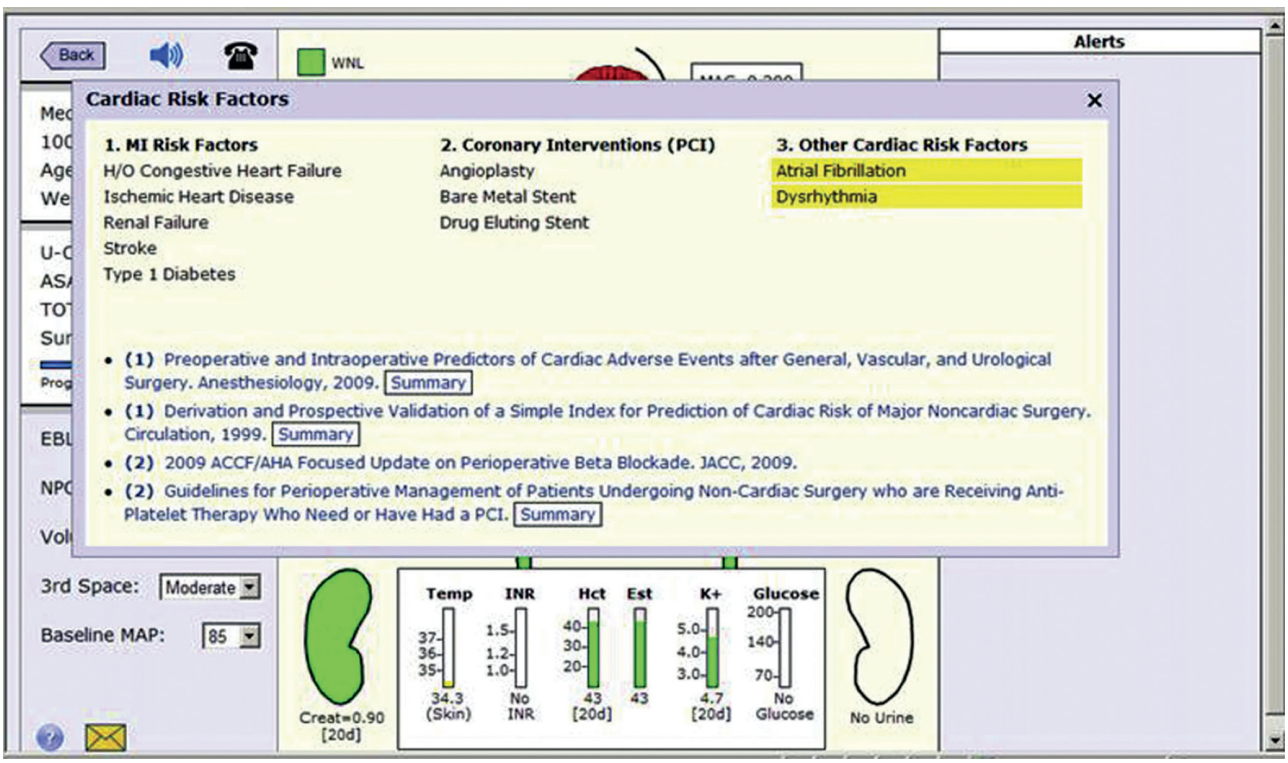
Analytical techniques such as visual analytics, natural language processing, and machine learning will be applied to large AIMS datasets for meaningful insights and to drive quality and clinical performance improvement efforts [1]. Visual analytics consist of interactive visual interfaces driving analytical reasoning, and have been utilized to enhance the evaluation of large, complex datasets within healthcare fields. AIMS can generate prohibitively large datasets that can be navigated and represented visually in near real time using visual analytics software tools [65]. One possible use of visual analytics is for advanced integrated real-time clinical displays that use sophisticated computer algorithms (artificial intelligence) to synthesize information from a patient's clinical history, current status of physiological monitor and anesthesia machine parameters, and evidence-based decision support to produce a display of patient "well-being" somewhat akin to current advanced avionics "cockpit" displays that a commercial airline pilot sees (Fig. 49.13) [71]. This visual analytical display approach was used to inform decision support algorithms in a retrospective study that compared 7954 adult surgical anesthetics that used this system to 10,933 parallel controls, and 7882 historical controls [72]. After propensity score adjustment and compared with the parallel controls, the decision support approach was associated with improvements in the three process measures (excessive fluid administration, minutes of hypotension, and tidal volumes >10 mL/kg, all $p < 0.001$), but did not improve the postoperative outcome measures of 30-day mortality, myocardial or renal injury, or hospital length of stay. Hospital charges were about US$3000 less with decision support, which was a statistically significant difference.

Natural language processing involves the software-based retrieval and extraction of information from unstructured, semistructured, and structured text, such as detecting surgical site infections using unstructured text in EHR clinical notes [73,74]. Machine learning consists of computer algorithms that can be trained to recognize meaningful patterns in large datasets. Thus, these algorithms can be applied to AIMS data to automate perioperative event annotation or to ascertain the clinical relevance of physiological data [73].

Real-time analysis of patient data across various health information systems via the application of sophisticated clinical decision support and surveillance systems is another promising application of technology to AIMS data [74]. AIMS-based clinical decision support will continue to be developed in a more sophisticated and meaningful fashion to enhance various facets of patient care. As AIMS continue to proliferate in pediatric anesthesia practice settings, clinicians should feel empowered to envision ways that these tools can be used to improve clinical workflow and enhance the care of children.



(A)



(B)

Figure 49.13 (A) Alertwatch display of one patient; the icons for each organ are self-evident, the lungs ventilate up and down with respiration, and the heart beats with heart rate. The left side of the screen shows case information, including current progress of case and percent completion, estimated blood loss (EBL), nil per os (NPO) hours, and preoperative baseline mean arterial pressure (MAP). Colors: green is normal (WNL), yellow is marginal, red is abnormal, and brown demonstrates organ system at risk. In this case, part of the patient's brain is orange, which indicates that he or she has a history of stroke; and the heart is orange, designating a cardiac history. This figure shows the heart volume to be low, which is based on an input/output calculation unless there is an objective measure, such as systolic pressure variation (SPV), central venous pressure, or pulmonary artery wedge pressure. The box at the bottom between the kidneys shows the current laboratory values and the last time they were drawn. There is also an alert portion of the screen on the right. BP, blood pressure. (B) If any organ at risk is selected (the screen is touched), a window will open; in this case it is the heart. On the left, the myocardial infarction (MI) risk factors are listed; the history of coronary intervention is in the middle; and a list of other cardiac problems is on the right. If the patient has these risk factors, they are highlighted in yellow. Below this are pertinent references and guidelines for cardiac care. In this case, the patient has a history of atrial fibrillation. H/O, history of; PCI, percutaneous coronary intervention. *Source*: Reproduced from Kruger et al [71] with permission of Elsevier.

CHAPTER 50

Operating Room Safety, Communication, and Teamwork

Thomas L. Shaw, Lauren M. Y. Lobaugh, and Stephen A. Stayer

Texas Children's Hospital; and Department of Anesthesiology, Perioperative, and Pain Medicine, Baylor College of Medicine, Houston, TX, USA

Introduction

"In solo or group practice, teamwork is a major part of the anesthesiologist's life. Whether a vital part of a surgical team, a member of an interdisciplinary group of diagnosticians at a pain clinic, or a partner on a research team or teaching faculty, an anesthesiologist works continuously with a variety of medical professionals."

This quote from the American Society of Anesthesiologists (ASA) career information webpage summarizes the importance of teamwork in the daily life of all anesthesiologists [1]. Teamwork can be defined as "the ability of team members to work together, communicate effectively, anticipate and meet one another's demands, and inspire confidence resulting in a coordinated collective action" [2]. In 2000, The Institute of Medicine published a report titled, *To Err Is Human: Building a Safer Health System* [3]. This report highlighted the fact that systemic failures in healthcare delivery account for more errors than poor performance by individuals. The Institute of Medicine recommended interdisciplinary team training to reduce the incidence of such medical errors. Effective teamwork can provide a safety net that can often prevent human errors from becoming patient safety issues. This chapter reviews the basic principles of operating room and anesthesia safety as they apply to pediatric patients, emphasizing the non-technical skills of communication and teamwork as crucial to patient outcomes.

Non-technical skills

In the 1970s, the investigation of several airplane crashes concluded that no mechanical failure of the aircraft or technical failure of the pilot had occurred. So why did these planes crash? The investigators blamed deficits in other human factors characterized as non-technical skills [4]. Non-technical skills are defined as "the cognitive, social, and personal resource skills that complement technical skills, and contribute to safe and efficient task performance" [5]. These skills do not directly relate to medical knowledge, technical expertise, drugs, or equipment. For example, a surgeon could demonstrate excellent technical skills during the amputation of the wrong foot (a lack of situational awareness). Non-technical skills have been increasingly recognized as crucial to maintaining patient safety. Non-technical skills can be classified as: (1) cognitive and mental skills (such as decision making, planning, and situational awareness); and (2) social and interpersonal skills (such as communication, teamwork, and leadership) [6]. Traditionally, medical training has not formally taught these skills and deficiencies in these skills have been reported amongst anesthesiologists [6,7]. Medical team training focuses on the cultivation of these non-technical skills.

Medical team training

Clinical training usually focuses on the individual execution of tasks. Safe and efficient patient care requires the coordination of activity among physicians, nurses, respiratory therapists, pharmacists, and other healthcare professionals. However, all of these team members are rarely trained together. Effective teamwork is not reliably learned without formal training and cultivation. Team training teaches a set of tools and strategies that requires a mental shift from an individual perspective to a team perspective.

Several different medical team training programs have been developed. Medical team training programs can be categorized into high-fidelity simulator-based programs and classroom-based programs. The high-fidelity simulator-based

Gregory's Pediatric Anesthesia, Sixth Edition. Edited by Dean B. Andropoulos and George A. Gregory.

programs rely upon patient simulators and include courses such as "anesthesia crisis resource management" [7] and "team-oriented medical simulation" [8]. The classroom-based team training programs rely upon lectures, videos, demonstrations, and role play. Classroom-based programs include TeamSTEPPS® (Team Strategies and Tools to Enhance Performance and Patient Safety) [9], MedTeams® [10], Medical Team Management, Lifewings™, and Geriatric Interdisciplinary Team Training.

There is considerable overlap between all of these training programs, and there is no evidence that one training program or method is superior to another. Advocates of high-fidelity simulator-based programs list several advantages [11]. Simulators provide hands-on training in a realistic environment. The environment mandates the integration of decision skills, procedural skills, and teamwork skills in a scenario that actually challenges and stresses the clinician. Advocates of classroom-based programs highlight the lower cost, mobility, and ability to train large numbers of students simultaneously [12]. A detailed discussion of ACRM and TeamSTEPPS follows.

Box 50.1: Anesthesia crisis resource management key points in healthcare

- Know the environment
- Anticipate and plan
- Call for help early
- Exercise leadership and followership with assertiveness
- Distribute the workload
- Mobilize all available resources
- Communicate effectively – speak up
- Use all available information
- Prevent and manage fixation errors
- Cross check and double check
- Use cognitive aids
- Re-evaluate repeatedly
- Use good teamwork – coordinate with and support others
- Allocate attention wisely
- Set priorities dynamically

Anesthesia crisis resource management

In 1989, David Gaba and his colleagues at Stanford University and the Palo Alto Veterans Affairs Medical Center pioneered the adaptation of aviation crew resource management to the practice of anesthesiology, resulting in the curriculum for anesthesia crisis resource management (ACRM) [7]. The phrases "crew resource management," "crisis resource management," and "cockpit resource management" are used interchangeably throughout the literature. Crew resource management can be defined as a management system that makes optimum use of all available resources (equipment, procedures, and people) to promote safety and focuses on teaching non-technical skills. The ACRM course begins with didactic presentations regarding anesthesia safety, decision making, specific anesthesiology crisis scenarios, and system-related failures that affect patient safety and human performance. Also, course participants critically analyze a video of an aviation accident. The bulk of the course consists of simulations followed by detailed debriefings. The simulator sessions feature a realistic patient simulator in an operating room environment in which each participant is the primary anesthesiologist managing critical event scenarios. Significant interaction between nursing and surgical personnel (role played by instructors) is required during the scenarios. Emphasis is placed on working more effectively with different leadership, followership, and communication styles. The simulation sessions are video recorded and analyzed by the team during debriefing sessions with the help of an instructor. The key points emphasized in ACRM are listed in Box 50.1. See Chapter 47 for a more detailed discussion of simulation in pediatric anesthesiology.

TeamSTEPPS®

TeamSTEPPS is another resource for training healthcare professionals in better teamwork practices. The Patient Safety Program of the Department of Defense and the Agency for Healthcare Research and Quality collaborated for 20 years to explore the field of medical teamwork. TeamSTEPPS is an evidence-based teamwork training system focusing on four complementary competency areas: leadership, situation monitoring, mutual support, and communication [9]. These are all teachable and learnable skills and should not to be viewed as skills that a person "either has or does not have." TeamSTEPPS offers a free public domain toolkit that can be tailored to any healthcare setting [13]. The free educational material on the TeamSTEPPS website includes presentations, group exercises, and videos. The Agency for Healthcare Research and Quality also offers a free TeamSTEPPS instructor course so that an institution can develop in-house expertise on team training. TeamSTEPPS can be used by all healthcare organizations and all medical specialties. This open availability may allow the entire medical field to begin using a common language and approach to team training.

TeamSTEPPS teaches specific tools and strategies to overcome barriers to team effectiveness. The tools and strategies are intimately linked to the four core competencies of the TeamSTEPPS framework: team leadership, situation monitoring, mutual support, and communication shown in Figure 50.1.

Leadership

"Leadership is the ability to direct and coordinate activities of team members, assess team performance, assign tasks, develop team knowledge and skills, motivate team members, plan and organize, and establish a positive team atmosphere" [14]. Effective team leaders organize the team, articulate clear goals, and make decisions through the collective input of members. They also delegate tasks, empower members to speak up and ask questions, actively promote and facilitate good teamwork, and are skillful at conflict resolution. Three strategies that leaders use to promote team information sharing are briefings, huddles, and debriefings.

A *briefing*, also known as a team meeting, is held for planning purposes and lets everyone on the team know what is going on and why. It is a short planning session to discuss subjects such as a patient's current condition, diagnosis, the role of team members, team goals, potential complications, and back-up plans. Briefings open the lines of communication so that everyone can contribute their unique knowledge to the task. The

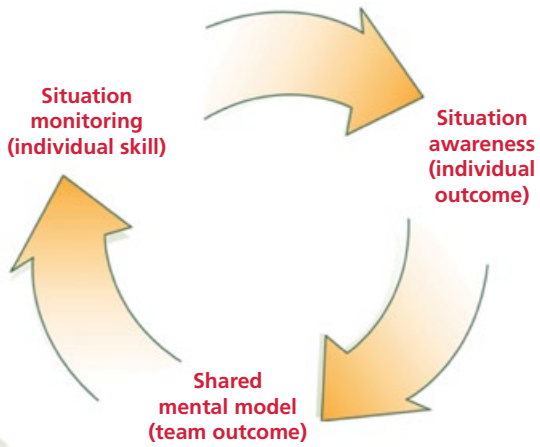

Figure 50.2 Continuum of situation monitoring, situation awareness, and a shared mental model. *Source*: Reproduced from Agency for Healthcare Research and Quality [13] with permission of AHRQ Publications Clearinghouse.

Figure 50.3 The STEP mnemonic for situation monitoring. *Source*: Reproduced from Agency for Healthcare Research and Quality [13] with permission of AHRQ Publications Clearinghouse.

team leader usually initiates the briefing, but any member of the team can do so. A *huddle* is an ad hoc discussion that focuses on problem solving. Huddles provide team members with an opportunity to update each other on changes in the status of the patient so that all team members can adapt. Huddles are used to re-establish situation awareness, reinforce plans already in place, and assess the need to adjust the plan. A *debriefing* takes place after a procedure or event and focuses on process improvement. It is an informal information exchange session designed to improve team performance and effectiveness. Debriefings are most effective in an environment where honest mistakes are viewed as learning opportunities and the focus is not placed on individual blame.

Situation monitoring

Situation monitoring is the process of continually scanning and assessing what is occurring around you to maintain situation awareness [14]. Situation awareness is "knowing what is going on around you." When everyone maintains their situation awareness and shares relevant facts to ensure that all team members are "on the same page," a shared mental model is formed. There is a continuum that begins with the individual skill of situation monitoring that leads to situation awareness and collectively results in a shared understanding of the situation (referred to as a shared mental model) (Fig. 50.2).

Situation awareness can be undermined by one team member's failure to share information, request information, and direct information to specific team members. Cross monitoring involves monitoring the actions of other team members and provides a safety net within a team. It involves "watching each other's back." Cross monitoring can help catch mistakes early before they compromise patient safety. The STEP mnemonic (Fig. 50.3) is a situation monitoring tool that is a mental reminder to constantly monitor the *status of the patient, team members, environment, and progress towards goal*.

Mutual support

Mutual support (or back-up behavior) is the ability to anticipate other team members' needs and to shift workload among members to achieve balance. Task assistance is a form of mutual support where team members protect each other from work overload situations. Some medical professionals are conditioned to avoid asking for help due to the fear of suggesting a lack of knowledge or confidence. Effective teams place all offers and requests for assistance in the context of patient safety and team members foster a climate where it is expected that assistance will be actively sought and offered.

Feedback is another type of mutual support. Feedback provides information to improve team performance. Effective feedback is timely (the behavior is still fresh in the mind of the receiver), respectful (should not be personal and should focus on behavior and not personality), specific (should relate to a specific situation), and directed (goals are set for improvement). Feedback can also be used to reinforce positive behaviors. Personal feedback is more effective when it is given in private as it causes less defensiveness on the part of the recipient.

Advocacy and assertion tools and strategies should be used when a team member's viewpoint does not coincide with that of the decision maker. The team member thus has the opportunity to correct errors or the loss of situation awareness. Failure to advocate and assert is frequently identified as a primary contributor to malpractice cases, sentinel events, and

aviation disasters. If the safety of the patient is at risk, even an unpopular viewpoint that questions authority should be advocated. The two challenge rule was initially developed to help airline pilots prevent disasters caused by momentary lapses in judgment. The two challenge rule states that if there is concern for potential harm to a patient, that concern should be asserted at least twice. If after two attempts the concern is still disregarded, a stronger course of action should be taken using the chain of command. This overcomes the natural tendency to believe the team leader must always be right. If challenged, it is the responsibility of the person challenged to acknowledge the safety concerns and resolve any safety issues. Leaders must foster an environment where all team members feel empowered to speak up when they notice a safety issue, knowing that their inputs are welcomed.

The healthcare environment is susceptible to frequent and sometimes disruptive conflict. This is not surprising given that it is an environment with a number of highly educated, experienced individuals with different training, backgrounds, and priorities. TeamSTEPPS teaches two basic conflict resolution strategies with two different scripts that can aid communication during times of conflict. The CUS script (concerned, uncomfortable, safety) uses signal words to catch an individual's attention. First a *concern* is stated, next the speaker states why they are *uncomfortable*, and finally they state that they believe there is a *safety* issue. The DESC script (describe, express, suggest, consequences) can be used to communicate effectively during all types of conflict. The specific situation is *described*. Concerns about the action are *expressed*. Other alternatives are *suggested*. Finally, potential *consequences* are stated. A private discussion between the individuals who have conflict will lead to more focus on resolving the conflict instead of a focus on saving face. The focus should be on *what* is right, not *who* is right. When resolving conflict, the goal should be to achieve collaboration, which means working together to achieve a mutually satisfying solution yielding a win–win situation.

Communication

Communication includes the efficient exchange of information and consultation with other team members. Communication is defined as the "exchange of information between sender and a receiver … the process by which information is clearly and accurately exchanged between two or more team members in the prescribed manner and with proper terminology and the ability to clarify or acknowledge the receipt of information" [15]. Communication is the lifeline of an effective team and the glue that holds all the team skills together. Improving the quality of information exchange decreases communication-related errors. In order for communication to be effective, it must be complete, clear, concise, and timely. How does communication relate to the other team skills? Effective leaders must communicate clear information so that team members are aware of their roles and responsibilities. Team members monitor situations and communicate any changes to keep the team informed. Finally, communication facilitates a culture of mutual support.

The Joint Commission (formerly the Joint Commission on Accreditation of Healthcare Organizations) has set specific safety goals related to communication including the need for standardized hand-offs with the opportunity to ask and respond to questions. Closed-loop communication is highly recommended and is defined as information exchange behavior whereby a sender initiates a message, a receiver acknowledges the message, and the message is verified by the initial sender.

TeamSTEPPS teaches four communication strategies and tools that have the potential to reduce errors associated with miscommunication. SBAR communication is described as one effective tool to communicate about a patient's condition. SBAR is a mnemonic that stands for s*ituation, background, assessment, and recommendation*. SBAR was originally developed by the United States Navy and adapted for use in the medical setting [16]. Many leading healthcare institutions support the use of SBAR including the Institute for Healthcare Improvement and the Joint Commission. SBAR is a standardized communication technique that allows the speaker to be clear and concise. A call-out is a communication strategy exemplified when a team member verbally states what they are doing, observing, or thinking in real time. A call-out is used to communicate important or critical information during a crisis so that all team members know what is going on. One example of using a call-out is stating the airway status, stating the vital signs, or announcing "clear!" before giving a patient a shock during cardiac arrest. A read-back (check-back) is a process of employing closed-loop communication to ensure that information conveyed by the sender is understood by the receiver as intended. Read-backs avoid orders being given into thin air and ensure proper understanding of orders. Hand-offs are emphasized as important communication processes that can result in patient harm if performed ineffectively. Hand-offs are discussed in detail in the following section. Many barriers to effective communication exist. These include language barriers, distractions, varying communication styles, workload, and conflict. The teamwork tools and strategies can be leveraged to overcome these barriers to effective communication. Figure 50.4 summarizes the barriers to team effectiveness, the tools and strategies to mitigate these barriers, and the desired outcomes of team training as taught by TeamSTEPPS.

KEY POINTS: NON-TECHNICAL AND MEDICAL TEAM TRAINING

- Team training involves multidisciplinary teams and can involve simulation or classroom-based training
- Anesthesia crisis resource management is simulation training that teaches leadership in a crisis and focuses on teaching non-technical skills
- TeamSTEPPS is a classroom-based system that includes team leadership, situation monitoring, mutual support, and communication

Hand-offs

A sentinel event is defined by the Joint Commission as "an unexpected occurrence involving death or serious physical or psychological injury" [17]. Examples of sentinel events include surgery on the wrong body part or the unintended retention of a foreign body such as a surgical instrument. The

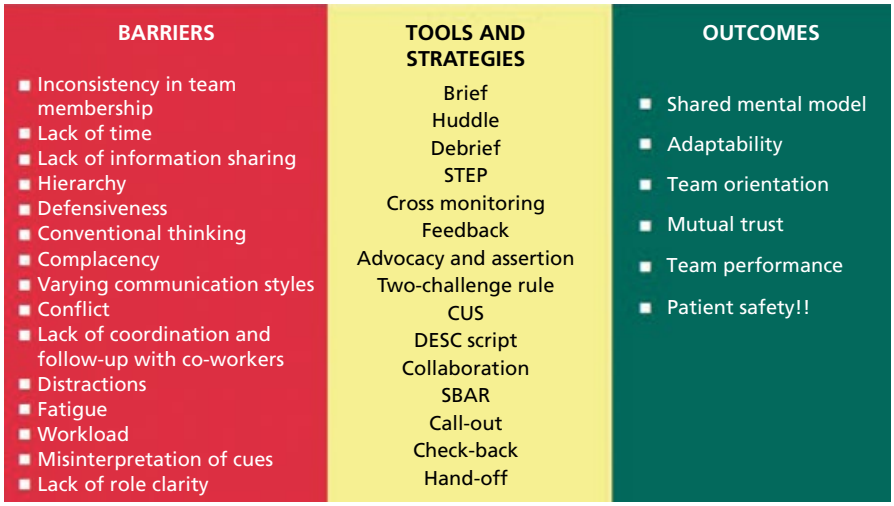

Figure 50.4 Barriers to team effectiveness, tools and strategies to overcome these barriers, and the desired team outcomes. *Source*: Reproduced from Agency for Healthcare Research and Quality [13] with permission of AHRQ Publications Clearinghouse.

Figure 50.5 Frequency of communication problems as the root cause of sentinel events. *Source*: Reproduced from Joint Commission on Accreditation of Healthcare Organizations [19] with permission of Joint Commission Resources.

Joint Commission determined that between 1995 and 2006, nearly 70% of all sentinel events were caused by communication problems (Fig. 50.5) [18,19]. More than half of the communication problems analyzed by the Joint Commission occurred during hand-offs. An analysis of one closed claim database showed that 40% of communication problems occurred during hand-offs [20].

A hand-off (also referred to as a hand-over, sign-out, transition, or sign-over) is defined as the transfer of accountability and responsibility of a patient from one healthcare provider to another. The Joint Commission states that the "primary objective of a handoff is to provide accurate information about a patient's care, treatment, and services, current condition and any recent or anticipated changes. The information communicated during a handoff must be accurate in order to meet patient safety goals" [18]. The daily workflow of anesthesiologists involves had-offs to and from other anesthetists, surgeons, neonatologists, critical care physicians, emergency physicians, respiratory therapists, and perioperative nurses. Pediatric patients are particularly vulnerable to ineffective hand-offs due to their reduced capacity to advocate for themselves and provide information regarding their own medical history [21]. Surprisingly, anesthesiologists are seldom formally taught how to effectively perform this duty. A recently published study of complete intraoperative hand-off of care in over 300,000 adult inpatients undergoing at least 2 h of anesthesia revealed an adjusted increase of 30-day mortality and major complications from 29.1% to 35.9% (relative risk 1.23, 95%CI 1.16–1.32) [22]. As the study authors note, the quality of the intraoperative hand-off was not assessed during this study, but "It is possible that an improved system of anesthesia handovers (in which critical components of handovers are mandated by a checklist) would eliminate the signal of harm while maintaining lifestyle benefits for clinicians."

Many specialties including anesthesiologists, surgeons, pediatricians, internists, and emergency medicine physicians have undertaken the qualitative evaluation of hand-offs, finding that hand-offs frequently lack a formalized structure [23–31]. They also note frequent omissions and distortions of important information. One study noted that pediatric interns overestimated the effectiveness of the hand-offs that they gave [30]. The same study showed that almost 40% of the recipients felt that the most important information about the patient was not reported.

The Joint Commission has commented on the negative consequences of ineffective hand-offs based on the relationship with sentinel events. Analysies of closed claims databases have also demonstrated the contribution of ineffective hand-offs to wrong site surgery, wrong patient surgery, and unintended retention of foreign bodies [20,32]. Ineffective hand-offs have also been shown to result in medication errors, delays in diagnosis and treatment [33], completely missed diagnoses [34], and omission of handed over tasks [26]. Studies have also demonstrated the frequent inability of the oncoming physician to find the missing information by means of the medical record [27].

There are many barriers to effective hand-offs. Most important is the lack of formal teaching of the hand-off process. Other barriers include interruptions, noise, distractions, and the time constraints on performing hand-offs in a busy practice [21,35,36]. Outgoing physician fatigue also can decrease the quality of a hand-off. Social hierarchy can have a negative impact on the quality of a hand-off. It is commonly noted that when receiving a hand-off from a more senior person, the more junior person is reluctant to ask questions and ask for

clarification [21,35,37]. This is because the junior person fears the perception that they are questioning a superior.

There is controversy amongst anesthesiologists regarding whether hand-offs should be formally structured. One survey of anesthesiologists reflected the perspective that standardization is burdensome and not needed, arguing that extra paperwork is an impediment to clinical care [38]. Another group of surveyed anesthesiologists felt that standardization would be valuable [39,40]. Regardless of the desire for or perceived need for the standardization of the hand-off process, it is clear that standardization and inclusion of a written and verbal component decreases omissions, decreases distortion, and improves recipient satisfaction with hand-off quality [23–26,28,29,35,41]. Another feature of high-quality hand-offs is the inclusion of a read-back (also referred to as a check-back) [21,36,42–45]. A read-back takes place by the oncoming provider (recipient of the hand-off) repeating what they heard during the hand-off to the outgoing practitioner who confirms accuracy or clarifies errors. This two-way feedback technique double checks information accuracy and verifies that the recipient was actually listening during the hand-off. Finally, face-to-face communication during a hand-off is ideal due to the non-verbal information that can be conveyed via facial expressions, body language, gestures, and eye contact. Box 50.2 summarizes the characteristics of effective hand-offs described in the literature [31,36,45].

At least 24 different mnemonics for hand-offs have been described in the medical literature [46]. It is recommended that each institution should consistently use one mnemonic throughout the hospital so that when surgeons, nurses, anesthesiologists, neonatologists, critical care physicians, and emergency medicine physicians communicate, they utilize a similar communication structure.

I-PASS system

Nine children's hospitals in the United States studied the effect of a resident hand-off improvement program using the I-PASS mnemonic [47]. I-PASS is a mnemonic that stands for *illness severity, patient summary, action list, suggestions, and synthesis*. I-PASS is copyrighted by Boston Children's Hospital, but the materials are freely available. After implementation of the hand-off improvement program based on I-PASS, the medical error rate decreased by 23% and the rate of preventable adverse events decreased by 30% at the hospitals studied. Box 50.3 shows a sample hand-off protocol in I-PASS format.

Box 50.2: Characteristics of effective hand-offs

- Format is standardized
- Contains a verbal and written component
- Read-back used to verify understanding
- Allows the opportunity to ask questions
- Pending studies are emphasized
- Hierarchy is flattened
- Interactive
- Information is up to date
- Contingency plans discussed
- Free of interruptions
- Quiet environment
- Face to face

I *Illness severity*: How sick is the patient?
- Stable, watcher (potential to become unstable), star (unstable)

P *Patient summary*: Brief overview, one liner
- Age, sex, past medical history, past surgical history
- Chief complaint, significant signs and symptoms, working diagnosis or differential
- Diet, meds, support, access, infection sources
- Hospital course so far
- Suggested plan

A *Action list*: To do
- What to do, when to do it, and what to do about it

S *Suggestions*: If/then
- What could happen and what intervention would be needed

S *Synthesis*: Receiver summarizes

Society for Pediatric Anesthesia's intraoperative hand-off tool

The Quality and Safety Committee of the Society for Pediatric Anesthesia (SPA) created an intraoperative hand-off tool and published it online (Fig. 50.6). This tool is helpful for promoting excellent communication during temporary or permanent intraoperative transfer of care from one anesthesia provider to another.

Effective team members are expected to ensure that their colleagues are well informed when sharing the care of a patient. Providing an effective standardized hand-off prevents lapses in information that can lead to mistakes.

KEY POINTS: HAND-OFFS

- Hand-offs are ubiquitous in healthcare, yet as many as 40% of communication problems occur during hand-offs
- Lack of formal teaching and ineffective hand-offs are important sources of error that lead to adverse patient outcomes
- I-PASS stands for illness severity, patient summary, action list, suggestions, and synthesis

Checklists

In 1978, a study revealed that 14% of anesthetic mishaps could be attributed to failure of the anesthesia machine [48]. In 1987, the ASA and the United States Food and Drug Administration (FDA) collaborated to produce a generic anesthesia machine checklist to increase detection of malfunctions.

A checklist is a simple tool designed to reduce error and encourage compliance with best practice. Checklists are memory aids that list action items or criteria that have been determined to be essential to the success of a process or procedure. Indeed, "a short pencil is better than a long memory." Utilization of checklists is considered essential to safety in the industries of aviation, nuclear power, construction, and manufacturing [49]. Recent studies have also demonstrated positive applications in the medical field. Checklists are a proven component of interventions to reduce the incidence of central venous line-associated bloodstream infections, reduce

intensive care unit (ICU) length of stay, and reduce surgical morbidity and mortality.

Central line-associated bloodstream infections occur too frequently, may result in death, and are now considered mostly preventable [50]. In 2001, Pronovost and colleagues undertook a quality improvement project aimed at reducing the incidence of line-associated infections [51]. The project included a checklist designed to ensure adherence to the infection control protocol. The checklist contained infection control guidelines that most practitioners recognize but do not always follow. Use of the checklist resulted in a reduction in the mean rate of infections from 7.7 per 1000 catheter-days to 1.4 per 1000 catheter-days. Subsequent studies have reproduced these results showing significant reductions in line-associated infection rates when a checklist is used [52–56]. Typical components of a central line insertion checklist are shown in Box 50.4.

The ICU is an environment where multidisciplinary coordination and communication are vital to patient safety and throughput. The entire care team must clearly understand the goals of care, list of tasks, and communication plan. The ICU daily goals form is a type of checklist designed to improve communication between team members [57–59]. The top two priorities of the daily goals form are the conditions necessary to discharge the patient from the ICU and reducing the patient's greatest safety risk. Several studies have demonstrated that the use of this form results in significant improvements in team understanding of the daily goals for a patient and significant reductions in length of stay for the patient [57,59,60].

Box 50.4: Central venous line insertion checklist

- Equipment assembled and supplies verified before procedure begins
- Nurse observes procedure and is empowered to intervene to ensure compliance
- Provider washes hands with antibacterial soap or waterless hand cleaner
- Provider wears hat, mask, sterile gown, and sterile gloves
- Insertion site scrubbed with 2% chlorhexidine (age >2 months) or povidone-iodine (<2 months)
- Patient covered from head to toe with sterile drape
- Sterile dressing applied and dated immediately after procedure

The World Health Organization (WHO) recognizes that surgical complications are common and often preventable. It has been estimated that over 230 million major surgeries take place per year [61]. Of these, 7 million major complications occur including 1 million deaths. A team of experts worked to create a checklist designed to improve teamwork and prevent common causes of perioperative morbidity and mortality. The WHO surgical safety checklist is shown in Figure 50.7.

The WHO surgical safety checklist promotes and facilitates good teamwork by helping the team develop a shared mental model with the use of a brief before anesthesia induction and a time out before skin incision. Before the procedure begins, the entire team introduces themselves by name in order to flatten hierarchy. The checklist also empowers team members to speak up if they notice any safety concerns. Several components of the checklist are related to the practice of anesthesiologists. The checklist specifically encourages vigilance related to the presence of a difficult airway, risk of aspiration, risk of significant blood loss, the presence of allergies, and timely administration of prophylactic antibiotics. The effect of the WHO surgical safety checklist was evaluated in eight hospitals across the world, including several in developing nations, and others in highly developed academic teaching settings. Implementation of the checklist resulted in a reduction of death from 1.5% to 0.8% and a reduction in inpatient complications from 11.0% to 7.0% [62]. Considering the high volume of worldwide surgeries and the high complication rates [61], global implementation of the WHO surgical safety checklist could lead to substantial reductions in surgical mortality and morbidity. One criticism of this landmark safety study is that although there was improvement in all hospitals, more of the improvement in outcome could be attributed to the hospitals in developing nations.

A recent study of a comprehensive perioperative safety checklist was conducted in six intervention hospitals, and five control hospitals in the Netherlands, all tertiary care and academic hospitals with previously demonstrated high standards and quality of care [63]. In 3760 patients studied before implementation of the checklist, and 3820 patients after implementation, the total number of complications decreased from 27.3 to 16.5 per 100 patients ($p < 0.001$), and in-hospital mortality decreased from 1.5% to 0.8% ($p < 0.001$). These outcomes did not change in the control hospitals. Surgical safety checklists should be modified according to local institutional needs, including those of a children's hospital, where the

A World Alliance for Safer Health Care

Before induction of anaesthesia
(with at least nurse and anaesthetist)

Has the patient confirmed his/her identity, site, procedure, and consent?
- ☐ Yes

Is the site marked?
- ☐ Yes
- ☐ Not applicable

Is the anaesthesia machine and medication check complete?
- ☐ Yes

Is the pulse oximeter on the patient and functioning?
- ☐ Yes

Does the patient have a:

Known allergy?
- ☐ No
- ☐ Yes

Difficult airway or aspiration risk?
- ☐ No
- ☐ Yes, and equipment/assistance available

Risk of >500ml blood loss (7ml/kg in children)?
- ☐ No
- ☐ Yes, and two IVs/central access and fluids planned

Before skin incision
(with nurse, anaesthetist and surgeon)

- ☐ **Confirm all team members have introduced themselves by name and role.**
- ☐ **Confirm the patient's name, procedure, and where the incision will be made.**

Has antibiotic prophylaxis been given within the last 60 minutes?
- ☐ Yes
- ☐ Not applicable

Anticipated Critical Events

To Surgeon:
- ☐ What are the critical or non-routine steps?
- ☐ How long will the case take?
- ☐ What is the anticipated blood loss?

To Anaesthetist:
- ☐ Are there any patient-specific concerns?

To Nursing Team:
- ☐ Has sterility (including indicator results) been confirmed?
- ☐ Are there equipment issues or any concerns?

Is essential imaging displayed?
- ☐ Yes
- ☐ Not applicable

Before patient leaves operating room
(with nurse, anaesthetist and surgeon)

Nurse Verbally Confirms:
- ☐ The name of the procedure
- ☐ Completion of instrument, sponge and needle counts
- ☐ Specimen labelling (read specimen labels aloud, including patient name)
- ☐ Whether there are any equipment problems to be addressed

To Surgeon, Anaesthetist and Nurse:
- ☐ What are the key concerns for recovery and management of this patient?

This checklist is not intended to be comprehensive. Additions and modifications to fit local practice are encouraged.

Revised 1 / 2009

Figure 50.7 World Health Organization's surgical safety checklist. *Source*: Reproduced from World Health Organization Surgical Safety Checklist (www.who.int/patientsafety/safesurgery/en/index.html) with permission of WHO.

surgical briefing may need to be done in the preoperative holding area with the parent present. One such modification is shown in Figure 50.8.

Checklists are important components of comprehensive patient safety interventions. It would be an oversimplification to state that checklists alone reduce central venous line-associated infections, ICU length of stay, and surgical morbidity [64]. Team education must first take place to build faith in the practices reinforced by the checklist. Barriers to the use of the checklist must be identified and eliminated or the checklist will often be left unused. Outcomes must be measured and feedback should be provided. Institutions should customize checklists to fit the needs and culture of their own organization.

One survey revealed that some physicians remain skeptical about whether or not checklists truly improve patient safety. The fact that almost all of those same skeptics wanted the checklist used if they themselves were having surgery speaks for itself [49]. The use of checklists that have shown evidence in improvements in patient outcomes should be embraced.

Society for Pediatric Anesthesia's critical events checklists

The Quality and Safety Committee of the SPA have developed a collection of checklists and cognitive aids to facilitate optimal management of common perioperative emergencies [65] which are available in PDF format and as a mobile application. Several institutions have incorporated these checklists into their anesthesia information management systems. These checklists compile the latest evidence-based and expert opinion-based management strategies that can be used in real time by the entire care team to help manage a patient with optimal teamwork. It is recommended that a paper or digital copy of the checklists be available in all anesthetizing locations. If an emergency occurs, the anesthesiologist, nurse, or any other person in the room should go to the appropriate checklist in real time and verbally call out the recommended therapies listed or diagnoses to be considered. The table of contents of the checklists, and a checklist for anaphylaxis, are shown in Figure 50.9. The SPA critical events checklists are available at http://www.pedsanesthesia.org/critical-events-checklist/ (accessed May 2019).

KEY POINTS: CHECKLISTS

- Checklists have long been utilized in high reliability industries and now are common in healthcare; their use can lead to lower adverse event rates such as central line-associated bloodstream infection
- The surgical safety checklist, including preoperative briefing, intraoperative time out, and intraoperative debriefing are now required in most institutions and their use can lead to decreased perioperative complications
- Intraoperative critical events checklists, or memory aids, can lead to more complete incorporation of all necessary steps in a crisis such as anaphylaxis

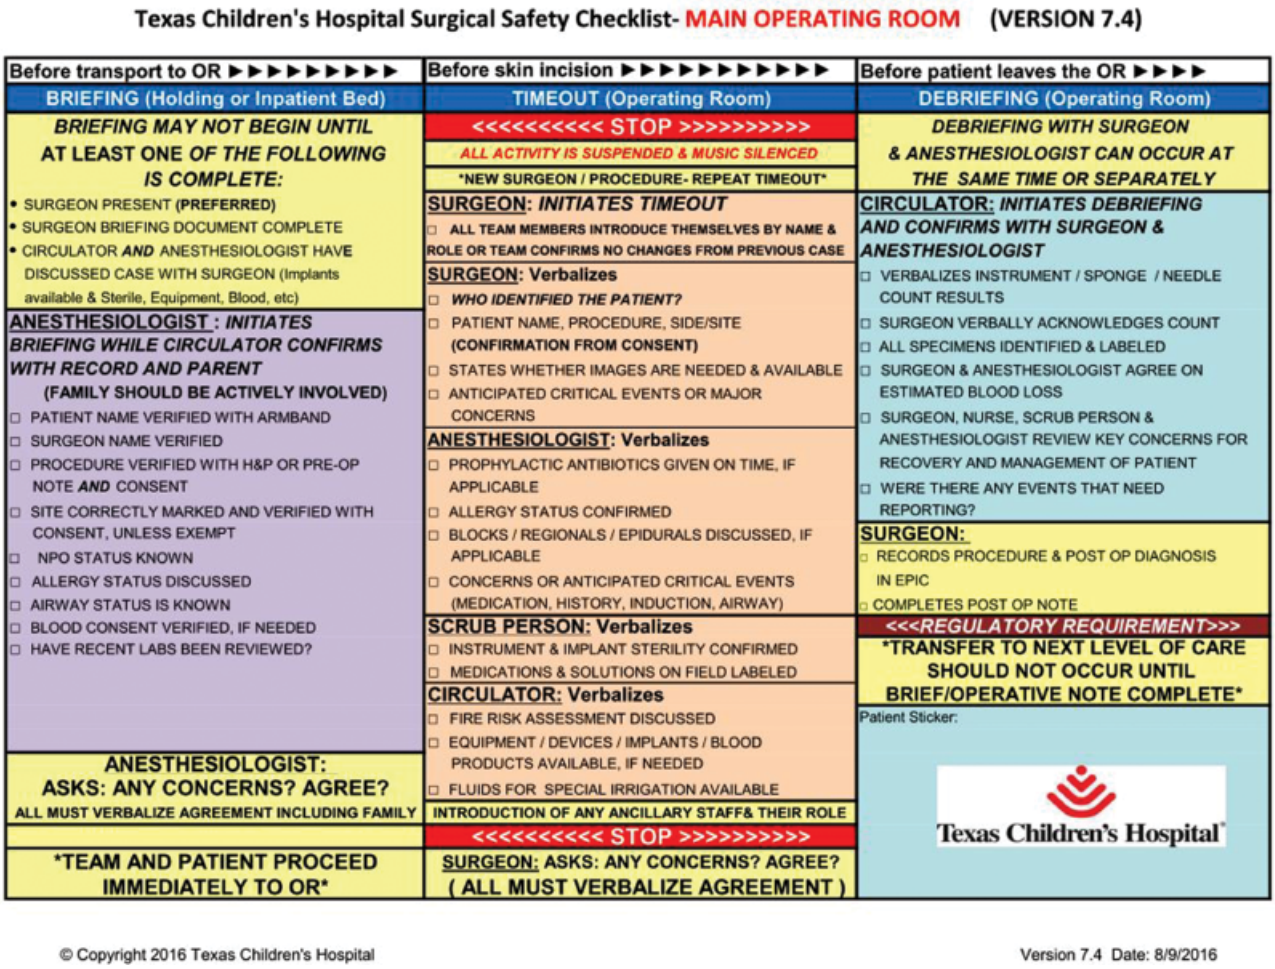

Figure 50.8 Texas Children's Hospital surgical safety checklist. The surgical briefing is done in the holding area, or intensive care unit bedside, and initiated by the anesthesiologist with the parent present to verify information. The surgeon must be present for the briefing, or have communicated to the anesthesiologist verbally or via written communication his/her plans and concerns for the case. *Source*: Reproduced with permission from Dr Andropolous.

Medication safety

The perioperative environment is unique with regards to medication administration since anesthesia providers are singlehandedly responsible for prescribing, preparing, administering, and documenting medications without a second person to cross check. In addition to the numerous medications needed to safely anesthetize a patient, providers must have immediate access to emergency medications should a life-threatening situation arise. Pediatric patients are particularly vulnerable to medication dosing errors since most medications are administered on a dose per weight basis. Incorrect measurement of weight, recording of weight, or calculation of dose can lead to significant over- or underdosing of medications.

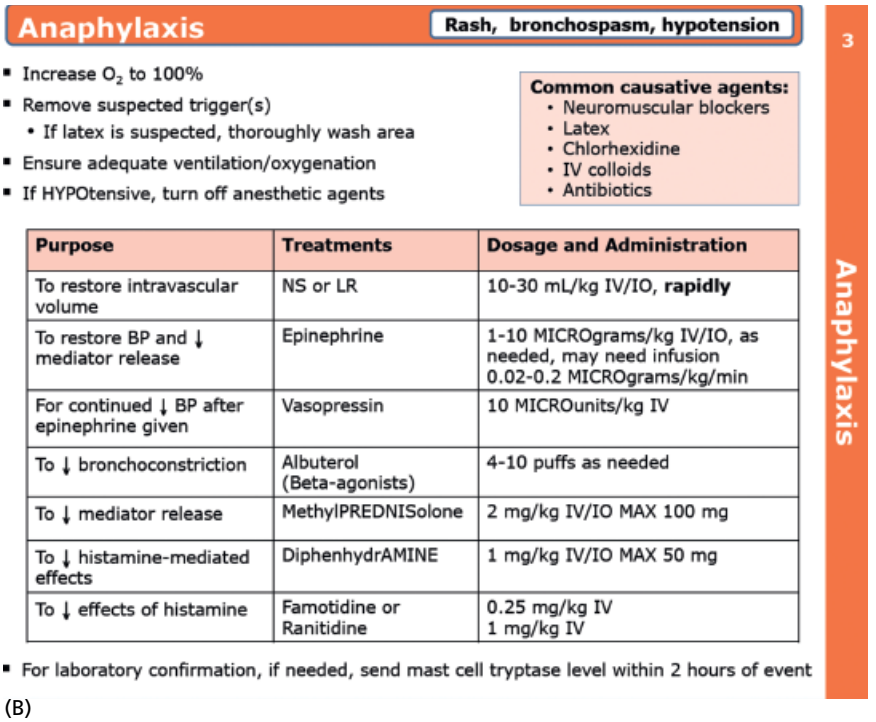
Incidence

Unfortunately, medication errors are a common occurrence in healthcare systems and are reported to be the seventh most common cause of death overall. The FDA reports medication errors as the cause of approximately 1.3 million injuries each year and one death every day in the United States [66]. These numbers are believed to be severely underestimated as most data sources rely on voluntary reporting. A survey of members of the Canadian Society of Anaesthesiologists from 2001 reported that 85% of respondents experienced at least one drug error or near miss [67]. However, another study determined that a medication error or adverse drug event occurred in approximately one in 20 perioperative medication administrations, and every second surgical procedure [68]. More than one-third of these errors led to patient harm, and the remaining two-thirds had the potential for patient harm. Of note, pediatric patients were excluded from this study.

Types of medication errors

Various groups have classified medication errors, and Table 50.1 is one proposed classification system [69]. Wake Up Safe is a multi-institutional quality improvement initiative for reporting and analyzing anesthesia and surgery safety events sponsored by the SPA. A recent report from the Wake Up Safe Quality Improvement Initiative revealed that medication errors occurred most frequently during the administration phase of the anesthetic, particularly with administration of the wrong dose and syringe swaps. Patient harm occurred in half of the reported medication errors that reached the patient, and a large majority of the reported errors were deemed preventable [70]. These findings are consistent with a 2010 report from New Zealand that also identified incorrect dosing as the most common medication error type [69].

(A)



(B)

Figure 50.9 (A) Table of contents of Society for Pediatric Anesthesia critical events checklists. (B) Checklist for intraoperative anaphylaxis. The checklists are available without charge at http://www.pedsanesthesia.org/critical-events-checklist/ (accessed May 2019). *Source*: (A) Reproduced with permission from Dr Andropolous.

Risk factors

A large study from New Zealand evaluated contributing factors to medication errors, finding a failure to check to be the most common (23%), followed by distraction (16%), inattention (13%), and haste or production pressure (10%) [69]. Interestingly, several other studies have evaluated the risk of emergency surgery and this does not appear to be a contributing factor with medication errors.

Table 50.1 Types of medication error

Medication error	Definition
Omission	Drug not given
Repetition	Extra dose of an intended drug
Substitution	Incorrect drug instead of the desired drug: a swap
Insertion	A drug that was not intended to be given at a particular time or at any time
Incorrect dose	Wrong dose of an intended drug
Incorrect route	Wrong route of an intended drug
Others	Usually a more complex event, not fitting the above categories

Prevention

One study evaluated the baseline incidence of medication errors in two hospitals, both of which used a standard color-coding labeling system for medications used by anesthesiologist [69]. They instituted a new system designed to reduce medication errors in one of the hospitals. This improvement strategy included: (1) labels with the class and generic name of each drug in large, clear lettering and incorporating a bar-code; (2) alerts for known allergies and expired drugs; (3) custom software and a barcode scanner to allow a drug identity cross check before each administration, by redisplay of the drug name and its international color code on a computer screen and an auditory announcement of the drug name; (4) reorganization of the workspace using syringe trays and a color-coded drug tray; (5) prefilled, standardized syringes for many commonly used medications; (6) a complete, automated anesthetic record; and (7) operational rules designed to decrease human error and facilitate safe practice. The two principal operating rules were: to scan each drug before administration and to retain used ampules and syringes in designated zones on the new trays as a physical "record" of what had been given; and an additional labeling system for the accurate preparation of infusion drugs. The new system using these strategies resulted in a relative reduction of 35% in drug errors.

On January 26, 2010, the Anesthesia Patient Safety Foundation (APSF) convened a consensus conference of 100 stakeholders from many different backgrounds to develop new strategies for "predictable prompt improvement" of medication safety in the operating room. Their recommendations are summarized in Box 50.5 [71].

Medication labeling systems

The Joint Commission requires that each medication syringe be labeled with the medication name, concentration, preparation time and date, expiration time and date, and preparer's initials. The Safe Label System SLS 500i™ (Codonics Inc., Middleburg Heights, OH, USA) is a computerized drug labeling system (Fig. 50.10). This system scans the barcode on medication vials, provides auditory feedback to confirm the drug name and concentration, and prints a color-coded syringe label. These labels facilitate compliance with Joint Commission regulations and achieve many of the strategies recommended by the APSF to improve medication safety. One study showed that implementation of this medication labeling system increased labeling compliance from 36% to 88% [72].

Further studies are needed to assess the effectiveness of proposed strategies for medication error reduction. However, accepting the current rates of medication errors is unacceptable. Anesthesia providers must remain vigilant and continue to strive to reduce harm to patients. Fostering a culture focused on safety in the perioperative setting and promotion of non-punitive, voluntary reporting of errors is important to foster a better understanding of the true scope of this issue.

KEY POINTS: MEDICATION SAFETY

- Anesthesiologists are some of the only providers who prepare, label, and administer medications frequently without a second person to cross check
- A recent Wake Up Safe study documented a rate of medication error of about 1.2 per 10,000 cases, with patient harm occurring in half the errors that reached the patient
- Prevention strategies include a drug scanning and labeling system, pharmacy premixed and prefilled syringes when possible, and special procedures for high-risk medications

Value-based programs

Many evidence-based clinical processes that are known to improve patient outcomes are not consistently achieved or are implemented slowly [73]. In the United States, the Centers for Medicare and Medicaid Services (CMS) and many other healthcare plans have adopted value-based purchasing programs (also referred to as pay-for-performance) methods to incentivize the reporting of quality data and achieving quality goals. Value-based purchasing initiatives create financial incentives for physicians to achieve quality goals by linking a portion of payments to reporting quality data and performance on quality measures. The Physician Quality Reporting System (PQRS) was established by the CMS in 2006. In 2017, the CMS began transitioning from the PQRS to the Merit-based Incentive Payment System (MIPS) which is a part of the CMS Quality Payment Program. Since January 2019, CMS adjusts payments from +4% to –4% based on satisfactory reporting of quality data and achieving quality goals. In other words, payments to a practice may be reduced by up to 4% or may be increased by up to 4%. That payment adjustment is scheduled to gradually increase to ±9% by 2022 [74]. The ASA has partnered with the Anesthesia Quality Institute to develop a Qualified Clinical Data Registry that can be a basis of performance measures [75]. A selection of MIPS measures related to anesthesiology is shown in Box 50.6.

The actual effect that value-based purchasing has on quality improvement is currently unclear. Studies have generally shown that such initiatives have no effect or minimal effect on improving quality measures [76–79]. Even as many third party payers are moving forward with value-based purchasing initiatives, caution may be warranted due to the fact that the data regarding effectiveness is weak at best.

Safe systems in the operating room

Operating room (OR) safety can potentially be improved through the application of technology and knowledge. Recent advances in technology have moved the traditional surgical

Box 50.5: Consensus recommendations for improving medication safety in the operating room

Standardization

1. High alert drugs (such as phenylephrine and epinephrine) should be available in standardized concentrations/diluents prepared by pharmacy in a ready-to-use (bolus or infusion) form that is appropriate for both adult and pediatric patients. Infusions should be delivered by electronically controlled smart device containing a drug library
2. Ready-to-use syringes and infusions should have standardized fully compliant machine-readable labels
3. *Additional ideas*:
   a. Interdisciplinary and uniform curriculum for medication administration safety to be available to all training programs and facilities
   b. No concentrated versions of any potentially lethal agents in the operating room
   c. Required read-back in an environment for extremely high-alert drugs such as heparin
   d. Standardized placement of drugs within all anesthesia workstations in an institution.
   e. Convenient required method to save all used syringes and drug containers until case concluded
   f. Standardized infusion libraries/protocols throughout an institution
   g. Standardized route-specific connectors for tubing (IV, arterial, epidural, enteral)

Technology

1. Every anesthetizing location should have a mechanism to identify medications before drawing up or administering them (barcode reader) and a mechanism to provide feedback, decision support, and documentation (automated information system)
2. *Additional Ideas*:
   a. Technology training and device education for all users, possibly requiring formal certification
   b. Improved and standardized user interlaces on infusion pumps
   c. Mandatory safety checklists incorporated into all operating room systems

Pharmacy/prefilled/premixed

1. Routine provider-prepared medications should be discontinued whenever possible
2. Clinical pharmacists should be part of the perioperative/operating room team
3. Standardized preprepared medication kits by case type should be used whenever possible
4. *Additional ideas*:
   a. Interdisciplinary and uniform curriculum for medication administration safety for all anesthesia professionals and pharmacists
   b. Enhanced training of operating room pharmacists specifically as perioperative consultants
   c. Deployment of ubiquitous automated dispensing machines in the operating room suite (with communication to central pharmacy and its information management system)

Culture

1. Establish a "just culture" for reporting errors (including near misses) and discussion of lessons learned
2. Establish a culture of education, understanding, and accountability via a required curriculum and continuing medical education and dissemination of dramatic stories in the *APSF Newsletter* and educational videos
3. Establish a culture of cooperation and recognition of the benefits of standardization, technology, and culture within and between institutions, professional organizations, and accreditation agencies

Source: Reproduced from Eichhorn [71] with permission of APSF.

suite toward one that is more efficient and safe. However, practice in most ORs does not differ greatly from that of 50 years ago. The Health Information Technology for Economic and Clinical Health Act, as part of the American Recovery and Reinvestment Act of 2009, pledged billions of dollars to improve access to data through technology and improve overall quality of care [80,81]. Yet, to date, electronic information systems do not have a common platform and do not effectively share data elements (pertinent patient information). Effective anesthesia information management systems (AIMS) should enhance patient care more than simply providing a legible record. In fact, although legible, most current information systems produce records that will automatically add data and descriptive text with the push of a button. Such a record may actually lead to inaccurate data entry, or produce a lengthy record that will fatigue users in the same way as inefficiently sorting through a voluminous paper chart. Also, the addition of complex technology to the OR can add hazards by distracting the anesthesiologist from the patient and surgical procedure. An effective AIMS is easy to use and provides decision support to the user in order to enhance patient care. See Box 50.7 [82] and Chapter 49 for a more detailed presentation of the electronic anesthesia record.

Other technologies that are being tested in the OR to improve patient safety include the use of barcodes, radiofrequency identification (RFID), and smart imaging. As described earlier, barcodes can be used to perform as a second check on medication administration. Additionally, barcodes can track instruments used in the surgical field. Most commercial warehouses and supermarkets track their inventories more effectively than supplies and equipment are tracked in the perioperative environment. Retailing giants closely track the location of their one dollar paper towel inventory, but a charge nurse in a typical operating

Figure 50.10 Codonics Medication Safety System. The device audibly reads the barcode on a medication vial, and prints out a color-coded medication label with all required information: drug name, concentration, preparation and expiration dates, and initials of preparer. *Source*: Courtesy of Codonics, Inc.

Box 50.6: Merit-based incentive payment system measures related to anesthesiology

- Perioperative temperature management
- Patient-reported experience with anesthesia
- Nausea/vomiting prevention with combination therapy
- Prevention of central venous catheter-related bloodstream infections
- Central line ultrasound guidance
- Use of checklist for transfer of care to postanesthetic care unit
- Use of checklist for transfer of care to intensive care unit
- Sleep apnea: assessment of sleep symptoms
- Multimodal pain management
- Pain assessment and follow-up
- Safe opioid prescribing practices
- Documentation of anticoagulant and antiplatelet medications when performing neuraxial anesthesia/analgesia or interventional pain procedures

Box 50.7: Examples of decision support from anesthesia information management systems

Quality assurance
- Maintenance of normothermia notifications
- Presurgical antibiotic management notifications

Medication support
- Drug–drug interaction checking
- Drug–dose calculations
- Drug redosing reminders
- Drug–allergy checking

Regulatory and compliance support
- Concurrency checking
- Ensuring electronic records contain elements required for billing
- Attending physician attestation statements
- Case times (start of anesthesia care, end of anesthesia care)
- Case type (general/monitored anesthesia care/regional)
- Patient details (American Society of Anesthesiologists (ASA) physical status)

Support around critical events
- Algorithm display and guidance (malignant hyperthermia, advanced cardiac life support, ASA difficult airway algorithm)
- Critical event detection:
  - Chaotic electrocardiogram + no pulse oximetry wave form → consider ventricular fibrillation
  - ↓ Blood pressure + ↑ heart rate + ↓ end-tidal CO_2 → consider ↓ cardiac output from hypovolemia

suite might have to search for a $25,000 ultrasound instrument. RFID can be used to track, plan, and send shared equipment for OR procedures thereby improving efficiency. RFID can be inexpensively incorporated into the patient's armband so that when the patient enters the OR the most recent labs, images, planned surgical procedure, ordered antibiotics, and allergies are automatically displayed on a common screen. Adding RFID tags to surgical sponges and instruments could potentially eliminate retained foreign material in the surgical wound; and an RFID label on blood products could identify an incorrect unit as it is brought into the OR. At the writing of this chapter, these technologies remain in a state of development.

Distractions in the anesthetic and operating room environments

The anesthetic and OR environments require that the anesthesiologist's primary focus of attention be on the patient: closely following the physiological monitoring parameters, anesthetic delivery, and requirements for the surgery or procedure to deliver safe and effective anesthetic care, often for medically complex and unstable patients. At times there are long periods of relative calm and stability where less intervention on the part of the anesthesiologist is required. The anesthesia environment is full of potential distractions diverting one's attention away from the patient. A direct observational study of 30 anesthetics comprising over 31 h of anesthetic time revealed 424 distracting events, or about one every 4 min [83].

Events included unrelated conversations, music, noises outside the room, personnel entering the room to locate equipment, OR teaching activities, the anesthetist briefly leaving the room to locate equipment, and many others. Twenty-two percent of events were judged to potentially have a negative effect on patient care, including deterioration in physiological variables, delays in procedures, and repeated attempts at procedures.

In recent years the ubiquitous presence of computers in the anesthesia work area, including workstations for AIMS and personal laptops, tablets, and the now omnipresent smartphone, have increased the potential for electronic distractions in the OR [84]. There are just a few published studies of electronic distraction in the anesthesia environment, and as yet no clear data that the presence of these electronics has adverse effects on patient care. In a study of 1061 anesthetics where the AIMS computer also had access to the internet for use not directly related to the case, 16% of anesthetic time had the computer accessing the internet for non-AIMS applications [85]. In a clever analysis of hemodynamic instability during those times, there was no increase in hemodynamic variability or instability. Another large observer study of 319 anesthetics targeting self-initiated non-clinical distractions revealed that they occurred in 54% of cases [86]. The most common distraction was personal internet use; but these distractions only accounted for 2% of case time, and were not deemed to be the cause of any adverse events. It should be noted that the study subjects knew they were being observed and data for this recently published paper were collected from 2007 to 2009, before the pervasive presence of smartphones and social media in the OR.

Over the past several years, the presence of powerful handheld computers with increasingly fast processing speeds, known as smartphones, has revolutionized daily life. They have become an indispensable aid to anesthesiologists' ability to stay in touch, both professionally and personally, with the people and activities that are important to them. However, the easy ability to connect to the internet, social media, electronic mail, and text messaging applications makes it tempting for some anesthesia providers to be in near continuous interaction with their phones when they are not directly engaged in performing a procedure. Smartphone addiction is now an established diagnosis with validated criteria, and a recent study from China of 1440 medical students noted a prevalence of 29.8% of this disorder [87]. A survey from Turkey of 955 anesthesia providers of all levels including anesthetic nurses, residents, and attending anesthesiologists, revealed that 93.7% used smartphones during anesthetized patient care [88]. The most frequent use was phone calls (65%), text messaging (46%), social media (35%), and internet access (34%); 97% of respondents indicated that smartphones were never or seldom used during critical stages of anesthesia care; 87% said that they were never distracted because of smartphone use but 41% responded that they had witnessed their colleagues being distracted at least once.

Besides the obvious issue of possible distraction from high-quality patient care, the unprofessional appearance to others (surgeons, nurses, trainees) in the OR environment, as well as the perception of medicolegal risk if the anesthesiologist is seen engaging with their electronic device during a time when an adverse event occurs, should caution the anesthesiologist to limit these activities and to focus on the needs of the patient during all phases of anesthetic care [84]. Although the ASA has a general statement on distractions in the OR that includes electronic devices, more study is needed before specific recommendations can be made, such as limiting electronic device access to matters directly relevant to patient care [89].

KEY POINTS: SAFE SYSTEMS IN THE OPERATING ROOM

- Appropriate anesthesia information management systems can improve care and documentation
- Barcode reading for medications and instruments, and radiofrequency identification to track sponges and other equipment, could enhance operating room safety
- Minimizing distractions, including personal use of electronic devices, can lead to more focused and possibly improved safety in the operating room

Summary

The Institute of Medicine's seminal report, *To Err is Human*, first published in 2000 [3], started the patient safety revolution in healthcare that continues to this day. That study used previously collected data from large population-based studies to determine that there were between 44,000 and 98,000 preventable hospital deaths, and up to 1 million patient injuries each year in the United States during the decade of the 1990s. In a recent report retrospectively reviewing adverse events from 2002 to 2007 in 10 randomly selected North Carolina general acute care hospitals, there was no reduction in patient harms on an annual basis over the 6 years of the study [82], with an average of 25.1 harms per 100 admissions. The perioperative period was a significant source of patient harms. These new data demonstrate that despite all the recent emphasis on patient safety and improving outcomes, that medical error is still common and that there is still a very significant amount of work to be done. The Institute of Medicine's stated goal of 50% reduction in medical error has clearly not been met. Although data specific to pediatric care are sparse, the same issues are identified in pediatric practice as in medical care in general. Pediatric anesthesiologists are in a unique position, interfacing with all members of the perioperative care team, to take a leadership role in teamwork, communication, and patient safety, to prevent adverse events and deaths in the vulnerable pediatric population.

APPENDIX A

Appendix: Pediatric Anesthesia Drugs and Other Treatments in the Perioperative Period

Dean B. Andropoulos

Texas Children's Hospital; and Department of Anesthesiology, Baylor College of Medicine, Houston, TX, USA

Drug doses and treatments are those commonly recommended; each patient's treatment must be individualized, drug doses double checked for accuracy, and drug concentrations and modes of administration used according to local guidelines. Information is current at the time of publication; however, the practitioner must always be aware of new recommendations, and is responsible for determining the best course of treatment. Consult the textbook, hospital formulary, or authoritative internet resources, for a complete listing of indications, contraindications, interval dosing schedules, and side-effects of these drugs and treatments. All drugs are intravenous (IV) unless otherwise noted. Source for dosing information is the Texas Children's Hospital Drug Formulary, current as of November 2019, except where otherwise noted in the references.

Gregory's Pediatric Anesthesia, Sixth Edition. Edited by Dean B. Andropoulos and George A. Gregory.

Category	Drug/treatment	Bolus/loading dose	Infusion/continuous dose
Anesthetic, sedative, and analgesic agents			
Opioids	Fentanyl	1–10 μg/kg; 50–200 μg/kg total dose	5–20 μg/kg/h
	Remifentanil	0.25–1 μg/kg	0.05–2 μg/kg/min
	Sufentanil	0.1–5 μg/kg	0.1–3 μg/kg/h
	Morphine	0.03–0.2 mg/kg	0.01–0.05 mg/kg/h
	Meperidine (shivering)	1–2 mg/kg	NA
	Methadone	0.1 mg/kg	NA
	Hydromorphone	0.02 mg/kg	0.006 mg/kg/h
Benzodiazepines	Midazolam IV	0.03–0.1 mg/kg	0.05–0.1 mg/kg/h
	Midazolam PO	0.5–1 mg/kg	NA
	Lorazepam	0.25–0.1 mg/kg	NA
	Diazepam IV	0.05–0.3 mg/kg, max. 10 mg	NA
	Diazepam PO	0.04–0.3 mg/kg, max. 10 mg	NA
Barbiturates	Thiopental	1–6 mg/kg	NA
	Pentobarbital	1–6 mg/kg	NA
	Methohexital	1–3 mg/kg	NA
Other sedative/analgesic agents	Ketamine IV	1–2 mg/kg	NA
	Ketamine IM	5–10 mg/kg	NA
	Etomidate	0.1–0.3 mg/kg	NA
	Propofol	1–3 mg/kg	50–200 μg/kg/min
	Scopolamine	10 μg/kg	NA
	Dexmedetomidine	0.3–1 μg/kg	0.3–0.7 μg/kg/h
Neuromuscular blocking drugs and reversals	Vecuronium	0.1–0.3 mg/kg	0.05–0.1 mg/kg/h
	Rocuronium IV	0.6–1.2 mg/kg	NA
	Rocuronium IM	2 mg/kg	NA
	Atracurium	0.4–0.5 mg/kg	NA
	Cisatracurium	0.15–0.2 mg/kg	NA
	Pancuronium	0.1–0.2 mg/kg	NA
	Succinylcholine IV	1–2 mg/kg	NA
	Succinylcholine IM	4 mg/kg	NA
	Neostigmine	40–80 μg/kg	NA
	Glycopyrrolate	8–16 μg/kg	NA
	Sugammadex [1]	2–4 mg/kg, 16 mg/kg for emergency reversal of profound block	NA
Vasoactive drugs			
Inotropes/vasoconstrictors	Epinephrine	0.5–10 μg/kg	0.03–0.1 μg/kg/min
	Atropine IV	10–20 μg/kg	NA
	Atropine IM	20–40 μg/kg	NA
	Phenylephrine	0.5–3 μg/kg	0.05–0.5 μg/kg/min
	Ephedrine	0.05–0.2 mg/kg	NA
	Calcium chloride	10 mg/kg	5–10 mg/kg/h
	Calcium gluconate	30 mg/kg	NA
	Dopamine	NA	3–20 μg/kg/min
	Dobutamine	NA	3–20 μg/kg/min
	Milrinone	25–75 μg/kg	0.25–0.75 μg/kg/min
	Norepinephrine	NA	0.05–0.1 μg/kg/min
	Vasopressin	NA	0.02–0.05 units/kg/h
	Isoproterenol	NA	0.01–0.1 μg/kg/min
	Levosimendan [2–5]	6–12 μg/kg	0.05–0.2 μg/kg/min
	Triiodothyronine (T3) [6]	NA	0.05 μg/kg/h
Vasodilators/antihypertensives	Sodium nitroprusside	NA	0.3–5 μg/kg/min
	Nitroglycerine	NA	0.3–5 μg/kg/min
	Prostaglandin E1	NA	0.0125–0.05 μg/kg/min
	Epoprostenol	100–500 μg/kg	1–2 ng/kg/min; increase every 4–8 h to 25–40 ng/kg/min
	Treprostinil		1–2 ng/kg/min, increase every 8–12 h to 20–40 ng/kg/min
	Nesiritide	NA	0.01–0.03 μg/kg/min
	Fenoldepam	NA	0.025–0.3 μg/kg/min initially, titrate to max. 1.6 μg/kg/min
	Nicardipine	NA	0.5–3 mg/kg/h, max. 15 mg/h
	Clevidipine [7]	10–15 μg/kg	0.5–7 μg/kg/min
	Hydralazine	0.1–0.2 mg/kg	NA
	Phentolamine	0.1–0.2 mg/kg on CPB	NA
	Phenoxybenzamine	0.25–1 mg/kg on CPB	NA

Category	Drug/treatment	Bolus/loading dose	Infusion/continuous dose
	Labetalol	0.25–0.5 mg/kg	NA
	Enalaprilat	5–10 μg/kg	NA
	Sildenafil [8,9]	0.35–0.44 mg/kg over 1–3h	0.067 mg/kg/h
Antiarrhythmics/β-blockers	Lidocaine	1–2 mg/kg	20–50 μg/kg/min
	Procainamide	10–15 mg/kg	20–80 μg/kg/min
	Esmolol	250–500 μg/kg	50–300 μg/kg/min
	Propranolol	0.01–0.1 mg/kg	NA
	Amiodarone	5 mg/kg over 10–15 min, may repeat × 2 to max. 15 mg/kg	NA
	Verapamil	0.1–0.3 mg/kg	NA
	Adenosine	25–50 μg/kg; double if ineffective	NA
	Magnesium sulfate	25–50 mg/kg over 30–60 min	NA
	Digoxin	8–10 μg/kg first loading dose	NA
Antibiotics	Cefazolin	25 mg/kg, max. 1 g	NA
	Ampicillin	50 mg/kg, max. 1 g	NA
	Vancomycin	15 mg/kg, max. 1 g	NA
	Gentamycin	2.5 mg/kg, max. 120 mg	NA
	Nafcillin	50 mg/kg, max. 2 g	NA
	Clindamycin	10 mg/kg	NA
	Cefuroxime	25–30 mg/kg	NA
	Cefoxitin	30–40 mg/kg, max. 2 g	NA
	Pipericillin/tazobactam	100 mg/kg piperacillin component, max. 4 g	
Non-steroidal anti-inflammatory drugs/non-opioid analgesics	Ketorolac	0.5 mg/kg, max. 30 mg every 6 h	NA
	Acetaminophen PO	15 mg/kg, max. 1000 mg	NA
	Acetaminophen PR	20–30 mg/kg (one time)	NA
	Acetaminophen IV	12.5–15 mg/kg, max. 60–75 mg/kg/24 h or 3000 mg/24 h	NA
	Ibuprofen IV	5–10 mg/kg, max. 400 mg	NA
	Ibuprofen PO	5–10 mg/kg, max. 400 mg	NA
Malignant hyperthermia treatment	Dantrolene (use Ryanodex®; dilute 250 mg vial in 5 mL sterile water)	2.5 mg/kg; may repeat × 3 up to 10 mg/kg	NA
Local anesthetics	Lidocaine	Max. 5 mg/kg	NA
	Bupivacaine	Max. 2.5 mg/kg	NA
	Levobupivacaine	Max. 2.5 mg/kg	NA
	Ropivacaine	Max. 2 mg/kg	NA
	Tetracaine (spinal – infants <6 months)	0.4–0.8 mg/kg	NA
Local anesthetic toxicity	20% intralipid [10]	1 mL/kg; repeat × 2 to max. 3 mL/kg	0.25 mL/kg/min
Corticosteroids	Methylprednisolone	1–30 mg/kg depending on indication	5.4 mg/kg/h × 23 h for spinal cord injury
	Dexamethasone	0.25–1 mg/kg, max. 20 mg	NA
	Hydrocortisone	1–2 mg/kg	NA
Anticoagulants	Heparin	CPB: 300–400 units/kg	NA
	Bivalrudin [11,12]	Interventional cardiac catheter: 0.75 mg/kg	Catheter: 1.75 mg/kg/h
		CPB: 1 mg/kg; plus 1 mg/kg CPB prime	CPB: 2.5 mg/kg/h
	Argatroban	CPB: 35–100 μg/kg (ACT >400 s)	2–10 μg/kg/min
	Antithrombin III	50 units/kg; target levels 80–120% of normal	NA
Hemostasis agents	ε-aminocaproic acid [13]	Neonate 0–4 weeks: 40 mg/kg weight of patient; 0.1 mg/mL of CPB prime	30 mg/kg/h
		Neonate >4 weeks: 75 mg/kg weight of patient; 75 mg/kg CPB prime	75 mg/kg/h
	Tranexamic acid [14,15]	5–10 mg/kg	2.5–5 mg/kg/h
	Recombinant factor VIIa	30–90 μg/kg; may repeat × 2	NA
	Fibrinogen concentrate(RiaStap®)	70 mg/kg	NA
	Prothrombin complex concentrate-4 (KCentra®)	25–50 units/kg, max. 5000 units	
	Anti-inhibitor coagulant complex (FEIBA)	50–100 units/kg	

Category	Drug/treatment	Bolus/loading dose	Infusion/continuous dose
Diuretics	Furosemide	0.5–1 mg/kg, max. 40 mg	0.1–0.4 mg/kg/h
	Bumetanide	0.015–0.1 mg/kg, max. 2.5 mg	NA
	Mannitol	0.25–1 g/kg	NA
Perioperative nausea and vomiting/ gastrointestinal prophylaxis	Ondansetron	0.1 mg/kg, max. 4 mg	NA
	Granisetron	10–20 μg/kg	NA
	Metaclopromide	0.1–0.2 mg/kg, max. 10 mg	NA
	Promethazine (over age 2 years only)	0.25–0.5 mg/kg, max. 25 mg	
	Sodium citrate PO	30 mL	NA
Antihistamines	Diphenhydramine	1–2 mg/kg, max. 50 mg	NA
	Ranitidine	1 mg/kg, max. 50 mg	NA
	Famotidine	0.5 mg/kg, max. 40 mg	NA
Alkalinizing agents	Sodium bicarbonate (dilute 1:1 sterile H_2O for neonates)	1–2 meq/kg	NA
	Tromethamine (THAM) 0.3 M solution	3–6 mL/kg	NA
Inhaled agents/bronchodilators			**Inspired dose**
	Sevoflurane		1–8%
	Isoflurane		0.5–3%
	Desflurane		2–12%
	Nitrous oxide (N_2O)		50–75%
	Nitric oxide (iNO)		5–20 ppm
	Levalbuterol	8–12 MDI puffs per ETT; 0.075–0.15 mg/kg nebulized in 3 mL normal saline	NA
	Racemic epinephrine	0.25–0.5 mL of 2.25% racemic epinephrine in 3 mL normal saline	NA
	Prostacyclin (iloprost, PGI_2) [16]	2.5–5 μg nebulized in 3 mL normal saline	NA
Electrolytes/dextrose			**Infusion/continuous dose**
	25% dextrose in water (50% dextrose diluted 1:1)	0.25–0.5 mL/kg	NA
	Potassium chloride (KCl)	0.5–1 meq/kg	NA
	3% NaCl	3–5 mL/kg	NA
Insulin (regular)	Insulin (regular): dose based on plasma glucose levels	0.02–0.1 units/kg	0.02–0.1 units/kg/h
Sedation/analgesia reversal	Naloxone	1–10 μg/kg	NA
	Flumazenil	1–5 μg/kg; repeat as needed, max. dose 1 mg	NA
Immunosuppressants (transplant)	Basiliximab	<35 kg: 10 mg; >35 kg: 20 mg	NA
	Mycophenolate	15 mg/kg, max. 1.5 g	NA
Miscellaneous drugs	Caffeine citrate	10–20 mg/kg	NA
Transfusions	Packed red blood cells	10–15 mL/kg	NA
	Whole blood	10–15 mL/kg	NA
	Platelets	1 unit/5 kg will increase platelet count by 50,000; 1 pheresis unit = 6 random donor units	NA
	Cryoprecipitate	1 unit per 5 kg, max. 4 units	NA
	Fresh frozen plasma	10–20 mL/kg	NA
Intravascular volume expansion	5% albumin	10–20 mL/kg	NA
	25% albumin	2–4 mL/kg; 0.5–1 g/kg	NA
Direct current cardioversion/ defibrillation	External synchronized cardioversion	0.5 J/kg; increase to max. 1 J/kg; max. 100 kg	NA
	External defibrillation	2–5 J/kg; increase if ineffective; max. 200 J biphasic; 360 J monophasic	NA
	Internal defibrillation	5 J; increase to 10 J if ineffective	NA
	Internal synchronized cardioversion	2 J; increase to 5 J if ineffective	NA

ACT, activated clotting time; CPB, cardiopulmonary bypass; ETT, endotracheal tube; IM, intramuscular; IV, intravenous; J, joules; max., maximum; MDI, metered dose inhaler; meq, milliequivalents; mg, milligram; μg, microgram; ng, nanogram; NA, not applicable; PO, per os; ppm, parts per million; PR, per rectum.

APPENDIX B

Appendix: Pediatric Normal Laboratory Values

Dean B. Andropoulos
Texas Children's Hospital; and Department of Anesthesiology, Baylor College of Medicine, Houston, TX, USA

Values are reference values from Texas Children's Hospital Clinical Laboratory, current as of November 2019. All practitioners are urged to consult the normal laboratory values for their local laboratory, as these may differ from those listed below. They are also advised to continually check for updated normal ranges.

For conversion of conventional (US) units to SI units, see: http://www.soc-bdr.org/content/rds/authors/unit_tables_conversions_and_genetic_dictionaries/e5196/index_en.html (accessed May 2019).

Gregory's Pediatric Anesthesia, Sixth Edition. Edited by Dean B. Andropoulos and George A. Gregory.

Clinical chemistry reference values (United States/conventional units)

Test	Reference range	
Albumin (CSF)	10–30 mg/dL	
Albumin (random urine)	<37 mg/L or <3.7 mg/dL	
Albumin (S, P)		
Age	*Male/female (g/dL)*	
0–14 days	2.6–4.2	
15–364 days	2.3–4.8	
1–7 years	3.5–4.7	
8–14 years	3.7–5.0	
	Male (g/dL)	*Female (g/dL)*
15–18 years	3.9–5.3	3.5–5.2
	Male/female (g/dL)	
≥19 years	3.5–5.0	
Albumin/creatinine ratio (random urine)	<16 mg/g	
Alanine aminotransferase (S, P)		
Age	*Male/female (U/L)*	
0–11 months	6–50	
1–3 years	6–45	
4–6 years	10–25	
7–9 years	10–35	
	Male (U/L)	*Female (U/L)*
10–11 years	10–35	10–30
12–13 years	10–55	10–30
14–15 years	10–45	6–30
16–18 years	10–40	6–35
≥19 years	21–72	9–52
Alkaline phosphatase (S, P)		
Age	*Male (U/L)*	*Female (U/L)*
0–7 days	77–265	65–270
8–30 days	91–375	65–365
1–3 months	60–360	80–425
4–6 months	55–325	80–345
7–12 months	60–300	60–330
1–3 years	129–291	129–291
4–6 years	134–346	134–346
7–9 years	156–386	156–386
10–11 years	120–488	116–515
12–13 years	178–455	93–386
14–15 years	116–483	62–209
16–19 years	58–237	45–116
≥20 years	38–126	38–126
Allergen-specific IgE	*kU/L*	
Class scoring 0: normal	≤0.34	
Class scoring 1: low level of allergy	0.35–0.69	
Class scoring 2: moderate level of allergy	0.70–3.49	
Class scoring 3: high level of allergy	3.50–17.49	
Class scoring 4: very high level of allergy	17.50–49.99	
Class scoring 5: very high level of allergy	50.00–99.99	
Class scoring 6: very high level of allergy	≥100	
Alpha-1-antitrypsin (S)		
Age	*mg/dL*	
0–1 years	92–282	
1–4 years	94–156	
4–13 years	102–159	
>14 years	97–203	

Test	Reference range	
Alpha-fetoprotein (S)		
Age	*ng/mL*	
0–30 days	50–100,000	
1–3 months	40–1000	
4 months–18 years	0–12	
Adult (≥19 years)	<10	
Ammonia (P)		
Age	*μmol/L*	
0–7 days	54–94	
8–30 days	47–80	
1–12 months	15–47	
1–15 years	22–48	
≥16 years	9–26	
Amylase (S, P)	30–115 U/L	
Amylase (U) – random	No reference range	
Amylase (U) – timed	4–37 U/2 h	
Asparate aminotransferase (S, P)		
Age	*Male/female (U/L)*	
0–5 days	35–140	
6 days–3 years	20–60	
4–6 years	15–50	
7–9 years	15–40	
	Male (U/L)	*Female (U/L)*
10–11 years	10–60	10–40
12–15 years	15–40	10–30
16–18 years	10–45	5–30
≥19 years	17–59	14–36
Beta-hydroxybutyrate (S, P)	<0.30 mmol/L (12 h fasting)	
Beta 2-microglobulin	1.1–2.5 mg/L	
Bilirubin (S, P)	*Premature (mg/dL)*	*Full-term (mg/dL)*
Age	*Total*	*Total*
Up to 23 h	1–8	2–6
24–48 h	6–12	6–10
3–5 days	10–14	4–8
≥1 month	*mg/dL*	
Bu unconjugated	<1.0	
Total	0.2–1.0	
All ages		
Bc conjugated	<0.3	
Blood gases: pH		
Capillary/arterial		
Age		
Newborn	7.33–7.49	
1 day	7.25–7.43	
2–30 days	7.32–7.43	
1 month	7.34–7.43	
2 months–1 year	7.34–7.46	
≥2 years		
Male	7.35–7.45	
Female	7.36–7.44	
Venous		
All ages	7.32–7.42	
Blood gases: pCO_2		
Capillary/arterial		
Age	*mmHg*	
0–1 month	27–40	
2 months–1 year	26–41

CKMB (S, P)		
Normal	<5 ng/mL	
Borderline	5–10 ng/mL	
Abnormal	>10 ng/mL	

(*Continued*)

Test	Reference range	
CKMB activity – West Campus only (P)	CKMB enzymatic (CKMBE): CKMB activity <16 U/L should be considered a negative finding in the context of a suspected ED MI CKMB percent (CKMBP): CKMB percentage of <4% or *greater than* 25% of total CK activity is likely not the consequence of an increase in plasma CKMB. A positive result should be confirmed by ordering the CK index (mass assay – test code CKMBI) available through the main campus	
Creatinine (S, P)

10–13 years	30–83
14–17 years	19–83
≥18 years	18–72

CKMB, creatine kinase MB band; CSF, cerebrospinal fluid; DHEA-S, dehydroepiandrosterone-sulfate; ED, emergency department; EDTA, ethylene diamine tetra-acetic acid; Hb, hemoglobin; HCG, human chorionic gonadotropin; HLD, high-density lipoprotein; HPLC, high-performance liquid chromatography; Ig, immunoglobulin; LDL, low-density lipoprotrine; MI, myocardial infarction; P, plasma; S, serum; SWT, sweat; U, urine; WB, whole blood.

Hematology reference ranges (United States/conventional units)

Test	Reference range						
White blood cells (B)							
Age	*×10³/μL*						
0–30 days	9.1–34.0						
1 month	5.0–19.5						
2–11 months	6.0–17.5						
1–6 years	5.0–14.5						
7–12 years	5.0–14.5						
13–18 years	4.5–13.5						
≥19 years	4.5–11.0						
Age	*Seg%*	*Band%*	*Lymph%*	*Monos%*	*Eos%*	*Baso%*	*ANC*
0–30 days	32–67	0–8	25–37	0–9	0–2	0–1	6.0–23.5
1 month	20–46	0–4.5	28–84	0–7	0–3	0–1	1.0–9.0
2–11 months	20–48	0–3.8	34–88	0–5	0–3	0–1	1.0–8.5
1–6 years	37–71	0–1.0	17–67	0–5	0–3	0–1	1.5–8.0
7–12 years	33–76	0–1.0	15–61	0–5	0–3	0–1	1.5–8.0
13–18 years	33–76	0–1.0	15–55	0–4	0–3	0–1	1.8–8.0
≥19 years	33–76	0–0.7	14–54	0–4	0–3	0–1	1.8–7.7
Red blood cells (B)							
Age	*×10⁶/μL*						
0–30 days	4.1–6.7						
1 month	3.0–5.4						
2–6 months	2.7–4.5						
7 months–2 years	3.7–5.3						
3–6 years	3.9–5.3						
7–12 years	4.0–5.2						
13–18 years/female	4.1–5.1						
13–18 years/male	4.5–5.3						
≥19 years/female	4.2–5.4						
≥19 years/male	4.7–6.0						
Hemoglobin (B)							
Age	*g/dL*						
0–30 days	15.0–22.0						
1 month	10.5–14.0						
2–6 months	9.5–13.5						
7 months–2 years	10.5–14.0						
3–6 years	11.5–14.5						
7–12 years	11.5–15.5						
13–18 years/female	12.0–16.0						
13–18 years/male	13.0–16.0						
≥19 years/female	12.0–16.0						
≥19 years/male	13.5–17.5						
Hematocrit (B)							
Age	*%*						
0–30 days	44–70						
1 month	32–42						
2–6 months	29–41						
7 months–2 years	33–39						
3–6 years	34–40						
7–12 years	35–45						
13–18 years/female	36–45						
13–18 years/male	37–49						
≥19 years/female	36–46						
≥19 years/male	41–53						
Mean corpuscular volume							
Age	*fL*						
0–30 days	86–115						
1 month	72–88						

(*Continued*)

Test	Reference range		
2–6 months	72–82		
7 months–2 years	76–90		
3–6 years	76–90		
7–12 years	76–90		
13–18 years	78–95		
≥19 years	78–100		
Mean corpuscular hemoglobin			
Age	*pg*		
0–30 days	33.0–39.0		
1 month	28.0–40.0		
2–6 months	25.0–35.0		
7 months–2 years	23.0–31.0		
3–6 years	25.0–30.0		
7–12 years	26.0–30.0		
13–18 years	26.0–32.0		
≥19 years	27.0–31.0		
Mean corpuscular hemoglobin concentration			
Age	*g/dL*		
0–30 days	32.0–36.0		
1 month	33.0–38.0		
2–6 months	28.0–36.0		
7 months–2 years	30.0–34.0		
3–6 years	32.0–36.0		
7–12 years	32.0–36.0		
13–18 years	32.0–36.0		
≥19 years	32.0–36.0		
Red blood cell distribution width, coefficient of variation			
Age	*%*		
0–30 days	13.0–18.0		
1 month	13.0–18.0		
2–6 months	13.0–18.0		
7 months–2 years	11.5–16.0

7–12 years	11.5–14.0		
13–18 years	11.5–14.0		
≥19 years	11.5–14.0		
Red blood cell distribution width, size distribution			
Age	*fL*		
0–30 days	38.5–49.0		
1 month	38.5–49.0		
2–6 months	38.5–49.0		
7 months–2 years	38.5–49.0		
3–6 years	38.5–49.0		
7–12 years	38.5–49.0		
13–18 years	38.5–49.0		
≥19 years	38.5–49.0		
Platelet count (B)	150,000–450,000 μL		
Mean platelet volume (B)	6–10 fL		
Immature platelet fraction (B)			
Age		*Female (%)*	*Male (%)*
0–6 months		1.3–6.8	2.0–6.8
6 months–<2 years		1.4–4.5	1.4–3.8
2–<6 years		1.0–3.6	1.1–3.6
6–<12 years		1.0–4.7	1.0–4.9
12–18 years		1.4–6.4	1.6–6.1
≥18 years		1.6–4.9	1.6–7.1

Test	Reference range
Reticulocyte count percentage (B)	
Age	*%*
0–2 days	3.0–7.0
3–4 days	1.0–3.0
>4 days	0.5–1.5
Reticulocyte count absolute (B)	
Age	*× 10^6/μL*
0–2 days	0.140–0.220
3–4 days	0.040–0.110
>4 days	0.020–0.080
Reticulocyte hemoglobin content (B)	
Age	*pg*
<2 years	24.5–35.2
>2 years	27.1–35.4
Sedimentation rate (B)	0–20 mm/h
Urinalysis (U)	
Specific gravity	1.001–1.035
pH	4–9
Protein	Neg
Glucose	Neg
Ketone	Neg
Bilirubin	Neg
Urobilinogen	0.1–1.0
WBC	0–4/ HPF
RBC	0–4/ HPF
EPI (epithelial cells)	0–4/ HPF

ANC, absolute neutrophil count; B, blood; EPI, epithelial cells; RBC, red blood cells; U, urine; WBC, white blood cells.

Clinical coagulation laboratory reference ranges (United States/conventional units)

Test	Reference range
ADAMTS13 (P)	>65% normal activity
Anti-β_2-glycoprotein1 – IgG (S)	<20.1 SGU
Anti-β_2-glycoprotein 1 – IgM (S)	<20.1 SMU
Anti-β_2-glycoprotein 1 – IgA (S)	<20.1 SAU
Anticardiolipin IgG (S)	<23.0 GPL
Anticardiolipin IgM (S)	<11.0 MPL
Antithrombin (P)	
Adult	85–130%
Normal ranges for healthy full-term infants	
Day 1	63% (39–87%)
Day 5	67% (41–93%)
Day 30	78% (48–108%)
Day 90	97% (73–121%)
Day 180	104% (84–124%)
D-dimer (P)	
Adult	≤0.40 μg/mL FEU
Neonatal reference range from cord blood	≤3.40 μg/mL FEU
Dilute Russell viper venom time (DRVVT) test (P)	
DRVVT S/C Ratio	<1.17
DRVVT result	Negative
Factor 2 (P)	50–150%
Factor 5 (P)	59–150%
Factor 7 (p)	58–150%
Factor 8 (P)	47–169%
Factor 9 (P)	67–141%
Factor 10 (P)	65–142%
Factor 11 (P)	48–139%
Factor 12 (P)	41–140%
Fibrinogen (P)	
Adult	220–440 mg/dL
Neonatal reference range from cord blood	135–283 mg/dL
INR (P)	
Adult	0.8–1.2
Neonatal reference range from cord blood	1.0–1.4
Lovenox (P)	
Prophylactic:	0.20–0.40 U/mL
Therapeutic:	0.50–1.00 U/mL
Platelet function assay (WB)	84–183 s
Collagen/epinephrine Collagen/ADP	69–126 s
Protein C (P)	
Adult	80–175%
Normal ranges for healthy full-term infants	
Day 1	35% (17–53%)
Day 5	42% (20–64%)
Day 30	43% (21–65%)
Day 90	54% (28–80%)
Day 180	59% (37–81%)
(AM J Pediatric Hematology Oncol 1990:12:95–104)	
Please note that these ranges were not established using the current ranges and analyzer at TCH Coagulation Lab	
Protein S (P)	
Adult	58–128%
Normal ranges for healthy full-term infants	
Day 1	36% (12–60%)
Day 5	50% (22–78%)
Day 30	63% (33–93%)
Day 90	86% (54–118%)
Day 180	87% (55–119%)
Please note that these ranges were not established using the current ranges and analyzer at TCH Coagulation Lab [1]	
Prothrombin time (P)	
Adult	11.4–15.8 s
Neonatal reference range from cord blood	12.9–16.9 s
Partial thromboplastin time (P)	
Adult	24.8–34.4 s
Neonatal reference range from cord blood	28.7–53.7 s
STACLOT tube 1–tube 2	<9.8
Result	Negative
Reptilase time (P)	16.3–19.8 s
ROTEM (WB)	
INTEM	
Clotting time (CT)	122–208 s
Clot formation time (CFT)	45–110 s
Alpha angle	70–81 degrees
A10	48–63 mm
A20	51–72 mm
Maximum clot firmness (MCF)	51–72 mm
Maximum lysis (ML)	7–21 %
EXTEM	
Clotting time (CT)	43–82 s
Clot formation time (CFT)	48–127 s
Alpha angle	65–80 degrees
A10	48–67 mm
A20	50–70 mm
Maximum Clot Firmness (MCF)	52–72 mm
Maximum lysis (ML)	8–22%
FIBTEM	
A10 A20	8–25 mm
Maximum clot firmness (MCF)	10–23 mm
	10–23 mm
Thrombin time (P)	15.0–19.0 s
VWF antigen (P)	56–176%
VWF ristocetin co-factor (P)	48–142%
VWF activity/antigen ratio	0.7–1.2
Unfractionated heparin (P)	0.35–0.70 U/mL

ADP, adenosine diphosphate; FEU, fibrinogen equivalent units; INR, international normalized ratio; P, plasma; S, serum; WB, whole blood.
