Contents

List of Contributors

Warwick Ames MBBS, FRCA
Assistant Professor of Anesthesiology and Pediatrics, Duke University Medical Center, Durham, NC, USA

Dean B. Andropoulos MD, MHCM
Anesthesiologist-in-Chief, Texas Children's Hospital; Professor of Anesthesiology and Pediatrics, Department of Anesthesiology, Baylor College of Medicine, Houston, TX, USA

James Armstrong MD, FRCPC
Assistant Professor of Anesthesia, Jacobs School of Medicine and Biomedical Sciences, John R. Oishei Children's Hospital, Buffalo, NY, USA

Elena Ashikhmina MD, PhD
Senior Associate Consultant, Department of Anesthesiology; Assistant Professor of Anesthesiology, Mayo Clinic, Rochester, MN, USA

Rahul G. Baijal MD
Associate Professor of Anesthesiology and Pediatrics, Baylor College of Medicine; Texas Children's Hospital, Houston, TX, USA

Melania M. Bembea MD, MPH, PhD
Associate Professor of Anesthesiology and Critical Care Medicine, Department of Anesthesiology and Critical Care Medicine, Johns Hopkins University School of Medicine, Baltimore, MD, USA

James Bennett MBBS, FRCA
Consultant Paediatric Anaesthetist, Birmingham Children's Hospital, Birmingham, UK

Charles Berde MD, PhD
Sara Page Mayo Chair in Pediatric Pain Medicine; Chief, Division of Pain Medicine, Department of Anesthesiology, Perioperative, and Pain Medicine, Children's Hospital; Professor of Anesthesia (Pediatrics), Harvard Medical School, Boston, MA, USA

Robert A. Berg MD
Russell Raphaely Endowed Chair, Division Chief, Critical Care Medicine, The Children's Hospital of Philadelphia; Professor of Anesthesiology and Critical Care Medicine, The University of Pennsylvania School of Medicine, Philadelphia, PA, USA

Bruno Bissonnette MD
Professor, Department of Anesthesia and Critical Care Medicine, University of Toronto, Toronto, Canada

Kara A. Bjur MD
Senior Associate Consultant, Department of Anesthesiology; Instructor of Anesthesiology, College of Medicine, Mayo Clinic, Rochester, MN, USA

Stephanie A. Black MD, EdM
Assistant Professor, Perelman School of Medicine, University of Pennsylvania; Associate Director, Pediatric Anesthesiology Fellowship Program; Lead, Professional Development Programs, Department of Anesthesiology and Critical Care Medicine, The Children's Hospital of Philadelphia, Philadelphia, PA, USA

Adrian T. Bosenberg MBChB, FFA(SA)
Professor, Department of Anesthesiology, University Washington and Seattle Children's Hospital, Seattle, WA, USA

Ken M. Brady MD
Professor, Departments of Anesthesiology and Pediatrics, Northwestern University Feinberg School of Medicine, Chicago, IL, USA

Peter N. Bromley MBBS, FRCA
Consultant Paediatric Anaesthetist, Birmingham Children's Hospital, Birmingham, UK

T.C.K. Brown AM, MB ChB, MD, FANZCA, FRCA (deceased)
(Formerly) Head of Anaesthesia, Royal Children's Hospital, Melbourne, Australia

Stefan Budac MD
Attending Anesthesiologist, Department of Anesthesiology and Pain Medicine, Seattle Children's Hospital; Washington School of Medicine, Seattle, WA, USA

Nicholas Carling, MD
Associate Professor, Department of Anesthesiology, Baylor College of Medicine; Texas Children's Hospital, Houston, TX, USA

Arvind Chandrakantan MD
Associate Professor, Department of Pediatric Anesthesiology, Perioperative, and Pain Medicine, Texas Children's Hospital; Department of Anesthesiology, Baylor College of Medicine, Houston, TX, USA

Julia Chen MD
Assistant Professor, Department of Anesthesiology, Baylor College of Medicine, Houston, TX, USA

Julianna Clark-Wronski MD
Pediatric Anesthesiology, UC Davis Children's Hospital, University of California, Davis, CA, USA

Joseph Cravero MD
Senior Associate in Perioperative Anesthesia and Pain Medicine, and Associate Professor of Anaesthesia, Harvard Medical School, Boston, MA, USA

Jayant K. Deshpande MD, MPH
University of Arkansas for Medical Sciences, Arkansas Children's Hospital, Little Rock, AR, USA

James A. DiNardo MD
Cardiac Anesthesia Service, Boston Children's Hospital; Professor, Department of Anesthesia, Harvard Medical School, Boston, MA, USA

Laura A. Downey MD
Assistant Professor of Anesthesiology and Pediatrics, Emory University School of Medicine; Children's Healthcare of Atlanta at Egleston, Atlanta, GA, USA

R. Blaine Easley MD
Professor, Departments of Pediatrics and Anesthesiology, Baylor College of Medicine, Houston, TX, USA

Claude Ecoffey MD
Chairman, Pôle Anesthésie-Samu-Urgences-Réanimations et Médecine Interne-Gériatrie, Hôpital Pontchaillou, Université de Rennes 1, Rennes, France

Ross Fairgrieve MBChB, FRCA
Consultant in Paediatric Anaesthesia and Pain Management, Department of Anaesthesia, Royal Hospital for Children, Glasgow, UK

Lynne Ferrari MD
Associate Chair for Perioperative Anesthesia, Department of Anesthesiology, Critical Care and Pain Medicine, Boston Children's Hospital; Associate Professor of Anaesthesia, Harvard Medical School, Boston, MA, USA

John E. Fiadjoe MD
Associate Professor of Anesthesiology, University of Pennsylvania School of Medicine; Attending Anesthesiologist, Department of Anesthesiology and Critical Care, The Children's Hospital of Philadelphia, PA, USA

Randall Flick MD, MPH
Consultant, Departments of Anesthesiology and Pediatrics; Professor of Anesthesiology and Pediatrics, College of Medicine, Mayo Clinic; Director, Mayo Clinic Children's Center, Rochester, MN, USA

Maria Victoria Fraga MD
Neonatology Fellow, Department of Anesthesiology and Critical Care Medicine, The University of Pennsylvania School of Medicine; The Children's Hospital of Philadelphia, Philadelphia, PA, USA

Gennadiy Fuzaylov MD
Assistant Anesthetist, Department of Anesthesia, Critical Care, and Pain Management, Massachusetts General Hospital; Assistant Professor of Anaesthesia, Harvard Medical School, Boston, MA, USA

Jeffrey Galinkin MD
US Anesthesia Partners, Greenwood Village, CO, USA

Priscilla J. Garcia MD
Staff Pediatric Anesthesiologist, Texas Children's Hospital; Associate Professor, Anesthesiology and Pediatrics, Department of Anesthesiology, Baylor College of Medicine, Houston, TX, USA

Dheeraj Goswami MD
Director of Cardiac Anesthesia, Assistant Professor of Anesthesiology and Critical Care Medicine, Johns Hopkins University School of Medicine, Baltimore, MD, USA

Erin A. Gottlieb MD
Chief, Pediatric Cardiac Anesthesiology, Texas Center for Pediatric and Congenital Heart Disease, Dell Children's Hospital; Associate Professor, Department of Surgery and Perioperative Care, Dell Medical School, The University of Texas at Austin, Austin, TX, USA

Christine Greco MD
Director, Acute Pain Services, Department of Anesthesiology, Perioperative, and Pain Medicine, Children's Hospital; and Assistant Professor (Anaesthesia), Harvard Medical School, Boston, MA, USA

George A. Gregory MD
Department of Anesthesia and Perioperative Care, University of California San Francisco, San Francisco, CA, USA

Susan H. Guttentag MD
Associate Professor of Pediatrics, Director, Neonatal-Perinatal Fellowship Program, Department of Anesthesiology and Critical Care Medicine, The University of Pennsylvania School of Medicine; The Children's Hospital of Philadelphia, Philadelphia, PA, USA

Zoe Harclerode FRCA
Consultant Paediatric Anaesthetist, Sheffield Children's Hospital, Sheffield, UK

Tracy E. Harrison MD
Consultant, Department of Anesthesiology; Assistant Processor of Anesthesiology, College of Medicine, Mayo Clinic, Rochester, MN, USA

Robert S. Holzman MD, MA (Hon), FAAP
Senior Associate in Anesthesia, Boston Children's Hospital; Professor of Anesthesia, Harvard Medical School, Boston, MA, USA

Philipp J. Houck MD
Department of Anesthesiology, Columbia University College of Physicians and Surgeons, New York, NY, USA

Todd J. Kilbaugh MD
Associate Professor of Anesthesiology and Critical Care Medicine, The Children's Hospital of Philadelphia; The University of Pennsylvania School of Medicine, Philadelphia, PA, USA

Remek Kocz MD, MS
Clinical Assistant Professor of Anesthesiology, Jacobs School of Medicine and Biomedical Sciences, John R. Oishei Children's Hospital, Buffalo, NY, USA

Barry D. Kussman MBBCh, FFA(SA), FAAP
Associate Professor of Anaesthesia, Department of Anaesthesia, Harvard Medical School; Senior Associate in Cardiac Anesthesia, Department of Anesthesiology, Critical Care and Pain Medicine, Boston Children's Hospital, Boston, MA, USA

Cathy R. Lammers MD
Pediatric Anesthesiology, UC Davis Children's Hospital, University of California, Davis, CA, USA

Sarah A. Lee MD
Assistant Professor and Director of Trauma Anesthesiology Fellowship, Department of Anesthesiology and Pain Medicine, University of Washington School of Medicine, Seattle, WA, USA

Jerrold Lerman MD, FRCPC, FANZCA
Clinical Professor of Anesthesia, Jacobs School of Medicine and Biomedical Sciences, John R. Oishei Children's Hospital, Buffalo, NY, USA

Ronald S. Litman DO
Professor of Anesthesiology and Pediatrics, University of Pennsylvania School of Medicine; Attending Anesthesiologist, Department of Anesthesiology and Critical Care, The Children's Hospital of Philadelphia, PA, USA

Lauren M. Y. Lobaugh MD
Staff Anesthesiologist, Texas Children's Hospital; Assistant Professor, Department of Anesthesiology, Perioperative, and Pain Medicine, Baylor College of Medicine, Houston, TX, USA

Justin L. Lockman MD, MSEd
Assistant Professor, Perelman School of Medicine, University of Pennsylvania; Director, Pediatric Anesthesiology Fellowship Program; Associate Director of Education, Department of Anesthesiology and Critical Care Medicine, The Children's Hospital of Philadelphia, Philadelphia, PA, USA

Andreas W. Loepke MD, PhD, FAAP
Endowed Chair in Pediatric Cardiac Anesthesiology, Professor of Anesthesiology and Critical Care, and Professor of Pediatrics, Perelman School of Medicine, University of Pennsylvania; Chief, Cardiac Anesthesiology, Department of Anesthesiology and Critical Care Medicine, The Children's Hospital of Philadelphia, Philadelphia, PA, USA

Mohamed Mahmoud MD
Professor of Clinical Anesthesia, Department of Anesthesiology, Cincinnati Children's Hospital Medical Center, University of Cincinnati, Cincinnati, OH, USA

Shobha Malviya, MD
Associate Director, Pediatric Anesthesiology; Professor of Anesthesiology, Department of Anesthesiology, University of Michigan, Ann Arbor, MI, USA

David Mann MD
Staff Pediatric and Obstetric Anesthesiologist, Texas Children's Hospital; Associate Professor, Anesthesiology and Pediatrics, Department of Anesthesiology, Baylor College of Medicine, Houston, TX, USA

Lynn D. Martin MD, FAAP, FCCM
Director, Department of Anesthesiology and Pain Medicine; Medical Director, Bellevue Clinics and Surgery Center, Seattle Children's Hospital; Professor of Anesthesiology and Pediatrics (Adjunct), University of Washington School of Medicine, Seattle, WA, USA

Markus Martini PD, Dr. med.
Department of Maxillo-Facial Surgery, St. Lukas Hospital, Solingen, Germany

Keira P. Mason MD
Senior Associate in Anesthesia, Department of Anesthesiology, Critical Care, and Pain Medicine, Boston Children's Hospital; Associate Professor of Anesthesia (Radiology), Harvard Medical School, Boston, MA, USA

Jean X. Mazoit MD, PhD
Staff Anesthetist, Département d'Anesthésie-Réanimation, Hôpitaux Universitaires Paris-Sud AP-HP, Paris, France

Jamie McElrath Schwartz MD
Medical Director, Pediatric Intensive Care Unit; Assistant Professor of Anesthesiology and Critical Care Medicine, Johns Hopkins University School of Medicine, Baltimore, MD, USA

Grant McFadyen MBChB, DA(SA), FRCA
Attending Anesthesiologist, Lucille Packard Children's Hospital; Assistant Professor, Stanford University School of Medicine, Stanford, CA, USA

Peggy McNaull MD
Professor of Anesthesiology and Pediatrics, Associate Chief Medical Officer, Quality and Safety, Vice Chair for Patient Safety and Quality Improvement, Department of Anesthesiology, University of North Carolina, Chapel Hill, NC, USA

Martina Messing-Jünger Prof., Dr. med.
Department of Neurosurgery, Asklepios Klinik Sankt Augustin, Sankt Augustin, Germany

Bruce E. Miller MD
Chief, Division of Pediatric Anesthesiology and Associate Professor of Anesthesiology and Pediatrics, Emory University School of Medicine; Director, Pediatric Cardiac Anesthesiology, Children's Healthcare of Atlanta at Egleston, Atlanta, GA, USA

Wanda C. Miller-Hance MD, FACC, FAAP, FASE
Associate Director, Arthur S. Keats Division of Pediatric Cardiovascular Anesthesiology, Texas Children's Hospital; Department of Anesthesiology, Perioperative and Pain Medicine, and Department of Pediatrics, Baylor College of Medicine, Houston, TX, USA

Katharina B. Modes MD
Department of Anesthesiology, Monroe Carell Jr Children's Hospital at Vanderbilt, Vanderbilt University Medical Center, Nashville, TN, USA

Anthony Moores MBChB, FRCA
Consultant in Paediatric Anaesthesia and Pain Management, Department of Anaesthesia, Royal Hospital for Children, Glasgow, UK

Ryan Morgan MD
Assistant Professor of Anesthesiology and Critical Care Medicine, The Children's Hospital of Philadelphia; The University of Pennsylvania School of Medicine, Philadelphia, PA, USA

Neil S. Morton MD, FRCA
Retired Reader in Paediatric Anaesthesia and Pain Management, Department of Anaesthesia, Royal Hospital for Children, Glasgow, UK

Vinay M. Nadkarni MD MS
Endowed Chair, Pediatric Critical Care Medicine, The Children's Hospital of Philadelphia; The University of Pennsylvania School of Medicine, Philadelphia, PA, USA

Olubukola O. Nafiu MD
Director, Pediatric Anesthesia Research, and Associate Professor of Anesthesiology, Department of Anesthesiology, University of Michigan, Ann Arbor, MI, USA

Manchula Navaratnam MD
Pediatric Cardiac Anesthesiologist, Lucille Packard Children's Hospital at Stanford; Clinical Assistant Professor of Anesthesia, Department of Anesthesia, Stanford University School of Medicine, Palo Alto, CA, USA

Roland Neumann MD
Consultant in Neonatal Intensive Care, Department of Neonatology, University of Basel Children's Hospital, Basel, Switzerland

Kirsten C. Odegard MD
Cardiac Anesthesia Service, Boston Children's Hospital; Associate Professor, Department of Anesthesia, Harvard Medical School, Boston, MA, USA

Olutoyin A. Olutoye MD, MSc
Professor, Department of Pediatric Anesthesiology, Perioperative, and Pain Medicine, Texas Children's Hospital; Department of Anesthesiology, Baylor College of Medicine, Houston, TX, USA

Christina M. Pabelick MD
Consultant, Department of Anesthesiology; Professor of Anesthesiology and Physiology, College of Medicine, Mayo Clinic, Rochester, MN, USA

Zoel Quinonez MD
Clinical Assistant Professor, Departments of Anesthesiology, Perioperative and Pain Medicine, Stanford University School of Medicine, Stanford, CA, USA

Ellen Rawlinson MA, MBBChir, MRCP, FRCA
Consultant Paediatic Anaesthetist, Great Ormond Street Hospital, London, UK

Mohamed A. Rehman MD
Professor of Anesthesiology, Critical Care, and Pediatrics; Chair, Department of Anesthesiology, Johns Hopkins All Children's Hospital, St Petersburg, FL, USA

Michael Richards BM, MRCP, FRCA
Attending Anesthesiologist, Department of Anesthesiology and Pain Medicine, Seattle Children's Hospital; Assistant Professor, University of Washington School of Medicine, Seattle, WA, USA

Becky J. Riggs MD
Assistant Professor of Anesthesiology and Critical Care Medicine, Johns Hopkins University School of Medicine, Baltimore, MD, USA

Margo R. Rollins MD
Assistant Professor of Pathology, Department of Pathology, Emory University School of Medicine; Assistant Medical Director of Tissue, Transfusion, and Apheresis, Center for Transfusion and Cellular Therapy, Children's Healthcare of Atlanta at Egleston, Atlanta, GA, USA

Mark D. Rollins MD, PhD
Professor and Director Obstetric Anesthesia, Department of Anesthesiology, University of Utah, Salt Lake City, UT, USA

Mark Rosen MD
Professor Emeritus, University of California San Francisco, Department of Anesthesia and Perioperative Care, San Francisco, CA, USA

Allison Kinder Ross MD
Associate Professor of Anesthesiology and Pediatrics, Duke University Medical Center, Durham, NC, USA

Faith Ross, MD, MS
Attending Anesthesiologist, Department of Anesthesiology and Pain Medicine, Seattle Children's Hospital; Washington School of Medicine, Seattle, WA, USA

Neeta R. Saraiya MD
Department of Anesthesiology, Columbia University College of Physicians and Surgeons, New York, NY, USA

Joseph A. Scattoloni MD
Assistant Professor of Anesthesiology, Department of Anesthesiology, University of Michigan, Ann Arbor, MI, USA

Ehrenfried Schindler Dr. med.
Department of Anesthesiology and Critical Care Medicine, Section "Pediatric Anesthesiology", University Hospital Bonn, Bonn, Germany

Mark S. Schreiner MD
Emeritus Associate Professor of Anesthesia and Critical Care, Perelman School of Medicine, University of Pennsylvania; The Children's Hospital of Philadelphia, Philadelphia, PA, USA

Alan Jay Schwartz MD, MSEd
Director of Education, Department of Anesthesiology and Critical Care Medicine, The Children's Hospital of Philadelphia; Professor of Clinical Anesthesiology and Critical Care, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA, USA

Thomas L. Shaw MD
Staff Anesthesiologist, Texas Children's Hospital; Associate Professor, Department of Anesthesiology, Perioperative, and Pain Medicine, Baylor College of Medicine, Houston, TX, USA

Allan F. Simpao MD, MBI
Assistant Professor of Anesthesiology and Critical Care, Department of Anesthesiology and Critical Care, Children's Hospital of Philadelphia; Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA, USA

Sulpicio G. Soriano MD
Professor of Anaesthesia, Harvard Medical School; Endowed Chair in Pediatric Neuroanesthesia, Department of Anesthesiology, Critical Care, and Pain Medicine, Boston Children's Hospital, Boston, MA, USA

Stephen A. Stayer MD
Staff Anesthesiologist, Texas Children's Hospital; Professor, Department of Anesthesiology, Perioperative, and Pain Medicine, Baylor College of Medicine, Houston, TX, USA

Paul A. Stricker MD
Associate Professor of Anesthesiology, University of Pennsylvania School of Medicine; Attending Anesthesiologist, Department of Anesthesiology and Critical Care, The Children's Hospital of Philadelphia, Philadelphia, PA, USA

Adam Suchar MD
Assistant Professor of Anesthesiology and Pediatrics, Department of Anesthesiology, University of North Carolina, Chapel Hill, NC, USA

Lena S. Sun MD
Department of Anesthesiology and Pediatrics, Columbia University College of Physicians and Surgeons, New York, NY, USA

Mike Sury MB BS, FRCA, PhD
Consultant Anaesthetist, Department of Anaesthesia, Great Ormond Street Hospital for Sick Children, London, UK

Robert M. Sutton MD MSCE
Associate Professor of Anesthesiology and Critical Care Medicine, The Children's Hospital of Philadelphia; The University of Pennsylvania School of Medicine, Philadelphia, PA, USA

Joseph D. Tobias MD
Chairman, Department of Anesthesiology and Pain Medicine, Nationwide Children's Hospital; Professor of Anesthesiology and Pediatrics, The Ohio State University, Columbus, OH, USA

Alexis A. Topjian MD
Associate Professor of Anesthesiology and Critical Care Medicine, The Children's Hospital of Philadelphia; The University of Pennsylvania School of Medicine, Philadelphia, PA, USA

Britta S. von Ungern-Sternberg MD, PhD
Chair of Paediatric Anaesthesia, Department of Anaesthesia and Pain Management, Perth Children's Hospital, The University of Western Australia; Telethon Kids Institute, Perth, Australia

Monica S. Vavilala MD
Professor and Vice Chair Clinical Research (Interim), Anesthesiology and Pediatrics, Department of Anesthesiology and Pain Medicine, University of Washington School of Medicine, Seattle, WA, USA

Rajeev Wadia MD
Assistant Professor of Anesthesiology and Critical Care Medicine, Johns Hopkins University School of Medicine, Baltimore, MD, USA

David B. Waisel MD
Associate Professor of Anaesthesia, Harvard Medical School; Senior Associate in Anaesthesia, Boston Children's Hospital, Boston, MA, USA

Ewan Wallace MBChB, FRCA
Consultant in Paediatric Anaesthesia and Pain Management, Department of Anaesthesia, Royal Hospital for Children, Glasgow, UK

Mehernoor Watcha MD
Associate Professor, Department of Pediatric Anesthesiology, Perioperative, and Pain Medicine, Texas Children's Hospital; Department of Anesthesiology, Baylor College of Medicine, Houston, TX, USA

David Whiting MD
Cardiac Anesthesia Service, Boston Children's Hospital; Assistant Professor, Department of Anesthesia, Harvard Medical School, Boston, MA, USA

Glynn Williams MD
Pediatric Cardiovascular Anesthesiologist, Lucille Packard Children's Hospital at Stanford; Professor of Anesthesia, Department of Anesthesia, Stanford University School of Medicine, Palo Alto, CA, USA

Michelle Wright BSc(Hons), MBBS, FRCA
Locum consultant paediatric anaesthetist, Great Ormond Street Hospital for Sick Children, London, UK

Cecile Wyckaert MD
Pediatric Anesthesiology, UC Davis Children's Hospital, University of California, Davis, CA, USA

Myron Yaster MD
Professor, Department of Anesthesiology and Pediatrics, Children's Hospital Colorado, University of Colorado at Denver, Aurora, CO, USA

Laura N. Zeigler MD, MPH
Department of Anesthesiology, Monroe Carell Jr Children's Hospital at Vanderbilt, Vanderbilt University Medical Center, Nashville, TN, USA

Preface

Since the publication of the fifth edition of *Gregory's Pediatric Anesthesia*, both knowledge and practice have advanced in myriad ways. This sixth edition addresses these changes with significant updates and additions to all chapters, reflecting the most recent important literature in pediatric anesthesia. Significantly more figures and tables in nearly all chapters allow us to better illustrate the important principles in each area. Key points boxes have also been added after major sections in each chapter to enhance learning. New chapters have been added addressing the pediatric perioperative surgical home and anesthesia for non-cardiac surgery in congenital heart disease. Several extensive chapters from the fifth edition have been divided into two chapters to allow more space and detail: these cover development of the cardiovascular system and physiology of the cardiovascular system, anesthesia for trauma and anesthesia for burns, and anesthesia for otolaryngologic surgery and anesthesia for ophthalmologic surgery. The very popular case studies have been updated in all the clinical chapters.

The use of ultrasound for anesthesia procedures has increased exponentially in recent years, and this sixth edition has major extensive updates in ultrasound-guided regional anesthesia, with detailed descriptions and ultrasound images of the sonoanatomy for all the major blocks of the upper and lower extremities and trunk. Expanded use of point-of-care ultrasound for vascular access, including peripheral venous cannulation, for assessment of the heart and lungs, and for the airway and gastric contents are exciting new uses of this modality and are presented in detail.

Pediatric anesthesia is truly an international field and this edition's authors include those from the USA, UK, Canada, France, Germany, and Australia, giving a global perspective on practice in our ever-changing discipline. The History of Pediatric Anesthesia chapter was authored by Professor Kester Brown, who was the Director of Anaesthesia at the Royal Children's Hospital in Melbourne, Australia from 1974 to 2000. Professor Brown also traveled extensively around the world to teach and train anesthetists in many countries; the chapter reflects his extensive personal knowledge of the history of our field and its international roots. Sadly, Professor Brown passed away in November 2018; he will be remembered as one of the pioneers of pediatric anesthesia who trained hundreds of clinicians all over the world and who was a role model of professionalism, compassion, scientific curiosity, and outstanding clinical skill. He is missed by all in the community of pediatric anesthesiologists.

We would like to thank the editorial team at Wiley, including Publisher Claire Bonnett, Senior Project Editor Jennifer Seward, Senior Production Editor Nick Morgan, freelance project manager Nik Prowse, freelance copy-editors Ruth Hamilton Swan and Jane Andrew, and Editorial Assistant Bobby Kilshaw. This team of experts has been an absolute pleasure to work with and made many suggestions to improve the content and presentation of the enormous amount of material in this textbook.

Finally, as we acknowledged in the preface to the fifth edition, we thank our students, residents, and fellows for teaching us as much, or more, than we taught them. Their insightful questions, thoughts, and prodding is what academic medicine is about. This probing forces us all to get out of our comfort zone and think differently. We also thank the surgeons and nurses for their support. Most of all, we thank the patients and their parents for giving us the privilege of caring for them and for their continuing to teach us every single day. They are the best teachers!

Dean B. Andropoulos
George A. Gregory

List of Abbreviations

α1-ATD	α1-antitrypsin deficiency
AA	artery-to-artery
AAA	asleep/awake/asleep
AAG	α1-acid glycoprotein
AAGA	accidental awareness under general anesthesia
AAP	American Academy of Pediatrics
ABA	American Board of Anesthesiology
ABC	ATP-binding cassette
ABP	arterial blood pressure
ACA	anterior cerebral artery
ACD	active compression-decompression device
ACE	angiotensin-converting enzyme
ACEi	angiotensin-converting enzyme inhibitor
ACGME	Accreditation Council for Graduate Medical Education
ACh	acetylcholine
AChR	acetylcholine receptor
ACL	anterior cruciate ligament
ACLS	advanced cardiac life support
ACO	accountable care organization
ACP	antegrade cerebral perfusion
ACRM	anesthesia crisis resource management
ACS	acute chest syndrome/abdominal compartment syndrome/ American College of Surgeons
ACTH	adrenocorticotropic hormone
ADAPT	Approaches and Decisions in Acute Pediatric TBI (trial)
ADH	antidiuretic hormone
ADHD	attention deficit hyperactivity disorder
ADP	adenosine diphosphate
ADPKD	autosomal dominant polycystic kidney disease
AED	automated external defibrillator
aEEG	amplitude-integrated EEG
AFP	α-fetoprotein
AGB	adjustable gastric band
AGP	α1-acid glycoprotein
AHA	American Heart Association
AHG	antihuman globulin
AHI	apnea-hypopnea index
AHT	abusive head trauma
AI	artificial intelligence
AICD	automatic implantable cardiac defibrillator
AIMS	anesthesia information management system/s
AIRS	Anesthesia Incident Reporting System
AKI	acute kidney injury
ALARA	as low as reasonably possible
ALCAPA	anomalous origin of the left coronary artery from the pulmonary artery
ALI	acute lung injury
ALL	acute lymphocytic leukemia
ALS	Advanced Life Support
ALT	alanine aminotransferase
AMC	arthrogryposis multiplex congenital
AML	acute myeloid leukemia
AMM	anterior mediastinal mass
AMPA	α-amino-3-hydroxy-5-methyl-4-isoxazole-propionic acid
AN!	Anesthesia Now!
ANH	acute normovolemic hemodilution
ANP	atrial natriuretic peptide
AoDP	aortic diastolic blood pressure
AoV	aortic valve
AP	anterior–posterior
APCC	activated prothrombin complex concentrate
APL	adjustable pressure limiting
APM	alternative payment model
APRICOT	Anaesthesia PRactice In Children Observational Trial
APSF	Anesthesia Patient Safety Foundation
aPTT	activated partial thromboplastin time
AQI	Anesthesia Quality Institute
AR	adrenergic receptor/anesthetic room
ARB	angiotensin receptor blocker
ARDS	acute/adult respiratory distress syndrome
ARF	acute renal failure
ARPKD	autosomal recessive polycystic kidney disease
ARR	absolute risk reduction
ARVD	arrhythmogenic right ventricular dysplasia
ARVD/C	arrhythmogenic right ventricular dysplasia/cardiomyopathy
ASA	American Society of Anesthesiologists
ASC	ambulatory surgery center
ASCA	anti-*Saccharomyces cerevisiae*
ASD	atrial septal defect/autism spectrum disorder
ASIS	anterior superior iliac spine
ASO	arterial switch operation
AST	aspartate aminotransferase
AT	antithrombin
ATLS	Advanced Trauma Life Support
ATP	adenosine triphosphate
AUC	area under the curve
AV	arterial-venous/atrioventricular
AVC	atrioventricular canal
AVM	arteriovenous malformation
BBB	blood–brain barrier
BC	bronchogenic cyst
BDG	bidirectional Glenn
BDL	balloon dilation laryngoplasty
BiPAP	bi-level positive airway pressure
BIS	Bispectral Index
BMD	Becker muscular dystrophy
BMI	body mass index
BP	blood pressure
BPCA	Best Pharmaceuticals for Children Act
BPD	bronchopulmonary dysplasia
bpm	beats/min
BPS	bronchopulmonary sequestration
BSA	body surface area
BSEP	bile salt export pump

BT	bleeding time
B-T	Blalock–Taussig (shunt)
BUN	blood urea nitrogen
CA	cardiac arrest
cAMP	cyclic adenosine monophosphate
CAS	central anticholinergic syndrome
CAV	coronary artery vasculopathy
CBC	complete blood count
CBF	cerebral blood flow
CBFV	cerebral blood flow velocity
CBV	cerebral blood volume
CCAM	congenital cystic adenomatoid malformation
CCAS	Congenital Cardiac Anesthesia Society
CCL	cardiac cycle length
CCLS	Certified Child Life Specialist
CCTGA	congenitally corrected transposition of the great arteries
CDC	Centers for Disease Control and Prevention
CDH	congenital diaphragmatic hernia
CDS	clinical decision support
cEEG	continuous EEG
CF	cystic fibrosis
CFTR	cystic fibrosis transmembrane conductance regulator
cGMP	cyclic guanosine monophosphate
CGRP	calcitonin gene-related peptide
CHCT	caffeine–halothane contracture test
CHD	congenital heart disease
CHEOPS	Children's Hospital of Eastern Ontario Pain Scale
CHF	congestive heart failure
CIOMS	Council of International Organization and Medical Sciences
CIRCI	critical illness-related corticosteroid insufficiency
CK	creatine kinase
CKD	chronic kidney disease
CLABSI	central line-associated bloodstream infection
CLD	chronic lung disease
CLE	congenital lobar emphysema
cLMA	classic laryngeal mask airway
CM	cardiomyopathy
C_{max}	maximum plasma concentration
CME	continuing medical education
cMEP	cortical motor evoked potential
$CMRO_2$	cerebral metabolic rate of O_2
CMS	Centers for Medicare and Medicaid Services
CMV	cytomegalovirus
CN	cranial nerve
CNI	calcineurin inhibitor
CNS	central nervous system
CO	cardiac output/carbon monoxide
COG	Children's Oncology Group
COX	cyclo-oxygenase
CP	cerebral palsy
CPAM	congenital pulmonary airway malformation
CPAP	continuous positive airway pressure
CPB	cardiopulmonary bypass
CPD	citrate, phosphate, dextrose
CPOE	computerized physician order entry
CPP	coronary/cerebral perfusion pressure
CPR	cardiopulmonary resuscitation
CrCL	creatinine clearance
CrCP	critical closing pressure
CRF	case report form/chronic renal failure
CRP	C-reactive protein
CRPS	complex regional pain syndrome
CRRT	continuous renal replacement therapy
CSF	cerebrospinal fluid
CSI	Cerebral State Index
CSV	Children's Surgery Verification
CT	closure time/computed tomography
CTFR	cystic fibrosis transmembrane conductance regulator
CUF	conventional ultrafiltration
CVA	cerebrovascular accident
CVC	central venous catheter
CVP	central venous pressure
CVR	CPAM volume ratio
CXR	chest x-ray
CYP	cytochrome P450
DA	dopaminergic
DAS	distal arthrogryposis syndrome
dB	decibel
DBS	double-burst stimulation
DC	direct current
DCD	cardiac (or circulatory) death/donation after cardiac death
DCM	dilated cardiomyopathy
DDAVP	1-deamino-8-D-arginine vasopressin
DEX	dexmedetomidine
DHCA	deep hypothermic circulatory arrest
DHPR	dihydropyridine receptor
DI	diabetes insipidus
DIC	disseminated intravascular coagulation
DILV	double-inlet left ventricle
DKA	diabetic ketoacidosis
DLCO	diffusing capacity for carbon monoxide
DLT	double-lumen tube
DMD	Duchenne muscular dystrophy
DNA	deoxyribonucleic acid
DORV	double-outlet right ventricle
DPPC	dipalmitoyl phosphatidylcholine
DS	Down syndrome
DSMC	data safety monitoring committee
d-TGA	dextro-transposition of the great arteries
DUF	dilutional ultrafiltration
EA	emergence agitation/esophageal atresia
EACA	ε-aminocaproic acid
EAT	ectopic atrial tachycardia
EB	epidermolysis bullosa
EBV	estimated blood volume/Epstein–Barr virus
ECC	emergency cardiovascular care
ECF	extracellular fluid
ECG	electrocardiogram
ECLS	extracorporeal life support
ECMO	extracorporeal membrane oxygenation
ECoG	electrocorticography
ECPR	extracorporeal cardiopulmonary resuscitation
ECW	extracellular water
ED	emergence delirium/emergency department
EDMD	Emery–Dreifuss muscular dystrophy
EDV	end-diastolic volume
EEG	electroencephalography
EF	ejection fraction
EGD	esophagogastroduodenoscopy
EGDT	early goal-directed therapy
eGFR	estimated glomerular filtration rate
EHR	electronic health record
EMA	European Medicines Agency
EMG	electromyography
EMLA	eutectic mixture of local anesthetics
EMO	Epstein Macintosh Oxford
EMR	electronic medical record
EMS	emergency medical services
ENaC	epithelial sodium channel
ENS	enteric nervous system
ENT	ear, nose, and throat
EP	evoked potential
EPA	Entrustable Professional Activity
EPO	erythropoietin
ERAS	enhanced recovery after surgery
ERCP	endoscopic retrograde cholangiopancreatography
ERF	established renal failure
ESR	erythrocyte sedimentation rate

ESRD	end-stage renal disease
ESRT	evoked stapedius reflex threshold
ERT	enzyme replacement therapy
ET	endothelin/end-tidal
$ETCO_2$	end-tidal carbon dioxide
ETT	endotracheal tube
ETV	endoscopic third ventriculostomy
EVD	external ventriculostomy drain
EXIT	*ex utero* intrapartum treatment
F_A	alveolar fraction
FAST	focused assessment with sonography for trauma
FC	fibrinogen concentrate
FCC	fetoscopic cord coagulation
FDA	Food and Drug Administration
FDAMA	FDA Modernization and Accountability Act
FET	end tidal fraction
FETO	fetal endoscopic tracheal occlusion
FEV_1	forced expiratory volume in 1 second
FFP	fresh frozen plasma
FGFR	fibrous growth factor receptor
FHF	first heart field
FHR	fetal heart rate
FiO_2	fraction of inspired oxygen
FISH	fluorescence *in situ* hybridization
FLACC	face, leg, activity, cry, and consolability (scale)
fMRI	functional MRI
FNHTR	febrile non-hemolytic transfusion reaction
FOB	fiberoptic bronchoscope
FRC	functional residual capacity
FS	fractional shortening
FVC	forced vital capacity
FVL	factor V Leiden
FWA	Federal Wide Assurance
G	Gauss
GA	gestational age/general anesthesia
GABA	γ-aminobutyric acid
GABAA	γ-aminobutyric acid receptor, A subunit
GAS	General Anesthesia compared to Spinal Anesthesia (Study)
GCP	Good Clinical Practice
GCS	Glasgow coma scale
GER	gastroesophageal reflux
GERD	gastroesophageal reflux disease
GFR	glomerular filtration rate
GH	growth hormone
GI	gastrointestinal
GP_i	globus pallidus internus
HAV	hepatitis A virus
Hb	hemoglobin
HbF	fetal hemoglobin
HBV	hepatitis B virus
HCG	human chorionic gonadotropin
HCM	hypertrophic cardiomyopathy
Hct	hematocrit
HCV	hepatitis C virus
HES	hydroxyethyl starch
HFOV	high-frequency oscillatory ventilation
HFPV	high-frequency percussive ventilation
HHS	US Department of Health and Human Services
Hib	*Haemophilus influenzae* type b
HIPAA	Health Insurance Portability and Accountability Act
HIV	human immunodeficiency virus
HLA	human leukocyte antigen
HLHS	hypoplastic left heart syndrome
HME	heat and moisture exchanger
HMWK	high-molecular-weight kininogen
HOCM	hypertrophic obstructive cardiomyopathy
HPV	hypoxic pulmonary vasoconstriction/human papillomavirus
HR	heart rate
HSA	human serum albumin
HSCT	hematopoietic stem cell transplantation
5-HT3	5-hydroxytryptamine-3
HTLV	human T-lymphotrophic virus
HTR	hemolytic transfusion reaction
HUS	hemolytic uremic syndrome
IAP	intra-abdominal pressure
IBD	inflammatory bowel disease
IBW	ideal bodyweight
IC	*in vitro* contracture (test)
ICD	implantable cardioverter-defibrillator
ICD-9	*International Classification of Diseases*, 9th edition
ICF	intracellular fluid
ICN	intensive care nursery
ICP	intracranial pressure
ICU	intensive care unit
ICW	intracellular water
ID	internal diameter
IDMs	infants of diabetic mothers
I:E	inspiratory:expiratory
IE	infective endocarditis
Ig	immunoglobulin
IHCA	in-hospital cardiac arrest
IHPS	idiopathic hypertrophic pyloric stenosis
IIS	interictal spikes
IJ	internal jugular
IJV	internal jugular vein
IL	interleukin
IM	intramuscular
IN	intranasal
IND	Investigational New Drug
iNO	inhaled nitric oxide
INR	international normalized ratio/interventional neuroradiology
INSS	International Neuroblastoma Staging System
IO	intraosseous
IOP	intraocular pressure
IPPV	intermittent positive pressure ventilation
IRB	institutional/investigational review board
ISHLT	International Society for Heart and Lung Transplantation
ITD	impedence threshold device
IU	international unit
IV	intravenous
IVC	inferior vena cava
IVH	intraventricular hemorrhage
JRA	juvenile rheumatoid arthritis
JVP	jugular venous pressure
LA	local anesthetic/left atrium
LBW	lean bodyweight
LC	locus coeruleus
LCR	laryngeal chemoreflex
LD50	median lethal dose
LDH	lactate dehydrogenase
LDLT	living donor lobar transplant
LED	light-emitting diode
LES	lower esophageal sphincter
LFCN	lateral femoral cutaneous nerve
LHR	lung to head ratio
LIC	low income countries
LiDCO	lithium dilution cardiac output
LITT	laser interstitial thermal therapy
LMA	laryngeal mask airway
LMIC	low middle income countries
LMWH	low molecular weight heparin
LOH	loss of heterozygosity
LOR	loss of resistance
LPS	lipopolysaccharide
LR	lactated Ringer's (solution)
L-R	left-to-right
LSMT	life-sustaining medical treatment
LV	left ventricle

LVAD	left ventricular assist device
LVEDP	left ventricular end-diastolic pressure
LVMI	left ventricular mass index
LVNC	left ventricular non-compaction
LVOT	left ventricular outflow tract
LVOTO	left ventricular outflow tract obstruction
MABL	maximum allowable blood loss
MAC	minimum alveolar concentration
MAP	mean arterial pressure
MAT	multifocal atrial tachycardia
MATE	multidrug and toxin extrusion transporter
MCA	middle cerebral artery
MCS	mechanical circulatory support
MDI	metered dose inhaler
MDR	multidrug-resistant
MEG	magnetoencephalography
MELD	model for end-stage liver disease
MEN2	multiple endocrine neoplasia type 2
MEP	motor-evoked potential
MER	microelectrode recording
MET	Medical Emergency Teams
MH	malignant hyperthermia
MIBG	metaiodobenzyl guanidine
MIPS	Merit-based Incentive Payment System
MIS	minimally invasive surgery
MMC	migrating motor complex/myelomeningocele
MMF	mycophenolate mofetil
MODS	multiple organ dysfunction syndrome
6-MP	6-mercaptopurine
MPAP	mean pulmonary artery pressure
MPD	maximum permissible dose
MPOG	Multicenter Perioperative Outcomes Group
MPP	myocardial perfusion pressure
MR	magnetic resonance
MRI	magnetic resonance imaging
MRI/A	magnetic resonance imaging and angiography
MRP	multiple drug resistance-associated protein
MRSA	methicillin-resistant *Staphylococcus aureus*
MS	molar substitution
MTD	maximal tolerated dose
MTHFR	methylenetetrahydrofolate reductase
mTOR	mammalian target of rapamycin
MTP	massive transfusion protocol
MUF	modified ultrafiltration
MVO_2	mixed venous oxygen saturation
MW	molecular weight
NAC	N-acetylcysteine
NACOR	National Anesthesia Clinical Outcomes Registry
NAD	nicotinamide adenine dinucleotide
NADPH	nicotinamide adenine dinucleotide phosphate
NAT	nucleic acid testing
NCA	nurse-controlled analgesia
nCPAP	nasal continuous positive airway pressure
NCS	non-convulsive seizures
Nd:YAG	neodymium:yttrium-aluminum garnet
NDA	New Drug Application
NE	norepinephrine
NEB	neuroendocrine bodies
NEC	necrotizing enterocolitis
NEHI	neuroendocrine hyperplasia of infancy
NF	neurofibromatosis
NFκB	nuclear factor κB
NGT	nasogastric tube
NICU	neonatal intensive care unit
NIPPV	nasal intermittent positive pressure ventilation
NIRS	near-infrared spectroscopy
NMB	neuromuscular blocking drug
NMBA	neuromuscular blocking agent
NMDA	N-methyl-D-aspartate
NNT	number needed to treat
NO	nitric oxide
NORA	non-operating room anesthesia
NPH	nephronophthisis/neutral protamine Hagedorn (insulin)
NPMODS	new and progressive multiple organ dysfunction syndrome
NPO	nil per os
NPPE	negative pressure pulmonary edema
NRL	natural rubber latex
NRP	Neonatal Resuscitation Program
NS	normal saline
NSAID	non-steroidal anti-inflammatory drug
NSQIP	National Surgical Quality Improvement Program
NTCP	Na^+/taurocholate co-transporting polypeptide
OAT	organic anion transporter
OATP	organic anion transporting polypeptide
OAVS	oculo-auriculovertebral spectrum
OCT	organic cation transporter
OELM	optimal external laryngeal manipulation
OHCA	out-of-hospital cardiac arrest
OHRP	Office for Human Research Protections
OI	osteogenesis imperfecta
OIB	Oxford inflating bellows
OLV	one-lung ventilation
OMV	Oxford miniature vaporizer
OPTN	Organ Procurement and Transplant Network
OR	odds ratio/operating room
OSA	obstructive sleep apnea
OSAS	obstructive sleep apnea syndrome
OSCE	Objective Structured Clinical Examination
PA	pulmonary artery/pulmonary atresia
PABD	preoperative autologous blood donation
PAC	premature atrial contractions
$PaCO_2$	partial pressure of CO_2 in arterial blood
PACU	postanesthesia care unit
PAED	Pediatric Anesthesia Emergence Delirium (scale)
PALICC	Pediatric Acute Lung Injury Consensus Conference
PALS	pediatric advanced life support
PaO_2	partial pressure of oxygen in arterial blood
PAS	periodic acid–Schiff
PBS	prune belly syndrome
PC	protein C
PCA	patient-controlled anesthesia/postconceptual age
PCC	prothrombin complex concentrate
PCRA	patient-controlled regional anesthesia
PCWP	pulmonary capillary wedge pressure
PD	pharmacodynamic/peritoneal dialysis
PDA	patent ductus arteriosus
PDE	phosphodiesterase
PEA	pulseless electrical activity
PEC	Program Evaluation Committee
PEEP	positive end-expiratory pressure
PEFR	peak expiratory flow rate
PEG	percutaneous endoscopic gastrostomy
PELD	pediatric end-stage liver disease
PELOD	PEdiatric Logistic Organ Dysfunction (score)
PET	positron emission tomography
PEVPPS	Preverbal, Early Verbal Pediatric Pain Scale
PFC	persistent fetal circulation
PFIC	progressive familial intrahepatic cholestasis
PFO	patent foramen ovale
PFT	pulmonary function test
PG	prostaglandin
PGD	primary graft dysfunction
PGE1	prostaglandin E1
P-gp	P-glycoprotein
PH	pulmonary hypertension
PHBQ	Post Hospitalization Behavior Questionnaire
PICC	percutaneously/peripherally inserted central catheter
PiCCO	pulse-contour analysis of the arterial waveform

PICOT	Population, Intervention, Comparison, Outcome, Timeline
PICU	pediatric intensive care unit
PIPP	premature infant pain profile
PIV	peripheral intravenous catheter
PK	pharmacokinetic/prekallikrein
PKA	protein kinase A
PKC	protein kinase C
PLV	protective lung ventilation
P-MODS	Pediatric-Multiple Organ Dysfunction Score
PN	parenteral nutrition
PNAM	presurgical nasal alveolar molding
PNB	peripheral nerve block
PNEC	pulmonary neuroendocrine cells
PO	per os
POAH	preoptic anterior thalamus
POCA	Pediatric Perioperative Cardiac Arrest (registry)
POCUS	point-of-care ultrasound
POLST	physician order for life-sustaining treatment
PONV	postoperative nausea and vomiting
POV	postoperative vomiting
POVL	postoperative visual loss
PPH	portopulmonary hypertension
PPHN	persistent/primary pulmonary hypertension of the newborn
PPIA	parental presence at induction of anesthesia
ppm	parts per million
PPROM	preterm premature rupture of membranes
PPV	positive pressure ventilation
PQRS	Physician Quality Reporting System
PRA	panel reactive antibody
PRAE	perioperative respiratory adverse event
PRAN	Pediatric Regional Anesthesia Network
PRBC	packed red blood cells
PREA	Pediatric Research Equity Act
PRIS	propofol infusion syndrome
PRS	Pierre Robin sequence
PS	protein S
PSH	perioperative surgical home
PSRC	Pediatric Sedation Research Consortium
PT	prothrombin time
PTLD	post-transplant lymphoproliferative disorder
PTP	post-transfusion purpura
PTSD	post-traumatic stress disorder
PTT	partial thromboplastin time
PUBS	percutaneous umbilical blood sampling
PUV	posterior urethral valves
PV	postoperative vomiting/pulmonary valve
PVB	paravertebral block
PVC	premature ventricular contractions/polyvinyl chloride
PVO_2	pulmonary venous O_2 content
PVR	pulmonary vascular resistance
pVT	pulseless ventricular tachycardia
QL	quadratus lumborum
Qp:Qs	ratio of pulmonary to systemic blood flow
RA	right atrium
RAE	Ring–Adair–Elwyn
RAP	right atrial pressure
RBBB	right bundle branch block
RBC	red blood cell
RCM	radiocontrast media/restrictive cardiomyopathy
RCP	regional cerebral perfusion
RCT	randomized controlled trial
RDS	respiratory distress syndrome
REC	research ethics committee
REM	rapid eye movement
RF	radiofrequency/rheumatoid factor
RFA	radiofrequency ablation
RFID	radiofrequency identification
rFVIIa	recombinant activated factor VII
R-L	right-to-left
RLFP	regional low-flow perfusion
ROP	retinopathy of prematurity
ROSC	return of spontaneous circulation
RPGN	rapidly progressive glomerulonephritis
RR	relative risk
RRT	renal replacement therapy
RSI	rapid-sequence induction
RSII	rapid-sequence induction and intubation
rSO_2	regional oxygen saturation
RSV	respiratory syncytial virus
RV	right ventricle/residual volume
RVOT	right ventricular outflow tract
RYGB	Roux-en-Y gastric bypass
SAE	serious adverse event
SAFEKIDS	Safety of Key Inhaled Anesthetics in Children (study)
SAH	subarachnoid hemorrhage
SaO_2	percent arterial oxyhemoglobin saturation
SAR	specific absorption rate
SCD	sickle cell disease
SCFE	slipped capital femoral epiphysis
SCh	succinylcholine
SCIWORA	spinal cord injury without radiological abnormalities
SCPA	superior cavopulmonary anastomosis
SCT	sickle cell trait/sacrococcygeal teratoma
$S_{CV}O_2$	central venous oxygen saturation
SD	standard deviation
SFLP	selective fetoscopic laser photocoagulation
SGA	small for gestational age/supraglottic airway
SGS	subglottic stenosis
SHF	second heart field
SIADH	syndrome of inappropriate secretion of antidiuretic hormone
SIDS	sudden infant death syndrome
SIOP	International Society of Pediatric Oncology
SIRS	systemic inflammatory response syndrome
$SjvO_2$	oxygen saturation in jugular venous bulb
SLC	solute carrier
SNP	sodium nitroprusside
SOFA	Sequential Organ Failure Assessment
SOS	Shikani optical stylet
SPA	Society for Pediatric Anesthesia
SPECT	single photon emission computed tomography
SPLIT	Studies in Pediatric Liver Transplantation
SR	sarcoplasmic reticulum
SSCG	Surviving Sepsis Campaign Guidelines
SSEP	somatosensory-evoked potential
SSRI	selective serotonin reuptake inhibitor
STN	subthalamic nuclei
STS	Society of Thoracic Surgeons
SV	single ventricle
SVAS	supravalvar aortic stenosis
SVC	superior vena cava
SVL	Storz video laryngoscope
SVR	systemic vascular resistance
SVT	supraventricular tachycardia
T	Tesla
TA	tranexamic acid/tricuspid atresia
T&A	tonsillectomy and adenoidectomy
TACO	transfusion-associated circulatory overload
TA-GVHD	transfusion-associated graft versus host disease
TAH	total artificial heart
TAP	transversus abdominis plane
TB	tuberculosis
TBI	traumatic brain injury/total body irradiation
TBSA	total body surface area
TBV	total blood volume
TBW	total body water/total bodyweight
TCD	transcranial Doppler ultrasound
TCI	target-controlled infusion
TCPC	total cavopulmonary connection

TEE	transesophageal echocardiogram
TEF	tracheoesophageal fistula
TEG	thromboelastography
TF	tissue factor
TFPI	tissue factor pathway inhibitor
TGA	transposition of the great arteries
TGF	transforming growth factor
THAM	tris(hydroxymethyl)aminomethane
THRIVE	transnasal humidified rapid insufflation exchange
TIVA	total intravenous anesthesia
TLR	Toll-like receptor
TLV	total lung volume
T_{max}	time to maximum concentration
TMJ	temporomandibular joint
TNF	tumor necrosis factor
TOF	tetralogy of Fallot/train-of-four
TOI	tissue oxygenation index
tPA	tissue plasminogen activator
TPN	total parenteral nutrition
TPTN	transpulmonary thermodilution
TRALI	transfusion-related acute lung injury
TRAP	twin reversed arterial perfusion (sequence)
TRICC	Transfusion Requirements in Critical Care (trial)
TRIM	transfusion-related immunomodulation
TSC	tuberous sclerosis complex
TSH	thyroid stimulating hormone
TT	thrombin time
TTN	transient tachypnea of the newborn
TTP	thrombotic thrombocytopenic purpura
TTTS	twin–twin transfusion syndrome
TV	tricuspid valve
TXA	tranexamic acid
UBF	uterine blood flow
UDP	uridine diphosphate
UDPGA	uridine diphosphate glucuronic acid
UDPGT	uridine diphosphate glucuronyltransferase
UDT	undescended testes
UGT	UDP-glucuronosyltransferase
UNOS	United Network for Organ Sharing
UPJ	ureteropelvic junction
URI/URTI	upper respiratory tract infection
US	ultrasound
UTI	urinary tract infection
UVJ	ureterovesical junction
VA	veno-arterial/ventriculo-arterial/Veterans Administration
VACTERL	vertebral, anal, cardiac, tracheoesophageal, renal and limb anomalies
VAD	ventricular assist device
VAE	venous air embolism
VAS	vesicoamniotic shunt/visual analog scale
VATS	video-assisted thoracoscopic surgery
VCFS	velocardiofacial syndrome
VEGF	vascular endothelial growth factor
VEPTR	vertical expandable prosthetic titanium rib
VF	ventricular fibrillation
VGAM	vein of Galen aneurysmal malformation
VHL	von Hippel–Lindau
VIP	vasoactive intestinal polypeptide
VMI	visual motor integration
VO_2	maximum oxygen uptake
VSD	ventricular septal defect
VT	ventricular tachycardia
VTi	velocity time integral
VUR	vesicoureteric reflux
VV	veno-venous
vWD	von Willebrand disease
vWF	von Willebrand factor
vWF:RCo	ristocetin co-factor assay
WB	whole blood
WBC	white blood cell
WEB	wire-guided endobronchial blocker
WFSA	World Federation of Societies of Anaesthesiologists
WHO	World Health Organization
Wu	Woods unit
WUS	Wake Up Safe
ZBUF	zero-balance ultrafiltration

CHAPTER 1

Ethics and Professionalism in Pediatric Anesthesia

David B. Waisel

Harvard Medical School and Boston Children's Hospital, Boston, MA, USA

Introduction

The key to the ethical practice of pediatric anesthesia is: *Treat every child and family with the grace and consideration with which you would want your child and family treated*. Here are seven maxims:

1. *Remember that surgery is a big deal*. Reminding yourself that this banal case is a lifetime event for the child and family helps you be kind and respectful to the child and family. It boosts your ability to mitigate the production pressure that hurries you to induce anesthesia before the premedication has taken effect, inadequately prepare a nervous adolescent for insertion of an intravenous catheter, or skirt safety guidelines.
2. *Meet the needs of the child and family*. Focus on process by being patient, calm, flexible, and nonjudgmental. Anxious, sleep-deprived parents receiving complicated information may need to hear it several times to understand it or may react strongly to the seemingly unremarkable. Interact with the intent of determining their needs, whether it be the extent of information, the preferences for decision making, or the need for reassurance. Respond directly to questions.
3. *Be humble*. As a professional, it is tempting to believe you know what is best. But many of the choices families make reflect values, anxieties, and personal, family, and community experiences that are difficult for you to know, much less appreciate. Denigrating families for choosing what you believe to be a less optimal albeit acceptable choice ravages professionalism and mars interactions with all patients. If you think a decision is unacceptable, consult with respected colleagues before pursuing administrative or legal interventions.
4. *Assume responsibility for the children and their families*. "Own" care for the child and family to ensure that every little thing goes as well as possible. This includes: bringing a chair for the third adult; finding someone to answer questions unrelated to perioperative clinical care; doing a thorough preoperative evaluation; making the extra effort to insert the IV in a way that does not impede the dominant hand; always using the optimal anesthetic technique; being alert for errors in the operating room unrelated to you; and ensuring children and families are physically and emotionally well postoperatively. If you would do it for your child, you should do it for every child.
5. *Serve patients*. Medicine is a noble service profession. For the most part, patients' preferences, values, and needs supersede ours. Our values become relevant only after thorough, thoughtful, and careful consideration and consultation.
6. *Hone your mastery*. Strive to provide first-rate care, critically consider what you know and how you know it, and seek help freely [1].
7. *Use empathic behavior*. Clinicians need to overtly communicate that they understand and appreciate the perspective and experience of the child and family [2]. An effective way to communicate empathy is a heartfelt "I wish things were different" [3].

Gregory's Pediatric Anesthesia, Sixth Edition. Edited by Dean B. Andropoulos and George A. Gregory.

Although clinicians may think of medical ethics in dramatic terms – withdrawing life-sustaining therapy, allocating organs for transplant – medical ethics floods our daily practice. Consider the clinician who recommends postponing surgery in an infant because of a borderline upper respiratory infection. Should they be flexible if the infant has missed three surgical dates for non-medical reasons? How should they respond to a parental request to proceed? Within these seemingly medical decisions lie the ethical components of informed consent and obligations to the child and family. How do we decide how much weight to give the parents' strong desire to proceed? Does it matter why they want to proceed (guilt over missing the previous appointments? Concern about their child's health? Convenience because grandma is in town to care for siblings? Concern about being able to get time off from work again? Scheduling because the child will spend the summer with an out-of-town parent, effectively delaying the operation until fall? etc.). Should we even consider the effects on the family? What if there is concern that the parents will not reschedule surgery?

Ethical dilemmas occur when clinicians are faced with "oughts" – that which a physician is bound by duty to do – that conflict. In the above example, clinicians ought to base proceeding with surgery solely on the child's best interest, which may include the effects of the upper respiratory infection and the likelihood that the child will get a timely operation. Medical ethics provides the process by which to resolve these apparently conflicting "oughts."

Resolving ethical dilemmas is not a matter of being a moral person. Identifying, diagnosing and managing ethical conflicts requires the same extent of expertise that is required to identify, diagnose, and manage myocardial ischemia. Training and experience in resolving ethical dilemmas enables ethics consultants to identify the dilemma and critical facts, apply ethical principles and case-based analysis, articulate precise questions, and have the moral imagination to create more palatable solutions.

Despite erstwhile efforts, fewer than 51% of pediatric residents correctly answered questions about some aspects of patient confidentiality, genetic testing, pediatric assent and the ethical similarity of withholding and withdrawing potentially life-sustaining medical treatments (LSMT) [4].

Deficits like these highlight the importance of ethics committees and their consultation services. Clinicians may find consultation services particularly helpful with concerns about disagreements among families and clinicians, appropriate decision-making roles for adolescents, decisions about end-of-life care, and professional obligations [5,6].

Members of ethics committees include representatives from throughout the hospital such as chaplains, administrators, social workers, nurses, and physicians. Many committees also include local community representatives. Depending on local practice, consultations may be performed by an individual, a small group, or the entire ethics committee. Most ethics consultation services permit anyone with standing to request a consultation, which fundamentally includes all clinicians who participate in the care of the patient [5]. Most services enter a written report into the clinical record. The standard of care is that ethics consultation services advise only and have no formal authority. A committee with a strong record, however, has substantial informal authority. The case study provides an example of an ethics consultation.

The law is not a desirable substitute for resolving ethical dilemmas. The law represents a lower bound for acceptable behavior, whereas ethics articulates a standard to which we should aspire. Pragmatically, the law does not provide clear guidance because most law surrounding ethical dilemmas is case law. In addition, the frequently adversarial legal process may pollute future family–clinician–hospital relations. Crude statutes and regulations are unable to govern complex medical care.

KEY POINTS: THE ETHICAL PRACTICE OF PEDIATRIC ANESTHESIA

- Pediatric medical ethics is a broad and changing field
- Identification, diagnosis, and management of ethical issues requires expert knowledge, experience, and skill
- Anyone involved in a patient's care can request an ethics consultation

The informed consent process for children

The doctrine of informed consent centers on the belief that patients have a right to self-determination. The right to self-determination is actualized through the legal concept of competency. Except in specific situations, minors are not legally competent to consent for healthcare. But minors do have varying degrees of decision-making capacity, and minors should be included in medical decision making to the extent permitted by the child and situation (Box 1.1) [7].

The process of pediatric informed consent depends on the age and development of the child (Table 1.1). The concepts

Box 1.1: Elements of consent and assent as defined by the American Academy of Pediatrics [7]

Elements of informed consent for medical decision making

- Provision of information about the following:
  - Nature of the illness or condition
  - Proposed diagnostic steps and/or treatments and the probability of their success
  - The potential risks, benefits, and uncertainties of the proposed treatment and alternative
  - Treatments, including the option of no treatment other than comfort measures
- Assessment of patient and surrogate understanding and medical decision-making capacity, including assurance of time for questions by patient and surrogate
- Ensure that there is voluntary agreement with the plan

Practical aspects of assent by pediatric patients for medical decision making

- Help the patient achieve a developmentally appropriate awareness of the nature of the condition
- Tell the patient what to expect with tests and treatments
- Make a clinical assessment of the patient's understanding of the situation and the factors influencing how they respond (including whether there is inappropriate pressure to accept testing or therapy)
- Solicit an expression of the patient's willingness to accept the proposed care

Table 1.1 Graduated involvement of minors in medical decision making

Age	Decision-making capacity	Techniques
Under 6 years	None	Best interest standard Harm threshold standard
Ages 7–11 years	Developing	Informed permission Informed assent
Ages 12–18 years	Cognitive skills developed Maturity developing	Informed assent (approaching informed consent as developmentally appropriate) Informed permission
Mature minor	Developed, as legally determined by a judge, for a specific decision	Informed consent
Emancipated minor	Developed, as determined by a situation (e.g. being married, in the military, economically independent)	Informed consent

This broad outline should be viewed as a guide. Specific circumstances always must be taken into consideration. When children are in the upper range of an age bracket, limited or full inclusion of a more developmentally advanced technique, such as the use of assent for a 6-year-old, may be appropriate.

of best interest, informed permission, and assent are used when considering pediatric informed consent. For convenience, the term "parent" will be used to describe the child's surrogate decision maker. Parents are not always the legal surrogate decision maker and parental authority may be limited in adolescents. The term "decision makers" will refer to those involved in the specific decision and may include parents, children, and their advisors.

The primary lesson of this chapter should be to respect the experiences and opinions of children. The American Academy of Pediatrics emphasizes that "no one should solicit a patient's views without intending to weigh them seriously. In situations in which patients will have to receive medical care despite their objections, the patient should be told that fact and should not be deceived." [8].

The best interest standard and informed permission

Informed consent can be given only by the patient. Some advocate for the term "informed permission" for when the parent provides legal consent and ethical decision making for the child, to emphasize that the consent is not by the patient [8]. This conceptual framework highlights the ethical limits of parental decision making. It does not affect the legal obligation to obtain informed consent from the parents as defined by local statutes.

Children younger than the age of 7 typically have insufficient decision-making capacities to participate effectively in the informed consent process. When children cannot effectively participate, or when parents are unable to base a decision on previous interactions with the child, the best interest standard traditionally guides decision making. This standard requires determining who will make the decision and what is in the child's best interest. Best interest does not mean the best care as defined by the clinicians. There are often several acceptable options, and clinicians rely on parents to determine which one is in the child's best interest. Parents are given considerable latitude in decision making because society values the role of family, parents want the best for their children, and families often have to live with the result of the choices. Although parents may be wrong in determining the preferences of their child's future self, many accept that parental values serve as a reasonable approximation of those future values [9].

Parental decisions should be scrutinized if they appear to fall outside of the boundaries of acceptable care. Boundaries are determined by the extent and likelihood of potential harms by the intervention or its absence, the likelihood of success, and the overall risk-to-benefit ratio.

The harm threshold standard may be more accurately named and conceptually useful than the best interest standard for determining whether to limit parental decision making. The harm threshold standard bases decisions on whether a parental choice threatens the health and safety of the child [10–12]. Many clinicians probably use a form of this standard to identify the borders of unacceptable decision making.

When parents appear to choose unacceptable treatments, clinicians should consult with colleagues to assess the acceptability of the decision and, if necessary and appropriate, to participate in the discussion. Seek to resolve disagreements without resorting to legal intervention. But the state has an interest in protecting those who cannot protect themselves. If other options have failed, clinicians should initiate an evaluation if they believe parents to be choosing unacceptable treatments.

Informed assent: the role of the child

Children should participate in decision making to the extent their development permits [7]. Decision-making capacity for children is based on the ability to understand and recall the information, to reason, which includes evaluating the risks and benefits of the options presented, to appreciate the effect of the decision on themselves, which requires advance abstract thinking, and to make a choice. Neurobiological evidence suggests that these abilities change with age and experience and are frequently present by the age of 12 [13].

For children between the ages of 7 and 11, clinicians should seek both informed permission from the parent and assent and participatory decision making from the child. Common decisions in which children participate include whether a 6-year-old wants sedation prior to an inhalation induction, whether a 10-year-old wants inhalation or intravenous induction of anesthesia, and whether an 11-year-old wants a peripheral nerve catheter for postoperative analgesia.

Clinicians should assume that adolescents 12 years and older have sufficient decision-making capacity to fulfill the ethical obligations of informed consent. Their decision-making capacities are affected, however, by their personality,

the situation, emotional impulsiveness, and a tendency to undervalue long-term consequences. The tendency to take risks increases in emotional situations. For these reasons, the influence an adolescent has on decision making is tempered by the adolescent's maturity and the risks of the decision. Decisions are considered higher risk when they include an increased likelihood of permanently lost opportunities that have noteworthy consequences. For example, delayed scoliosis surgery may increase the extent of the curve, subsequently impairing cardiopulmonary function. These impairments can affect the quality of life, future morbidity, and lifespan. In determining the extent of risk in a decision, the quality and relevance of the data must be rigorously considered.

Emancipated minors and the mature minor doctrine

Emancipated minors are minors who have a statutory right to legally consent for their own healthcare decisions. States often award this status to patients who are in the military, who are married, who have children, and who are economically independent. To be declared a mature minor, the patient must be determined by a judge to be legally and ethically capable of giving legal consent in a specific situation. Judges consider mature minor status based on the extent of the risk in the decision and the developmental maturity and age of the child.

Disclosure

The legal standard for most of the United States is the reasonable person standard, which declares that the information disclosed should satisfy the hypothetical reasonable person.

It is ethically, morally, and legally unclear as to what satisfies the reasonable person standard for informed consent for pediatric anesthesia. Children and families differ about the type and depth of information they want to receive, their desire to participate in making decisions, and their goals of the informed consent discussion [14]. For example, some want information to make decisions, some want information because they feel obligated to be informed, or some want reassurances that everything will go well, which often results in wanting less information. Sociodemographic characteristics do not reliably predict preferences for disclosure and decision making. These preferences may change given the surgery, stress, and other factors present that day.

A better approach is for the clinician to communicate only the necessary information based on the child's medical status, the risks of the procedure, and the availability of acceptable clinical options, and then seek to meet the informational and decision-making needs of the child and family by asking if they want to know more [15]. This does not burden those tepid about further information while meeting the needs of those who seek a more complete discussion. Patient-driven interactions likely reduce malpractice lawsuits. The likelihood of being sued based on informed consent malpractice issues is very rare. But the improved satisfaction that comes from patient-driven interactions (or, more simply, from listening to and responding to the decision makers' needs and requests) leads to decreased complaints and lawsuits in general [16].

Postoperative nausea and vomiting (PONV) is an archetype of the issues clinicians may want to routinely communicate unless explicitly deferred. PONV is: (1) of great concern to parents; (2) addressable by early use of medications; (3) modifiable by behavioral and eating strategies; and (4) relevant to seeking postoperative medical interventions. Yet, in one study, PONV was discussed in only 36% of preoperative discussions [17].

The literature varies in what must be told to patients and is rarely prescriptive [18]. Practices vary, even within the same institution. For example, in a 2012 observational study of consent for pediatric anesthesia, the five most commonly discussed risks per conversation were nausea and vomiting (36%), sore throat (35%), allergy (29%), hypoxia (25%), and emergence delirium (19%) [17]. Trainees discussed about three risks in each conversation as compared to attendings who discussed only one. Nearly a third of interactions used only general statements about anesthesia risk without further information about their nature, ramifications, or incidence. It is unclear whether these variations are appropriate responses to decision makers' needs or baseline variations in standards.

Adjunct techniques, like regional analgesia, require a modification of the "meet the decision makers' needs" approach. Consider extensive knee surgery in an otherwise healthy young adolescent. Because decision makers understand that general anesthesia is essential for the surgery to proceed, they may defer more thorough risk information because it will not sway their decision. But in this child, regional analgesia is an option but not a necessity. Decision makers should be aware that regional analgesia is not essential to the surgery, and, because there is a greater role for choice, decision makers should be more extensively informed about the risks and benefits.

Patients have difficulty understanding quantitative risks. Table 1.2 describes strategies for communication [19–21].

Informed refusal

Refusal of a significant recommendation requires clinicians to more fully inform decision makers about the risks, benefits, and alternatives than if the decision makers were following the recommendation. This helps ensure that decision makers are as knowledgeable as possible about the risks of selecting a less desirable path.

Children with significant decision-making capacity (perhaps around the age of 10 years but certainly by the age of 12 years) might refuse non-emergent procedures. Clinicians should respect this refusal of assent and conscientiously avoid pressuring the child. Coercing or manipulating a child into having a procedure damages the child's trust of the medical profession and impairs future cooperation with their care. Maintenance of trust is particularly important in children with chronic medical conditions.

Strategies for resolving conflicts center on maintaining communication, clarifying misunderstandings about the anesthetic and surgical experience, and decreasing the anxiety of both the child and parents. The goal is to resolve the problem without impairing the relationships among the child, parents, and clinicians. Clinicians may want to emphasize that nothing will happen without the child's approval, *but only if that is true*. Moving the discussion away from the preoperative area or letting the child dress in street clothes will often reduce stress and improve communication.

Clinicians should recognize the distinction between using pharmacologic agents to calm an anxious adolescent to enable

Table 1.2 Communicating quantitative risk to patients [19–21]

Understanding quantitative risks may help patients make decisions. Presentation is key to understanding. Consider a patient who is concerned about PONV. They want to know the relative risks of PONV in regional anesthesia (30%) versus general anesthesia (50%).

Approach

1. Use language at the 8th grade level.
2. Use absolute risks and frequencies.
3. Avoid relative descriptions like "regional anesthesia decreases the rate of PONV by 50% compared to general anesthesia."
4. Because patients have different abilities, data should be presented in a variety of ways cautiously. Too much information too quickly is confusing.

Verbal presentations	Analysis
"With regional anesthesia, there is a 30% chance of PONV. With general anesthesia, there is a 50% change of PONV"	• Relies on an understanding of percentages that is not universally present
"With regional anesthesia, there is a 30% chance of PONV, which is *3 out of 10 patients*. With general anesthesia, there is a 50% change of PONV, which is *5 out of 10 patients*"	• Adds a frequency (*3 out of 10 patients; 5 out of 10 patients)* ◦ Presents a second avenue to understanding ◦ Is often easier to understand
"With regional anesthesia, there is a 30% chance of PONV, which is 3 out of 10 patients. With general anesthesia, there is a 50% chance of PONV, which is 5 out of 10 patients. That means that *2 more patients out of 10* will have postoperative vomiting if we use general anesthesia	• Adds a direct comparison using an absolute number (*2 more patients out of 10*), which is often helpful • Increases the language complexity • Possible solutions ◦ Present information in smaller chunks, which makes it easier to understand ◦ Use pictorial representation

Pictorial presentations — **Analysis**

Pictorial representation #1

- Clinician can draw ten dots and fill in the appropriate number
- Described as the number of patients out of 10 who will have PONV with that type of anesthesia

proceeding and using pharmacologic agents to manipulate the adolescent into proceeding. Consider the 15-year-old who becomes overwhelmingly anxious and refuses surgery. It would be inappropriate to unilaterally administer midazolam to gain cooperation. On the other hand, it is wholly appropriate to seek the adolescent's assent to receive sufficient anxiolysis so they may undergo the procedure. Time, respect, and simple strategies often resolve issues satisfactorily and efficiently.

Children of Jehovah's Witnesses

Jehovah's Witnesses interpret biblical scripture to mean that anyone who accepts blood will be "cut off from his people" and not receive eternal salvation [22]. Adults may refuse potentially life-sustaining transfusion therapy. The presumption is that they are making an informed and voluntary decision. Courts commonly authorize necessary perioperative transfusions for children of Jehovah's Witnesses. The courts base these decisions on the doctrine of *parens patriae,* the obligation of the state to protect the interests of incompetent patients.

Clinicians should directly address perioperative transfusion therapy when caring for a child of Jehovah's Witnesses. The child and family should be informed that, as with all patients, attempts will be made to follow the family's wishes within the standard of care. Because refusal of transfusion therapy is deemed a "matter of conscience," the clinicians should clarify acceptable interventions. Deliberate hypotension, deliberate hypothermia, and hemodilution are often acceptable techniques. Synthetic colloid solutions, dextran, erythropoietin, desmopressin, and preoperative iron are usually acceptable. Some Jehovah's Witnesses will accept blood removed and returned in a continuous loop, such as cell saver blood. The family should be informed that in unexpected critical situations requiring transfusion, the clinician will transfuse while concomitantly or later seeking legal authorization. Clinicians should be familiar with the hospital's preferred mechanism for obtaining legal authorizing. In instances where the likelihood of requiring blood is high, or the local judiciary is not that familiar with case law for Jehovah's Witnesses, clinicians may choose to obtain the court order preoperatively if there is a palpable likelihood of transfusion.

Elective procedures may be postponed until the child is of sufficient age and maturity to decide about transfusion therapy. But delays may increase the risk of morbidity or the quality of outcome. Factors affecting whether to proceed

include the quantitative and qualitative changes in risks and benefits.

Reasonable people disagree as to whether clinicians should change their transfusion triggers for a child of a Jehovah's Witness. On one hand, when to transfuse is often a judgment call, affected by the child's baseline health, clinical findings, lab values, expectation of future blood loss, knowledge of surgeon and procedure, risk tolerance, and gestalt. Given that, it may be reasonable to transfuse later than normal. On the other hand, although clinicians acknowledge transfusion triggers vary, they presumably transfuse only when necessary. In this analysis, changing transfusion triggers provides less optimal care, which is inconsistent with the obligation to treat the child of a Jehovah's Witness like any other child.

When an adolescent wishes to refuse perioperative transfusion, the minor needs to articulate sufficiently mature reasons, be properly engaged with the religion, and understand ramifications to self and family about possible outcomes. A private conversation is necessary to assess for coercion or manipulation. Ethics consultations are particularly useful in making these determinations. When brought to court, judges often determine whether adolescents may refuse transfusion by the likelihood of significant benefits like 5-year survival and the practicality of initiating and maintaining transfusion therapy. Children as young as 14 have been given the right to decline transfusion therapy, even when they had a high probability of 5-year survival.

When arrangements are made to honor an adolescent's preferences to refuse transfusion, plans must be made to ensure other perioperative and postoperative clinicians are willing to honor the agreements, as well as to ensure a plan is in place to honor the agreement in case the child needs to return to the operating room urgently.

Emergency care

Emergency therapy is considered desirable and should be given to the minor who does not have a parent available to give legal consent or informed permission [23]. Clinicians should err on the side of treating if they are unsure whether to wait for parental consent.

Emergency therapy becomes more complex when adolescents nearing the age of majority refuse to assent to care. Urgency may not permit the extended evaluation necessary to determine whether the minor has sufficient decision-making capacity. Clinicians should use the best interest standard to guide therapy acutely. Consider a 15-year-old with an acute cervical fracture who refuses emergency stabilization. Forgoing cervical stabilization may cause irrevocable harm. The typical adolescent's decidedly short-term outlook and overvaluation of physical abilities make it unlikely that the adolescent possesses sufficient decision-making capacity in the acute situation. It is hard to imagine honoring an adolescent's refusal of emergent therapy in this case.

The temporarily impaired parent

Chemically intoxicated parents may be disruptive, dangerous, and incapable of fulfilling surrogate responsibilities. Clinicians should use the least restrictive means to protect patient and parent confidentiality while ensuring the safety of the child, the impaired parent, and others present.

Although it seems ethically and legally prudent to postpone routine treatment until informed permission and legal consent can be obtained from an unimpaired parent, clinicians should weigh the benefits of postponement with the risk that impaired parents may not reliably return. It may be in the child's best interests to proceed with a routine procedure even though the impaired parent is unable to give informed permission and legal consent. Consultation with legal, risk management, and ethics colleagues may help.

Consent for pediatric procedures without direct benefits

Pediatric clinicians may encounter children undergoing bone marrow donation for siblings who would benefit from hematopoietic stem cell transplantation [24]. The stem cell donor receives no direct medical benefit from the donation. The major risks of donation are the anesthetic and the potential need for transfusion.

The benefit of donation is commonly considered to be the psychosocial benefit of helping a family member. Pediatric donors report that the benefits of donations outweigh the physical harm [25]. As can be expected in such a complex dynamic, however, donation can result in moderate post-traumatic stress. Some donors felt they did not have a choice about being a donor and that they may be responsible for unsuccessful transplants.

Given the risks and benefits and the unique position of families in society, the American Academy of Pediatrics believes it is ethically permissible for minors to donate bone marrow when certain requirements are met, including a close relationship between donor and recipient, considerations of the risks of bone marrow donation, a likelihood of benefit to the recipient, and an absence of a suitable medically equivalent adult relative. Parental consent and patient assent is needed. Independent advocates for potential donors have been used to minimize the potential for inappropriate parental influence [26].

Genetic testing and biobanking

While genetic testing can provide the substantial benefits of confirming a diagnosis, determining carrier status, or testing for disorders of late onset, it can also harm by informing people about their genetic lineage without their consent or adequate preparation.

Whether to test is particularly hazardous with children. Genetic testing may affect personal psychosocial development and business and insurance opportunities and removes the opportunity to choose whether to obtain that genetic information. Testing should be performed only when there are immediate medical benefits to the child or when there are medical benefits to a family member and no expected harm to the child. Otherwise, testing should be deferred until the child can display an understanding of the consequences of genetic testing.

Consent for biobanking, the keeping of tissues for genetic research, is problematic, assuming that the revisions to the more than 25-year-old Common Rule begin as expected in 2018. The Common Rule is the core ethics regulations governing human research in the United States. The revision permits

using broad consent for biobanking [27,28]. Within some limitations, broad consent permits the use of tissues without additional permission from the donor [29]. One of the problems with broad consent is that donors or their surrogates may be consenting to unknown unimaginable risks [29]. No matter the protections, privacy is always at risk [30]. Consequences can include denial of life insurance, and, potentially in the future as health insurance laws change, denial or exorbitant premiums for health insurance.

Children should be involved in the consent process for biobanking to the developmentally appropriate extent [31]. The issues of consent change when the child reaches adulthood. One potential solution is to require biobanks to contact donors when they reach adulthood to either require the now adult to opt in for biobanking or provide the opportunity to opt out. This is not being done routinely [32].

KEY POINTS: THE INFORMED CONSENT PROCESS FOR CHILDREN

- Respect the "experience, perspective, and power of children" [8]. Legitimately involve children to the developmentally appropriate extent. Avoid pro forma solicitations
- Prioritize meeting the child and family's informational, decision-making, and emotional needs during the informed consent process
- Use verbal and pictorial strategies to quantify risks
- Under certain circumstances, adolescents may refuse potentially life-sustaining transfusion therapy for religious reasons
- Genetic testing and biobanking can lead to unforeseen consequences for the donor and their relatives

Forgoing potentially life-sustaining treatment

Children, like adults, have the right to limit LSMT when the likelihood and quality of potential burdens outweigh the likelihood and quality of potential benefits, as defined by the child and family [33]. Benefits include a prolonged acceptable quality of life. Burdens include intractable pain, disability, emotional suffering, or effects that diminish the child's quality of life.

The term "life-sustaining medical treatment" is preferred to the older term "do not resuscitate" to emphasize that treatment preferences range along a continuum instead of being binary. "Potentially" acknowledges the uncertain effectiveness of the treatments.

Perioperative limitations on potentially life-sustaining treatment

Limiting perioperative potentially LSMT allows children to have an opportunity to receive beneficial therapy without being forced to accept unwanted burdens [33,34]. Treatments may include procedures that increase quality of life, enable living at home, improve ability to interact, improve pain management, decrease pain, and treat non-terminal problems or urgent problems unrelated to the primary problem. Potential burdens from procedures may arise from resuscitation attempts, post-resuscitation medical care, or resultant functional or cognitive decrements. These burdens may make further resuscitation or intensive care therapy not "worth it." Considering both short- and long-term potential benefits and burdens helps clinicians understand the child's perspective, which improves honoring preferences.

The American Society of Anesthesiologists, the American Academy of Pediatrics, and the American College of Surgeons mandate reconsideration of existing limitations on LSMT before going to the operating room or procedure area.

Reconsidering the order prior to surgery requires clarifying the goals for the procedure and end-of-life care through discussions with the child, parents, and relevant clinicians such as surgeons and primary care physicians. Children should be involved in a developmentally appropriate manner. In practice, the reconsideration of LSMT for the perioperative period should result in either full resuscitation or a goal-directed approach toward perioperative resuscitation.

Goal-directed approaches permit decision makers to guide therapy by prioritizing outcomes (e.g. "I don't want to suffer in the ICU for two weeks before I die.") rather than specific therapies (e.g. cardiopulmonary resuscitation) [35]. Clinicians can guide the discussion by exploring acceptable burdens, desirable benefits, and the likelihood of the ranges of outcomes. Clinicians should explain the differences between ward and operating room resuscitation, emphasizing the idea that a dedicated clinician with understanding of the end-of-life goals and the ability to make a real-time assessment of the clinical problem as well as the ability to institute treatment immediately will be present throughout. Box 1.2 lists additional information to include in the discussion.

Operating room clinicians use their clinical judgment to determine whether and to what extent resuscitation will help achieve these goals. The decision about whether to use a certain intervention, such as chest compressions, will likely be more consistent with the end-of-life goals if the decision to

Box 1.2: Components of the discussion for perioperative limitations on potentially life-sustaining medical treatment (LSMT) [33–35]

- Planned procedure and anticipated benefit to child
- Description of advantages of perioperative LSMT as compared to ward LSMT
- Likelihood of requiring resuscitation
- Reversibility of likely causes that require resuscitation
- Description of potential interventions and their consequences
- Chances of successful resuscitation including differences between outcomes to witnessed and unwitnessed arrests
- Ranges of outcomes with and without resuscitation
- Responses to iatrogenic events
- Intended and possible venues and types of postoperative care
- Use of postoperative trials of therapy
- Postoperative timing and mechanisms for reinstitution of previous limitations of LSMT
- Establishment of an agreement through a goal-directed approach or revocation of the do-not-resuscitate order for the perioperative period
- Documentation

institute is made when the etiology of the event is known. This model encourages the ethically redoubtable strategy of trialing therapies. A trial of chest compressions that do not achieve specific goals provides evidence that continuing the therapy would be inconsistent with the goals of end-of-life care. Witnessed arrests in the operating room often have a better outcome than unwitnessed arrests due to the more immediate intervention and the greater likelihood that the cause of the arrest is known.

Most decision makers choose to use a goal-directed approach that authorizes temporary therapeutic interventions to manage quickly and easily reversible events, but reject those interventions that will likely result in permanent sequelae, such as neurologic impairment, from receiving potentially LSMT. For example, a brief bradyarrhythmia that responds to intravenous epinephrine and chest compressions would be consistent with the authorization to treat events that are temporary, easily reversible, and unlikely to have significant sequelae. On the other hand, if the bradyarrhythmia resulted in an extended resuscitation, continued therapy would require unacceptable burdens that in any case would be unlikely to achieve the patient's return to previous functional status. In that case, it would be appropriate to cease resuscitation efforts.

This common goal-directed preference can be documented as "The patient desires resuscitative efforts during surgery (and in the postanesthesia care unit (PACU)) only if the adverse events are believed to be both temporary and reversible in the clinical judgment of the attending anesthesiologists and surgeons."

The goal-directed approach requires determining when the child returns to their previous status for LSMT. Given that the goal-directed approach requires intimate knowledge and that it is intended to respond to the vicissitudes of anesthesia and surgery, the perioperative agreement is often discontinued when the patient is discharged from the PACU.

Clinicians should also discuss whether to try a postoperative trial of therapy before concluding that the burdens of continuing therapy outweigh the benefits. A trial of therapy allows decision makers and clinicians to determine how well a treatment achieves a defined agreed-upon goal, rather than presuming whether the therapy would work [3]. Trials may be limited by time or other factors. Trials permit children to tolerate a relatively small amount of burden, such as brief mechanical ventilation, to see if it would accomplish their defined goals. This information guides further decision making with greater certainty of burdens and benefits.

In pediatrics, precisely defining and documenting postoperative plans is often less essential, because parents are often available in the postoperative period to make decisions regarding therapy. Parents are often cognitively capable of participating in discussions of withdrawal of therapy because they have already grappled with analyzing the benefits and burdens of end-of-life care. The presence of parents permits greater trials of perioperative resuscitation while still respecting the decision to limit the burdens. However, developmentally appropriate conversations with the patient are essential when a child is able to participate in these discussions. A child's preferences should be incorporated into decision making similar to obtaining assent.

Resist the hegemonic instinct to overreact to iatrogenic events. Decision makers chose to limit care because they do not want the burden of undesirable outcomes. Iatrogenic issues do not supersede agreed-upon preferences for limitations on potentially LSMT unless knowledge of the event makes the associated burdens and benefits of treatment consistent with the agreed-upon plan.

That said, putting aside personal feelings about an iatrogenic event is hard. But children and families care about how they are, not how they got there.

Physician orders for life-sustaining treatment

A physician order for life-sustaining treatment (POLST) promotes the honoring of resuscitation preferences by giving the preferences the power of a physician order. This order is valid across in- and out-of-hospital locations [36]. As compared to other advance directives, which can be prepared without professional medical guidance, POLSTs ensure the advice of a physician on how to achieve end-of-life care preferences. POLSTs document preferences for LSMT, other medical interventions, and management of artificial nutrition [37]. POLST documents appear to improve communication and honoring of preferences, particularly across settings [38–40].

Perhaps the biggest impediment to POLSTs is physician unfamiliarity [41]. From the perioperative clinician's point of view, it should be taken as if the child has a duly authorized limitation of LSMT. It should thus undergo required reconsideration.

Barriers to honoring perioperative limitations on life-sustaining treatment

Although honoring limitations on LSMT is improving in the main, clinicians still poorly honor end-of-life care preferences [36,42,43]. Clinicians remain inadequately informed about policies, law, and ethics, hindered by sabotaging systems and poisoned by lore and misinformation [44–48].

Insufficient early identification and communication about a child who needs a perioperative reconsideration of LSMT, such as one with a POLST, limits the ability to find the right clinicians, have a robust discussion, and reach an agreement satisfactory to the child, family, and clinicians. Children having minor surgery or those who have not had a preoperative visit are more likely to remain unidentified until the day of surgery.

Lore and break room gossip reinforce the incorrect perception that honoring perioperative limitations on LSMT may result in being sued [49]. Statutes that address requirements for limitations on LSMT often include immunity provisions that protect clinicians from liability. Given the right of children to avoid inappropriate treatment, and the lack of judgments against clinicians who honor properly documented LSMT, the risk of honoring limitations on LSMT is likely to be lower than the risk of not honoring it.

Barriers that are less obvious include the natural desire to avoid most risk, particularly what is incorrectly perceived as a significant risk for little benefit [49]. Many clinicians like to avoid ambiguous situations in which they

have little experience making judgments and in which they are more prone to private or public criticism. These concerns can lead to anticipatory regret, letting an uninformed or overactive imagination create a fictional horrifying outcome that makes honoring limitations too risky. Clinicians overcome these honest but inappropriate feelings by reality testing with experts, seeking to become more skilled in these areas, and remembering that clinicians serve patients.

Potentially inappropriate interventions

Most of the confusion surrounding the concept of futility comes from imprecise terminology. Futile therapy should be viewed as treatments that cannot accomplish a specific physiological goal. In that sense, dilemmas about whether to use futile therapy rarely arise. Interventions with a low likelihood of success, on the other hand, may be considered potentially inappropriate but they cannot be considered futile. An intervention may be considered potentially inappropriate if there is "no reasonable expectation" that a significant defined endpoint will be reached, the burdens to the child, feasibility, or, at times, cost [50].

At the clinician level, discussions about inappropriate interventions center on the benefits and burdens to the child. Qualitative and quantitative considerations should be defined carefully and clinicians should explain whether the information used to form the estimation is based upon intuition, clinical experience, or rigorous and sufficiently relevant scientific studies. Complicating matters is the dubiety in predicting the likelihood and range of outcomes of therapeutic interventions in very young children. In the end, in the absence of national standards, decision making for a child regarding inappropriate care should be based on the benefits and burdens on the child and not on cost [51]. Hospitals should have established processes for resolving conflicts [52].

Perioperative clinicians encounter cases that seem to be inappropriate treatments. Aside from differences in core values and beliefs, parents have other influences that encourage them to seek seemingly inappropriate care (Box 1.3). Understanding these factors helps clinicians be empathetic.

Box 1.3: Why are we doing this case? Factors that affect parental desire to seek seemingly inappropriate care

Parents seek seemingly inappropriate care for personal, familial, and societal reasons. These latent factors influence decision making.

- Unrealistic expectations about prognosis or effectiveness of treatment
  - Previously incorrect prognoses about their child ("Won't live past age 2")
  - Local rumors about "miraculous" cures
  - Public stories about "miraculous" cures
- Influence/disapproval from insufficiently informed family
  - Fear of damaging personal reputation in their community
  - Fear of subtle ostracism
  - Internal or external pressure not to damage family reputation
- Guilt
  - Responsible for previous actions (e.g. left with "irresponsible" relative)
  - Responsible for "delaying" treatment because they "missed' something
  - Vague but wholly wrong feeling that it was their fault
  - Emotional overtones of "causing death"
- Mistrust of clinicians, hospitals, or medical systems
  - Personal disturbing individual interactions
  - Legitimate and illegitimate stories and events engendering distrust
  - Coming from communities that have experienced organizational prejudice (e.g. racial, gender, ethnic, socioeconomic, etc.)
- Inadequate education/guidance from clinicians
  - No clearly identified clinician coordinating care
  - Inadequate communication among clinicians
  - No process to address LSMT with family
  - Breakdown of communication among family and clinicians
  - Well-meaning but poorly considered comment by a peripheral clinician (sometimes medical student) on to which families latch

LSMT, life-sustaining medical treatment.

What would you do in my situation?

Parents may ask clinicians what they would do in the same situation. Clinicians should attempt to determine what the parent is asking before directly answering this question.

If they are asking for help making a decision, either because of difficulty managing the complexity of information or because of uncertainty, it is important to clarify the goals or values of the parents. Clinicians can then answer the question, "If that were my goal, I would do this, because…." Explaining why allows parents to apply their own values to the reasoning.

If parents are unsure about how to weigh competing values, it is appropriate for clinicians to share their values, with the caveat that many other approaches are acceptable and that the parents' values take priority. Clinicians can explain that to parents: "My job is to help you make one of the several reasonable choices that fits your values. Let's discuss how we can apply your values to this decision."

If parents are looking for reassurance for a reasonable decision that is not the one the clinician would have chosen, clinicians can respond by affirming both the appropriateness of the decision and the naturalness of feeling uncertain [53]. Admitting uncertainty about the "right" thing to do confirms to the parents the difficulty of the decision.

Organ procurement after cardiac death

In organ procurement after death by neurological criteria, the child is declared dead before going to the operating room. In organ procurement after cardiac (or circulatory) death (DCD), a child in whom the decision has been made to withdraw potentially LSMT is brought to the operating room and then treatment is withdrawn. If the child is declared dead by cardiac status within a pre-established time, organ procurement proceeds. Although widely accepted, concerns about DCD include whether the dying process is altered by interventions to facilitate organ procurement. See Chapter 30 for more information about organ donation after cardiac death.

KEY POINTS: FORGOING POTENTIALLY LIFE-SUSTAINING TREATMENT

- Children have the same right as adults to limit potentially LSMT, but predictions about the likelihoods and range of outcomes are less reliable
- Orders for limitations for LSMT must be reconsidered for the perioperative period. They may be honored under a goal-directed approach
- Trials of therapy increase the likelihood of honoring preferences for end-of-life care. Trials allow decision makers to test the assumption that a treatment may achieve specific goals while permitting it to be withdrawn if the treatment becomes too burdensome
- Desires for what appear to be inappropriate treatment come from values, beliefs, perceptions, personal experience, and community history
- Work with children and families to apply their values to decision making

Special circumstances in pediatric anesthesia

Research in pediatric patients

The anesthesiologist Henry K. Beecher was one of the first to recognize that research in pediatric patients requires greater oversight than research in adults [54]. Research subjects requiring surrogate consent are vulnerable to abuse. Pediatric research exposes children to unknown risks of long-term harm because research interventions occur during growth and development of the child [55].

The increased risk of harm and lack of direct benefit to the child increase the obligation to obtain the developmentally appropriate assent from the child. This obligation is not always met, particularly in diseases that have a strong emotional overlay, like cancer [56,57]. Assent may be waived if there is the prospect of direct benefit to the child that is available only through participation in research. Although undesirable, assent also may be waived if the study exposes the child to no more than minimal risks or if the study could not sensibly proceed without the waiver [50,51].

Federal guidelines define four categories of pediatric research (Box 1.4). The hallmark of these categories is that potential benefits must increase commensurate with potential risks. Most controversy about pediatric research concerns the interpretations of minimal risk and minor increase over minimal risk [52].

Minimal risk is defined as "the probability and magnitude of harm or discomfort anticipated in the research are not greater in and of themselves than those ordinarily encountered in daily life or during the performance of routine physical or psychological examinations or tests" [58,59].

The common interpretation is that minimal risk refers to risks encountered by healthy children in a safe environment, such as playing sports and riding in a car [59,60]. A previous competing interpretation, now out of favor, used the more relative interpretation of basing the standard of "daily life" on the events to which children enrolled in the research are routinely exposed. In other words, if a child enrolled in the study routinely receives lumbar punctures as part of therapy, then it may be acceptable to expose a child to the risk of a lumbar puncture for study purposes.

The category "*greater than minimal risk* and no prospect of direct benefit to individual subjects, but likely to yield generalizable knowledge about the subject's disorder or condition … which is of vital importance" defines when it is acceptable to expose a child to what is called "minor increase over minimal risk" [58]. "*Minor increase over minimal risk*" has been interpreted as pain, discomfort, or stress that is transient, reversible, and not severe [61]. Risk assessment is based on the combined exposure to risks throughout the study and the relationship between the risks and the patient population. For example, although drawing blood in healthy 15-year-olds may be considered acceptable, drawing blood from 15-year-olds with severe autism spectrum disorder may be unacceptable because their inability to understand may cause intolerable stress [62].

"Condition" is used to mean characteristics "that an established body of scientific or clinical evidence has shown to negatively affect children's health and wellbeing or to increase the risk of developing a health problem in the future" [62]. For example, consider a protocol to assess insulin resistance in obese children who do not have type 2 diabetes. If the investigator presented sufficient scientific support to the institutional review board that obese children are at increased risk of developing diabetes because of their obesity, then those obese

Box 1.4: Federal classifications for pediatric research [50]

1. Research not involving greater than minimal risk.
   a. IRB determines minimal risk
   b. IRB finds and documents that adequate provisions are made for soliciting assent from children and permission from one of their parents
2. Research involving greater than minimal risk but presenting the prospect of direct benefit to the individual subjects.
   a. IRB justifies the risk by the anticipated benefit to the subjects
   b. The relation of the anticipated benefit to the risk is at least as favorable as that presented by available alternative approaches
   c. Adequate provisions for assent and permission from one of the parents
3. Research involving greater than minimal risk and no prospect of direct benefit to individual subjects, but likely to yield generalizable knowledge about the subject's disorder or condition (commonly known as "minor increase over minimal risk").
   a. IRB determines the risk represents a minor increase over minimal risk
   b. The intervention or procedure presents experiences to subjects that are reasonably commensurate with those inherent in their actual or expected medical, dental, psychological, social, or educational situations
   c. The intervention or procedure is likely to yield generalizable knowledge … which is of vital importance for the understanding or amelioration of subject's disorder or condition
   d. Adequate provisions for assent and permission from both of the parents
4. Research not otherwise approvable which presents an opportunity to understand, prevent, or alleviate a serious problem affecting the health or welfare of children.

IRB, institutional review board.

children would be acceptable research subjects for this study. Svelte children would not be acceptable, because they would not be considered at risk for developing diabetes.

Stringent regulations certainly hinder necessary and beneficial research [56,57]. But regulations are often responses to previous transgressions. At some point, relaxation of regulations will reanimate the abuses that beget the regulations. It is difficult to identify that line until it is crossed.

Improving the institutional review board (IRB) process may minimize the inaccurate estimations of risk that hinder appropriate research and permit inappropriate research. An individual's intuition about the risk level of an activity is hampered by cognitive biases, such as familiarity, control of activity, and reversibility of the potential harms [63]. Systematizing evaluation of research risks may reduce inaccurate estimations of risk. One approach is to use a standardized scale to categorize the extent and likelihood of each potential harm and then compare the potential harms with comparative activities [64].

Socioeconomically disadvantaged children are overrepresented in clinical research [65]. Their environments may drive or worsen diseases such as reactive airway disease, and most research is performed in urban hospitals. Children in more economically settled situations get the benefit of the research without bearing proportionate risk. In addition, socioeconomically disadvantaged children and families may be more enticed to participate in research because of the commonly offered relatively inexpensive tokens of gratitude. But to socioeconomically disadvantaged families, what the researcher or IRB perceives as a minor gift can be a strong incentive to participate. See Chapter 4 for additional discussion about research consent and ethics.

Confidentiality for adolescents

Open discussion, the lynchpin to a successful adolescent–clinician relationship, occurs only when the adolescent believes in the openness and confidentiality of the discussion [66,67]. Confidentiality means the adolescent owns their information, and, as such, it may not be shared without the adolescent's permission [68]. The adolescent's emerging desire for autonomy and their cognitive decision-making abilities make them developmentally ready for this responsibility.

Clinicians are obligated to protect patient information from unauthorized and unnecessary disclosure. With adolescents, confidentiality is crucial for even the anodyne. Adolescents concerned about confidentiality withhold pertinent information and defer necessary treatment [66,67,69]. Clinicians may want to ask sensitive questions without the parents present. Squarely addressing confidentiality concerns often improves truthfulness.

But adolescent confidentiality is not absolute. Honoring an adolescent's preferences for autonomy may compete with the obligation to ensure the adolescent is making a reasonable decision. It is ethically justifiable to breach confidentiality only when complying with reporting statutes or when breaching confidentiality will prevent serious harm to the child or another. These decisions are not obvious, and clinicians should use patient, family, and case characteristics in consultation with ethics or legal consultations to determine the appropriateness of breaching confidentiality.

Confidentiality breaches occur by sloppy and insecure use of medical records and electronic communications, by discussing patients in front of other patients or uninvolved clinicians in public areas like elevators, hallways, and cafeterias, and by clinicians being forced to have public discussions with patients or families because of inadequate private facilities, such as in the family waiting room. The most common breaches were to clinicians uninvolved in patient care about patients' sexual activities, mental or other stigmatizing illnesses, and racial or ethnic backgrounds [70].

The pregnant adolescent

Hospitals and clinicians should have a defined approach to the preoperative adolescent who has a positive pregnancy test. As described previously, this information is the adolescent's and should only be shared with the patient's permission. State statutes may limit clinicians to informing only the adolescent about a positive pregnancy test [71,72]. In addition to ethical principles and practical reasons, these statutes are specifically present to address concerns about child abuse in pregnant adolescents.

Clinicians in possession of sensitive information should encourage the adolescent to share the relevant information with the parents. Involving adolescent specialists or social workers may facilitate communicating with the parents and receiving future care.

The ethical complexity increases logarithmically when pregnant adolescents do not want to inform their parents and it is appropriate to postpone the procedure [73]. Even though clinicians must postpone the case in a manner that does not breach confidentiality, the details of how the postponement is communicated affect the ability to maintain confidentiality. For example, clinicians can issue a terse communiqué to the parents that the procedure will be postponed. While this approach avoids explicit lying, its oddness may confuse parents and trigger a cascade of questions leading to a loss of confidentiality. On the other hand, clinicians may actively deceive, correctly reasoning that because parents have no right to that information, their primary obligation is to preserve confidentiality.

Albeit peculiar in a medical textbook, perhaps a short course in deception is useful [74,75]. Clinicians should try to avoid deception. But, when necessary, as a later resort to maintain confidentiality, it may be the least objectionable approach. It is perhaps easier to mitigate the sting of being deceptive by considering that, ethically, only the patient has the right to that information, and you are doing what is practically necessary to maintain confidentiality.

Clinicians should deceive in ways that will be successful, not require diagnostic or therapeutic interventions, and not unduly worry parents. For example, while intimating about unavailable operating room space and emergency surgeries may be useful, the excuse is rather weak if stated in the morning, when the family could offer to wait until one is available. Using a "new murmur" as an excuse may worry parents and cause unnecessary consultations. More simple deceits, such as postponement due to concerns about inadequate fasting or upper respiratory infections, tend to minimize unintended consequences.

The American Academy of Pediatrics supports confidentiality for adolescents seeking information about having an abortion [76]. Unless restricted by state law, adolescents may have abortions without parental consent. The rules surrounding parental involvement in elective abortions vary by state [71]. States may require either parental consent or notification prior to an elective abortion [71]. To ensure that adolescents can seek an abortion confidentially in states with parental involvement laws, states must have a judicial bypass procedure to preclude parental involvement. In a judicial bypass hearing, the judge interviews the adolescent to determine sufficient maturity to consent for an abortion. Even if the judge determines the adolescent insufficiently mature, the judge may grant permission for the abortion if the judge believes it is in the adolescent's best interest.

LGBTQI+ patients

Although the number of LGBTQI+ adolescents and the incidence of gender dysphoria are increasing, the specialization of care for these individuals means there is often clinical inexperience. LGBTQI (lesbian, gay, bisexual, transgender, transsexual, queer, intersex) is an insufficient term to describe the variations of preferences for gender identification or no identification. A person's genetic biology is called sex. Gender is a self-identified social construct of how a person presents themselves to those around them. Gender identification is unconstrained, and includes no gender, gender fluid and combined or unnamed genders. Because covering the spectrum would be unwieldy, the "+" is to indicate those unmentioned, without prejudice.

The wholly legitimate issue of gender variation or dysphoria in the prepubescent child is widely misunderstood and not infrequently grotesquely mocked. Different treatments are appropriate. Decisions about more definitive interventions are usually postponed until puberty, given the uncertain natural history [77]. Clinicians must be supportive in following the chosen treatment (e.g. support for gender transition) for their patient.

Being an adolescent is hard. Isolation, prejudice, and even implicit or explicit condemnation from parents and other family make the difficulty of being an LGBTQI+ adolescent unimaginable for those who have not had the experience. Because of these factors, LGBTQI+ children have higher rates of substance abuse, homelessness, suicidal ideation, and physical harm. Reprinted rather widely is part of the 2015 suicide note of Leelay Alcorn, who self-identified as transgender. This note exemplifies the isolation, shame, and pain. "Please don't be sad, it's for the better. The life I would've have lived isn't worth living in… because I'm transgender….I never told anyone and I just continued to do traditionally 'boyish' things to try to fit in." [78].

Clinicians should avoid heteronormative assumptions (asking if someone has a boyfriend or a girlfriend), identify preferred name (often incorrectly identified on records if the name has not been legally changed), identify preferred pronouns or use non-gender pronouns, although in conversation with children their name should be used, articulate the purpose of potentially awkward questions, and use genderless language.

KEY POINTS: SPECIAL CIRCUMSTANCES IN PEDIATRIC ANESTHESIA

- Adolescents deserve confidentiality for ethical and practical reasons. Clinicians are responsible for maintaining appropriate confidentiality
- Diligently assess yourself for personal but unintended behaviors that may lead to health or healthcare disparities, particularly across race, gender, and socioeconomic status. Develop strategies to minimize these actions
- Be cautious about seemingly innocuous language that makes presumptions that may hurt or shame adolescents

Professionalism in pediatric anesthesia

Advocacy and good citizenship

Physicians owe their ability to train, practice, and thrive to society's largesse. The implicit social contract therefore obligates physicians to manage matters within their sphere of influence, with a special obligation to address issues that "directly influence individuals' health" in the physician's community [79,80]. Community may refer to a physical location or a type of patient to whom the physician is particularly obligated. Pediatric anesthesiologists have a special obligation to further pediatric healthcare [81,82].

Pediatric anesthesiologists fulfill obligations to society by participating in activities that are consistent with the individual's "expertise, interests and situations" (Fig. 1.1) [80]. Pediatric clinicians in particular should address the healthcare disparities of quality of care and access to care seen across socioeconomic, racial, gender, geographical, and other cohorts that lead to the health disparities in morbidity and mortality [83,84].

Safety and quality care initiatives

Clinicians must work to improve safety. Clinically, clinicians need to actively support safety initiatives that seek to improve care such as the procedural time out and the Clean Hands Count initiative. Ignoring or bypassing inefficient, impractical, or harmful policies prevents developing a functional policy and leads to a dysfunctional culture of clinicians choosing which rules to follow [85]. Clinicians need to bring unsuccessful policies to leadership, who must be willing to honestly discuss and address concerns without blaming clinicians or demeaning them by declaring "try harder." Even one brush-off by leadership will chill future communication from the front lines.

Clinicians should do their best to improve care by reporting near misses or other potential risks. Clinicians are suspicious (sometimes rightly) of the trumpeted "blame free" approach to reporting potential errors or near misses [86]. To fulfill professional obligations of identifying potential risks, suspicious clinicians should reality test their perception or find a different way to highlight the risk. System flaws that lead to medical errors can only be identified by honest reporting and by participating in root cause analyses.

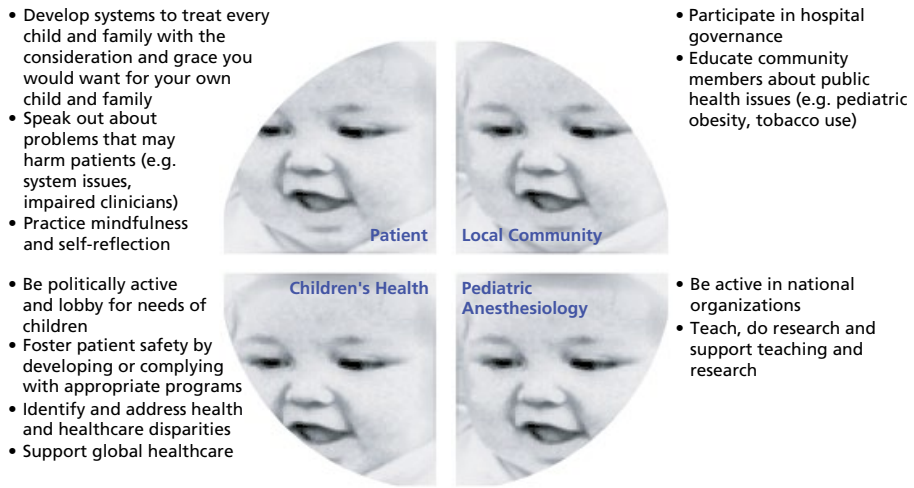

Figure 1.1 Obligations of pediatric anesthesiologists. Pediatric anesthesiologists are obligated to these four communities. Individual anesthesiologists are not expected to fulfill every obligation. "Units" of anesthesiologists such as private practice groups, academic departments, and state societies should fulfill these obligations collectively. A few examples are given.

Disclosure and apology

Although viscerally seductive, hiding medical errors violates informed consent principles, destroys trust when the error is inevitably revealed, and leads to legal action [87]. To be sure, it is understandable to want to hide a medical error. Clinicians foresee mercurial treatment by the hospital or legal system, do not receive adequate psychosocial support, and are inadequately educated about how to manage these conversations [88].

Children and parents wish to be informed about medical errors. Proper disclosure and apology can improve trust, communication, and respect and may give them a greater sense of control, which some research suggests may lead to better outcomes [89]. They also wish to receive appropriate apologies, even if it makes them more anxious.

Thoughtful full disclosure should commence upon recognition of the problem. Wise clinicians unskilled in disclosure and apology involve an expert. The expert can prepare clinicians by rehearsing process and content and by providing support for the clinician. The expert can arrange for continuing communication and provide emotional support for the family. Clinicians who make errors, sometimes referred to as "second victims" [90], may be understandably rattled and may not be able to provide emotional support. Clinicians should share what is known as quickly as reasonably possible, but they should not make assumptions about what is not known, particularly about fault. Decision makers should be informed about the medical implications of the event and any necessary treatment. Because disclosure is a process over time, the child and family should be given a contact person skilled in disclosure and apology who will be available to answer questions, arrange meetings, explain the results of the investigation, and describe plans to prevent comparable events.

Most arguments against apology about and disclosure of errors center on increasing the risk of being successfully sued and on protecting the patient from unnecessary anxiety regarding the event or future care. Upon examination, these arguments are weak. An apology is an expression of regret or sorrow. A sincere apology followed by actions consistent with regret is invaluable; an insincere apology is costly. Even though more than half the states have laws prohibiting the admission of apology or sympathy as evidence of wrongdoing, it is conceivable that an apology may increase the risk of being sued or losing a suit. But the best protection against being sued is a good patient–doctor relationship [16]. Hiding, dissembling, or being indifferent about an event destroys trust and galvanizes a lawsuit much more than a sincere apology.

For example, some recommend apologizing for the effect on the child but not taking responsibility for the actual event. This apology is appropriate for a rash caused by an appropriately administered antibiotic. But it seems bizarre not to take responsibility when a clinician errantly administers a neuromuscular blocking agent instead of an anti-cholinesterase agent when attempting to antagonize muscle relaxation. Although an investigation should be done to assess for system flaws that contributed to the error, not taking responsibility in that case (unless there was a good reason) would likely aggravate parents.

Parents are naturally sensitive about the perioperative experiences of their children. Clinicians should consider apologizing or at least sympathizing about unpleasant experiences such as multiple, painful attempts to insert an intravenous catheter or an out-of-control inhalation induction of anesthesia. These discussions can include an acknowledgment that it was a bad experience and recommendations for the future. For example, a clinician could say, "I am sorry the intravenous catheter took so many sticks," and "Next time, we should probably give oral sedation prior to attempting the intravenous catheter." These comments simply acknowledge what happened, express regret, and educate the family for the future.

"Communication-and-resolution," a transparent disclosure of injury or error presented with appropriate compensation, can lead to improved relationships with patients and families, better analysis of events to implement improvements, and possibly forestall legal action [91,92]. Defense of appraised care is essential for clinicians to participate in this system [93,94].

Production pressure

Production pressure is the ubiquitous "internal or external pressure on the anesthetist to keep the operating room schedule moving along speedily" [95]. As a consequence, clinicians may feel pressure to curtail preoperative discussions, inadvisably proceed with cases, or prematurely extubate the trachea to speed turnover. Clinicians should be aware of pressures to provide anesthesia inconsistent with their level of skill or to permit surgery in inappropriate settings. For example, the "routine" tonsillectomy for a child with achondroplasia may be too complex for some clinicians or some surgery centers. Clinicians have an obligation to their patients and to themselves only to provide care for which they are competent and to recognize when economic and administrative pressures induce them to do otherwise.

Suspicion of child maltreatment

Physicians are legally obligated to report even the suspicion of child maltreatment and may be criminally liable for not reporting it. It is natural to downplay concerns because of a hesitancy to inform authorities, particularly if the parents are from a socioeconomic class similar to the physician's. But child abuse should never be minimized as a one-time event. Early intervention minimizes disastrous consequences.

Children may be physically abused, sexually abused, emotionally abused, and neglected [96]. Clinicians may be the first to recognize child abuse because evidence of abuse frequently occurs on the arms, hands, head, face, neck, and mouth. Signs of abuse include bruises or burns in shapes of objects, injuries that fit a biomechanical model (e.g. a handprint), fractures in infants, and developmentally inappropriate injures that are not explained by the offered history. Child abuse might occur in the hospital during diagnostic or therapeutic care. Children with chronic cognitive delays or physical limitations are more prone to abuse [97]. Munchausen by proxy syndrome is a type of abuse in which parents either cause or fictionalize clinical problems in their children. The signs and symptoms of the resultant diseases are often difficult to explain coherently.

KEY POINTS: PROFESSIONALISM IN PEDIATRIC ANESTHESIA

- Pediatric clinicians have a societal responsibility to improve children's health through supporting professional or lay efforts in local, national, or international communities
- Disclose and apologize for medical errors promptly, factually, blamelessly, and with colleagues trained in disclosure and apology. Remember that clinicians are the "second victims" and deserve grace. Put in place systems to identify and support "second victims"
- Reject production pressure by treating each child as if they were your own

CASE STUDY

This case study is designed: (1) to emphasize that superficially defining cases such as "a 17-year-old wants to refuse transfusion therapy" overlooks relevant complexities; (2) to examine the process and relevant factors in determining maturity for medical decision making in an adolescent; (3) to provide an example of how dilemmas may be evaluated; and (4) to provide an example of the content in an ethics consultation. Characteristics of consultations include clarifying medical issues, identifying stakeholders and their relative extent of influence, defining the ethical questions and issues, and providing an assessment and recommendation.

Summary

Candace is a 17-year-old who has a rare type of rhabdomyosarcoma. She presents for resection of a tumor intertwined with major blood vessels. Candace is a Jehovah's Witness and wants to refuse receiving transfusion therapy during and after the resection of the tumor.

Medical questions

This type of rhabdomyosarcoma is too rare to reliably predict outcome. The best guess, though, is a 5-year survival of 5–10%. While there is a low likelihood of significant bleeding during the operation, the position of major blood vessels presents the possibility of sudden, rapid, and substantial bleeding.

Family

Candace is the daughter of Linda and Larry. Through a friend, Larry began exploring the Jehovah's Witness community 9 years ago and became baptized as a Jehovah's Witness 6 years ago. Linda describes herself as spiritual but has no interest in organized religion. She very much supports the authority of Candace's decision making.

Candace "was very skeptical the first month of learning about [the Jehovah's Witness religion]. I had friends who had 'found' religion … but it never made sense to me." Jehovah's Witness "made sense to me, in an easy to understand manner. This is it, this is the right religion." Following thorough study, at age 14 she chose to become a baptized member to show her dedication to being a Jehovah's Witness.

Candace leads an active high school life. She is a starting wing on the field hockey team, and she frequently participates in school theater productions. She leads bible study and weekly youth group meetings. She is an accomplished public speaker, speaking to groups "over 100 people" about being a Jehovah's Witness.

Linda and Larry like the person Candace has become. Candace, Linda, and Larry share decision making about family matters. They have the normal disputes about things like curfew.

Candace is an active participant in her care. She asks appropriate and extensive questions about options and short- and long-term implications.

In private discussions with Candace, she emphasized that she did not want to die. However, because she believes that Bible and God forbid taking blood, receiving blood would fill her with incredible guilt and sadness because she had disappointed her God. While she was concerned that taking blood would separate her from God, her primary concern was the overwhelming sense of failing her God. When asked whether being transfused forcibly or while unconscious would ease her conscience, she answered that she would feel the same because she had actively put herself in a position in which she could involuntarily receive blood. She equated being transfused forcibly while unconscious as "rape." She stated in a factual and calm way that "if I woke up and found I was getting blood, I would rip it out of my arm."

Candace coherently articulates her religious and spiritual faith. Her beliefs are consistent with the teachings of her chosen faith community. She views herself as able to reason and be responsible for acting on personal moral judgments. She can imagine separating from the Jehovah's Witness community if guided so by her conscience.

Ethical questions

1. If individuals of majority age have the right to refuse potentially life-sustaining transfusion therapy, do minors have this right?
2. What characteristics and criteria can be used to determine whether a minor possesses sufficient decision-making capacity and maturity to make this decision?
3. What issues should be discussed to ensure that their desired blood therapy wishes are followed?

Maturing adolescents are granted increasing authority in decision making. Relevant characteristics that give evidence of adolescent maturity and decision-making capacity include an understanding of their options and associated consequences, an internally coherent rationale, an ability to articulate their positions, an intellectual and emotional freedom to entertain alternate perspectives, and an indication of mature relationships with older individuals. Not all characteristics need to be present for an adolescent to be considered mature. The threshold for the evidence necessary to have decision-making capacity for a specific decision increases as the consequences of the decision increase.

Legitimate concerns about adolescents being overly influenced by short-term consequences should not be tainted by less relevant concerns that preferences may change as adolescents become older. Mature individuals are able to change their minds based on experience and evidence. That adolescents may change their mind as they mature does not invalidate current choices inasmuch as sufficient decision-making capacity is present.

Pragmatism affects considerations about whether to force adolescents to receive undesired healthcare. Adolescents are most capable of physical protest, either by yanking intravenous catheters or by not presenting for therapy. For example, Billy Best, a 16-year-old with Hodgkin lymphoma, ran away so that he would not have to complete his chemotherapy regimen [98].

Assessment

The ethics advisory committee believes that Candace meets the requirements of being a mature individual with substantial decision-making capacity who understands the gravity of her choice. Her active participation outside the Jehovah's Witness community indicates a wider view of the world rather than a more narrow view that may be present with exposure only to the Jehovah's Witness community. Given her beliefs and her extensive missionary and teaching activities, we believe that she has thoughtfully chosen to become a Jehovah's Witness. She has a loving and comprehensive relationship with her parents. Although her refusal of potentially life-sustaining therapy may lead to significant morbidity or death, we believe she exceeds the criteria to make these decisions.

Recommendations

1. The ethics committee believes that Candace should be considered primary decision maker.
2. We are aware that the surgeon requests a court order permitting Candace to be able to consent for refusal of potentially life-sustaining transfusion therapy. We encourage Candace and her family to seek as much information about this process as possible, including the process of seeking this status, the possible drawback of pursuing and securing mature minor status, the role of the parents after achieving this status, and the use of healthcare proxies. A court order may minimize chances that wayward individuals may transfuse Candace.
3. To ensure fidelity in regard to the hospital's implicit promise to honor her preferences, a cadre of clinicians committed to honoring Candace's wishes must be identified. Necessary clinicians include operating room nurses and technicians, anesthesiologists, trainee anesthesiologists, certified registered nurse anesthetists, surgeons, and postoperative nurses and physicians, particularly ICU physicians. Arrangements must be made to ensure willing clinicians in case of an emergent re-operation. The needs of these clinicians (e.g. to meet Candace) should be met.
4. This consultation is solely advisory. Our comments are restricted to the ethical interpretation of the issues facing Candace, her family, and the care team. You may wish to contact the Office of Legal Counsel for their input on existing regulations as well.

Postscript: A court order granted Candace the authority to make decisions about transfusion therapy. In informal conversation later, the judge declared that one of the primary considerations aside from Candace's maturity was the very low likelihood of survival. If her possible survival had been higher, they would have been much less likely to grant Candace the legal authority to make decisions about transfusion therapy.

CHAPTER 2

History of Pediatric Anesthesia

T.C.K. Brown
(Formerly) Head of Anaesthesia, Royal Children's Hospital, Melbourne, Australia

Introduction

History is different when written by people who were there at the time compared to that written more recently by people who rely on information derived from other sources. Insights into the use of clinical signs and acumen by older anesthesiologists, many of whom also had good technical skills unaided by modern equipment (for example, difficult and blind nasal intubation and locating nerves when injecting local anesthetics), help one to appreciate the developments that have taken place and how they managed before.

This chapter will mention events in the first hundred years of anesthesia but will cover mainly 1950–2000, the period of greatest change in children's anesthesia.

The beginning of anesthesia as a specialty and the first drugs used, 1842–1921

The first anesthetic agents had all been experimented with as party inhalations and observed to relieve pain when the inhalers were accidentally injured. Humphrey Davy had made the observation that led him to remark in 1799 that nitrous oxide might be useful to relieve surgical pain where no great effusion of blood took place. In 1824 Henry Hill Hickman thought that a gaseous inhalation might have the desired effect but selected ineffective carbon dioxide.

In 1844 Horace Wells, a dentist in Hartford, Connecticut, tried nitrous oxide successfully in his practice for extractions. Subsequently his public demonstration failed because his patient cried out, although he claimed he felt no pain.

Ether was used in 1842 by Crawford Long in Georgia to anesthetize several patients for surgical procedures, including children. As he did not report his cases for several years, until after William Morton performed his successful public demonstration with ether in Boston in 1846, he has not been given his due credit for inventing anesthesia. Neither has the chemist, William Clark, who had a tooth extracted painlessly as an experiment, after ether frolics, in January 1842.

The speed with which the news travelled around the world was remarkable considering the rate of sea travel at the time. William T.G. Morton's first successful public demonstration of anesthesia was held in Boston on 16 October 1846. The first anesthetics were given in Britain on 16 December and in Australia by Pugh (surgical) on 7 June 1847 and Belassario (dental) in Sydney about the same time.

In 1847 James Young Simpson, Professor of Midwifery in Edinburgh, introduced chloroform as an anesthetic, having previously used it and ether at dinner parties to exhilarate his guests. So the three agents that were to dominate anesthesia for the next century had been introduced. Later, ethyl chloride was often used for induction because of its rapid onset and short duration of action. It was first introduced in 1848 but did not come into general use until 1895. Embley reviewed its pharmacology in 1906 [1,2].

Gregory's Pediatric Anesthesia, Sixth Edition. Edited by Dean B. Andropoulos and George A. Gregory.

Figure 2.1 Pediatric Schimmelbusch masks (left), with gauze insert in the middle. Chadborne's modification is shown on the far right.

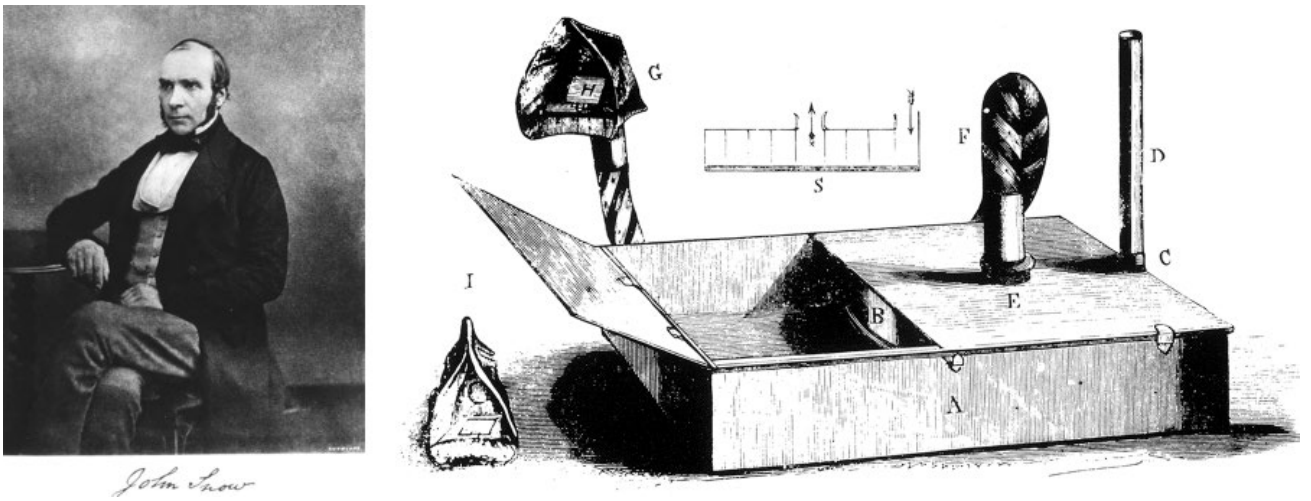

Figure 2.2 John Snow and his inhaler showing the waterbath (right).

These anesthetics were administered in many cases by open drop on to a handkerchief or on to gauze, which was later held in a wire frame such as the Schimmelbusch mask [3] (Fig. 2.1).

Ether was regarded as a relatively safe anesthetic. It has sympathomimetic properties, which sustain cardiovascular stability, and is a very potent bronchodilator that was used successfully to treat status asthmaticus before specific bronchodilators were available. It also produced secretions that liquefied sticky mucus so that it could be more easily sucked out. Secretions were usually a nuisance during anesthesia but could be controlled with atropine or hyoscine – a major reason for including these drugs in premedication. The smell was unpleasant and many children were sick but most often only vomited once. Guedel developed a scale of eye signs and breathing patterns which is a useful guide to the patient's depth of anesthesia during ether administration.

Ether is flammable. Electrical plugs were placed higher than 5 feet (150 cm) to minimize the possibility of ignition or explosion because ether is heavier than air. Ethylene was a weak anesthetic gas like nitrous oxide. Its use was limited because it was flammable and lighter than air and was dangerous with these electrical installations. Ether has continued to be used in many less affluent countries because it is cheap and relatively safe and simple to administer by trained nurses and medical assistants. These people provide an important service, particularly in many parts of Africa where medically trained personnel are scarce.

John Snow (Fig. 2.2) in London soon became the expert in the administration of anesthetics. He built a vaporizer that took into account several principles of vaporization of ether: baffles increased contact time between liquid and gas so that more vapor was taken up, and a warm waterbath surrounded it to prevent the liquid from cooling too quickly on vaporization. Snow also kept meticulous records of his cases and published large series with both ether and chloroform without fatalities. He recorded 145 cases of infants under 1 year who received chloroform, the youngest being 10 days old [4]. Many of these were for operations on cleft lip. He emphasized the importance of avoiding high concentrations. With chloroform he did not exceed 2%. He also noted that the effects of chloroform came on more rapidly in infants and children than in adults.

There was much discussion about the choice between ether and chloroform. The latter was sweet-smelling and caused less vomiting but was associated with more deaths, mostly cardiac but some due to liver failure. In 1896 there were 85 deaths in England, of which 65 occurred before surgery began. These statistics led the first anesthetist at the Melbourne Hospital, Edward Henry Embley (Fig. 2.3), to undertake a huge study on 284 dogs which showed that death was due to cardiac failure rather than respiratory failure as suggested by the Hyderabad Commissions in India. He also showed that some protection was offered by vagal section or atropine. Another feature of the study was that half the animals received

Figure 2.3 Edward Henry Embley.

morphine and curare 40 years before curare's introduction into clinical anesthesia. The animals were ventilated via tracheostomy prior to the administration of chloroform. The results were published in 20 pages of the *British Medical Journal* in April 1902 [5]. In 1905 Embley published another major paper on ethyl chloride, used for over half a century to induce anesthesia. Embley was appointed as lecturer in anesthetics at Melbourne University in 1901. He must have been one of the earliest academic appointments in anaesthesia in the world.

The first recorded death with chloroform was that of Hannah Greener, a 15-year-old girl who succumbed during induction like so many others afterwards [6]. It was probably because her heart, sensitized by chloroform, was exposed to high levels of circulating catecholamines (she was very anxious). After the development of the electrocardiogram (ECG) by Levy in 1911 it was shown that this combination could cause ventricular fibrillation. There were no defibrillators then.

Premedication

The purpose of premedication was to reduce patient anxiety and thereby reduce the amount of anesthetic drugs needed, and to reduce secretions, particularly with ether (atropine or hyoscine). Forty years ago heavy premedication with an opiate, atropine, or hyoscine with or without a hypnotic was often used. Children did not like injections and nurses did not like giving them so there was a change to oral (or nasal) administration in about the 1980s. Now, with increasing parental involvement and more day-of-surgery admissions, many anesthesiologists rarely use premedication. It has been shown that preschool children are as calm when their parents are present as with premedication if they are not there [7].

Local anesthesia

The discovery of the local anesthetic properties of cocaine on the eye by Koller in 1884 led to the development of other local anesthetic drugs such as amylocaine (1904) and procaine (1905).

Local and regional anesthesia was developed initially by surgeons. August Bier in Germany performed spinal anesthesia and had two children among his first six patients (1898) [8]. Spinal anesthesia became popular in some centers and, by 1907, 2000 cases were reported from France and another 1000 by Bier's group in Germany.

In 1920 Gaston Labat, a French surgeon, spent a year at the Mayo Clinic teaching regional anesthesia and writing his well-known book *Regional Anesthesia: Its Techniques and Clinical Applications* [9].

Fidel Pages (Madrid, 1921) introduced epidurals [10]. Mario Dogliotti (Turin, Italy, 1933) has been credited with popularizing this technique [11].

KEY POINTS: THE BEGINNING OF ANESTHESIA

- Crawford Long in Georgia used ether in the first recorded anesthetics starting in 1842, including children
- Horace Wells first used nitrous oxide for dental extraction in 1844 in Hartford, Connecticut
- William T.G. Morton staged the first successful public demonstration of anesthesia, with ether, in 1846 in Boston
- James Young Simpson introduced chloroform as an anesthetic for labor and delivery in 1847 in Edinburgh, Scotland

Early regional anesthesia in children, 1909–1933

Papers relating specifically to regional anesthesia in children began to appear in the early twentieth century. In 1909–10 Tyrell Grey, Medical Superintendent of Great Ormond Street Hospital for Sick Children in London, published three papers on spinal anesthesia in children, each covering 100 cases [12]. The patients were not anesthetized but comforted by a nurse who knew them. Spread of the local anesthetic was controlled by increasing specific gravity of amylocaine with glucose. The patient benefits were absolute anesthesia, no surgical shock, analgesia was localized to the area of the block, and postoperative vomiting was minimal. The surgical advantages were good operating conditions, easy access to the abdomen, the gut was contracted, the surgery was quicker, and the spinal anesthesia could be administered by the surgeon himself. There was less pain and feeding could be started sooner.

In 1945 Etherington-Wilson was well known for the use of baricity in determining the height of spinal block. He included 30 patients between 16 days and 3 years of age when describing his methods of calculating dosage in a series of 1600 patients [13]. Successful experience with spinal anesthesia was also reported by Stephen and Slater in Montreal (1949) [14] and Leigh and Belton [15].

If one knew this and had read the positive reports of its use in sick infants it should not be surprising that many years later Abajian et al advocated spinal anesthesia as an effective form of anesthesia in neonates and premature infants, especially as it does not cause hypotension in that age group [16,17]. A major problem of general anesthesia in this age group was postoperative apnea. This can be largely overcome by retaining less diffusible nitrogen in the lungs by inhaling air, thus stabilizing the alveoli. Déry et al demonstrated the importance of this in maintaining functional residual capacity in adults [18]. The same applies to infants and babies but, although effective, the method has not been widely practiced in neonates.

In 1920 Farr, in Minneapolis, reported 129 spinals in children with nine failures. Many were for pyloromyotomies [19]. In 1932 Marian from Bucharest, Romania, reported 653 spinals in children, mainly with 4% procaine, with 15 failures [20]. Interest continued and spread. In 1935, Balacesco, also from Bucharest reported 1241 spinals in children with good results – only some older children (older than 15 years) had headaches. He used amylocaine and later 4% procaine [21].

Spinals were used in children as young as 2 weeks of age in Toronto by 1933 [22]. They had also done four thoracic cases. The patients were mostly premedicated with pentobarbitone and morphine, and the needle was inserted at L4–5 as it had been recognized that the spinal cord reached lower in infants but, conveniently, the intercristal line between the iliac crests at the level where the needle was inserted, was also a segment lower than in older children. Junkin, in Toronto, made two important observations: that hypotension was less than in adults and headaches were uncommon in children [22].

Caudals were introduced for cystoscopies and urethral surgery in children 4–14 years old by Meredith Campbell (1933) [23]. In 1936 Sievers reported the use of peridural block for cystoscopy [24].

Harry Curwen in Durban, South Africa, presented a paper on caudal anesthesia in 92 neonates in 1950 [25]. Armando Fortuna led the development of regional anesthesia in Brazil. He wrote several papers relating to caudal anesthesia and its safety, even in poor-risk children, and then produced a good historical review of regional anesthesia in children in 2000 [26,27].

By the 1970s caudal anesthesia was being used in several parts of the world including Australia, Britain, France, and Mexico [28–31].

The French Paediatric Anaesthetic Society, ADARPEF, analyzed 224,409 cases done with regional or local blocks: 50% were caudals [32]. There were eight dural perforations, four accidental spinals, two inadvertent vascular injections with convulsions, and one rectal penetration. Another reported complication is syringe swap and the incorrect drug being given. This can be disastrous if a toxic substance is injected. The same society later published another review of 24,005 cases (1982–91), mostly caudals followed by lumbar epidurals and spinals [33]. This paper caused some concern because there were five patients with serious neurological sequelae, three of whom died. They were all less than 2 months old. Three had tetraplegia, one had hemiplegia, and one had cardiac arrest with brain damage. Dalens et al suggested that the injection of air could cause problems [34], as it did in some of these catastrophes [35].

When large numbers of failures are recorded (25%) [21] or there are many serious complications it suggests that the knowledge of technique or dose was inadequate or the operators were careless [36]. For example, textbooks previously described performing femoral nerve block by fanwise injection lateral to the femoral artery. It is more accurate to insert a short beveled needle vertically lateral to the femoral artery and feel the resistance of two "pops" as the needle penetrates fascia lata and fascia iliaca. If it is easy to inject, the tip is in the correct place [37]. Otherwise withdraw the needle with pressure on the syringe plunger until it is easy to inject – occasionally the two fascial layers are fused. The other aid to finding depth is that there is resistance to injection while the needle tip is in muscle but it is easy to inject into spaces where nerves often lie [38].

KEY POINTS: EARLY REGIONAL ANESTHESIA IN CHILDREN

- Tyrell Grey of Great Ormond Street Hospital in London published three papers on spinal anesthesia in children in 1909–10
- In the 1920s and 1930s there were four major case series of spinal anesthesia in children in over 2000 patients
- The first caudal anesthetics in children were reported by Meredith Campbell in 1933

Delivery systems and anesthetic machines, 1916–1937

Many varieties of inhalers were developed before gas, oxygen, and ether machines such as the one produced by Gwathmey came into being in the early twentieth century. Edmund Boyle, at St. Bartholomews Hospital (Barts) in London, dissatisfied with the older methods of anesthesia, obtained a Gwathmey machine from the United States in 1916. As it developed gas leakage problems at joints he decided to make his own machine beginning about 1917. Initially this provided oxygen, nitrous oxide, and ether. This continued to develop as the Boyle machine, which became widely used around the world [39]. In the United States Forreger and then Heidbrink machines were developed. As all these progressed, flowmeters and vaporizers improved and became more accurate. By the 1950s Lucien Morris had developed the copper kettle vaporizer [40] and Cyprane had made the Fluotec with split gas flow and temperature compensation to provide accurate lower concentrations of halothane. It was then modified for other agents [41].

Another important addition was carbon dioxide absorption with soda lime, introduced in a circle system by Dennis Jackson (1915) [42]. Waters developed the to and fro system using his canister which had a small pediatric version [43]. These avoided the use of high gas flows and were particularly useful with cyclopropane which was an expensive and explosive agent. It also required special flow meters.

Anesthetic machines such as the Boyle evolved, and variations remained in use for six to eight decades (Fig. 2.4). Jeffrey Cooper in Boston designed a brilliant delivery system with electronic feedback safety features [44] which suffered commercial suppression. Rod Westhorpe (see Fig. 2.11H) and colleagues in Melbourne produced a machine with many ergonomic features such as height adjustment, sloping light emitting diode (LED), flow meters, and gas delivery from either side (Fig. 2.5). It did not get past prototype development before the new concept workstations were introduced which combined anesthesia delivery, ventilator, and monitors. They were revolutionary.

Pediatric anesthesia delivery systems

For infants and small children low-resistance circuits were desirable to minimize work of breathing. In 1937 Philip Ayre (Fig. 2.6) introduced his T piece which had the advantages of low resistance (no valves), simplicity, and allowing controlled ventilation away from the operative field in patients who were intubated, particularly for cleft lip and palate and neuro surgery. His original T piece was part of an older Philips circuit which had a gas delivery tube entering the side but turning a right angle to face the expired gas flow. He recognized that the patients did better this way because the flow creates slight resistance to expiratory flow which would tend to keep the alveoli open – actually it was a form of continuous positive airway pressure (CPAP). Unfortunately when the T piece was manufactured it was made with the fresh gas flow tube entering at right angles. About 40 years later an acute-angled fresh gas inflow was made and Portex made a similar device in plastic, thus restoring the original benefit of slight CPAP.

The volume of the expiratory limb of the T piece should exceed tidal volume to avoid air dilution. For controlled ventilation the expiratory limb is occluded to force fresh gas into the lungs. The tidal volume then depends on the fresh gas flow rate and the duration of occlusion (flow generator).

Ayre was an unusual man: he had alopecia, wore a ginger wig, and had had a cleft lip and palate repair which left him with a honking voice that mesmerized the children during induction. He gave about 2000 anesthetics while he was still a medical student [45]!

Later, Jackson Rees from Liverpool, England, added an open-ended bag to increase versatility (Fig. 2.7). With spontaneous ventilation it acted as a respiratory monitor but it could

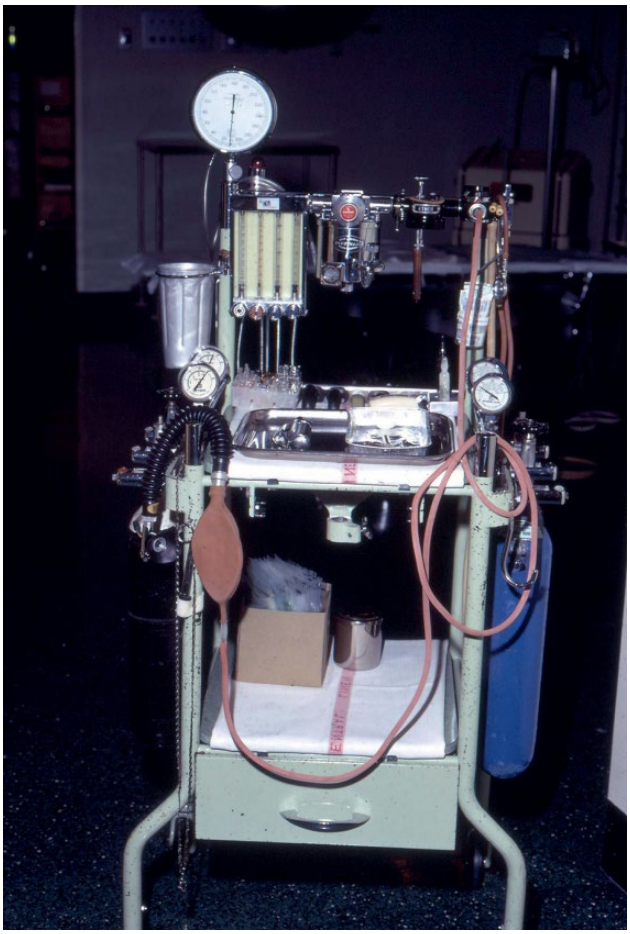

Figure 2.4 CIG Boyle machine, 1963.

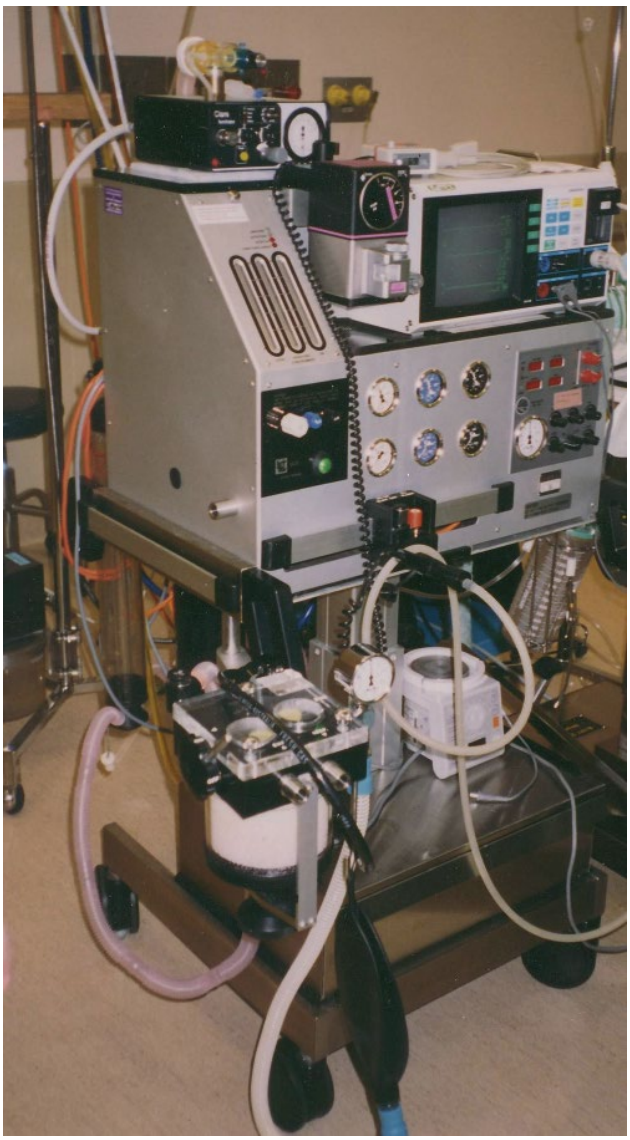

Figure 2.5 Ergonomic anesthetic machine with Claire ventilator and monitor on top.

Figure 2.6 Philip Ayre, Newcastle upon Tyne, England.

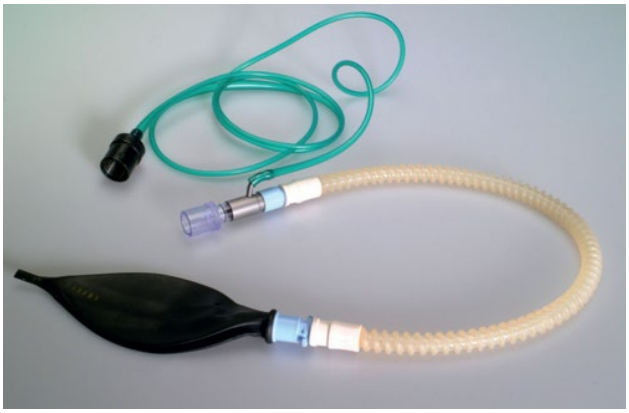

Figure 2.7 Jackson Rees T piece modification with his prolonged intubation tube attached.

be used for controlled ventilation as demonstrated in Figure 2.8. It was important to use three fingers to squeeze the bag because using four caused thenar muscle fatigue.

Other low-resistance devices used more in North America were the Lewis–Leigh and Stephen–Slater one-way valves. They allowed fresh gas to flow to the patient but during expiration a flap valve stopped the inflow and directed the gas out of the circuit.

The Bloomquist pediatric circle with miniaturized soda lime canisters and narrow tubing were used in North America, while Ian McDonald in Melbourne made a similar miniature circuit. They had valves which increased work of breathing and so were better used with controlled ventilation. The circle system conserved the expensive gas, cyclopropane, and reduced the risk of fire.

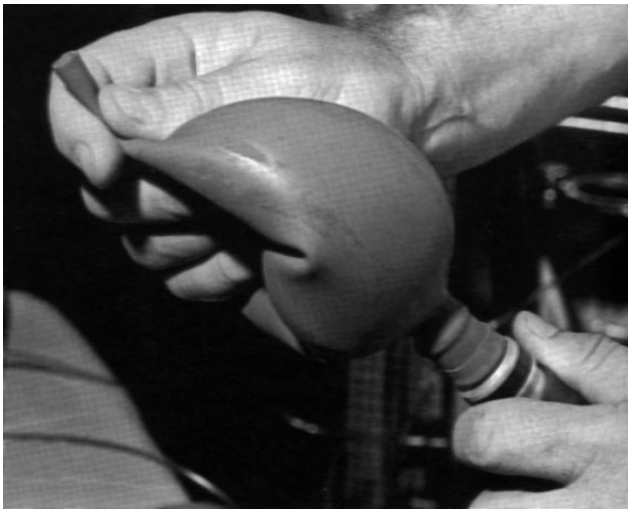

Figure 2.8 Ventilating with the open-ended bag of the Jackson Rees T piece. Three movements are required. (1) Close open end with thumb and index finger. (2) Squeeze bag with the other three fingers (shown). (3) Stop squeezing and allow expiration.

KEY POINTS: DELIVERY SYSTEMS AND ANESTHETIC MACHINES

- Anesthesia machines delivering oxygen, nitrous oxide, and ether were developed as early as 1916–17
- Carbon dioxide absorption with soda lime was introduced by Jackson in 1915
- The Ayre T piece was introduced in 1937 specifically for pediatrics

New drugs in the 1930s, 1940s, and 1950s

Several new anesthetic drugs were introduced in this period. Cinchocaine/dibucaine (1929) was a longer-acting local anesthetic which was widely used to extend spinal anesthesia. Vara-Lopez from Burgos, Spain, reported 438 spinals in children using cinchocaine/dibucaine in 1942 [46].

The short-acting barbiturates, hexobarbital and thiopental, were introduced in 1932 and 1934. Although many continued to induce anesthesia using inhaled agents, thiopentone was the favored intravenous induction agent for over 60 years. There were circumstances in which the usual dose (about 5 mg/kg) needed to be modified. It was often avoided in neonates but could be used in small doses – 2–3 mg/kg. The infant dose was higher and declined after 2 years with age [47,48]. Premedication reduces anxiety and the sympathetic response. An anxious child will have an increased cardiac output and muscle blood flow with proportionately less of the cardiac output going to the brain so that more drug is needed to induce anesthesia. The opposite situation prevails when the patient is hypovolemic, usually due to blood loss. If the usual dose is given, the concentration in the reduced blood volume is greater and a greater proportion of cardiac output and the drug goes to the brain and heart. Onset of anesthesia is quicker and myocardial depression is more likely to occur.

Cyclopropane is a gas, discovered in Toronto but introduced to clinical anesthesia by Waters in 1934 [49]. It was not only flammable but explosive. There was an explosion in Chile that killed five staff and the patient. Cyclopropane had a low blood:gas solubility (0.47) and provided rapid induction and emergence. Deep anesthesia could be reached quickly and the muscles relaxed so that patients could be intubated and good operative conditions achieved. This facilitated the development of thoracic surgery before muscle relaxants were introduced. Cyclopropane had sympathomimetic properties so that blood pressure was maintained even when some blood had been lost. The downside was hypotension when the vasoconstrictive action wore off.

Cyclopropane was popular for children because of the rapid, smooth induction. In inexperienced hands laryngeal spasm during emergence could be a problem but after three or four spasms one soon learnt how to deal with that complication – *continuous* positive pressure on the bag full of oxygen would force oxygen into the patient with the slightest opening of the vocal cords. It was a matter of timing whether one extubated the child while still deeply anesthetized or nearly awake. Ralph Waters taught to turn on nitrous oxide and discontinue cyclopropane near the end of an anesthetic to reduce the tendency to spasm. The use of cyclopropane declined after the introduction of halothane.

Trichloroethylene (Trilene) was a dry cleaning agent. Langton Hewer, in London, introduced it as an anesthetic in 1941. It had several good points including low cost, potent analgesia (good for obstetrics and peripheral procedures), and non-flammability. Its minimum alveolar concentration (MAC) was 0.17%. Unlike other inhalational agents it was a poor hypnotic and increased muscle tone, resulting in rapid shallow breathing (like restrictive lung disease). Unlike other inhalation anesthetics it increased consumption of non-depolarizing muscle relaxants when used with them. This was thought to be due to an effect on muscle spindles increasing muscle tone which reduced chest wall compliance.

Trichloroethylene was found to have neurotoxic effects when used with soda lime which, in those days, contained 5% potassium hydroxide [50]. The exothermic reaction of this compound with carbon dioxide produced toxic breakdown products, affecting most commonly the trigeminal nerve. Potassium hydroxide was later replaced with sodium, calcium, or barium hydroxide in soda or baralyme (80% calcium hydroxide and 20% barium hydroxide) which were safer.

Trichloroethylene was used in a few pediatric centers as an adjunct in neurosurgery, as an agent which did not cause cardiovascular changes during cardiac catheterization, and in primitive situations where it could even be used instead of nitrous oxide which, being a gas, was too expensive or not readily available in less affluent countries.

High concentrations had to be avoided otherwise rigidity, prolonged sleep, and a high incidence of postoperative vomiting occurred, especially if narcotics were used as well. One could just detect the smell when 1 MAC was delivered. Trichloroethylene was very cheap but it was discontinued when the manufacturing plant needed to be replaced.

Lidocaine (lignocaine) was synthesized by Lofgren and Lundquist in Sweden in 1946. It became widely used. Despite its shorter action (about 1½ h) it was used by infusion, if necessary, for longer cases in less affluent countries where cost mattered and new drugs were too expensive. About 18 years later it was found to have antiarrhythmic effects on the heart.

More recently longer-lasting local anesthetics such as bupivacaine were introduced (1963) which led to a rekindling of interest in nerve blocks and regional anesthesia. Although newer agents with claimed advantages have been introduced, bupivacaine was safely used thousands of times by keeping to safe doses (3 mg/kg) and avoiding intravascular injection. Moore suggested convulsions were unlikely below plasma levels of 4 μg/mL. He recorded 5.1–5.4 μg/mL in one case [51]. In another report 7.5 μg/mL was recorded during unexpected convulsions because the plunger of the syringe was pulled back to ascertain the absence of blood. The 12-year-old patient was ventilated with oxygen until she recovered. Although a decrease in heart sounds occurred, indicating a transient decrease in cardiac output, no dysrhythmias were detected [52].

KEY POINTS: NEW DRUGS IN THE 1930S, 1940S, AND 1950S

- Cyclopropane was introduced into practice by Waters in 1933
- Trichloroethylene was first used by Hewer in 1941
- Lidocaine was synthesized by Lofgren and Lundquist in 1946

Neonatal anatomical and physiological factors in relation to anesthesia and monitoring

There are some important anatomical points relevant to ventilation of infants and small children [53]. Looking at a chest radiograph, small infants' ribs are more horizontal which prevents an increase in antero-posterior diameter, also, lacking the bucket handle movement of older children and adults prevents increases in transverse chest diameter. The consequence is that a baby's tidal volume is more dependent on diaphragmatic movement. Anything that splints the diaphragm such as air in the stomach or abdominal distension diminishes tidal volume. Gentle ventilation will avoid stomach distension.

In tracheo-esophageal fistula, positive pressure ventilation, if used, must be gentle (low pressure), particularly if a lower esophageal fistula is large. In the early years (1960s) the size was sometimes estimated by the air in the fistula on a lateral chest radiograph. If it was more than 2 mm across, it indicated that inflating the stomach was a potential hazard.

Another observation when looking at a neonatal chest radiograph is that the left bronchus comes off the trachea at a greater angle (47°) than the right bronchus (30°) [54]. Adriani and Griggs [55] stated in 1954 that the angles were equal, a point that was assiduously reproduced in textbooks for many years.

When an endotracheal tube is inserted too far, it is usually on the right side. Many people think this is because the right bronchus is in a more direct line from the trachea or that the right bronchus and lung are larger, but it is mainly due to the fact that the tip of the bevel of the tube is on the right. The

practical implication is to turn the tube so that the point of the bevel is on the left if one is aiming for left endobronchial intubation. In the days before endoscopic placement of tubes was available these were important points for the anesthesiologist to know.

Anesthetic dead space must be kept to a minimum and hence the Rendell-Baker–Soucek low dead space mask was developed. Some anesthesiologists cut endotracheal tubes to reduce dead space but this is unnecessary and even undesirable when controlled ventilation is used because of the tendency to overventilate.

Babies breathe faster and have more rapid heart rates so that more oxygen is delivered to the tissues to satisfy their higher metabolic rate and oxygen consumption. Cardiac output is heart rate dependent because stroke volume varies little. Also, the heart rate slows in response to hypoxia (unlike adults) so that cardiac output is adversely affected.

Fifty years ago monitoring was simple and depended more on observation of clinical signs. Anesthesiologists could glean most of the essential information from these. The pulse would indicate rate, rhythm, volume, and character (e.g. bounding, soft).

The stethoscope, either precordial or esophageal, provided valuable information about ventilation and correct placement of the tube as well as heart rate, rhythm, and intensity of heart sounds. The last are created by heart valve closure and will be softer if stroke volume or myocardial contractility is reduced. The sounds give a sensitive indication of changing cardiac output (provided the stethoscope has not become loose) and, more recently, it is a quick way of telling whether a falling oxygen saturation is a patient or probe attachment problem.

Capillary refill was a useful indicator of peripheral perfusion. It would decrease when there was blood loss and with cold temperatures. Skin color could indicate adequacy of hemoglobin; for example, if it was low, the skin exhibited pallor. Cyanosis was a rather late sign of hypoxia, particularly if the hemoglobin was low. This is why the introduction of the pulse oximeter was such an important development in anesthesia.

Over the years fluid and electrolyte therapy has improved. Initially it was felt that babies needed to be kept hydrated and needed glucose for energy. Pediatricians gave 5% glucose in water or 4% glucose in 1/5 normal saline which provided inadequate sodium resulting in hyponatremia.

An important difference between neonates and small infants compared to older children is that the extracellular (ECF) and smaller intracellular (ICF) fluid compartments are larger, which makes them sicker than older patients if they become dehydrated (easy loss from ECF and less fluid in the ICF to buffer losses in the ECF) (Fig. 2.9).

The kidneys, including the cortical nephrons which control sodium reabsorption, are not fully developed at birth. While much water is reabsorbed in the proximal tubules, the urine osmolality (700 mOsm/L in neonates compared with 1400 mOsm/L in adults) is adjusted by water reabsorption in the loops of Henle where interstitial urea is less (nitrogen is being used for tissue building). This information was only reported in the 1960s and early 70s.

Nowadays a balanced electrolyte solution (e.g. Hartmann's, lactated Ringer's) is a commonly used intraoperative fluid in children. Normally the stress of surgery will ensure an adequate blood sugar level in children. Some glucose may be added to the intravenous fluids in premature babies because glucose and glycogen storage may be insufficient at birth. Neonates require less fluid during the first few days. One calculation for daily fluid requirement was:

- 0–7 days: day of life/7 × 100 mL/kg
- 0–6 months: 100 mL/kg
- 1–13 years: weight (kg) – age (years) × 90 mL/kg.

Total parenteral nutrition (TPN) was a concept developed in the 1970s, advocated because it shortened length of stay in ICUs by providing essential calories, nutrients, and fluids. The savings offset the cost of TPN.

Heat loss may be greater because infants have large heads that contribute to their greater surface area:body weight ratio. They are poorly insulated with less subcutaneous fat, they do not shiver, and they have a narrower thermoneutral range, i.e. ambient temperature where heat loss is minimal. Steps such as a warming blanket beneath the baby on the operating table, wrapping in foil, warmed humidification, and the use of overhead heaters were used to prevent cooling. Before these steps were taken, outcomes of surgery were less favorable.

There have been many developments in physiology, some of which also affect the handling of drugs, which impact on pediatric anesthesia. A better understanding of these has helped improve the care of children and the results of surgery.

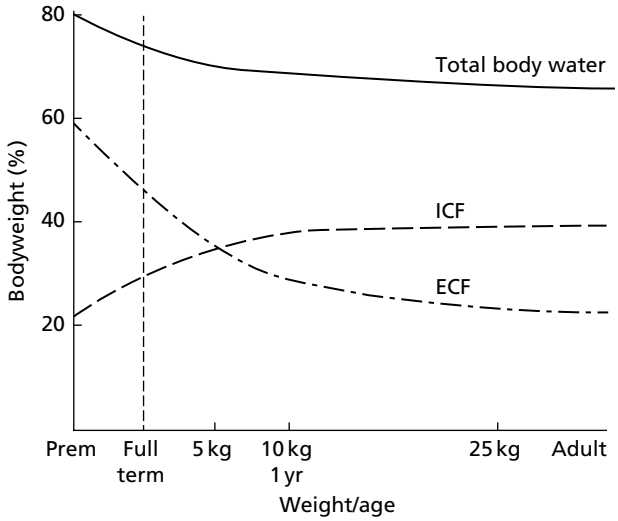

Figure 2.9 Changes in intracellular and extracellular fluid compartments (ICF and ECF) during the first months of life. *Source:* Adapted from Cheek [125] and Friis-Hansen [126].

KEY POINTS: NEONATAL ANATOMICAL AND PHYSIOLOGICAL FACTORS

- Small infants' ribs are more horizontal, preventing "bucket handle" movement and making tidal volume more dependent on the diaphragm
- In early years monitoring was by clinical observation only: skin color, capillary refill, pulse
- Balanced electrolyte solutions, preservation of body temperature, and neonatal pharmacology have contributed significantly to survival in neonatal anesthesia

Early anesthesiologists interested in children: pediatric anesthesia emerges into the specialist era, 1920s to 1950s

During the transitional years (1920–1950) when doctors who gave anesthetics first began to take a special interest in children, particularly babies, changes began to occur mainly in some of the more progressive children's hospitals. Pediatric surgery was beginning to expand but success was only possible when anesthesia improved and there was still a long way to go.

Pediatric anesthesia refers to anesthesia for children of all ages. In the first 100 years it was part of the amalgam of anesthesia generally, with few references to studies in children who were regarded as miniature adults. Few doctors devoted their practice to anesthesia, mostly doing some general practice as well. Before World War II few people took a special interest in children's anesthetics. In countries like Canada, Britain, Australia, and New Zealand, doctors, sometimes young and inexperienced, gave the anesthetics while in the USA and Europe nurses were often involved. Betty Lank was one who made an outstanding contribution, working with Robert Gross in Boston for 20 years from 1936.

Canada

Charles Harold (Robby) Robson (Fig. 2.10A) [56,57] came from British Columbia. He graduated in medicine at McGill in Montreal in 1913. He interned at Montreal General and trained in anesthesia at Royal Victoria Hospital before going to France in World War I, later becoming Senior Consultant Anesthetist to the Canadian Army.

In 1919 he returned to Canada and became Chief Anesthetist at the Hospital for Sick Children (HSC), Toronto, where he remained until he retired in 1951. Adenotonsillectomy constituted about a third of cases. Anesthesia was mainly open drop ethyl chloride and ether. Robson had a special skill of tactile intubation when necessary – he used his fingers to guide the tube into the trachea. He became Clinical Demonstrator in 1935, published one paper on "anesthesia for children" in 1936 and made a movie on the hazards of the immediate postoperative period. He was a frequent speaker on pediatric anesthesia and trained a generation of anesthesiologists, including five who became department heads. He was probably the first pediatric anesthetist to have such a major influence on the field and has been called the grandfather of pediatric anesthesia in Canada.

In 1927, Charles Junkin joined the staff of HSC but like many doctors involved with anesthesia in those days he anesthetized adults and children and also did general practice. In 1945 he became a full-time pediatric anesthetist and went on to become Chief from 1951 to 1960 [58].

At the conclusion of World War II the department was enlarged by better trained and more experienced full-time anesthetists coming back from the war, such as Norman Park, who was joined by others in Toronto including Code Smith, a wonderful pharmacology teacher who made the subject more interesting by discussing structure–action relationships of drugs (notably barbiturates and local anesthetics). This made the subject easier to follow and remember. He was mainly a neuroanesthetist.

Digby Leigh (Fig. 2.10B) [58], also from British Columbia, graduated in Montreal (McGill) in 1932. He began surgical training until Wesley Bourne, later the first Professor of Anesthesia in Montreal and Canada, persuaded him to change to anesthesia. He spent three years with the legendary Ralph Waters at Madison, Wisconsin, the first Professor of Anesthesia in the USA (1937), before returning to become Chief at the Montreal Children's Hospital in 1940. He developed a non-rebreathing valve and an infant circle absorber so that cyclopropane could be administered in a closed circuit.

During the war, Leigh with Wesley Bourne and Harold Griffiths (later first President of the World Federation of Societies of Anaesthesia – WFSA) each organized 3-month anesthesia courses for doctors in the armed forces before they went overseas. Many of these trainees went on to become part of the rapid expansion of specialists after the war. Digby Leigh established the Montreal Diploma of Anesthesia course which set the pattern for training in Canada. In 1947 he moved to Vancouver where he set up a department which supplied the total service for Vancouver General and Children's Hospitals. Among those who went with him was Eric Webb, a brilliant clinical teacher who also inspired an interest in the history of anesthesia among trainees. Leigh later went to Lagos, Nigeria, as part of a Canadian initiative to help establish training in that country. Others who accompanied Leigh were Horace Graves, Harold Kester, John Poole, and Herb Randall. The last also trained with Waters and had a limited practice until he was 92 (possibly the oldest anesthesiologist still to practice).

Leigh produced the first textbook on pediatric anesthesia in North America with Kay Belton, Supervisor of Pediatric Anesthesia at Vancouver General Hospital (1949) [59]. It is an interesting book, first discussing the care of the child in hospital, and later including a chapter on local anesthetic blocks including caudals and spinals, which were used in about 10% of their cases.

In 1954 Digby Leigh moved to Los Angeles Children's Hospital, having failed in his request for a separate department and chair of anesthesia in Vancouver. He started the annual weekend courses on pediatric anesthesia that were run for many years by Wayne Herbert. Later his idea of half-day release for teaching trainees was taken to Australia. His influence on teaching and training both generally and in pediatrics was immense. He was regarded as father of pediatric anesthesia in Canada.

C.R. Stephen followed Leigh as chief at Montreal Children's Hospital until 1950, when his colleague H.M. Slater succeeded him when he moved to Duke, North Carolina [57]. They had developed the Stephen–Slater non-rebreathing valve.

Children's hospital anesthetic departments and major hospitals with separate pediatric sections began to acquire more and more full-time pediatric anesthesiologists although in many places general anesthesiologists performed children's anesthetics as part of their practice. The full-timers were largely responsible for leading the way in the advances in the specialty, which was developing from the 1950s onwards.

In 1954 Ruston, working in Hamilton, Ontario, reported on epidural anesthesia for Infants and children, and 10 years later updated their experience [59,60].

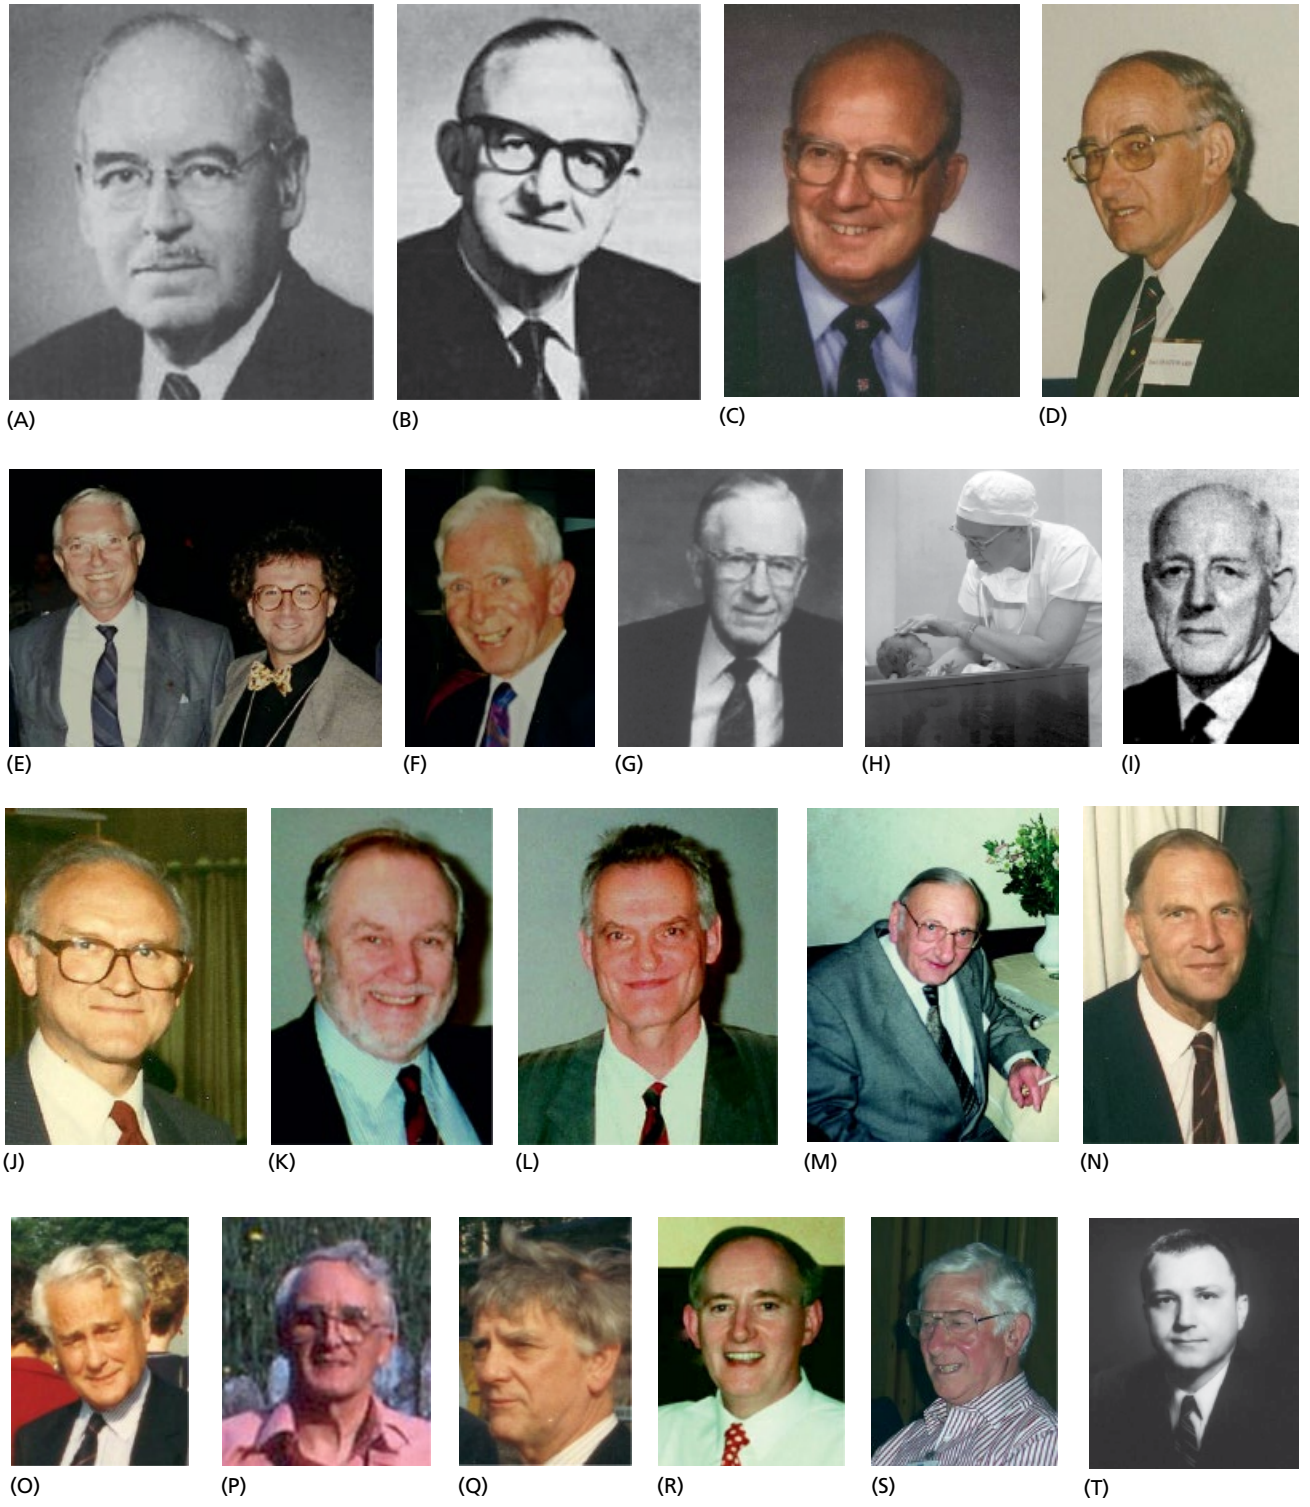

Figure 2.10 Prominent pediatric anesthetists: Canada, USA, and Britain. (A) Charles Robson, Toronto; (B) Digby Leigh, Montreal, Vancouver, Los Angeles; (C) Alan Conn, Toronto; (D) David Steward; Toronto, Vancouver, Los Angeles; (E) Robert Creighton (left), Jerrold Lerman (right), Toronto; (F) Tom McCaughey, Winnipeg; (G) Robert Smith, Boston; (H) Virginia Apgar, Columbia, New York City; (I) Robert Cope, London; (J) William Glover, London; (K) David Hatch, London; (L) Ted Sumner, London; (M) G. Jackson Rees, Liverpool; (N) Gordon Bush, Liverpool; (O) Gerry Black, Belfast; (P) Harold Love, Belfast; (Q) Peter Morris, Manchester; (R) George Meakin, Manchester; (S) Ted Armitage, Brighton; (T) Arthur Keats, Houston, TX.

During the 1960s and 1970s the next group of leading contributors in Canada included Alan Conn (Fig. 2.10C), Chief at HSC Toronto, who went on to become Chief of Intensive Care with a special interest in near drowning. He was succeeded by David Steward (Fig. 2.10D), who was a very active teacher and editor of his well-known *Handbook of Pediatric Anesthesia*. One of his interests was anesthesia for ex-premature infants. He later opened up Vancouver Children's Hospital before concluding his clinical career as Chief at Los Angeles Children's Hospital. He was succeeded by Bob Creighton and

then Jerry Lerman (Fig. 2.10E), who was an enthusiastic researcher.

Many others specialized in the field. Jeremy Sloan was a cardiac anesthetist at HSC who came from South Africa. Later he contributed to international standards committees. Harold Davenport was chief at the Montreal Children's Hospital before moving to Vancouver for a short period. He then returned to England. He authored a small book about pediatric anesthesia. Tom McCaughey (Fig. 2.10F) became well known as chief at Winnipeg Children's Hospital.

United States of America

Robert Smith (Fig. 2.10G) [4], after war service in Europe where he became involved in anesthesia, was appointed Chief of Anesthesia at the Boston Children's Hospital in 1946. Previously anesthesia at this hospital had been given by nurses including Betty Lank, who made special equipment such as small blood pressure cuffs and masks for infants and children. Smith was interested in patient safety and was an advocate of the use of appropriately sized endotracheal tubes and of wrapping babies to prevent heat loss. In the 1950s he pioneered the use of the precordial stethoscope.

Robert Smith was a great teacher and trained people from all over the world. He had a calm demeanor and never roused antagonism. He produced a famous, comprehensive book in 1959 called *Anesthesia for Infants and Children*. He was regarded as the father of pediatric anesthesia in the USA [61].

Virginia Apgar (Fig. 2.10H), having trained with Ralph Waters, became Director of Anesthesia at the Babies Hospital in New York in 1938. Following her research on neonatal resuscitation she became known around the world for the APGAR scoring system (1953) which she developed to assess the condition of babies at birth and soon afterwards: skin color, pulse, reflex irritability, muscle tone, and respiration each scored as 0, 1 or 2. It was simple and had predictive value – a score below 5 indicated that the baby was in trouble. Later in her career she moved to Johns Hopkins University where she took an interest in birth defects [62].

There were others who contributed to the development of pediatric anesthesia such as Robert McQuiston at Chicago Children's Hospital and Herbert Rackow and Ernest Salanitre at the Babies Hospital at Columbia Presbyterian Medical Center in New York [63]. They established departments that advanced training and practice of pediatric anesthesia after World War II. The latter had research interests in the uptake and elimination of inhalational agents and the risk of cardiac arrest in infants and children.

Margot Demming was the first full-time pediatric anesthesiologist in Philadelphia. She observed that infants required higher concentrations of inhalational agents than adults [64]. Many others followed such as Jack Downes, also in Philadelphia, who was involved in the early days of intensive care [65]. Some places benefitted by the immigration of established pediatric anesthesiologists like Digby Leigh and C.R. Stephen from Canada, and elsewhere.

United Kingdom

In Britain, Great Ormond Street Hospital for Sick Children in London appointed Robert Cope as head anesthetist in 1937 (Fig. 2.10I) [66]. Others joined him such as Sheila Anderson, Bill Glover (Fig. 2.10J), and later David Hatch (Fig. 2.10K) who became the first Professor of Paediatric Anaesthesia in the United Kingdom. David Hatch, with Ted Sumner (Fig. 2.10L), produced a valuable book on neonatal anaesthesia.

Liverpool became influential later when people like Jackson Rees (Fig. 2.10M), Gordon Bush (Fig. 2.10N; the first editor of *Pediatric Anesthesia*), Alan Stead, and Tony Nightingale joined the group there. People from many parts of the world gained experience with them. Britain had many children's hospitals, and places like Glasgow (Douglas Arthur, Roddie McNicol – nerve blocks, especially the anterior approach to the sciatic nerve), Belfast (Harold Love, Fig. 2.10O; Gerry Black, Fig. 2.10P), Manchester (Peter Morris (Fig. 2.10Q), George Meakin (Fig. 2.10R) – muscle relaxants in children), Birmingham (Susan Jones) and others developed good reputations as their staff became well known. Even places like Brighton contributed through the work on caudal anaesthesia by Ted Armitage (Fig. 2.10S) and, in Derby, by Brian Kay. Many of the leaders became President of the Association of Paediatric Anaesthetists.

Jackson Rees was an enthusiast who was well recognized for his teaching, research, and constant search for new ideas [67]. He was largely responsible for the Liverpool technique: thiopental, d-tubocurarine, and rapid ventilation with nitrous oxide and oxygen. Many people incorrectly described it as hyperventilation but the method as he performed it was very rapid, small breaths ventilated with the bag he attached to the T piece on which he kept a slight positive pressure. Unwittingly he was using high-frequency ventilation and positive end-expiratory pressure (PEEP) long before the value of these were appreciated. He was guest lecturer to the Australian Society of Anaesthetists and ran a 2-week course in Melbourne in 1963. During his visit he saw the work with prolonged nasotracheal intubation, with ventilation if needed, that had developed in Adelaide [68] and Melbourne [69]. He returned to Liverpool via Toronto and conveyed his enthusiasm for what he had seen. He began pediatric intensive care in Liverpool and developed his special complex tube for nasal intubation.

In 1973 Britain led the way in Europe when the Association of Paediatric Anaesthetists of Great Britain and Ireland (APA) was formed. They had foreign members who were leaders in Europe and the rest of the world who were well represented at their meetings before other regular meetings had started [70]. These became an important step in building the bonds between pediatric anesthesiologists.

Australia

In Australia a handful of the more experienced general anesthetists took care of most of the babies and pediatric cases needing special care before and during World War II. These included Gilbert Brown (first President of the ASA – Australian Society of Anaesthetists) and Mary Burnell (Fig. 2.11A) who established pediatric anesthesia at the Adelaide Children's Hospital (later President of ASA and Dean of the Faculty of

Anaesthetists), Gilbert Troup in Perth (1922–1947), and Andrew D. Morgan, the first specialist pediatric anesthetist to be appointed in Sydney in 1940. It was Morgan who provided anesthesia for the first lung lobectomy in 1942 and ligation of ductus arteriosus in 1947. He retired in 1957. Charles Sara (Fig. 2.11B), whose research interests were muscle relaxants, humidification, and the management of prolonged respiratory insufficiency, joined the department in 1957. Verlie Lines,

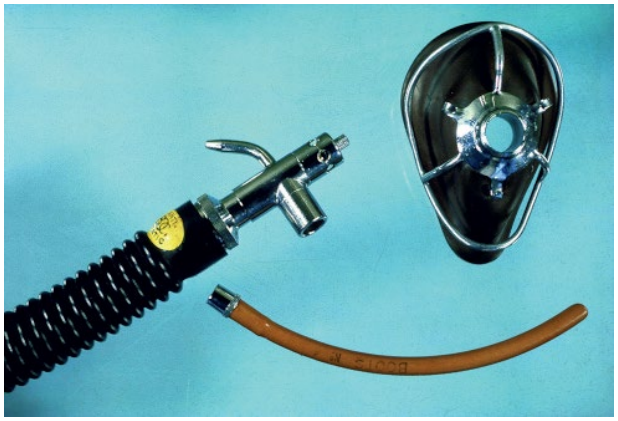

Figure 2.12 Pediatric anesthetic equipment designed by Margaret McClelland and Harry Adams.

who became their first full-time anesthetist in 1955, had a special interest in airway problems. In Perth, Douglas Wilson, who was part-time Honorary Director (1946–1956), made his own equipment and anesthetized most of the neonates there. In 1960 Nerida Dilworth began 30 years as Director, helped by part-timer Peter Brine who later became President of the Australian Society of Anaesthetists [71].

In 1946, Margaret McClelland (Fig. 2.11C) returned to Melbourne, having spent the war years in London giving anesthetics and gaining her Diploma of Anaesthetics. She was in demand immediately but spent some time at the Children's Hospital, eventually becoming the first Director of Anaesthesia (part-time in 1949, full-time in 1956). A training rotation with the Women's Hospital was started. As well as local trainees, others came from interstate and New Zealand. Providing good training and competent assistance in the form of anesthetic technicians, several of whom stayed 30–35 years, McClelland ensured that her concerns about the care of the children in hospital and anesthetic mortality were considerably improved. She collaborated with Harry Adams of Commonwealth Industrial Gases to make a range of equipment for pediatric use (Fig. 2.12) and initiated the use of new drugs including muscle relaxants.

Margaret McClelland was ably supported by Ian McDonald (Fig. 2.11D, right) and later by John Stocks (Fig. 2.11E). They began prolonged intubation and ventilation which led to the development of intensive care in Melbourne Children's Hospital, initially in half of the recovery room [69]. She also did research into hypothermia in relation to cardiac surgery and into anesthetic mortality. She retired in 1970, having also been President of the Australian Society of Anaesthetists in 1964.

She was succeeded by John Stocks, who was a quiet, diligent doctor, highly regarded by his colleagues [71]. He had become Director of Intensive Care in 1969. He wrote *Notes on Paediatric Anaesthesia* which were widely read and utilized. He had intended to write a book but unfortunately he died in 1974 from complications of cancer surgery when only 43. The book was eventually written by Kester Brown, who succeeded him as Director for the next 26 years. Brown was very involved in teaching, continuing education, and research. His co-author was Graham Fisk, who established the second pediatric anesthesia and intensive care units in Sydney and also became a leader in research and education in Australia. Geoff Barker succeeded Stocks as Director of Intensive Care. He had done training in Toronto and returned there later to become Chief of Intensive Care at HSC and eventually Professor of Critical Care in Toronto University.

Tess Brophy was another outstanding woman who advanced pediatric and neuroanesthesia in Queensland, later becoming Dean of the Australian and New Zealand Faculty of Anaesthetists.

By 1967 there were ten full-time and five part-time pediatric anesthetists in Australia who led the rapid changes that occurred during the next 20 years. It was noteworthy how many pediatric anesthetists held leading roles in the Australian Society or Faculty of Anaesthetists and how many were outstanding women. Kester Brown was involved with the WFSA for 20 years, the last four as President. He was able to promote pediatric anesthesia when he organized courses, lectured, and taught in many countries.

Many overseas anesthetists came to Australia for further experience – from 40 countries to Melbourne, and many others to Sydney, Adelaide, and Perth. The majority returned home, where they taught and raised the standard of anesthesia in their own countries.

Victor Mwafongo (Fig. 2.13A) returned to become Head Anaesthetist in Tanzania and later Director of Emergency Medicine. Radha Krishna (Fig. 2.13B) and then Ng Siew became heads of government anesthesia in succession in Malaysia. Rebecca Jacob (Fig. 2.13C, centre), who spent 2 years in Adelaide, became Professor at Vellore Christian Medical College, one of the major hospitals in India. She was also a leader in the Asian Society of Paediatric Anaesthesia which was started by Agnes Ng (Fig. 2.13C, right) from Singapore. Many others, like Dilip Pawar from India (Fig. 2.13C, left), had leadership roles.

During the following ten years (1970–1980) many able young men and women in Australia specialized in pediatric anesthesia (Fig. 2.11F). Many made outstanding contributions. Robert Eyres (Fig. 2.11G) performed cardiac anesthesia and pioneered epidurals in the Royal Children's Hospital in Melbourne. He did the first studies on blood levels of local anesthetics in children which showed that even with doses of 3 mg/kg bupivacaine the levels in caudals and epidurals did not exceed safe levels of 2 µg/mL [72]. Rod Westhorpe (Fig. 2.11H) became an expert on the history of anesthesia, was a leader in the Australian Patient Safety Foundation, and contributed to the development of an ergonomic anesthetic machine and the Claire ventilator. He also became President of the Australian Society of Anaesthetists. Johns Overton, Kennealy, and Vonwiller became the leaders in Sydney where Overton performed the first infant open heart surgery under deep hypothermia in 1969.

This section is included to show the development and some changes in practice during the years of pediatric anesthesia's evolution. In 1967 over 700 patients were managed for 24 h or more in the Royal Children's Hospital ICU in Melbourne. Mortality had begun to decline in neonatal conditions such as esophageal atresia (Fig. 2.14) and diaphragmatic hernia. In those days diaphragmatic hernia, which presented as a blue baby with a barrel chest and scaphoid abdomen because of the displaced abdominal contents, was treated as an emergency to prevent the gut

distending with gas before the small abdomen was closed after the hernia was repaired. One infant operated on after 24 h had a red upper half of its body and a blue lower half after surgery. The lung was a reasonable size and the patient recovered. A clinical assessment of lung size was considered useful in prognosis. If it was one-third or less of normal size the outlook was poor. It is now recognized that if the lung on the compressed side was that small, the other lung would be compressed as well and pulmonary hypertension would occur. Over the years things changed with the advent of new technology: the use of ECMO (extracorporeal membrane oxygenation) and the treatment of pulmonary hypertension. Another factor that seemed to have a greater influence on poor survival was the patient becoming cold during transport to the hospital. When the baby was kept warm and had a reasonably developed lung, the outlook was good. An important point in the anesthetic management was not to try to inflate the small lung. It cannot be fully inflated. With time the lung grows once the compression is relieved.

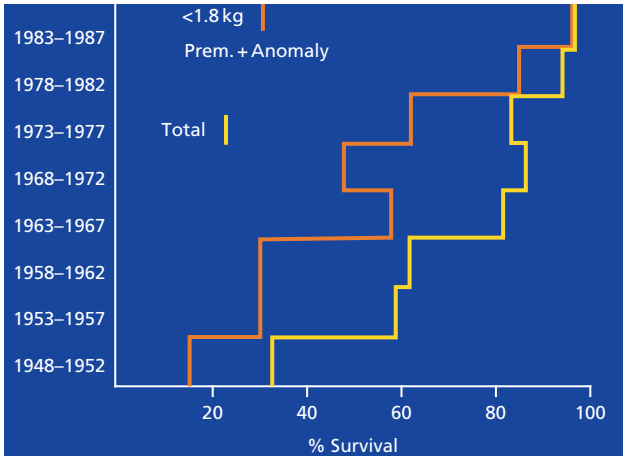

Figure 2.14 Improving results in esophageal atresia with the development of intensive care.

New Zealand

New Zealand did not have a children's hospital until Starship opened in Auckland in 1991. New Zealanders regularly came to Melbourne for some pediatric anesthesia training but Peter Kempthorne (Fig. 2.11I) was the first to return to do pediatric anaesthesia and neonatal intensive care. Brian Anderson (Fig. 2.11J), who did pediatric anesthesia training in Melbourne and Rotterdam, led the academic developments when the new hospital opened in Auckland.

Scandinavia and Europe

Anesthesia in Scandinavia remained the responsibility of the surgeon, who supervised specially trained nurses, until after World War II when the ether/chloroform era began to pass with the advent of new drugs and equipment [73].

In Sweden, Goran Haglund was appointed anesthesiologist at the Children's Hospital in Gotenburg in 1951, having spent a year training in Chicago. His experiences in the United States led him to conclude that critically ill patients with cardiovascular and respiratory problems would be better managed in one location. He opened the world's first multidisciplinary pediatric intensive care unit in 1955. But he did much more. Before that, he handled respiratory and fluid and electrolyte problems in part of the surgical ward. A positive–negative pressure ventilator was described in 1954, and in 1958 the team reported respirator treatment which included four newborns, two of whom had infant respiratory distress syndrome, probably another first. Haglund developed diagnostic and treatment skills for respiratory problems including bronchoscopies. He proposed the use of mouth-to-mouth breathing some years before Peter Safar's important publication. Haglund was a talented man and great contributor to the specialty [74,75].

In 1958 Hans Feychting (Fig. 2.13D) was appointed as the first pediatric anesthetist at the Children's Hospital in Stockholm. In 1961 he established a postoperative ward that over the next 5 years evolved into an intensive care unit for which he became well known. Later he played a role in establishing international standards for anesthetic equipment. Alvar Swenson (Fig. 2.13E) was appointed chief of pediatric anesthesia at Karolinska Sjukhuset in 1966. He had a special interest in ventilator treatment. Pediatric anesthesia was in good hands when these people were followed by Barbro Ekstrom Jodal (Fig. 2.13F), Krister Nilsson (an active researcher) (Fig. 2.13G), Gunnar Olsson (chronic pain), and others.

Toivo Suutarinen (Fig. 2.13H) served in the winter war with Russia in 1941. He became the father of pediatric anesthesia in Finland. He began training in surgery but recognized the need for good anesthesia, so changed. He went to the United States for 2 years (Chicago and Massachusetts General Hospital). Shortly after his return in 1956 he was appointed to the Children's Hospital in Helsinki where they developed high standards of surgery ably supported by good anesthesia and intensive care. He retired in 1981 to be followed by Olli Meretoja, a leading researcher on muscle relaxants in children.

Otto Mollestad was the first anesthesiologist in Oslo, Norway, in 1947. Signe Gullestad in Bergen was the first to have a special interest in children. It was not until the 1980s before Gunnar Bo (Fig. 2.13I) and some colleagues managed to get agreement to organize a small group to care for the infants and children at Rikshospitalet in Oslo.

Across Europe there were many children's hospitals. Paris had several, including Enfants Malades and St. Vincent de Paul, where Claude St. Maurice (Fig. 2.13J) and later Isabel Murat (Fig. 2.13K) worked. They were leaders in regional anesthesia. Later, Bernard Dalens (Fig. 2.13L, centre) published a definitive textbook on regional anesthesia in children. St. Maurice co-edited a book on local anesthesia in children with Ottheinz Schulte Steinberg (Fig. 2.13M) who trained with Bromage in Montreal. He worked in Starnberg, near Munich in Germany. The latter undertook one of the first studies on the spread of local anesthetic from caudal injection. He also introduced the technique of threading a caudal catheter up the epidural space in small children (who do not have obstructing ligamentous partitions in the epidural space) to the thoracic region if necessary. The idea was promoted further by Paolo Busoni (Fig. 2.13L, left) in Florence at Ospedale Pediatrico A. Meyer, where much of the surgery was done with caudal anesthesia [75]. Their common technique where appropriate was halothane induction, intravenous diazepam, and caudal block without continuing the general anesthetic. Their postoperative vomiting rate was a low 7%. Busoni also did a study with a psychologist, getting the children to draw their perception of their anesthetic. One drew the upper half of the body red and the lower half green.

Other Europeans who became well known by the 1970s included Professor Mickelson at Filitov Children's Hospital in Moscow where epidural anesthesia, including thoracic, had been used since the 1970s; Karl Rondio in Poland; Josef Holzki (Fig. 2.13N) at University Children's Hospital in Liege, Belgium; and Peter Dangel in Zurich. He was particularly involved in intensive care and was one of the early doctors involved in helicopter transport of very sick children. Much of the anesthesia was done by nurses trained in anesthesia.

Although there are several children's hospitals in the Netherlands, much of the pediatric work is done in university hospitals. Anneke Meursing (Fig. 2.13O) visited several major centers in Britain and America and spent 6 months in Melbourne in 1986 before she raised the profile of Sophia Children's Hospital in Rotterdam which, at the time, was the

largest in the Netherlands (Meursing A, personal communication, 2016). She introduced teaching and active research programs. She persuaded Jackson Rees, who had just retired, to come on regular visits from Liverpool to supervise their research. She also had people come from other countries to gain further experience. Several of these, such as Brian Anderson from New Zealand and Andrew Davidson from Melbourne, later became leaders in the field at home. All this development came to an end when Sophia was amalgamated into the University Hospital and the staff numbers were reduced so that the remaining ones had to limit their activities mainly to clinical service.

Anneke Meursing played a big role in anesthesia generally. She organized the first two European Pediatric Anesthesia Congresses in Rotterdam in 1986 and 1989, with the foundation of the Federation of European Associations of Pediatric Anaesthesia (FEAPA). She was secretary for the World Congress of Anaesthesia Organizing Committee for 1992 and thereafter was a WFSA Executive Committee member, Secretary and President of the WFSA.

Another European pediatric anesthesiologist who gained prominence was Sten Lindahl, who became Professor at Karolinska in Stockholm and later chairman of the Nobel Prize Committee for Physiology and Medicine.

South Africa

Harry Curwen (Fig. 2.13P, holding a typed copy of his 1950 paper [25]), in Durban, began a series of caudals in neonates and by 1950 he had done 92. He reported his experience at a South African meeting. He was uncertain whether the technique would be adopted but did suggest that it might be useful for practitioners working in smaller centers in relative isolation.

Red Cross Memorial Hospital was opened in Capetown in 1955, intended as a children's hospital open to all races. The Red Cross provided a large part of the funds to build it. Tom Voss became full time in charge of anesthesia in 1958 and became Associate Professor in 1968. He moved to Australia in 1977 and became the pediatric anesthetist at the new Westmead Hospital in Sydney in 1980. While he was in Capetown he was part of a team that had operated on five pairs of conjoined twins (Voss T, personal communication, 2016).

Adrian Bosenberg (Fig. 2.13Q) worked in Durban as a pediatric anesthetist and, following Schulte Steinberg's visit on sabbatical leave, used caudal catheters, threaded even to the thorax, in neonatal surgery. The advantage was that the patients could be nursed without ventilator care postoperatively with a catheter passed up to the thorax in an environment where there were not enough experienced nurses [76].

Dorothy Ffoulkes-Crabbe was a prominent anesthesiologist at Lagos University Teaching Hospital, Nigeria, who published a number of papers on airway management, regional anesthesia, and carbohydrate metabolism under anesthesia in children over a career spanning more than 30 years (Fig. 2.13R).

South America has many children's hospitals. One of these, Calvo McKenna in Santiago, Chile, is now a WFSA training center for pediatric anesthesia in the region. The first trainee was from Bolivia. Armando Fortuna (Fig. 2.13S) from Brazil reported his experience with caudals, mostly in poor-risk infants using lidocaine in 1963 [25,77]. He was a leader in the field, starting in the late 1950s. Carlos Riquelme (Fig. 2.13T) from Chile organized the first pediatric anesthesia symposium in Chile in 1984. He has been an outstanding teacher who has well thought out reasons for what he does. Carlos da Silva (Fig. 2.13U) in Brazil examined trainees by watching an anesthetic and then getting them to give reasons for how they conducted it.

Japan

The first recorded anesthetic in Japan was a herb mixture including mandragora called *Tsu Sen San*, administered by a surgeon, Hanaoka, in 1804. Its use in children over 5 for cleft lip repair was reported by Gencho Homma in 1837. Japan was an isolated country so anesthesia did not progress until after 1950. Mitsuko Satayoshi (Fig. 2.13V, right) established general anesthesia with intubation for the neonatal surgical pioneer, Keijiro Surugu, and was later joined by Seizo Iwai (Fig. 2.13V, left) when he returned from training with Digby Leigh in Los Angeles in 1961. National Children's Hospital was the first children's hospital when it opened in 1965. By 1990 there were 17. Seizo Iwai was the first head of the Anesthetic Department. The department began day surgery in 1966. Initially understaffed, this was improved and it became the leading center in the country [78].

Iwai became professor in Kobe in 1968 and was followed at Tokyo Children's Hospital by Hiroshi Sankawa (Fig. 2.13W) and later by Katuyuki (Kats) Miyasaka (Fig. 2.13X) who had spent several years at HSC Toronto. Miyasaka undertook early trials of sevoflurane. He was also involved in ten separations of conjoined twins and in planning a new paperless National Children's Hospital to which he managed to have a previously non-existent Emergency Department added.

The Japanese Society of Paediatric Anaesthetists was formed in 1971 to promote the transfer of knowledge. Genichi Suzuki (Fig. 2.13Y) was a major participant. Maseo Yamashita (Fig. 2.13Z) played a role in the Asian Society of Paediatric Anaesthesia after its establishment.

KEY POINTS: EARLY PEDIATRIC ANESTHESIOLOGISTS, 1920–1950

- Charles Robson in Toronto became the first recognized pediatric anesthesiologist in 1919
- Robert Cope in London was the first full-time pediatric anesthetist in the UK in 1937
- Robert Smith in Boston, starting in 1946, was the first full-time pediatric anesthesiologist in the United States, and the author of an early textbook
- Brown, Burnell, Troup, and Morgan established pediatric anesthesia in Australia in the pre-World War II years

The specialty of pediatric anesthesia develops further, 1950s to 1970s

From the 1950s through the 1960s and 1970s great changes took place. Anesthesia had become a recognized specialty, more and better equipment became available including endoscopes, which helped both anesthesiologists and surgeons, and operating microscopes, as well as a wide range of drugs

and adjuncts to resuscitation, all of which helped to cope with the demands of more difficult surgery. The introduction of polyvinyl chloride (PVC) tubes, intravenous butterfly needles and cannulae, and intensive pre- and postoperative care contributed to better survival.

More recently the advent of endoscopic surgery has brought about another major change in surgical practice to which anesthesiologists have had to adapt.

Cardiac surgery

Cardiac surgery began, tentatively at first, with the ligation of a patent ductus arteriosus by Gross in Boston in 1938. At Johns Hopkins Hospital, Merel Hamel and Austin Lamont were involved with Blalock and Helen Taussig in the development of their palliative operation for Fallot's tetralogy in 1944 [79].

Denton Cooley at Texas Children's Hospital was the most prolific cardiac surgical operator between 1955 and 1970. The most prominent pioneer anesthesiologist who worked with him was Arthur Keats [80] (Fig. 2.10T). He published many papers on related subjects such as anesthetic techniques, outcomes, premedication, airway management, induction and maintenance of anesthesia, arrhythmias and their intraoperative treatment, perfusion, and descriptions of the postoperative ventilator they made in 1958. He also described anesthesia for cardiac catheterization (1958) and the reversal of heparin with protamine in 1959. He made a great early contribution to the field. Another pioneer was W.O. McQuiston in Chicago who wrote one of the first papers on pediatric cardiac anesthesia in 1949 [81].

In 1969 and the 1970s corrective heart surgery was successfully carried out on infants under 10 kg down to neonates under deep hypothermia (18°C) with circulatory arrest by the technique suggested by Mori in Japan [82]. (Drew, in London, had earlier tried deep hypothermia but the technique did not catch on.) This was an exciting time. To see a heart gradually beginning to beat and become more regular with stronger contractions as it rewarmed after an hour or more of cardiac standstill was a most amazing experience. At least part of the success of the technique was due to adding CO_2 to the oxygenator before the pump was switched off. The aim was to maintain a corrected $PaCO_2$ for temperature (pH stat) but importantly it moved the oxygen–hemoglobin dissociation curve back to the right allowing greater release of oxygen to the tissues before circulatory arrest. Normally in hypothermia it moved far to the left.

Because the heart is vital to survival, anything that could help, such as drugs or technical support, was useful in the intensive care of these patients. Gradually more and more anesthesiologists specialized in this field and increasingly complex abnormalities were corrected. Cardiac surgery has become a subspecialty with its own experts and meetings.

Some patients were ventilated after cardiac surgery. In Toronto this began in 1961 [83], contributing to the beginning of their intensive care, initially in part of their recovery room.

The beginning of intensive care

In 1952 there was a pandemic of poliomyelitis. Copenhagen, Denmark, was badly hit and had many cases. Nearly 90% of the early cases with respiratory involvement died. Bjorn Ibsen [74,84], recently returned from anesthesia training in the United States, when the specialty was first recognized in Denmark, was invited to consult. He found that many patients were dying from CO_2 retention and respiratory failure. He instituted tracheotomy, suction, and hand ventilation by medical students and later dental students. They only had one iron lung and a few inefficient negative pressure cuirass ventilators. Eventually, after 165,000 h (equivalent to 1000 weeks or over 19 years) of hand ventilation, the epidemic passed and the respiratory mortality had been reduced to 25%. The first successfully treated patient was a 12-year-old girl. This episode was the start of the development of intensive care. It was also a stimulus for the developments of ventilators, and of acid base, pH, and $PaCO_2$ measurement by Paul Astrup, Ole Sigaard Andersen, and John Severinghaus [85].

Polyvinyl chloride endotracheal tubes and pediatric intensive care

The advent of PVC endotracheal tubes opened the door for the development of pediatric intensive care. In 1962 Bernard Brandstater (Fig. 2.11D, with Ian McDonald, when they met 50 years later), an Australian working in Beirut, Lebanon, reported the first cases of prolonged intubation. Most of his patients had tetanus but one had croup [86].

Tom Allen became Director of Anaesthesia at the Adelaide Children's Hospital in 1960 [68,87]. Having seen nasotracheal intubation used successfully in adults, he persuaded the physicians to try prolonged nasotracheal intubation in their more severe cases of croup (laryngotracheobronchitis). He was a leader in the field but there were others starting about the same time. In Melbourne, Ian McDonald ventilated a baby by hand overnight following a lobar lung resection in 1960. He and John Stocks suggested nasotracheal intubation as a step in decannulating a baby with a retained tracheostomy following esophageal atresia repair. After 5 days the tube was successfully removed. When they reviewed their first 60 cases of prolonged intubation, three had developed subglottic stenosis [69]. Ethylene oxide sterilization and organotin in the tubes were eliminated as possible causes. There was no tissue reaction when PVC was implanted under the skin. It was eventually concluded that pressure on the mucosa around the cricoid ring, the narrowest part of the larynx, from too tight a tube was the cause. None of the next 300 patients suffered this complication after it was recommended that a slight leak of gas around the tube should occur when positive pressure was applied. People working in that era would question the justification of cuffed tubes which have been advocated in recent years. The main reasons are cost and mucosal trauma from pressure from the cuff further down the trachea. A larger-diameter plain tube can be used instead, which fits comfortably through the cricoid ring and has proved satisfactory for many years. Such tubes mold, when warm, to the shape of the airway which, in that region, is almost circular. Also, where the cuff lies, the diameter of the trachea expands and contracts with each breath.

There were many other details that had to be worked through, which modern intensivists take for granted. When the normal humidifying mechanism in the nose is bypassed by a tube some form of humidification must be employed to prevent encrustation of secretions and tube blockage. There

was much debate over whether gas should be passed over heated water or a nebulizer, producing fine water droplets, should be used. The size of the droplets was critical: if they were too small (0.5–3 µm) they could reach the alveoli and "drown" the patient, whereas if too large (30 µm) they would fall out in the trachea and not reach the bronchi.

In time nebulizers lost out to humidification. The simplest form was a hot water tank over which the gas flowed. There were several hazards. The temperature had to be set so that it was about 35°C when it reached the patient. This maximized humidity and prevented burning and overheating. Loops in the tubing had to be avoided to prevent water condensation and obstruction to gas flow. Later, a heating wire was inserted into the tubing so that the required temperature that the patient received could be set at the humidifier. The problem was that at 35°C bacteria grew well while in the former hotter environment (55–60°C) they were killed. It was not just a matter of using antibiotics to treat infections because in those days a common pathogen, *Pseudomonas pyocyaneus*, was not susceptible to the available antibiotics. When infections and cross infection became problems the obvious solutions of strict hand washing and changing suction catheters had to be enforced.

Various methods were developed to hold the nasotracheal tube in place. Tunstall in Aberdeen, Scotland, devised a special clip [88]. Jackson Rees made a complex tube for good fixation (Fig. 2.7) but its cost and difficulty of insertion led to its abandonment. A commonly used method was to split two pieces of waterproof tape for half their length. Half of the first piece would be laid across the face just below the nose (Fig. 2.15). The other half was wound round the tube and fixed up the nose. The upper half of the second piece would be laid across the nose and the nasal part of the first tape used to hold it in position and prevent a downward pull on the tube. The lower half was wound around the tube and across the face. To protect the skin and add stickiness, tincture of benzoin compound was wiped on the face where the tape would be attached. The tapes had to be changed from time to time if they became wet with secretions. The most urgent emergencies were accidental extubation and tube blockage which required immediate removal, mask ventilation, and rapid reintubation.

Figure 2.15 Fixing a nasal tube with waterproof strapping around the tube and up the nose to prevent downward pull. Another strap then fixes it. The whole is then covered with sticking plasters (not shown).

Figure 2.16 shows an ergonomic method of holding the mask with the mouth open to make it easier to ventilate with a mask.

Intubation technique must be proficient both for anesthesia and in intensive care, especially in infants in whom oxygen consumption is greater and hypoxia develops rapidly. A good ergonomic approach for infants and small children, which did not require someone to hold the head steady, is shown in Figure 2.17. Note the head being stabilized and the way the laryngoscope is held, allowing the left little finger to press the larynx back so that the tube can be seen passing between the vocal cords. It is advanced for 2–3 cm to avoid endobronchial intubation. (Tracheal length at birth is usually 4.5 cm at full term.) In nasal intubation the tube is passed through the nose and guided towards the larynx, which can be moved by pressure from the left little finger or by rotating the tube. Sometimes flexing the neck slightly as the tube is advanced will allow it to pass more easily.

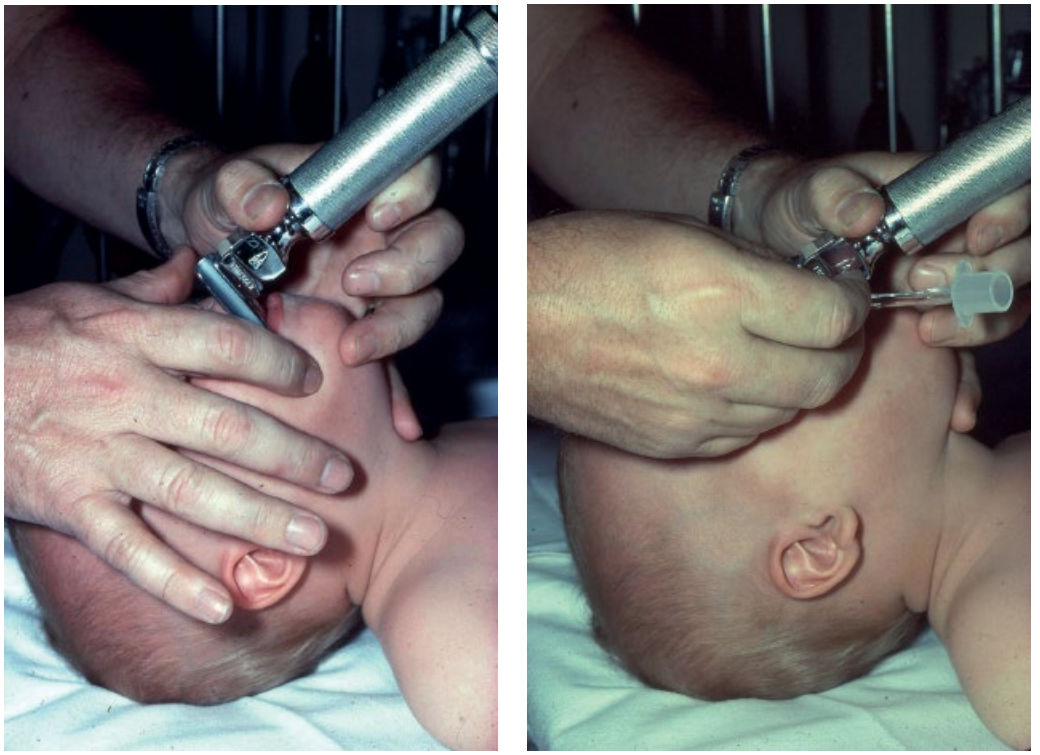
Ergonomics is how to carry out tasks most efficiently with the least effort. Such ergonomic approaches made these techniques easier to teach and learn.

The question remained, "How long could a PVC tube be left in?" At the meeting at HSC, Toronto, in November 1964 a panel with Drs Leigh, Cope, and Jackson Rees were discussing 5–7 days when Tess Brophy, the leading pediatric anesthetist from Brisbane, rose and said that a child in Australia had been successfully extubated after 34 days. There was a stunned silence. Tubes have since been left in situ for much longer (6 months) but nowadays if very prolonged intubation is necessary a tracheotomy is done so the infant's facial muscles can develop [89].

Ventilators

The first positive pressure ventilator was developed by Crafoord in Stockholm in 1937. He was a thoracic surgeon. Many places did not have mechanical ventilators until after the late 1950s. Only a few used in the early days of the

Figure 2.16 Ventilating with a low dead space mask. The mask is placed in the groove on the chin with the mouth open. It is then pressed gently on to the face by the thumb and index finger and the jaw is pulled forward by the little finger (note the Portex y connector).



(A) (B)

Figure 2.17 Intubation. (A) The neck is extended, the right thenar eminence fixes the forehead, and the right index finger opens the mouth to ease insertion of the laryngoscope. (B) Note how the laryngoscope is held so that the left little finger can reach to press the trachea backwards. The tube is inserted in the right corner of the mouth so that the trachea is visible. For nasal intubation the tube is inserted and guided towards the trachea with slight external rotation if necessary. Slight flexion of the neck sometimes helps.

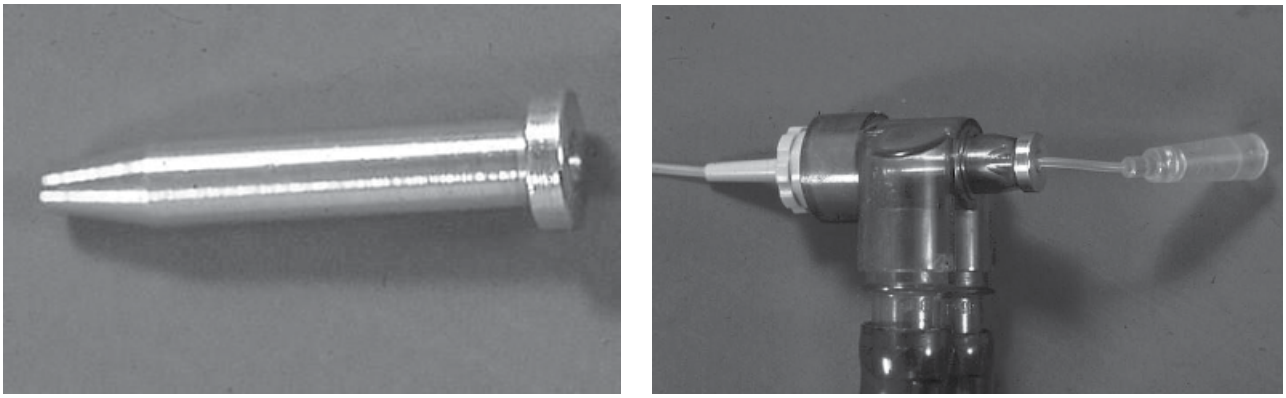
pediatric intensive care unit (PICU) will be mentioned here. With pressure-controlled ventilators (e.g. Bird Mark VIII or Bennett PR2) the pressure was adjusted to produce a suitable tidal volume. The ventilator could also have a time cycling mechanism in case it could not achieve the maximum inspiratory pressure. These required frequent adjustment. The volume-cycled ventilators (e.g. Engstrom) delivered the set volume provided there was not a significant leak around the tube.

The Engstrom ventilator was developed just prior to the polio epidemic that reached Sweden in 1953. It was a large machine driven by a large piston with an eccentric cam which produced a sine wave positive pressure curve. The inspiratory thrust was applied to squeeze the bag containing the gas in a polymethyl methacrylate cylinder. The amount delivered was determined by the amount added to the circuit and hence to the bag. It was volume controlled. The flow pattern was slow to start with, allowing flow into all parts of the lungs before the rate increased. The bag had to be empty before the sine wave reached the top of the curve. This provided time for the pressure to equilibrate while gas redistributed from easily ventilated areas to less well-ventilated ones with narrower airways and higher resistance to gas flow. Most other ventilators did not have this facility and hence the patient needed a periodic large inflation or "sigh" to prevent atelectasis. The main problem with the Engstrom ventilator was its large size.

Intermittent positive pressure ventilation (IPPV)

IPPV produces many physiological changes. Mean intrathoracic pressure is raised. The amount depends on the inspiratory:expiratory (I:E) ratio and the pressure applied. This reduces venous return, which causes a decrease in blood pressure in hypovolemic patients. Some ventilators had a negative expiratory phase to compensate. There was a strong divergence of views between those who thought a negative phase was useful because venous return was important and those who thought some positive expiratory pressure was desirable to prevent alveolar collapse and diminution of functional residual capacity in the lungs. In 1968 John Inkster from Newcastle upon Tyne, England, presented a paper and gave a workshop describing his valve to achieve the latter [90]. Professor Mary Ellen Avery of Montreal was there. She spoke of the concept of PEEP keeping the airways open at the Royal Children's Hospital Centenary meeting in Melbourne in 1970. About the same time George Gregory in San Francisco struck on the idea of using CPAP to keep the lungs inflated in premature babies with hyaline membrane disease (respiratory distress syndrome). Charlie Bryan, at HSC, Toronto, had similar ideas. Was there any transfer of information or had they all come to their ideas independently? Now it seems such an obvious solution to the problem which greatly expanded the field of neonatology and provided pediatric anesthesiologists with the challenges of anesthesia for very small babies with consequent conditions such as inguinal hernias, necrotizing enterocolitis and patent ductus arteriosus.

All was not over. CPAP raises mean intrathoracic pressure but in so doing it raises venous pressure required to get the blood back to the heart and maintain end diastolic volume. That leads to capillary pressure alterations so that more fluid is retained in the tissues – edema develops. Extra fluids are



(A) (B)

Figure 2.18 (A) The Stocks bullet. (B) Catheter inserted through the bullet, enabling suction while continuing ventilation.

needed to compensate for these losses from the circulation and to ensure an adequate stroke volume. CPAP or PEEP has to be adjusted to maximize the benefits to ventilation while minimizing the vascular problems. Another important problem arose. With improved alveolar ventilation FiO_2 increased, sometimes to the extent that oxygen toxicity in the lungs developed, sometimes causing death, and having the potential of causing retrolental fibroplasia and blindness [91]. Now the problem of hyaline membrane disease has been solved by the instillation of surfactant, the substance which was lacking, and which prevents alveolar collapse.

The Stocks bullet

Another problem was the effect of suction, which is necessary to remove secretions [92]. It is necessary to interrupt ventilation and oxygen supply with resultant drop in the patient's PaO_2. Like so many early anesthesiologists who had inventive minds, John Stocks designed a very simple device, the Stocks bullet, which fitted into the circuit where it attached to the tube (Fig. 2.18). A small hole through it allowed the passage of a suction catheter while ventilation continued during suction, thereby lessening the fall in PaO_2 and the amount of recruitment necessary after suction [93].

Airway obstruction

Airway obstruction is one of the great challenges of pediatric anesthesia. It can be life-threatening. In 1927 Scholes reported the use of O'Dwyer tubes [94], devised to treat diphtheritic obstruction, in 1175 patients. Eventually immunization solved the problem.

Laryngeal papilloma and obstructive cysts and nodules can create anesthetic challenges unless a tracheostomy is present. The operating microscope, laser, and inflating devices (bronchoflator) [95] have made these treatments easier [96].

Epiglottitis was a frightening condition to treat, especially if obstruction was nearly complete and the epiglottis looked like a cherry with maybe a bubble of air the only indication of the airway. Initially, tracheostomy was the treatment but intubation became the preferred method because the artificial airway was only needed for a few hours after the antibiotic was given until the swelling decreased [97]. Immunization against *Haemophilus influenzae* type B has virtually eliminated this disease.

Tracheal obstruction could be caused by a foreign body within it, stenosis in the wall, or compression from outside such as by an aberrant subclavian artery or a mediastinal mass. The latter tumors require a diagnostic biopsy to determine the most appropriate treatment. This can create a very hazardous anesthetic, especially if the patient cannot lie down because obstruction to the trachea, bronchus, or even the superior vena cava may occur in certain positions. In this situation careful positioning is important and experience suggests that ketamine, which maintains muscle tone, is the safest induction agent.

The development of pediatric intensive care was in the domain of anesthesiologists because of their expertise in airway management and ventilation. As critically ill patients with other conditions were admitted to ICU, staff from other specialties became involved and intensive care became a separate specialty in some countries. Originally anesthesiologists took their skills to intensive care but now it is important for those who want to become top-class pediatric anesthesiologists to spend some time working in intensive care so that they acquire expertise with the technical skills and equipment used when treating the sickest patients.

KEY POINTS: THE SPECIALTY DEVELOPS FURTHER

- Congenital cardiac surgery developed significantly from 1955 to 1970 with Denton Cooley and Arthur Keats in Houston
- Intensive care originated in the early 1950s under Ibsen during the polio epidemic in Denmark
- The Engstrom ventilator was one of the earliest ventilators, developed in Sweden in the early 1950s

Unraveling mysteries and challenges: malignant hyperthermia, massive hyperkalemia, and anaphylaxis

Unexpected situations created fear in anesthesiologists' minds, especially when the cause was unknown and treatment was not known. Jim Villiers in Melbourne (Fig. 2.19) was twice in this unenviable situation but succeeded in being the

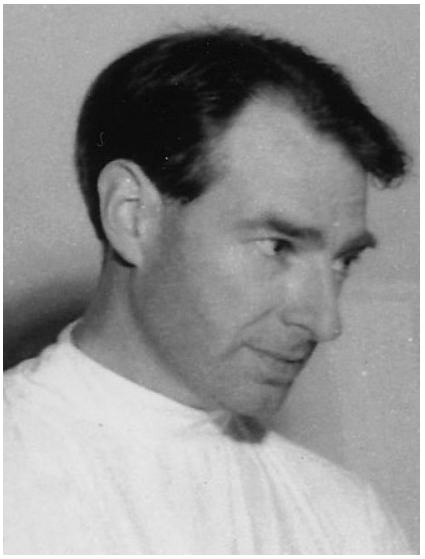


Figure 2.19 Jim Villiers.

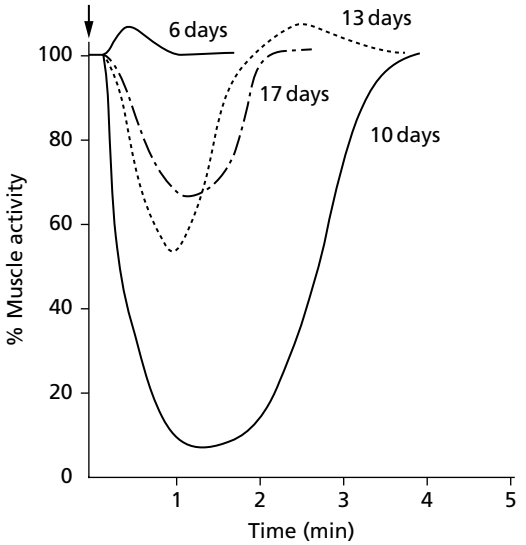

Figure 2.20 Electromyograph recordings following 0.1 mg/kg succinylcholine in a 6-year-old with 30% burns showing varied response and sensitivity during the first 2 weeks post burn.

first to keep his patients alive in both instances of newly described anesthetic "diseases": malignant hyperthermia, and massive hyperkalemia after succinylcholine administration.

The syndrome of malignant hyperthermia was described in 1962 by Denborough and colleagues after a 20-year-old male presented with a broken leg for manipulation and plaster. He had a family history of deaths associated with anesthesia but a cousin had recently survived. Preoperative enquiry and examination gave no clues to a problem but as soon as a halothane anesthetic started, the patient and the soda lime canisters began to get hot. There was still no clue but Villiers immediately discontinued the anesthetic and gave oxygen. The procedure was completed promptly and the patient was taken to the relatively new recovery room where, by good fortune, there were buckets of ice waiting to be used on a neurosurgical case. These were dumped on the patient who cooled and survived. They still did not know the cause. The patient was referred to physicians who worked out from the family history that the cause was genetic [98].

In 1965 a 13-year-old girl in Toronto was receiving Harrington rods for scoliosis when she arrested due to hyperthermia. She could not be resuscitated. It was before the use of dantrolene was discovered. The metabolic derangement is caused by excess calcium release on exposure to succinylcholine and halogenated inhalation agents leading to excessive muscle contraction, heat, increased oxygen consumption, carbon dioxide production, and acidosis. When the temperature reaches 44–45°C the buffering mechanisms fail and death ensues. Nowadays the early warning sign is a rising end-tidal CO_2 despite increasing ventilation, and effective treatment is with dantrolene infusion. It was a condition that terrified anesthesiologists and introduced regular temperature monitoring.

Jim Villiers had another first survival, described in 1960, in a 6-year-old girl with extensive burns who was given succinylcholine prior to intubation so that she could lie prone to have grafting undertaken on her back. Cardiac arrest occurred with no explanation [99]. The event preceded closed chest cardiac massage and the only defibrillator in Melbourne was several miles away at another hospital. The team opened the chest and massaged until the heart was beating 20 min later. They had no idea why the girl arrested. A week later the patient was intubated again for a dressing change with same response – cardiac arrest. The chest was opened and 25 min massage performed before eventual recovery. What had happened? No one knew, but the patient recovered and lived for at least another 50 years. Gordon Bush, a well-known Liverpool anesthetist, wrote a paper with several suggestions which led to some research in Vancouver [100]. The normal potassium response to succinylcholine had not been studied in humans but turned out to be minimal – a rise in serum potassium not exceeding 0.5 mmol/L, less in adults (TCK Brown, unpublished data). Badly burned patients in the Vietnam War were later shown to have massive increases in potassium [101]. Later, Brown showed that the rise in potassium in large burns was related to the dose of succinylcholine and to the size of the burn [102]. He confirmed the findings of Viby-Mogensen that the rise did not occur until about 10 days post burn [103]. Using small doses of 0.1 or 0.2 mg/kg (so as not to produce large rises in potassium) he showed electromyographically that a period of acute sensitivity to succinylcholine developed about 7–10 days post burn when transient paralysis followed these small doses [104] (Fig. 2.20). Although there was a short time when succinylcholine could be used, most anesthesiologists avoided the problem by not using the drug.

Anaphylaxis is another "out of the blue" experience. It can occur in response to a number of drugs but fortunately is rare. It can be serious, even lethal, but on the other hand can be less serious as with cremophor in the formulation of the induction agent, propanidid (1965). Althesin which, 10 years later, seemed to be the new wonder drug for induction and could be given by infusion because of its short action, was taken off the market because of the tendency to anaphylaxis, although usually mild.

Latex allergy then appeared. Avoidance of latex is essential if the patient or staff are latex allergic. It is desirable to avoid problems in unknown cases. Patients with spina bifida were

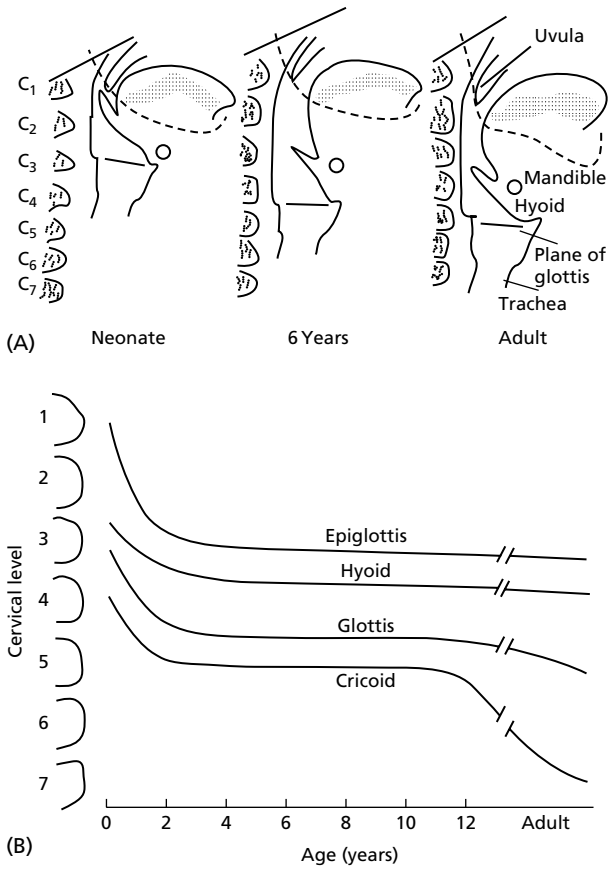

Figure 2.21 The position of the larynx (vocal cords) in relation to the cervical vertebrae during growth.

particularly prone to reactions because of their exposure to latex products like urinary catheters. With advocacy of anesthesiologists, patient groups, and others, latex products were gradually replaced by non-latex substitutes making the environment now virtually latex free.

Some other congenital abnormalities and genetic diseases caused difficulties for anesthesiologists. It is recognized that with early bone marrow transplantation or enzyme replacement some of these conditions will be rectified or disappear.

One example of how a problem was identified and managed will be given. Maintaining the airway and intubating patients with some forms of mucopolysaccharidoses (especially Hurler and Hunter syndromes) could be extremely difficult [105]. A lateral neck radiograph provided the clue. Normally the larynx in a baby lies opposite C3 and gradually descends to C4–5 by 3 years and C6 in adults [106] (Fig. 2.21). In mucopolysaccharidosis patients the upper cervical vertebrae are abnormal and the larynx is higher than expected so when a Guedel airway was used it pushed the epiglottis back over the entry to the larynx making ventilation more difficult. (Fig. 2.22). When intubation was attempted it was harder to align the higher larynx so the opening could be seen to insert the tube. This problem could be overcome by one person positioning the laryngoscope and forcefully pushing back on the larynx with his/her other hand to bring it into view while another guided the tube between the vocal cords. Because of the extreme difficulty this task was undertaken in some

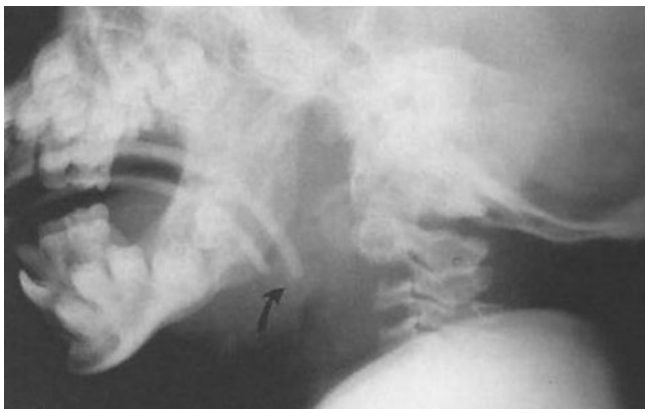

Figure 2.22 Lateral neck radiograph of a 2-year-old with Hurler syndrome showing abnormal upper cervical vertebrae, a high larynx and the epiglottis being depressed by a Guedel airway.

centers by the most experienced members of the department. The airway could be more easily maintained by using a nasopharyngeal tube. If a laryngeal mask airway (LMA) is used it should not be inserted as far as usual to avoid epiglottic obstruction of the glottis. Fiberoptic bronchoscopy and videolaryngoscopy may now simplify the task or, if intubation is not essential, a nasopharyngeal tube or LMA can be used but requires careful positioning.

KEY POINTS: UNRAVELING MYSTERIES AND CHALLENGES

- Malignant hyperthermia was described in 1962 after a 20-year-old man with a family history of anesthetic deaths survived a high fever during anesthesia
- Massive hyperkalemia after succinylcholine in a burn patient was described in 1960
- Anaphylaxis to anesthetic drugs, including propanidid and althesin, was described starting in the 1960s

Newer drugs in the development period (1950s to 1970s)

Halothane

Halothane (1956) played an important role, particularly in pediatric anesthesia where liver complications were exceedingly rare. After usurping cyclopropane it remained the most commonly used inhalational agent in children for many years until it lost out to sevoflurane. It could cause arrhythmias, especially when exposed to catecholamines. Laryngeal spasm sometimes occurred when the concentration was increased past 2% too quickly or during emergence. When sevoflurane was introduced and the vaporizer was turned full on to 8% and spasm did not occur, people tried putting halothane full on at 5% briefly until consciousness was lost – spasm did not occur. This negated the supposed faster induction with sevoflurane because the lower blood gas solubility was counterbalanced by the higher MAC of halothane when turned full on. The slower emergence from halothane was more peaceful in the recovery room than the restlessness with sevoflurane.

The cost of sevoflurane, when it was introduced, was 10 times that of halothane.

It was demonstrated by Gregory et al that halothane requirements (MAC) varied with age. Premature infants were very sensitive, and full-term neonates were more sensitive (required less) than older infants and children, who required more than adults. MAC decreased with advancing age [107]. This was then shown to apply to other inhalation agents such as isoflurane [108].

Methoxyflurane

Methoxyflurane (1960) is a halogenated ether with some of ether's properties but it is non-flammable. It has a slow onset and recovery. It is 25% metabolized to produce fluoride which can cause high-output renal failure in adults if given in excess (more than 2 MAC h) but in children the fluoride blood levels achieved are about half for the same exposure because more is taken up by bones and teeth (free dental prophylaxis) [109]. It can be a useful drug as a supplement in airway anesthesia and in neonatal anesthesia when given with a muscle relaxant and air because it provides good analgesia and using air prevents microatelectasis and diminished functional residual capacity (FRC) [18]. The latter avoids postoperative apnea in premature and small neonates, except in some babies who had apneic spells preoperatively.

Bupivacaine

Bupivacaine is a local anesthetic whose action lasted 4–6 h but could be extended, when used in the epidural space, by adrenalin, morphine, or clonidine. Unlike lidocaine, where convulsions (10 mg/kg) precede cardiac depression and arrest, with bupivacaine cardiac arrest was thought to occur before convulsions, and therefore the toxic dose of bupivacaine is more difficult to estimate. Maximum blood levels did not exceed 2 μg/mL with doses of 3 mg/kg given by the caudal or epidural routes [72]. Estela Melman from Mexico (Fig. 2.13A') reported no toxic effects seen when even 4 mg/kg were used. This drug was associated with a revival in interest in regional anesthesia and nerve blocks particularly in Brazil, Australia, France, and the UK, spreading to other countries as interest in its use in postoperative analgesia increased in the 1980s.

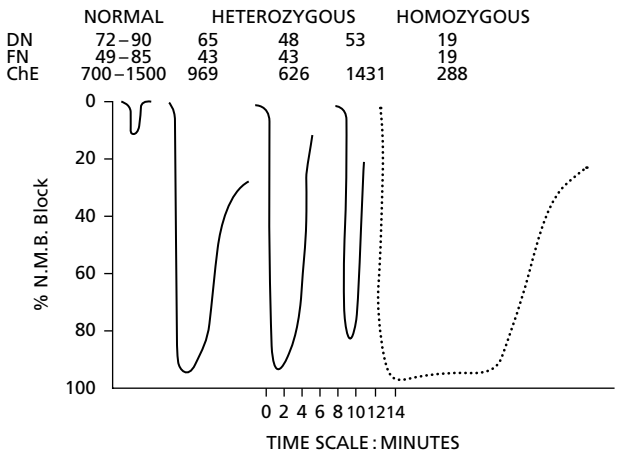

Figure 2.23 Electromyographic responses in patients with abnormal cholinesterase to 0.1 mg/kg succinylcholine with accompanying dibucaine (DN) and fluoride (FN) numbers and cholinesterase (ChE) levels.

Muscle relaxants

d-Tubocurarine, introduced by Griffith and Johnson in 1941 in Montreal [110], was a slow entrant to clinical anesthesia considering its muscle paralyzing effects had been demonstrated by Charles Waterton in 1815 when he brought back some Indian arrow poison (wourali) from South America. Having experienced two fatalities following injection into donkeys, Griffith and Johnson kept the next one alive after ventilating it for 4 h with a bellows inserted through a tracheostomy [111]. The drug was then used by Claude Bernard in physiological experiments and later by Embley in his studies on chloroform [5]. The action of d-tubocurarine lasted about 40–45 min (0.6 mg/kg) and had a gradual offset of action. Neonates were sensitive to it, requiring half the adult dose – 0.3 mg/kg.

It was later observed that infants and children with malignant liver, Wilms (kidney) and bone tumors exhibited resistance to d-tubocurarine. This resistance disappeared if the tumor was successfully treated with chemotherapy, removal or amputation [112].

Succinylcholine was structurally like two acetylcholine molecules attached together, which depolarized the receptors at the neuromuscular junction. The similarity of structure accounts for its vagal-like action on the heart. Normally paralysis lasted 4–5 min except when the patient had a genetic variant cholinesterase that did not metabolize it normally and thus prolonged its action. In heterozygotes this was about 15–20 min but in homozygotes paralysis might last 20–40 min and sometimes even longer [113] (Fig. 2.23). Patients, particularly homozygotes, were encouraged to carry an indicator of this hazard. Alternatively the dose could be reduced to 15–20% in homozygotes to produce the normal duration of action. This is an interesting example of pharmacogenetics.

Ketamine

Ketamine was a different type of drug – a dissociative anesthetic with which the airway and muscle tone were well maintained. It was used in burn anesthesia and for peripheral operations in less affluent countries where it could be administered intramuscularly by people with minimal training. It later became more important in low dose as an analgesic. As a sympathomimetic drug it was an effective bronchodilator.

Ketamine given to rats produced the first evidence of brain-specific neuroapoptosis [67]. Four years later the same group reported the finding that other anesthetics interacting with the γ-aminobutyric acid (GABA) receptor caused similar effects. This raised concerns that learning in babies and young children might be affected. Unfortunately ketamine later became a "street drug."

As other chapters of this book deal with the latest drugs and their use they will not be considered in this chapter.

KEY POINTS: NEWER DRUGS IN THE DEVELOPMENT PERIOD

- Halothane was introduced in 1956 and was the most commonly used agent in children for the next 50 years
- Gregory was the first to demonstrate that halothane MAC varied with age
- Methoxyflurane was a non-flammable anesthetic introduced in 1960
- d-Tubocurarine was the first muscle relaxant, introduced into clinical use in 1941

Adjuncts which were useful in difficult procedures

Hypothermia

Hypothermia was a topic researched during the early development of cardiac anesthesia because of the brain protection it provided. There was a subsequent period of research in the early 1970s when deep hypothermia for infant cardiac surgery developed (see section "Cardiac surgery").

Hypothermia has had other uses besides cardiac surgery. It is a useful adjunct to have when brain protection is desired, usually when large blood losses can occur such as during aneurysm surgery, removal of large hemangioma, liver trauma, and tumor resection such as that of intrapelvic sacrococcygeal teratoma [114]. The popularity of hypothermia has waxed and waned. Some people cite increased bleeding as a problem but it recovers on rewarming and can be counteracted locally by use of warm packs which speeds up coagulation.

Research on electrolytes showed that during surface cooling serum potassium decreases about 2 mmol/L between 37 and 27°C. If arrhythmias occur (usually between 28 and 29°C) administration of small increments of potassium chloride will abolish them – a useful piece of information when cooling. Hypokalemia is associated with a decrease in plasma insulin which results in commonly seen hyperglycemia [115].

Deliberate hypotension

Hypotensive anesthesia is another useful adjunct when bleeding can be a problem. Sodium nitroprusside was first made in 1888 and its cardiovascular effects were described by Johnson in 1927 [116]. It is a vascular smooth muscle relaxant with a very short action and is usually administered by infusion.

Vasodilators can be used to reduce bleeding when it was expected, or when it occurs unexpectedly and cannot be controlled, in cardiac surgery to reduce afterdrop in temperature postoperatively by adequate filling of the capacitance vessels before coming off cardiac bypass, and to reduce afterload postoperatively.

Phenoxybenzamine was an α-sympathetic blocker with a very long (up to 24 h) action which had the advantage in neurosurgery of not dilating cerebral vessels. It was also used successfully to treat neurogenic pulmonary edema which results from acute vasoconstriction and heart failure [117]. Otherwise a nitroprusside infusion was a good alternative. Unfortunately, like many other useful drugs used in anesthesia, phenoxybenzamine was removed from the market by its maker.

Janice Peeler, in Melbourne, used sodium nitroprusside induced hypotension for scoliosis surgery, initially for insertion of Harrington rods, for over 30 years from 1972. Blood loss, commonly 3–4 units, was reduced to about 1, but importantly operating time decreased when it was introduced from about 3 to 1–1¼ h because the surgeons had a clearer view of the operating field.

Another acute situation was where endless bleeding was stopped in a neurosurgical tumor resection. The rate of bleeding prevented the surgeon finding the bleeding point. This was compressed with a swab until blood loss had been replaced and extra fluid was given. A small dose of sodium nitroprusside was given, the blood pressure decreased, and the surgeon could see and cauterize the bleeder when the pack was removed. The blood pressure normalized in 2–3 min. Massive transfusion was avoided, the patient recovered, and the stress on the surgeon and anesthesiologist was removed.

Sodium nitroprusside has also been useful in reducing blood loss in ruptured liver and in liver tumor resections in children where significant blood loss can occur [118]. It is also useful in controlling rising blood pressure in pheochromocytoma surgery and to stop dysrhythmias by lowering blood pressure.

Other vasodilators have been used such as nitroglycerine, trimethaphan, and phentolamine [119].

Vasodilators are safer in children with unobstructed vessels than in older people with atherosclerotic vascular disease who are more prone to develop ischemia.

Pain management

Pain management became more rational in the 1980s, partly due to the work of Anand and colleagues who demonstrated that babies feel pain [120], though Robson of Toronto recognized this years before [57]. Applying basic pharmacological principles that an intravenous infusion will give a more constant blood level of analgesic than painful intramuscular injections, which were often given after pain had begun to return, was another factor. It is hard to believe that in earlier years it was thought that babies did not feel or respond to pain and, if they did, they would not remember it anyway.

Much interest was generated in the use of regional anesthesia and nerve blocks. Caudals and epidurals gained popularity, sometimes with infusions to prolong the block. Nerve blocks could be done quickly and effectively [38] but the techniques have largely been replaced with ultrasound-guided methods.

Pain management and regional anesthesia are covered elsewhere in this text (see Chapters 20 and 37) and in books on the subject [121].

Improved pain management required extra training of staff and more staff to supervise its administration. The extra costs of staff and equipment inhibited the development of pain teams initially in many places where funds were short but they are now well accepted, especially in more affluent countries. Dilip Pawar, when he was chair of the WFSA Pain Committee, developed simplified protocols for teaching improved pain management systems in some less developed countries in Asia.

Children also suffer chronic pain associated with cancer and conditions such as complex regional pain syndrome (CRPS) II [122]. This tends to be managed by separate pain specialists but anesthesiologists played an important part in its development and doing blocks which helped, such as sympathetic nerve blocks in CRPS [123].

Outpatient anesthesia and non-operating room anesthesia

Out of the operating room anesthesia and shorter stay were among the big changes in anesthetic practice in the later years of the twentieth century.

In the earlier years the radiology department might have been the only venue where anesthesiologists worked outside the operating suite. Neuroradiology before computed tomography (CT) and magnetic resonance imaging (MRI) consisted of cerebral angiograms and pneumoencephalography [124]. In the latter, air was injected through a lumbar puncture, with the child sitting up, and allowed to rise in the subdural space. The air was then moved around the ventricles, with films being taken in each position, by laying the child supine, somersaulting, prone, and finally supine again. With all these changes in position attachments to multiple monitors was undesirable. The patient was anesthetized, intubated, and allowed to breathe spontaneously. Clinical assessment of the pulse could provide much valuable information and ventilation could be observed. Although there are problems associated with anesthesia for scans, especially MRI, with avoidance of magnetic objects and usually observing the patient from outside the scanner room and using non-magnetic monitors, they are not quite as extreme as pneumoencephalography.

Anesthesia in radiology departments and the development of day surgery units were the first moves out of the operating suite. Increasingly anesthesiologists have provided anesthesia or sedation for other procedures such as lumbar puncture, bone marrow aspiration, and many others to avoid patient discomfort and stress. They have also established safe guidelines for non-anesthetists to provide sedation for some procedures. A significant part of a department's workload can now be fulfilling these needs.

One can even be moved from the operating suite to neonatal units to operate on premature babies to avoid disruption of their stable environment caused by transfer.

Pediatric anesthesia societies and meetings

Communication in pediatric anesthesia was enhanced by courses and meetings that allowed interchange of ideas [70]. One example was 2-day meetings begun in Los Angeles by Digby Leigh. These were run for many years by Wayne Herbert. Alan Conn began similar annual weekend courses at HSC in Toronto which alternated between anesthesia and intensive care. He had an impressive group of speakers for the first one in 1964 including Digby Leigh, Jackson Rees, and Bob Cope from England, Robert Smith from Boston, Tony Davenport from Montreal, and Tom McCaughey from Winnipeg.

In 1970, following the Asian Australasian Congress in Canberra, a Centenary Meeting was held at the Royal Children's Hospital (RCH) in Melbourne. After Kester Brown became Director there in 1974 he instituted meetings every 3–4 years from 1975 until 2000 which brought most of the Australian pediatric anesthetists together, forming a very cohesive little group which gradually grew. Visiting overseas lecturers came from many countries. In 1988, two eminent pediatric anesthetists stopped at each of Kuala Lumpur, Singapore, Bangkok, Manila, Hong Kong, and one to Colombo, Brisbane, and Perth on the way to the Australian Society and Melbourne Paediatric Anaesthetic conferences. This was a big exposure for pediatric anesthesia in the region. In 1995 the Royal Children's Hospital celebrated its 125th anniversary. That year an anesthesiologist from each continent was invited as a guest speaker, recognizing the spread of expertise around the world. Estela Melman spoke on fetal surgery in Mexico and how repair of cleft lip left no scar. A case of separation of conjoined twins was presented from Chile. In the ensuing discussion it was found that members of the audience had been involved in 27 cases including ten in Japan and five in Capetown. We should never underestimate the experience of colleagues in other countries.

World and other large congresses usually have pediatric anesthesia sessions. Special world Pediatric Meetings were held during World Congresses in Manila in 1984 (organized by David Steward and Seizo Iwai) and in Washington, and following the World Congresses in Amsterdam, Melbourne, and Halifax, Nova Scotia.

The Association of Paediatric Anaesthetists in Britain began regular annual meetings in 1974. Later they also held joint meetings with some national societies, the first being in Helsinki in 1981.

The American Academy of Pediatrics established an anesthetic section in the 1960s. Alan Conn and Leonard Bachmann were initial organizers. Its membership was confined to full-time specialist pediatric anesthesiologists. In the United States, the Society for Pediatric Anesthesia started later, in 1987, and was open to all anesthesiologists interested in children's anesthesia.

As the specialty has grown there has been a proliferation of regional and national societies. The Asian Society was set up

by Agnes Ng in Singapore. Other major contributors in the region have been Rebecca Jacobs (Vellore, India), Dilip Pawar (Delhi), Angelina Gapay (Philippines), and Masao Yamashita in Japan (Fig. 2.13).

Pediatric anesthesiologists' tours following or between conferences have given groups of pediatric anesthetists the opportunity to meet, spend time, and make lasting friendships while they travel together. These have occurred in Finland, Australia (Fig. 2.24), Canada, and South Africa.

Visiting other departments (Fig. 2.25) and meeting colleagues in these ways has built up a vibrant and friendly subspecialty – pediatric anesthesia.

Pediatric Anesthesia journal

The beginning of *Pediatric Anesthesia* as a specialty international journal in 1980 brought papers together which previously had been scattered through other journals. It encouraged more

specialists to contribute. Gordon Bush from Liverpool was the first editor followed by Ted Sumner (London), Neil Morton (Glasgow), and Andrew Davidson (Melbourne), all of whom helped it to become a high-quality, well-recognized journal worldwide. The first Editorial Board and Committee met in Rotterdam in 1989 (Fig. 2.26).

Training in pediatric anesthesiology

The development of organized pediatric anesthesiology was accompanied by the initiation of pediatric anesthesiology fellowship programs in the 1970s and 1980s based primarily in the prominent children's hospitals in North America, the UK, and Australia including Boston Children's Hospital, the Children's Hospital of Philadelphia, the Hospital for Sick Children in Toronto, Great Ormond Street Hospital, the University of California, San Francisco, and the Royal Children's Hospital in Melbourne. The early fellowships were served after residency or registrar training, were 6–12 months in duration, and were devoted primarily to exposure to and mastery of specialized pediatric anesthesia cases, especially neonatal anesthesia. In the United States training evolved to become a 12-month fellowship certified by the Accreditation Council on Graduate Medical Education in 1997. In 2013 the American Board of Anesthesiology offered its first Pediatric Anesthesiology certifying examination. See Chapter 3 for more information about education and training.

Conclusion

We will conclude with some highlights. Probably the most important development to enhance safety was the pulse oximeter, introduced in the mid-1980s. Capnography, introduced several years later, also provides much useful information. The laryngeal mask airway (LMA) introduced by Archie Brain in the late 1980s (Fig. 2.27) had a major influence on anesthetic practice. The most important factor in raising the standards of anesthesia and reducing morbidity and mortality is the improvement in the training of anesthesiologists. Ralph Waters, of Madison, Wisconsin, was the first professor of anesthesia in the United States and trained many of the early influential leaders in the specialty including Digby Leigh who initiated training programs and whose influence spread far beyond his native Canada.

Introduction

Reflect for a moment on a powerful, positive learning experience you have had. Perhaps you were the learner, or perhaps you were in a teaching role. What were the elements that created such a learning moment? What factors were attributable to individual performance such as the attitudes, beliefs, or communication style of the teacher, the learner, or other people involved? How much of the impact of that experience is attributable to the situation or to factors invisible to you in the moment? When you reflect on positive learning experiences, what features stand out? What are the common threads?

Powerful, positive education in pediatric anesthesiology does not occur by chance alone, but is a deliberate, examined practice. It is necessary not only for the provision of the safe perioperative care of children, but for fostering a discipline imbued with a culture of inquiry, respect, and the pursuit of excellence.

This chapter explores tenets of education in pediatric anesthesiology: identification of the need (the "Why"); grounding the practice in theory (the "How"); and elements of successful execution (the "What").

Why pediatric anesthesiology education? The needs assessment

Educating anesthesiologists about pediatric patients is essential if children are to receive the most effective and efficient anesthesia care. This important concept was a major impetus for the development of accredited subspecialty educational programs in pediatric anesthesiology [2]. What justifies the existence of a special subspecialty of anesthesia patient care devoted to children and the need for education specially focused on this clinical care area?

The need for expertise in pediatric anesthesiology

Pediatric population data alone are a compelling justification (Box 3.1). The Federal Census Bureau has recorded that as of 2015, the US population under 18 years of age included 73,683,825 children. This number represents 23% of the 2015 US population [3]. While recent trends indicate a small decrease in the total number of births and the birth rate, in 2015 there were 3,978,497 births in the US [4]. An appreciable portion of these newborns present with clinically significant morbidity necessitating surgical and non-surgical diagnostic and therapeutic procedures which can only be safely accomplished under the care of a skilled pediatric anesthesiologist. Approximately 1 in 33 babies born in the USA has a birth defect. A baby with a congenital anomaly is born every 4½ minutes in the USA, which means that 120,000 babies are affected by birth defects each year [5]. While some defects may be minor abnormalities, others may significantly affect the infant's physiology.

Approximately 40,000 babies are born every year with congenital heart disease, the most common birth defect requiring intervention in the first year of life [6]. Twenty-five percent of these babies have high acuity cardiac defects needing anesthesia care for surgery or diagnostic procedures. Some of the other significant pathophysiological birth defects include more than 7000 babies born each year with cleft lip and/or palate defects [7] and approximately 6000 babies born each year with Down syndrome [8]. Birth anomalies are the

Box 3.1: Births in the United States: data for 2015 [3,4]

- Number of births: 3,978,497
- Birth rate: 12.5 per 1000 population
- Fertility rate: 62.9 births per 1000 women aged 15–44 years
- Percent born low birthweight (less than 2500 g): 8.0%
- Percent preterm births (infants delivered at less than 37 weeks of gestation): 9.57%
- Percent unmarried: 43.9%

Box 3.2: The 10 leading causes of infant death (under 1 year of age) (2014) (23,215 deaths from all causes) [9,10]

1. Congenital malformations, deformations and chromosomal abnormalities (congenital malformations)
2. Disorders related to short gestation and low birthweight, not elsewhere classified (low birthweight)
3. Newborn affected by maternal complications of pregnancy (maternal complications)
4. Sudden infant death syndrome (SIDS)
5. Accidents (unintentional injuries)
6. Newborn affected by complications of placenta, cord, and membranes (cord and placental complications)
7. Bacterial sepsis of newborn
8. Respiratory distress of newborn
9. Diseases of the circulatory system
10. Neonatal hemorrhage

leading cause of all infant deaths and predispose newborns to a greater chance of acute illness and long-term disability than babies without birth defects (Box 3.2) [9,10].

On a yearly basis, approximately 9.2 million children (0–19 years of age) are treated in emergency departments for unintentional injury. More than 12,000/year (approximately 1 every hour) die as a result of their injury [11]. A clinically significant number of these children will need diagnosis and therapy requiring pediatric anesthesia patient care.

Availability of expert pediatric anesthesiology care

The number of children needing anesthesia patient care is large yet the distribution of pediatric patients in hospitals is quite uneven. There are more than 5500 hospitals in the US [12]. There are only approximately 250 children's hospitals in the US, with fewer than 50 as freestanding [13]. Current data about the pediatric surgical volume and acuity are lacking. In 2009, more than 216,000 pediatric procedures were projected with as many as 40% of inpatient surgical procedures being performed in adult hospitals [14]. The full range of resources specifically geared to pediatric patients, i.e. pharmaceuticals, equipment, and knowledgeable, skilled, and psychologically savvy physicians and paraprofessionals, is intuitively more plentiful in hospitals that care exclusively for children and their families.

In a 2005 report in the Newsletter of the American Society of Anesthesiologists (ASA), Hackel and Gregory highlighted that pediatric patients and their anesthesia patient care needs are clearly different from those of the adult population [15]. Recognition and acceptance of this resulted in the development of special practice guidelines for pediatric anesthesia patient care, published in 1999–2004 by the ASA, American Academy of Pediatrics (AAP), and the Society for Pediatric Anesthesia (SPA) [16–18]. Yet many community hospitals, with less than the full complement of pediatric anesthesiology resources, are faced with a need to care for children. The American College of Surgeons in 2017 instituted a Children's Surgery Verification Quality Improvement Program, similar to their existing Trauma Verification Program, whereby institutions performing children's surgery are designated Level I, II, or III [19]. Level I cares for the most complex pediatric patients, and Level II less complex pediatric patients; both of these levels require that Board Certified Pediatric Anesthesiologists be on staff and available to care for patients aged 2 years or less. Level III centers care for ASA I–II patients >6 months old with simple pediatric procedures, and require an anesthesiologist with pediatric experience be available for patients 2 years and under.

In all pediatric patient care settings, pediatricians, pediatric surgeons, and pediatric subspecialists want anesthesiologists who are knowledgeable and skillful in pediatric anesthesia patient care. As the public has become more informed about pediatric healthcare, with understandable health information easily accessed on publicly available Internet websites, parents have also requested, and in some instances demanded, anesthesia patient care for their children provided by anesthesiologists knowledgeable and skillful in pediatric practice. "Data from other areas of medicine support this demand and show that fewer complications arise the more often practitioners perform a procedure" [20].

Building the case for education in pediatric anesthesiology

The intuitive assumption is that provision of expert pediatric anesthesia patient care requires sufficient manpower (anesthesiologists with pediatric anesthesiology expertise) and sufficient sophistication (fully educated and certified as pediatric anesthesiologists) to care for all of the children (all acuity, patient care scenarios).

In 1999, the American Academy of Pediatrics Section on Anesthesiology published Guidelines for the Pediatric Perioperative Anesthesia Environment, providing a foundation for pediatric anesthesia patient care [17]. This was preceded in 1997 by a publication that made the case for the establishment of a standardized curriculum for pediatric anesthesiology [2]. The Accreditation Council for Graduate Medical Education (ACGME) through its Anesthesiology Residency Review Committee established requirements for standardized education in pediatric anesthesiology that have guided pediatric anesthesiology education for more than a decade. In 2012, the American Board of Anesthesiology (ABA) approved a certification process to recognize clinicians with special expertise in this subspecialty [21]. In the first 3 years (2013–2015) of the ABA pediatric anesthesiology examination, 2734 candidates were certified.

In 2012, the Pediatric Anesthesia Leadership Council, in conjunction with the Pediatric Anesthesia Program Directors' Association in the US, organized a Second Year Advanced Fellowship Network. Recognizing the increasing need for extended subspecialty training in pediatric

anesthesia subspecialties and for further training in leadership and academic disciplines, the network included 12-month voluntary non-ACGME program requirements and curricula in Cardiac, Pain, Education, Research, and Quality and Outcomes fellowship training [22]. In 2015, 24 of 53 (45%) of the US ACGME Pediatric Anesthesia Fellowship programs offered one or more advanced fellowships in this network. Approximately 15–20% of ACGME fellows pursued additional training in these programs from 2012 to 2017 [23]. As of this writing, these same groups were leading an effort to explore lengthening the duration of the ACGME Pediatric Anesthesia Fellowship to 2 years, and enabling the programs to offer extended formalized training in these and other areas. The rationale for this effort is to better prepare leaders in pediatric anesthesiology who will also take on significant roles in hospital, health system, and academic leadership, in an increasingly complex and challenging healthcare environment.

The "How" of pediatric anesthesiology education: theory and strategy

With the need for subspecialty education of pediatric anesthesiologists clearly identified, the question arises: How do we educate anesthesiologists to capably care with confidence and skill for the sickest children? And how do we prepare these well-trained practitioners to pass on their expertise as skilled physician educators of the rising crop of pediatric anesthesiologists? Answers to these questions come from identifying key elements of the "how" of educating expert pediatric anesthesiologists, and what grounded theories and systems exist to support excellence in the education of these specialty physicians.

The medical educator: preparing the doctor to teach

It is taught early in medical school that the root of the word from which "doctor" arises is the Latin *docere*, "to teach." However, most medical schools lack formalized curricula to educate rising physicians on theories of education and provide little opportunity for teaching, let alone coaching toward teaching excellence. Education in pediatric anesthesia for medical students, residents, and fellows occurs primarily in academic settings, wherein the physician must embrace (regardless of comfort level) the role of teacher. Many academic physicians report that they feel ill-equipped for this role, having never received formal training in education. With increasing recognition of the importance of interdisciplinary teams, even in non-academic environments, the pediatric anesthesiologist must be facile at assessing receptivity of surrounding practitioners of varying levels of sophistication, and at conveying complex and nuanced information in readily-understood ways. In addition, a skilled physician teacher must be able to provide information that may challenge the beliefs of the learner, whether it be a nurse, colleague, or patient, in a manner that preserves the integrity of the intended audience. These tasks can be challenging even for experienced educators. For those with no formal grounding in education theory or practice they may seem potentially daunting.

Learners of pediatric anesthesiology are sophisticated and resourceful. A rapidly increasing scope of medical information needed for mastery of the subject is available in easily-searchable electronic formats [24,25]. With such sophisticated learners, it is no longer enough to presume that the authority of being a physician confers expertise in the educational domain.

Many institutions have responded to the lack of formal training for physicians in education by developing teaching academies or teaching scholar programs, which expose physicians to a variety of educational theories and practice, allow for education project development, and provide mentoring and support for physician educators as they develop teaching aptitude [26,27]. There are also an increasing number of masters programs in medical education, which provide in-depth exposure and build expertise in education theory and program development for practicing physicians.

In addition to these structured programs, it is also important for educators in pediatric anesthesiology to remember the value of modeling professionalism in their demeanor with patients, colleagues, and trainees alike [28]. Learners are savvy observers of their surroundings, and their behaviors will be shaped by the actions of those around them. Modeling effective teamwork, communication, expertise, leadership, and patient ownership, among several other professionalism domains, is likely to have a lasting effect on learners, even outside of a formalized curriculum [29].

Learning theory

Learning can be conceptualized as a change in thinking or behavior based on evaluated experience. Several theories attempt to shed light on how learning occurs. From the stimulus-response of operant conditioning [30], to the theory of multiple intelligences [31] (still being refined), there are virtually hundreds of ways to understand how we learn. Postgraduate medical education in pediatric anesthesiology engages a highly specialized subset of learners and embeds them in a unique learning environment with specific outcome needs. As a result, certain learning theories may prove more germane than others to this context.

Experiential education

To some, residency and fellowship represent an apprenticeship, wherein learners partner with both institutions and experts to build the knowledge base and hone the skills to prepare them for independent practice. This is experiential education in one of its purest forms. The philosophy of experiential education is well described in a 1938 treatise by John Dewey, wherein he describes the fundamental need for learning by *doing*. Dewey [32] is among the constructivist learning theorists, and like contemporaries Leo Vygotsky and Jean Piaget, believed that learning is an active and contextualized process of building rather than acquiring knowledge [33]. Understanding and learning are built on the existing scaffold of the learners' psyches, informed by previous experiences and viewed through subjective lenses. Dewey describes the "educative experience" as powerful, embracing all the senses to build multifaceted knowledge, with far greater likelihood to engrain memory and impart

meaning than cognitive preparation alone. In evaluated experiential education, simply *doing* is not enough, however – the *doing* of residency and fellowship specialty training in pediatric anesthesiology is an examined one, with preparation and active reflection as necessary complements to the development of psychomotor skills.

The adult experiential learner

The learner of pediatric anesthesiology is an incredibly sophisticated one, having been successful in traditional educational models relying on both cognitive and psychomotor skills throughout undergraduate education and medical school, while having accumulated a life of experiences. By the time they reach residency these learners are skilled, curious, and questioning, but most of all they already carry with them a minimum of two decades of life experience that will inform how they engage in learning [34]. Adult learners play many roles in their lives that will influence their learning style. They themselves may already be, among other roles, parents, teachers, scientists, writers, or businesspeople. They may come from varied social backgrounds which may contextualize the same event very differently for them depending on the individual. Adult learners are highly motivated, self-directed, results-oriented, and tend to be more intrinsically motivated than their younger counterparts [35]. They should be involved with the planning and evaluation of their instruction, and will often actively engage in processes to improve their own education built around their own insights.

Learning and performance orientation

The learner's approach to novel experiences also influences how events are interpreted and integrated to form new understanding. This has been described as "learning" versus "performance" orientation [36]. In learning orientation, when the student encounters a challenging novel task (such as intubating a neonate or generating a perioperative plan for a medically complicated child), she embraces it as an opportunity to build mastery, even if early attempts are unsuccessful. This relies on the belief that the student holds within herself the necessary skills or motivation to eventually achieve mastery. In performance orientation, when the student encounters a challenging task at which she was not successful, the inclination is to blame extrinsic factors. While this also represents a degree of confidence (perhaps beyond a skill level that is justified), it dangerously presumes that the student bears minimal responsibility for the events (i.e. lack of preparedness is blamed on equipment failure; negative patient outcome is blamed on non-compliance or poor baseline status). From a lifelong learning perspective, the safe and expert practicing pediatric anesthesiologist should favor learning over performance orientation, with a robust sense of accountability and intellectual curiosity. As educators in pediatric anesthesiology, it is important for us to encourage learning over performance orientation, to build confidence and skill while identifying factors attributable to the student.

Strategies for educating in pediatric anesthesiology

Grounding educational practice in theory is important, and several strategies exist to guide teachers of pediatric anesthesiology on how to approach the task. While there are a practically limitless number of methodologies that may help shape how we educate pediatric anesthesiologists, there are a few highly practical ones.

The intraoperative learning environment

The intraoperative arena is a unique learning environment, wherein even the most skilled pediatric anesthesiologist must work to balance the potentially competing priorities of patient care and protection, education of the anesthesia learner, and the flow of the operating room. While many of the psychomotor and affective skills of crisis resource management for high-stakes rare events are best learned in high-fidelity simulation, often the development of skills in frequently-occurring events (such as routine airway management, intravenous catheterization, or speaking with families) is mastered in the course of clinical care. Varying levels of proficiency and comfort of front-line clinician learners may dictate their need, interest, and readiness to learn. Providing graded autonomy while maintaining appropriate supervision is key to supporting the growth of the rising pediatric anesthesiologist. Powerful anesthesiology education involves the support of practice with evidence or literature, maintenance of personal clinical expertise, providing rationales for clinical decision making, and embedding teaching in a relevant context [37]. Anesthesiology learners may also be struggling to develop their own sense of competency, and messages of support of their development, as well as simply making teaching a priority, are well received.

Deliberate practice

Deliberate practice is described as the repeated rehearsal of specific tasks to achieve mastery, under the guidance of a mentor with directed feedback [38,39]. It is suggested that those who engage in deliberate practice, strategically striving to be better on a regular basis, will continue to build skill and develop expertise. Those who engage in their profession in a rote manner will quickly reach a plateau in performance well below that of a top performer. Many of the "tasks" of pediatric anesthesiology are challenging even to those who have achieved consultancy status, and mastery of these skills is paramount in the discipline. We owe it to our patients to be at our very best, dedicated to continuing to improve, in every stage of training and well into our practice as attendings. Active coaching of pediatric anesthesiologist learners also forces the teacher ("coach") into an active role of examined practice, which can serve as a form of learning for teachers themselves.

Facilitated reflection and feedback

Facilitating performance feedback is not only critical to practice improvement, it is longed for by learners. While there are multiple barriers to providing feedback (investment of time, comfort with difficult conversations, fear of retaliation in teaching evaluations even if feedback is constructively critical), engaging in reflective conversations with learners about their performance, while sensitive in nature, is crucial to their learning. Feedback may be *formative*, designed to be integrated in the moment for learner growth, or *summative*, evaluation after completion of observed performance. Feedback takes many forms, but increasing evidence supports creation of an entire culture of feedback. This includes not only making it part of the daily routine for all providers and the creation of a safe environment for feedback, but also a transition in attitudes about

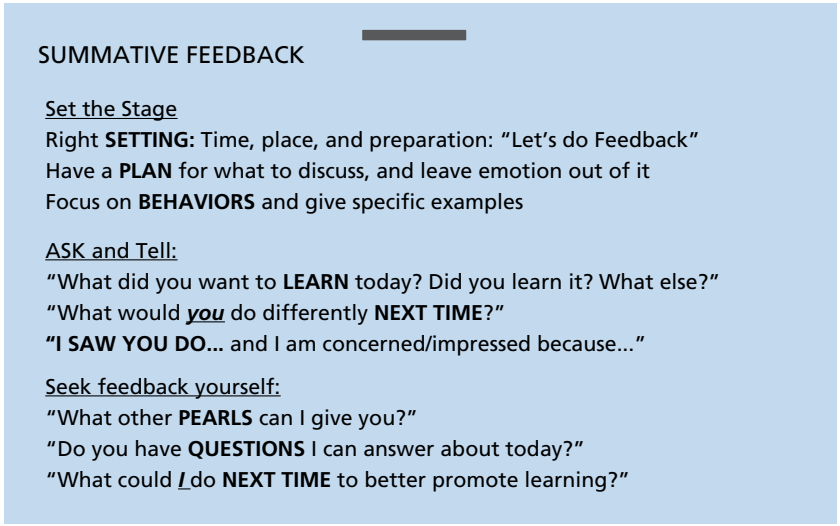

Figure 3.1 An example of a feedback-related cognitive aid. This image is laminated and provided to all staff anesthesiologists as well as anesthesiology fellows for use in real time during end-of-day discussions.

feedback: evidence supports the use of facilitated reflection as more effective than corrective comments [40,41]. In other words, during the modern feedback session the learner should be talking more than the teacher.

There are several tools and strategies useful for providing feedback. The "R2C2" model describes a four-phase approach: building **R**elationship, exploring **R**eactions, exploring **C**ontent, and **C**oaching for performance change [42]. Alternatively, the Pendleton Model uses a different four-step technique, designed to solicit learners' insights on their own performance [43]. In step one, the learner states the positives of his or her performance; in the second step, the educator identifies positives of the learner's performance. In step three, the learner identifies areas in need of improvement, and in the final fourth step the educator notes areas for the learner's development. Another approach, the "reflective feedback" conversation, invites learners to reflect on their own practice and identify areas in need of development. This strategy relies heavily on learner ownership and investment in improvement. Figure 3.1 shows one example of a cognitive aid used for providing feedback in a reflective model. Multiple other methods also exist, but regardless of the approach to feedback, several themes remain (Box 3.3).

Box 3.3: Suggestions on giving feedback

- Feedback should be routine and viewed as part of the daily work
- Learners should be clear on the standard by which they are judged
- Feedback should be directed at specific behaviors, not generalities
- Only a few, directly observed behaviors should be commented on
- Feedback should be given soon after observations, but in a setting where learner integrity is preserved
- Seek the learner's perceptions as feedback evolves
- Provide strategies for implementation of practice change

Adapted from Cantillon and Sargeant [43].

Curriculum development

Development of educational programs, while sometimes serendipitous or borne of necessity, should be a deliberate practice in itself. In the same way that physician educators are often not exposed systematically to teaching strategies or educational theory, often those responsible for developing education programs or curricula may feel ill-equipped to do so. Different structures may provide guidance for these efforts, in which there are several consistent themes about how to approach curriculum development. An effective curriculum must be collaborative and contextualized. It will be more relevant and successful if stakeholders (learners, educators, administrators) contribute to its construction.

Guidelines for developing medical curricula can be complex, but several approachable texts make the task less daunting [44]. Major phases of curriculum development should include the following:

1. *Planning*: Perform a "needs assessment" – identify the problem, contextualize it to the target learner.
2. *Development:* Outline goals (ideals) and objectives (measurable targets), and identify educational strategies (content, methods, materials).
3. *Implementation:* Execute the proposed curriculum.
4. *Evaluation:* An ongoing process, to refine the program for greater efficacy.

With strategies that include learners in each stage, curricula will be more adaptive and relevant. Having concrete, measurable learner outcomes after engagement with the curriculum will also increase effectiveness.

The "What:" pediatric anesthesiology education in practice

Having discussed the rationale and some methods of pediatric anesthesiology education, germane questions remain, such as:

- What are the necessary essentials for implementation of pediatric anesthesiology educational programs, including accredited core anesthesiology residency and the advanced subspecialty fellowship in pediatric anesthesiology?
- What is the role of pediatric anesthesiology in the education of non-anesthesiology patient care providers?
- What are effective methods of evaluation for learners, teachers, and programs?
- What is the role of faculty education in the development of any high-quality educational program?

These questions, among others, will here be partly addressed by outlining existing strategies and programs; understanding the responses to these complex questions may allow the reader advance the goal of excellence in specific educational programs.

Core residency education in anesthesiology in the United States

The relatively recent development of Pediatric Anesthesiology as a certified subspecialty of the ABA has altered expectations for core resident education in pediatric anesthesiology. In the few years since certification became available, the number of pediatric anesthesiology fellows in the nation has doubled to over 200 per year. As a consequence, many practices, even those with primarily adult patient populations, employ at least one fellowship-trained pediatric anesthesiologist for care of pediatric patients.

The downstream impact of this has been some national disagreement about what a core anesthesiology resident "should" learn about pediatric anesthesiology, and whether or not the current fellowship training model meets the goals for creating the workforce for the future [2,21]. It can be anticipated that in the next decade there will be more clarity on these issues. In the meantime, the ACGME and the ABA have helped guide the minimum pediatric educational experience by setting standards that all residency educators should be aware of. These two organizations have traditionally taken different approaches to their guidelines. The ACGME defines the experience using an apprenticeship model defined by duration (a minimum of 2 months of pediatric anesthesiology rotations during the Clinical Anesthesiology CA-1 to CA-3 years and a maximum of 6 months during the same interval) and case mix (minimum number of patient experiences by differing age groupings). In some institutions, this exposure may be augmented with either pediatric residency rotations or a complete pediatric internship year (postgraduate year 1) prior to the start of the CA-1 year. Alternatively, the ABA defines the expected education in terms of topics that should be mastered in order to achieve Primary Certification in Anesthesiology (Box 3.4). Educators should be aware of both of these guidelines, and have an obligation to ensure that core anesthesiology residents are adequately prepared for primary anesthesiology board certification and the practice of anesthesiology as it pertains to the subspecialty of pediatric anesthesiology.

Box 3.4: Pediatric topics for primary certification in anesthesiology (adapted from the American Board of Anesthesiology)

- Apparatus
- Premedication
- Agents and techniques
- Fluid therapy, blood replacement, and glucose requirements
- Problems in intubation and extubation
- Neonatal physiology
- Congenital heart and major vascular disease
- Emergencies in the newborn
- Pediatric medical problems with anesthetic implications
- Anesthetic implications for common non-neonatal pediatric subspecialty surgery

Fellowship education in anesthesiology

If the purpose of resident education in pediatric anesthesiology is to prepare the learner for a broad career in anesthesiology that may include the care of children, the next logical question is, "For whom is fellowship training in pediatric anesthesiology warranted?" What is the purpose and value of extended education in pediatric anesthesiology? This may not be self-evident, bearing in mind the considerable opportunity cost that learners cope with by delaying full, unrestricted licensure and employment by at least 12 months. In addition, there is a potential financial risk of an ultimately lower salary should the learner choose a career at an academic or free-standing children's center compared to the private sector jobs for which they are eligible upon successful completion of core anesthesiology residency training.

First, there is no question that both the breadth and depth of cases mastered at graduation are greater for fellowship-trained pediatric anesthesiologists. In many institutions pediatric cases are divided into "resident cases" and "fellow cases," either implicitly or sometimes explicitly. A 1-kg, 1-day-old neonate, for example, with a congenital heart defect and trachea-esophageal fistula who is scheduled for thoracotomy for tracheal repair is unlikely to be cared for by a core resident in anesthesiology in most circumstances. Furthermore, many residents would consider this case to be out of the scope of any practice they would anticipate joining, and thus are not surprised to see this patient cared for by expert pediatric anesthesiologists (including fellows).

Clinical exposure

While this guiding principle of "relevance to practice" is helpful, the ACGME has also outlined program requirements for pediatric anesthesiology fellowships, including a list of "index cases" required of each fellow for graduation (Table 3.1) [45]. Any center considering expanding or creating fellowship positions in pediatric anesthesiology must have adequate case volumes in each of these categories in order to ensure the appropriate clinical experience among graduates. This must be accomplished without negatively impacting core anesthesiology resident education and clinical experiences. Similarly, the ABA has created a subspecialty certification examination in pediatric anesthesiology with a detailed content outline (see abbreviated version in Box 3.5). Completion of an ACGME-accredited 12-month pediatric anesthesiology fellowship program is now prerequisite to sitting for this examination.

Developing the academic pediatric anesthesiologist

Anesthesiology is one of the few medical fields in which being an outstanding resident does not necessarily translate into expert function as an attending anesthesiologist. This can be attributed to the differences in roles between front-line providers in the operating room and faculty members who engage in such activities as managing multiple anesthetizing locations, teaching educational conferences, and serving on hospital committees. For this reason, perhaps more importantly than the *clinical* experience of subspecialty training, one of the major goals of fellowship is the development of academic skills prerequisite for a successful career as an expert pediatric anesthesiologist. This includes scholarly expertise

Table 3.1 Pediatric anesthesiology fellowship case minimums

Category	Minimum number
Total number of patients	240
Age of patient	
Neonates	15
1–11 month olds	40
1–2 year olds	40
3–11 year olds	75
12–17 year olds	30
ASA physical statement	
ASA 1	25
ASA 2	42
ASA 3	50
ASA 4	20
Procedures	
Arterial cannulation	30
Central venous cannulation	12
Epidural/caudal	10
Flexible fiberoptic technique	4
General anesthetic	200
Peripheral nerve block	11
Type of surgery	
Airway surgery (excluding T&A)	7
Cardiac with cardiopulmonary bypass	15
Cardiac without cardiopulmonary bypass	5
Craniofacial surgery (excluding cleft lip/palate)	3
Intra-abdominal (excluding hernia)	12
Intracranial (excluding shunts)	9
Intrathoracic, non-cardiac	5
Major orthopedic surgery	5
Other non-operative	10
Other operative	55
Total neonate emergency	3
Pain management	
Consultations and PCA	17

Box 3.5: Content outline for pediatric subspecialty certification

Basic science
- Anatomy
- Physics and anesthesia equipment
- Anesthetic pharmacology

Organ-based basic and clinical sciences
- Respiratory system
- Cardiovascular system
- Central and peripheral nervous systems
- Gastrointestinal system
- Renal/urinary systems
- Endocrine/metabolic systems
- Hematology/oncology
- Genetics

Clinical subspecialties
- Fetal
- Neonatal
- Painful disease states
- Otolaryngology
- Plastic and oral-maxillary facial surgery
- Ophthalmology
- Orthopedic surgery
- Trauma and burns

Clinical science of anesthesia
- Evaluation and preoperative preparation of the pediatric patient
- General considerations of the perioperative period
- Regional anesthesia and analgesia
- General anesthesia
- Complications of anesthesia
- Special techniques and situations
- Postoperative period
- Monitored anesthesia care and sedation
- Acute and chronic pain management

Special problems or issues
- Special surgical procedures
- Professional issues
- Principles of biostatistics and study design

(e.g. original research or educational workshop development) and skills for leadership outside the operating room, fostering of an understanding of practice management, and educational mentorship. For example, a program may pair fellows with faculty members for recurring resident didactic teaching sessions. The faculty member role in this setting is to silently observe the fellow as teacher, then to provide meaningful feedback about teaching style and efficacy to the fellow following the session. With this approach, over the course of the year the fellows not only master the topic they choose to present but also begin to think of teaching as a skill unique from the rest of their practice and one about which they often have had no prior training.

As noted above, for those physicians who are interested in mastery of an even more focused clinical field within pediatric anesthesiology, select centers offer advanced fellowships in pediatric cardiothoracic anesthesiology, pediatric acute pain, pediatric regional anesthesiology, and more. Documentation of successful completion of one of these advanced fellowship programs is increasingly mandated for those anticipating, for example, a career caring for children with congenital heart disease undergoing cardiothoracic surgery at major centers. From a programmatic standpoint, advanced second-year pediatric anesthesiology fellowship programs share an important similarity: they are often tracks to faculty positions at large centers. In fact, several large centers in recent years have decided to hire only faculty with such advanced training. Medical educators should bear this in mind and should develop these programs with an emphasis on academics and scholarly work in addition to clinical mastery, building on the academic foundation initiated during the general pediatric anesthesiology fellowship training. With the exception of select pediatric pain fellowships that have paired with adult pain programs, there are no board certification examinations yet in any of these advanced subspecialties.

Oversight of educational programs

For any ACGME-accredited educational program (including resident and fellow programs) there are considerable regulatory and administrative expectations that change on a regular

basis. To avoid misinformation, review of the most accurate information available about specific requirements for fellowship is accomplished via the ACGME website (www.ACGME.org). Program directors and coordinators should be aware of both common program requirements (that apply to all programs) and specialty-specific program requirements. On this site there is also a "Program Directors Virtual Handbook" as well as a section called "Resources for New Program Directors." Program directors are encouraged to review this information to ensure compliance with existing regulations and provide feedback on proposed changes to regulations. Directors of non-ACGME fellowship programs may also find the resources helpful.

In addition to the ACGME, every teaching hospital has a Graduate Medical Education office, directed by a Designated Institutional Official (DIO). The DIO is a physician who takes accountability for the management of all GME programs in the hospital and is a useful resource for troubleshooting educational program issues as they arise. Both ACGME-accredited and non-ACGME accredited programs benefit from the umbrella of the GME office and the DIO. Establishing relationships with the DIO and the GME team is paramount to the success of educational programs.

Education of non-anesthesia providers

Pediatric anesthesiology education extends well beyond the "accredited training program." Many pediatric anesthesiologists are likely aware that for every anesthesiology trainee, there is one or more non-anesthesia provider who rotates to the operating room for "anesthesia experience." Some of these learners seek basic or advanced airway management education. Others come to practice vascular access skills in immobile and insensate children. Others may use anesthetic drugs in practice and seek experience with dosing and titration. There is a wide variation in level of experience of the learners, including but not limited to non-anesthesiology residents and fellows, attending physicians, medical students, sedation nurses and physicians, student nurse anesthetists and anesthesiology assistants, transport paramedics, and pre-hospital providers.

Key to the success of any program with rotating learners of varying experience and educational goals is the thoughtful formulation of specific learning objectives for each individual or group of learners. Care must also be taken to avoid altering or potentially diminishing the educational experience of anesthesiology trainees in the planning of education for non-anesthesia learners. It is imperative to ensure also that all patients receive safe anesthetic care. Having non-anesthesia providers in the operating room requires intense supervision to prevent unintended patient harm.

There are potential vast differences in baseline knowledge, skills, and perceptions of self-confidence among non-anesthesiology learners. Because of the limited resource of patient encounter opportunities compared with the seemingly unlimited supply of learners, larger institutions may find it helpful to create curricula or programs to optimize learning for visitors to the operating room, rather than encouraging sporadic opportunistic visitation.

One example of such a program is the Pediatric Airway Skills Education (PASE) curriculum at The Children's Hospital of Philadelphia (CHOP), with standardized prerequisites to visiting the operating room. This multi-modal educational program includes online learning modules focused on: (1) pediatric airway anatomy and assessment; (2) pediatric manual ventilation and adjuncts; and (3) endotracheal intubation and resources for failed intubation. Following completion of the online modules, learners attend Part 4 – a 1-hour, facilitated, hands-on training session with simulation equipment to practice mask ventilation, oral and nasopharyngeal airway insertion, endotracheal intubation, and laryngeal mask airway insertion. This is similar to the American Heart Association approach to the various advanced life support learning programs. Online learning occurs at the learner's own pace and upon successful acquisition of the content, skills competence is assessed. This approach enables learners to invest in their own education, limits patient contact to those who are prepared for it, and focuses the role of the teacher at building on previously acquired knowledge and skills.

Evaluation in pediatric anesthesiology education

Evaluation is a crucial foundation to any educational endeavor, offering insight through critical reflection and identifying opportunity for improvement. In pediatric anesthesiology, evaluation of the learner, teacher, and program can together create educational experiences of excellence.

Evaluating the learner

There have been major changes to the way that learners are evaluated over the past decade. Educators in pediatric anesthesiology must be aware of both the rationale and the implementation of these new evaluation systems. Gone are the Likert scale-associated "ACGME Core Competencies" wherein "Medical Knowledge" was assessed on a 1-to-5 scale. What has replaced them is a tool similar to that used by pediatricians for generations: the ACGME milestones [46,47].

Each specialty and subspecialty has developed unique milestones in conjunction with the ACGME and the ABA. The milestones expectations for anesthesiology residents on the pediatric anesthesiology rotation will be different from those for the pediatric anesthesiology fellow. The pediatric anesthesiology fellowship milestones are available online [48].

The concept of the milestones is that an intern can be outstanding but is expected to function differently from an outstanding fellow. Using the old 5-point Likert scale, should both receive a score of 5? Each metric in the milestone system represents a continuum of knowledge, skills, and attitudes. Trainees are rated based on their actual performance on these scales, and anchors are put in place to guide expectations. For example, for pediatric anesthesiology the target for graduation is a milestone score of 4. Five is considered aspirational and some faculty may not function at a level of 5 for all milestones. Fellows are expected to enter fellowship with approximately a 1 on the fellowship-specific milestones. This may represent a psychological burden for both faculty and trainees, since an outstanding fellow may receive "low scores" at the start of the year, and this is different from previous evaluation systems. While the system is clearly imperfect, it is far more helpful than the old evaluation system at guiding the development of the learner. Increasingly non-ACGME

programs have begun using similar systems and the medical educator is bound to encounter these systems in practice.

Borrowing from the mounting corporate literature, 360-degree evaluation has become an important component of evaluation (and is now mandated by the ACGME). Depending on the setting and the relevant stakeholders, this may take many forms; the common theme is that attending physicians are not the only, or the best, judges of how trainees interact with nurses, staff, children, parents, or others. Tools for 360-degree evaluation such as the one shown in Figure 3.2 can serve as enormous, otherwise untapped, sources of data about learners.

In addition to board certification examinations, there is a growing demand from both the public and regulatory agencies such as the ACGME for "Entrustable Professional Activities" (EPAs). The concept of the EPA is very simple: how do we know that *Resident X* is able to perform *Skill Y* without direct supervision? [49,50]. Not long ago, autonomy was granted based on postgraduate training year alone. In the modern era, it is clear that this is inadequate due to the variability of learning acquisition for different tasks. How do we know, for example, if a resident is competent to place a jugular central venous line? Can we confirm not only that she has performed enough lines (quantity), but that she has done them correctly and without complications (quality)? In the EPA model, this procedure would be tracked, and after successful completion of a requisite number with appropriate performance (both of which need to be agreed by educators and conveyed to learners) the resident is considered eligible to perform the procedure with indirect supervision only. Anticipate increasing discussion about the role of EPAs in anesthesiology education in the coming decade; this area is ripe for research on validated tools at this time.

Evaluating the teacher

What is a good teacher? How does the medical educator evaluate teaching efficacy? If a student does not learn, is it the fault of the teacher or the student – or both? Questions like these haunt medical educators, who often think of teaching as their life's work. It can be daunting to effectively evaluate learners. But the meaningful evaluation of teachers has an added challenge: the evaluator is usually also the student, leading to a complex interaction of interests.

Consider two teachers: a pleasant person who always brings food to lectures and is rated very highly by students, and a faculty member who corrects every action (with explanations of her rationale) in the operating room. The latter may suffer from poor "teaching scores" when students react to corrective statements, but may in fact be teaching at a far higher quality than the former. Perhaps a more accurate method of assessing the teacher would be regular third-party observation, however this poses logistical and interpretive challenges, and risks a Hawthorne effect on the educational interaction, wherein the act of observing influences the behavior observed.

Consider another example of two teachers: one teaches a very mundane but often misunderstood concept, and another teaches a very eccentric and rarely used technique. Both are potentially valuable; however, most faculty would likely argue the former is higher value than the latter, while residents may give lower teaching scores to the former teacher. This example demonstrates two important concepts. First, it is not always clear whether it is the teacher or the subject matter that is being evaluated. Second, in many cases there is a discrepancy between what the learner *wants* to learn and what the teacher *knows the learner needs*.

Within academic medicine there exists significant motivation to evaluate teaching effectiveness, and although no system is perfect, relying exclusively on learner-driven teaching evaluations is potentially perilous. Teaching evaluations may be more reflective of how the learner feels about the educator ("likeability" and character traits of the teacher) than actual teaching effectiveness, and may even penalize teaching that challenges the learner's assumptions about his or her own performance or aptitude [51]. There exists concern among faculty at academic institutions of "reciprocity bias," wherein learners are predisposed to evaluate the teacher as they feel the teacher will evaluate them. Despite their imperfections, teaching evaluations play a significant high-stakes role in advancement and promotion of academic physician educators. This should prompt the academy to consider complementary data on teaching effectiveness.

In defining good teaching, more remote learner outcomes should be examined to know if educational efforts have made a lasting difference, rather than relying on how a learner feels about the educational experience in the teaching–learning moment [51]. In addition, data from educational outreach activities such as peer education, conference or institutional workshops, lectures and grand rounds presentations, to name a few, should also be considered.

Evaluating the program

Many books have been written by business professionals about the evaluation of programs [52,53]. The medical education community has begun to realize the value of such a strategy and thus structured evaluation has become a routine part of the maintenance of teaching programs. At a minimum, this takes the shape of the ACGME-mandated Program Evaluation Committee (PEC) meeting.

The PEC is made up of a cross-section of faculty members and at least one trainee; it may also include other staff as the program director deems appropriate. The PEC must be chaired by the program director and is required to meet at least once per year. Sources of information to be gathered prior to the meeting may include faculty evaluations, fellow evaluations, alumni surveys, ancillary staff input, lecture evaluations, curriculum assessment, and board certification pass rate for graduates. The PEC is required to suggest changes each year for program improvement; the program director is charged with implementing and assessing improvements over time. Details about the PEC function can be found on the ACGME program requirements website for the educational program in question [45]. In addition to the minimum-required annual PEC review, some programs utilize other measures of program efficacy. The PEC may meet more frequently, or data may be gathered in an ongoing fashion for continuous program improvement. At CHOP for example, regular fellow debriefing sessions are utilized to proactively gather real-time data about concerns, suggestions for improvement, and other relevant outcomes. The PEC meetings facilitate structured annual changes.

Parent Survey of Pediatric Anesthesiology Fellow

Fellow Name: _____

Dear Parent,

Training future pediatric anesthesiologists is an important part of our mission at The Children's Hospital of Philadelphia. Today, your child was cared for by a team that included a "fellow" physician – one who has completed training in anesthesiology but has chosen to continue further training as a pediatric anesthesiologist.

We need your help to make sure our fellows are the best doctors they can be. Please take a moment to provide us with feedback, and return this form to your recovery room nurse or to the locked "FELLOW EVALUATION BOX" in the PACU/recovery room. Your answers are anonymous and will not affect the care your child receives today or in the future.

Thank you!

When you think about your interactions today with the fellow physician who cared for your child, did he/she:

1. Introduce him/herself and explain his/her role clearly?
☐ Needs improvement ☐ Met my expectations ☐ Exceeded my expectations

2. Listen attentively to your concerns and questions?
☐ Needs improvement ☐ Met my expectations ☐ Exceeded my expectations

3. Respect your child, your family, and your culture?
☐ Needs improvement ☐ Met my expectations ☐ Exceeded my expectations

4. Examine your child before surgery, using appropriate respect and gentleness?
☐ Needs improvement ☐ Met my expectations ☐ Exceeded my expectations

5. Explain a clear plan of care for the day using language that you understood?
☐ Needs improvement ☐ Met my expectations ☐ Exceeded my expectations

6. Appear knowledgeable about medical issues?
☐ Needs improvement ☐ Met my expectations ☐ Exceeded my expectations

7. Follow-up with my child in the recovery room (PACU) to be sure he/she was comfortable?
☐ Needs improvement ☐ Met my expectations ☐ Exceeded my expectations

8. Ask me whether I had concerns after surgery and prior to my discharge?
☐ Needs improvement ☐ Met my expectations ☐ Exceeded my expectations

Overall, in thinking about the care provided to your child by a pediatric anesthesiology fellow today, would you be comfortable having this doctor care for your child again? *(please check one)*

☐ YES ☐ NO

Please add any additional comments (or explanations to answers above) you would like us to know in the future when we review the results of this survey with your pediatric anesthesiology fellow.

Revised 11/2014

Figure 3.2 Parent evaluation form for pediatric anesthesiology fellows. A similarly structured, yet different in content, form is used for allied health professional evaluation of pediatric anesthesiology fellows.

Mid-year changes are employed when needed to guarantee that educational goals are met.

An often-overlooked, yet important, aspect of program evaluation is succession planning. In the ideal setting, the program director has a co-leader and shadow in an associate program director, and the associate program director may also have an identified successor. These individuals should understand the issues and share in the program director tasks. Annual program requirements and other administrative tasks should be clearly delineated so that, in the event of unplanned or planned change in program director, the program can continue to run without interruption. Too often, "local champions" are responsible for running programs; the result is that if the champion disappears there is no one in the organization with the full knowledge of how to maintain the program in its current state, let alone

which changes need to be made as part of the ongoing program improvement process.

Continuing education in pediatric anesthesiology

In addition to the various graduate medical education programs that involve pediatric anesthesiology, anesthesiology departments (and educators) must be thoughtful about continuing education for faculty and staff. In addition to formal "Continuing Medical Education" (CME) courses that are often offered locally or are available nationally through organizations such as the Society for Pediatric Anesthesia (www.pedsanesthesia.org), there is a renewed focus on internal faculty development programs. These programs should be based on a local needs assessment and may cover topics as diverse as technical skills (for example, a refresher on defibrillator use or other rarely used skills), workshops in medical education techniques, professionalism education series, and burnout prevention strategies [54]. The ABA Maintenance of Certification Program for Pediatric Anesthesiology includes required activities for lifelong learning for both the base anesthesiology certification and the pediatric anesthesia subspecialty boards. These occur over a 10-year cycle requiring substantial CME credits, periodic review questions, of which 50% are on pediatric anesthesia topics, and evidence of significant quality improvement activities [55]. Many anesthesiologists have significant professional educational needs that are distinct from those of medical trainees, yet the stigma associated with admitting a knowledge gap among experienced faculty members inhibits appropriately directed educational efforts. It is the role of the educational leaders of the department to find a means to perform needs assessments and to provide meaningful educational experiences for all community members.

Conclusion

Education in pediatric anesthesiology is itself a model of deliberate practice, an opportunity for developing expertise through curricular reiteration, grounded in philosophy with practical application in design. Regardless of strategy, the paramount goals are to establish a culture of support for learning and find a way for both education and clinical work to serve the same master: the provision of expert anesthesiology care for children, both now and for the future.

CHAPTER 4

An Introduction to the Ethical Design, Conduct, and Analysis of Pediatric Clinical Trials

Myron Yaster[1], *Jeffrey Galinkin*[2], *and Mark S. Schreiner*[3,4]

[1]Department of Anesthesiology and Pediatrics, Children's Hospital Colorado, University of Colorado at Denver, Aurora, CO, USA

[2]US Anesthesia Partners, Greenwood Village, CO, USA

[3]Department of Anesthesiology and Critical Care Medicine, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA, USA

[4]The Children's Hospital of Philadelphia, Philadelphia, PA, USA

Introduction

Pharmacology and physiology, drug behavior, and organ function are the fundamental underpinnings of perioperative anesthetic practice. At our core, anesthesiologists are physiologists and pharmacologists; we titrate drugs against an individual patient's response to achieve a desired therapeutic goal. Understanding the pharmacokinetics (uptake, distribution, elimination, and sensitivity of a drug's effects in an individual patient) and pharmacodynamics (clinical effects of the drug on effector sites; hemodynamic, respiratory, renal, and central nervous system function) of the drugs we administer is essential for the safe provision of anesthesia. But more fundamentally, how can one determine if a therapy will be effective in the first place? Or if given a choice of therapies, which one is best? Further, although anesthesiologists titrate drugs to an individual patient's response, how do they know the population kinetics on which to determine how much drug to administer to produce the average or typical response? Or, over what period of time should a drug be administered and be expected to last? Equally important, how are outcomes determined or tested, and over what period of time?

Historically, most studies involving anesthetic drugs and techniques looked at the perioperative period as the time frame for outcome. However, what if the effects of these drugs or techniques only reveal themselves weeks or years later? At one time, this would have been considered preposterous. However, we now know from long-term studies where follow-up was years rather than days that the consequences of how an anesthetic was delivered can have profound effects years later [1]. Studies examining the effect of variations in perioperative anesthetic management of adults with coronary artery disease and newborn infants undergoing anesthesia have revealed significant effects years after the anesthetic was provided [1,2].

The randomized, double-blind, placebo-controlled trial (RCT) is the "gold standard" for determining the efficacy and safety of therapeutics. No other study design can provide better evidence for cause and effect between an intervention and an outcome. Unfortunately, when children are participants, ethically acceptable RCTs are more difficult to design and there are numerous impediments to practical implementation. When an RCT is not feasible, clinicians must rely on weaker forms of evidence from other trial designs such as pragmatic clinical trials, clinical trials without placebo controls, cohort studies, case–control studies, and even anecdote. While all of these are valuable, their results are less convincing due to the potential for confounding and bias.

Gregory's Pediatric Anesthesia, Sixth Edition. Edited by Dean B. Andropoulos and George A. Gregory.

No matter what the specifics of the study design, performing a clinical trial is challenging, often expensive and, when done to Good Clinical Practice (GCP) standards, challenging and expensive to conduct. Clinical trials strain resources and patience and are often viewed by investigators as an ordeal to overcome rather than as a welcomed ally.

New therapies approved for adults rapidly assume the mantle of the "standard of care" for pediatric patients, increasing the barrier to conducting an RCT and encouraging off-label prescribing which is rampant in pediatric practice [3,4]. Psychologically, this creates a very narrow window of time during which investigators are willing to conduct clinical trials of new therapies for children. When either clinicians or patients accept a therapy as effective, they do not want to participate in a study with the risk of enrolling into a placebo or control arm. However, using drugs off-label in children exposes them to ineffective care and untoward side-effects. Children who receive off-label drugs during an inpatient hospitalization have nearly double the likelihood of having an adverse drug reaction [5,6]. It is well established that children can have unique responses to drugs (e.g. weight gain, decreased growth), require different dosages and delivery methods, and often fail to show a therapeutic response even when the therapy provided is very effective for identical problems in adults (e.g. the use of triptans for migraine headaches or selective serotonin reuptake inhibitors (SSRIs) for depression) [7].

Given that it is not possible to predict whether children, from neonates to adolescents, will respond to a given drug in the same way as adults, RCTs remain essential. The alternative to evidence of safety and efficacy is perpetual uncertainty with acceptance of unproven therapies. In this chapter, we will provide an introduction to clinical trials and discuss the special problems of performing them in infants, children, and adolescents.

What is a clinical trial?

A clinical trial is a planned experiment that involves assigning subjects to an intervention with the objective of evaluating the effect of the intervention on the participants. Usually, the objective is to determine the efficacy and safety of the intervention (Fig. 4.1). Although vital, for the purposes of this chapter, we will not discuss clinical trials that involve a single group, such as pharmacokinetic studies. The intervention need not be limited to drugs, biological agents, or devices, but could include diets (e.g. preoperative fasting interval), a method or processes of delivering care, or any other procedure that can be manipulated by the investigator. At a defined point in time, the outcomes between one or more groups of subjects who receive the test intervention are compared with those of one or more parallel comparable populations of subjects in a control group.

Common impediments

Nothing can be more frustrating for investigators than to realize that there is a clinical question that requires an RCT for a definitive answer but only then to realize that it is not possible to address the question because of organizational, design, or execution issues. This can be true not just for investigator-initiated single-center trials; obstacles can also impede industry- or government-sponsored multicenter trials. Common impediments in all trials include inadequate planning, protocol development issues, and lack of available subjects or funding. Furthermore, almost all clinical trial investigators, both in industry and in academia, have unrealistic or overly ambitious timelines for study completion. Indeed, data from the National Institutes of Health (NIH) indicate that 85% of clinical trials fail to complete on time.

Overly ambitious objectives or rushed timelines can result multiple revisions to a protocol, an inability to get contracts between trial sponsors and centers finalized, and investigational review board (IRB, also referred to as research ethics committee or REC) approval delays [8,9]. (A sponsor or sponsoring agency is the institution, organization, or foundation that provides the fiscal and often the administrative and scientific support for a given clinical trial or project.) Inappropriate subject selection and incomplete data collection due to inadequate instructions or collection forms can result in unnecessary protocol deviations that compromise the fidelity of the study or in unanticipated adverse events that can compromise the entire study. Unrealistic or overly ambitious timetables may also raise doubts in the minds of the investigators about their ability to participate, forcing them to opt out rather than taking part in the trial. These factors result in approximately 30% of sites in multicenter studies failing to enroll even a single subject. Alternatively, some investigators who are frustrated by the time required to perform a proper trial may begin an inadequately designed trial before all the necessary procedures and support systems have been adequately tested and developed. This not only endangers the trial but, worse, exposes subjects to unnecessary risks of a trial that produces unusable data.

Getting started

To avoid many of these pitfalls, an organized stepwise approach, involving teamwork and an understanding of

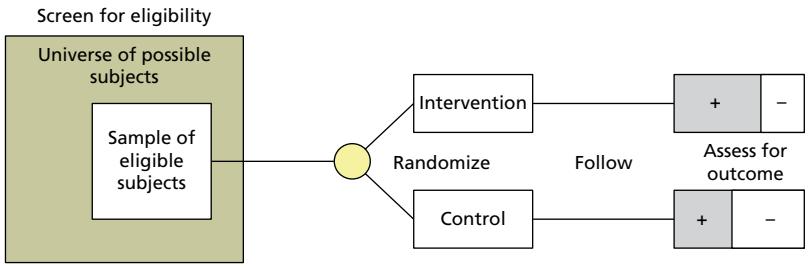

Figure 4.1 A clinical trial is a planned experiment that involves administration or implementation of an intervention to a sample group of subjects who are representative of the general population and is intended to determine the efficacy and safety of the intervention.

clinical trials methodology, is necessary [10–12]. More than ever, clinical research is a collaborative venture between clinicians, research methodologists, statisticians, study coordinators, IRBs, and study participants.

Defining the research question

Research begins with the research question that derives from a clinical problem. The research question is a general formulation and addresses the global question of interest such as "Does this drug or medical procedure or device work?" This overarching research question is unfocused and first needs to be formulated into a PICOT (Population, Intervention, Comparison, Outcome, Timeline) question [13]. The population refers to those patients intended to be recruited for the trial based on age group and other inclusion and exclusion criteria. The intervention needs to be defined precisely: dose or doses, interval between doses, and duration of administration. Comparison means the group against whom the intervention will be compared. The outcome of interest involves the plan for assessing whether or not the intervention works. The measures – morbidity, mortality, change in physiological variable, scale, or test, etc. – to be used need to be specified ahead of time. Finally, the timeline at which the comparison will be made must be agreed upon. In our experience, it can take considerable time and negotiation amongst the various investigators or between investigators and the sponsor to arrive at mutually agreed upon definitions for the PICOT question. Nevertheless, the time it takes to do this is vital for the success of a trial. The efforts expended upfront will avoid disappointment and potential failure later on.

There is often confusion about the meaning of three related but distinctly different terms – objectives, endpoints, and hypotheses. The study *objectives* serve as a statement of the general purpose of the clinical trial. In general, they are written in the form "to determine the …" and this is followed by the thing to be determined such as "the efficacy of the study drug for the treatment of … or "the pharmacokinetics of oral study drug …" An example may help. Assume that a clinical trial will test a new antihypertensive drug and the primary objective could be to determine the efficacy of the study drug for the treatment of moderate-to-severe hypertension in adults 18–65 years of age (P and I in PICOT). The primary objective serves as the basis for the sample size calculation while the secondary objectives are often exploratory (inadequate sample size to definitely address the objective).

The study *endpoints* convert each objective into an explicit operational definition that clearly defines how the objective will be measured and when it will be measured. The endpoints specify the comparison groups, the time points at which the comparison will be made, and the exact measurements or evaluation that will be used for the comparison (C, O, and T in PICOT). In our antihypertensive example, the primary endpoint might be the difference in the change in noninvasively measured systolic (or diastolic) blood pressure in mmHg after 4 weeks of treatment compared to baseline in the study drug group compared to the placebo control group. Lastly, there is frequent confusion about where to place the study *hypotheses*. They are often mistakenly included with the study objectives but in reality belong in the protocol statistical method section. The hypotheses are expressed in statistical terms as a null hypothesis and as an alternative hypothesis.

After development of the objectives and endpoints, the next question in any clinical trial is simply: "Is it worth the effort to mount a trial in the first place?" The answer to this question is predicated on the following questions: What is already known about the research question? Is this question worth the time and effort to answer? If the results were available today how would it change clinical practice? Is it ethically permissible to conduct this study in humans? and, finally, is it feasible to answer this research question with a clinical trial or would an alternative approach be better?

Choice of control group

The choice of the test and control treatments is the obvious and most important next step in designing a clinical trial [14]. The groups must differ from one another and investigators and subjects must be willing to enroll into both. The principle of equipoise is one approach for determining whether or not it is ethically permissible to conduct a comparative trial [15]. When low-quality evidence accumulates suggesting that one treatment may be superior to another, investigators may be reluctant to participate in the trial because they are unwilling to randomize their patients. However, even when the investigator is convinced that the experimental intervention will be superior to the alternative, provided that there is genuine uncertainty within the clinical community based on the available evidence, then the research question is in a state of equipoise and it is ethical to proceed. There is a long history of unexpected results in clinical trials, often with the placebo group having a survival advantage compared to what was perceived as the preferred treatment [16]. In 50% of the Children's Oncology Group clinical trials, the new study drug fails to outperform the standard treatment arm, emphasizing that frequently we are in a state of true equipoise [17].

By the time pediatric clinical trials begin, data from adults frequently suggest that the drug is active and effective, at least to some extent, for the proposed indication. In this situation, true equipoise might not exist. The requirement for true equipoise can be quite constraining and a number of alternative formulations have been proposed to substitute for it [18–20]. Many ethicists contend that in this situation, the decision about whether or not it is ethical to conduct the trial hinges on the risks associated with assignment to the control group (theoretically the less advantageous arm of the study). When the potential harms are minor and temporary then it may still be ethical to conduct the trial [21]. For example, a trial of a drug to replace acetaminophen for tension headache or a new treatment for allergic rhinitis could be ethically conducted because in neither situation would subjects suffer undue harm from assignment to a placebo.

The control group may be historical or concurrent, and assignment to groups may be via a randomized or nonrandomized process. While it is tempting to simply use an historical control to compare to a study intervention, the practice should be avoided. Considerable experience has shown that trials using historical controls are much more likely to conclude that a new therapy is effective than those using concurrent controls [22]. Choices for concurrent controls include placebo,

different doses of the same intervention (dose-ranging or dose–response studies), an established intervention/treatment (active control), or a combination of all of the above. The International Conference on Harmonization (ICH) "Choice of Control Group and Related Issues in Clinical Trials" document provides an extensive discussion of the advantages and disadvantages of each of these options [14].

The use of placebo controls remains a contentious and controversial topic [19,23,24]. The US Food and Drug Administration (FDA) has a clear mandate from Congress to only approve drugs, biologics, and devices that have proven to be safe and effective. In making their determinations, it is obvious that the FDA's clear preference is for placebo-controlled trials. Since many drugs that worked in adults have failed to establish efficacy in pediatric clinical trials (e.g. triptans [25] and antidepressants [26]), the FDA's preferences have considerable basis. Active controlled trials that seek to demonstrate equivalence suffer from the conundrum that if no difference is found between the two intervention arms, then it is possible that neither worked or both worked. As many as 40% of clinical trials for drugs for the treatment of depression, pain, and hypertension (amongst other conditions) fail to demonstrate superiority to placebo, contributing to the reluctance of the FDA to rely on active-controlled trials [23]. Placebo provides assay sensitivity – the ability to distinguish an active drug from an inactive one. Placebos also allow an accurate estimation of the magnitude of effect and help distinguish low-frequency adverse events caused by the intervention from background. Clinical trials of antidepressants in children firmly established that suicidality was a major concern, something that would not have been possible without a placebo control.

While a more complete discussion of this issue is beyond the scope of this chapter, in general, it is ethically permissible to use a placebo control in the following circumstances: whenever there is no proven treatment for the condition or disease, if the available treatments work poorly or have undue toxicities, if the participant has failed to respond to existing alternative therapies, or if there will be no undue discomfort or serious or permanent morbidity as a consequence.

Receipt of placebo is not usually equivalent to the absence of treatment. Frequently subjects receive standard care plus or minus the study intervention. There are two methods that can be built into a clinical trial to provide a margin of safety. First is the option for early escape – the study ends when the subject reaches an endpoint rather than after a fixed duration; the second is the use of immediate rescue treatment [14,27]. For example, in placebo-controlled pain studies, intravenous (IV) patient-controlled analgesia (PCA) morphine has been used as a rescue if the placebo (or study drug or procedure) is ineffective. The use of the rescue, the time to rescue, and the difference in the amount of rescue treatment have been used in some trials as the study endpoints rather than pain scores [27–29]. Finally, for many clinical trials involving anesthetic agents, it is not possible to use a placebo control but it often is for adjuvant therapies. As a result, trials of many anesthetic drugs focus on pharmacodynamics rather than efficacy. For example, trials of a muscle relaxant focus on dose–response, the time of onset, and duration of effect rather than on comparisons in efficacy between agents.

Ensuring validity: randomization and allocation concealment

Clinical trials rely on two processes to ensure their validity: masking (or blinding) of allocation assignment, and randomization [30]. Masking has two components: concealment of the allocation assignment at the time of randomization, and prevention of discovery of the assignment during the trial. The term masking is preferred to "blinding" because blinding has the potential for confusion, particularly when used in conjunction with a trial where loss of vision is the outcome measure or in a trial involving patients who have lost their vision. Indeed, the common phrase that "the investigators were blinded …" provokes comical imagery. It does not really mean that the investigators were actually "blinded," rather, it means that the allocation to treatment groups was masked. Randomization assures that all confounding variables, known and unknown, are distributed at random and hopefully equally between the two groups. A variety of techniques can be used to generate the treatment assignment including use of a table of random numbers or computer-generated sequences [31–33].

Simple random assignment can result in large imbalances in the number of subjects between the two groups in a trial. There are alternative techniques that ensure that the randomization sequence keeps the number of subjects in both groups relatively equal, both for the study as a whole and, for multicenter trials, within centers [34]. The most frequent approach is to randomize subjects in blocks such as groups of two, four, or six subjects, to ensure that the number of subjects is equal within each block. For example, if the block size is two, then subjects are randomized to treatments A and B in the order AB or BA. However, if the treatment assignment is discoverable (e.g. the masking is incomplete), then knowledge of the first subject assignment in each block could permit prediction of what the next subject's assignment would be. Using a larger block size increases the number of possible treatment assignment combinations and makes it harder to predict the subject's assignment. Another method used to ensure balance between the study groups is the use of permuted block sizes. In this technique, two different size blocks are used at random, making it very difficult to predict treatment allocation. For example, some blocks would consist of four subjects and some would include six. Without knowledge of the block size, it becomes impossible to predict the next subject's treatment group assignment.

The treatment group allocation process must not only be random but the outcome must be concealed, which is the first part of masking. If the investigator knows the group assignment for the next subject, this can affect their willingness to enroll the subject, can bias the consent process, or could lead to measures to manipulate procedures to influence the assignment. There are reports of studies where investigators have held sealed envelopes up to bright lights or found other measures to defeat the randomization schedule to choose the subject's group assignment.

To prevent discovery of the treatment assignment, the statistician should not reveal either the randomization schedule or the block size to any member of the investigative team. In a single-center trial, someone other than the investigator should generate and maintain the randomization sequence. If the study is a drug trial, having a pharmacist not otherwise associated with the trial prepare the study drug for administration is

a very effective way of concealing assignment. When the outcome measure is subjective, the subject, the investigator, and the statistician should ideally all be masked to the subject's treatment assignment. Concealment of treatment assignment after start of the intervention limits expectation bias on the part of the subject and biased assessments by the investigator. If the outcome measure is unbiased, for example death, then it may be less important to maintain masking. Since concealment is key to a valid study, an assessment should be made and included in any publication of the extent to which the masking was preserved during the clinical trial [35].

In comparing two active treatments, it may not be possible to disguise the drugs because of method of administration, size, or color of the drug. Using a double dummy approach where both active treatments have matching placebos can be an effective alternative. Each subject takes one of the two active treatments and a placebo to match the other treatment. For many anesthesia and pain studies, it may be quite difficult to mask the treatment if it involves a volatile anesthetic whose concentration must be monitored or if the intervention is invasive (e.g. an epidural nerve block). When treatment assignment cannot be concealed from the investigator, it may still be possible to prevent the subject from discovering their treatment assignment and to have someone other than the investigator perform the assessments of outcome to minimize bias.

Outcomes measures

Meaningful clinical trial outcomes include clinical events that change an individual's health in some discrete and meaningful way (to them), e.g. prevention of death, prolongation of life, prevention of morbidity, change in quality of life, or an improved economic endpoint [36]. All other outcomes, such as change in a physiological variable or a biological measure, are considered surrogate endpoints [37–39]. Surrogate endpoints are frequently used in place of clinical events because they are easier to measure and the variable measured is believed to be correlated to the clinical outcome of interest. Surrogates may be easier to assess but unless proven to predict the outcome of interest, i.e. they have been validated, they are poor substitutes for patient-relevant outcomes [40,41]. In the Cardiac Arrhythmia Suppression Trial (CAST), those patients receiving encainide or flecainide had less ventricular ectopy (surrogate outcome) but nearly three times the number of deaths as the placebo group [16].

In a hypothetical clinical trial designed to determine which of several different anesthetics had the best outcome for children with upper respiratory infection, hemoglobin-oxygen saturation <94% would be considered a surrogate measure of adverse respiratory outcome compared to pneumonia requiring hospitalization, brain injury, or death. However, the relationship of hemoglobin-oxygen saturation <94% to death, morbidity, quality of life, or cost is very tenuous. Therefore, it is always better to select an outcome directly related to something that matters to the patient or the healthcare system (cost).

Sample size and power

Even experienced investigators must consult with a biostatistician early in the protocol development process. David Sackett, one of the founders of evidence-based medicine, sagely advised that "If you don't start looking for a biostatistician co-principal investigator the same day that you start formulating your study question, you are a fool, and deserve neither funding nor a valid answer" [12]. A key decision in any clinical trial is to determine the number of patients needed to detect a clinically important difference in outcome with specified type I and II error protection [10,42]. A type I error is the probability of rejecting the null hypothesis when it is true (false-positive result) and is usually designated in most formulas by the Greek letter alpha (α). The null hypothesis postulates no underlying difference in the population or groups being compared with the factor, trait, characteristic, or condition of interest. In clinical trials this means that the true underlying effect of the test treatment, as expressed by a specified outcome measure, is no more or less than that for the control treatment. A type II error is the probability of accepting the null hypothesis as true when it is false (false-negative result) and is usually designated in most formulas by the Greek letter beta (β) with power defined as 1-β. Power in this context is the probability of rejecting the null hypothesis when it is false. Thus, calculations based on type I and II error and power will determine the number of patients needed in a trial and will often determine a trial's feasibility, cost, and the number of study sites needed to perform the study.

Power is typically set at 0.8 and occasionally at 0.9; this means that if a real difference exists of the magnitude specified, the trial has an 80% (or 90%) chance of detecting that difference. The variables in the power calculation include the magnitude of the clinically important difference, the number of events observed, and the variability (standard deviation). The greater the difference or the number of events anticipated, the fewer the number of subjects required. The greater the variability in outcome of interest (i.e. the wider the standard deviation), the greater the number of subjects required in a trial. Unfortunately, few treatments have as dramatic an effect as most investigators presuppose. Indeed, a 25% effect is actually quite large. Overestimating the efficacy of the new treatment will result in an underpowered trial which has an impact on the ethics of conducting the trial. An underpowered trial cannot achieve its stated objectives and exposes participants to unnecessary risk without prospect for answering the research objectives [43,44].

The variables that enter into the power calculation are amongst the most manipulated and debated elements in a study design. Often, when the number of subjects needed is large, event rates are adjusted or the magnitude of the anticipated effect is exaggerated. With or without these manipulations, in worse-case situations, if the number needed to study is so large, it may preclude conduct of the study. On the other hand, if the sample size is manipulated by altering the pretrial assumptions regarding the number of anticipated outcome events or the standard deviation, the results of the study may become inconsequential or invalid. Many have called for a re-evaluation of the methods used to estimate sample size, preferring the use of the width of confidence intervals or effect sizes rather than simply performing power calculations. This further underlines the importance of collaborating closely with a biostatistician during the initial planning phases of a trial [43,44].

Deciding on the number of subjects needed for a trial requires an active interaction between the investigators, study

sponsor, and the study biostatistician with input from the regulatory agencies who will review the study results. Although it is beyond the scope of this chapter to discuss the details of how one calculates for type I and II errors or estimates the required sample size, we have referenced several good reviews and textbooks that will provide an overview [45–47]. Interestingly, the choice of type I and II error protection is somewhat arbitrary. At first blush, the study team may want a trial that prevents both types of error. In reality, this may not be possible and the final decision as to which factor should take precedence may depend on the medical and practical implications of the two kinds of errors. Thus, relatively high error rates ($\alpha = 0.10$ and $\beta = 0.2$) are usually used for preliminary trials that are likely to be replicated. On the other hand, smaller error rates ($\alpha = 0.01$ and $\beta = 0.05$) are used when replication is unlikely.

Pilot studies

Investigators often classify underpowered clinical trials as "pilot studies." This is a misuse of the term and intent of a pilot study. Pilot studies are intended to refine the research question, or to establish the feasibility of executing the proposed study design. This can include assessing the ease of recruitment and retention of subjects, the clarity of the inclusion/exclusion criteria, the feasibility of the study procedures, refining the data collection forms, ensuring that the study management procedures are optimized, and study capacity issues [48–50]. For new drugs, pilot studies (phase I studies) obtain pharmacokinetic data and early safety data needed to plan later phase trials. The analysis of pilot studies should be primarily descriptive with a sample size determined not by a power calculation but by other pragmatic factors need to achieve the study objectives. Some contend that the pilot studies can be used to assist in formal power calculations. However, given the small sample size, the standard deviations, point estimates, and confidence interval widths will typically be quite large, making this a fraught exercise.

Single-center versus multicenter

Anesthesiologists (the authors included) have most frequently resorted to single-center trials because they are relatively easy to mount and carry out. The research personnel are all located within the same institution, know each other, and can achieve a higher degree of uniformity in the execution of the study procedures and data collection. Perhaps most importantly, single-center trials are significantly less expensive and more efficient to perform because the bureaucratic structure required to design, execute, and supervise a multicenter trial is unnecessary. The publication and academic promotion issues that are so critical for academic investigators are more clear-cut and without conflict.

Publication and the recognition investigators receive for publication are amongst the most important driving forces creating resistance to participation in multicenter pediatric clinical trials; it is also one of the least publicly discussed issues. Promotion, at most academic institutions, is based on the number, quality, and originality of, and authorship position in published papers. In single-center trials, the investigator's name will be listed and he/she may even be the first or senior author, the most prized position for academic promotion. In multicenter trials, pharmaceutical sponsors often base authorship on recruitment success and not on intellectual contribution. Indeed, most investigators are often only listed in the footnotes of the journal article within the membership of the study group. Furthermore, if the study is an industry-sponsored trial, authorship is often considered "tainted." Some have advocated abandoning authorship for contributorship, where each individual's role in the research is listed at the end of the publication rather than perpetuating the current inaccurate system [51]. Academic centers and promotion committees would need to agree to reward contributions listed rather than just authorship for this model to take hold.

While most academicians prefer the single-center model, there are serious limitations to this model. It may be difficult, if not impossible, to recruit enough participants in a timely fashion if only one center is involved. Further, when all the subjects come from within the same geographic area and are treated by a small group of clinicians, the results may have internal validity but may lack external validity, making them less generalizable to other practice settings [52]. Medical care has fortunately also reduced the number of poor outcomes, making differences in discrete clinical events that much harder to detect. For example, survival for childhood cancer has improved dramatically. Similarly, death related to anesthesia has dropped precipitously over the past 30 years. As a result of these successes, the size of the expected differences in outcome between two treatment groups has grown smaller. Since power is based on the number of events, not the number of subjects, better outcomes overall have translated into the need for clinical trials with larger and larger sample sizes.

Collaborating on large, simple trials, with multiple sites participating is the logical approach to addressing the limitations of the single-center trial [53]. To ensure the validity of a multicenter trial, all sites need to use a common protocol, the data collection tools need to facilitate accurate recording and transmission of data, and an administrative and organizational structure to coordinate all activities. To make this all happen can be very expensive [54]. The NIH has been creating a mechanism to facilitate multicenter trials through networks such as the Clinical Translational Science Award centers (CTSA), and various subspecialty component groups focusing on rare diseases and at-risk populations have done so as well (e.g. cystic fibrosis, sickle cell disease, Marfan syndrome, etc.). Additionally, multicenter data management software has made computerization and standardization of data entry much easier. Before embarking on a clinical trial, it is important for the investigator to check for these institutional resources because they can be invaluable (and often free) in setting up a clinical trial.

Funding

All clinical trials cost money, lots of money. Where the money comes from and how much there is to spend are two of the key stumbling blocks in all clinical trials. Ideally, funding should come from a mix of private and public sources, including the government, the drug and device industry, and health insurance companies. Unfortunately, this ideal is rarely met and much of the funding comes from the government, private

grants, and the pharmaceutical industry. The NIH, the primary healthcare research funding agency of the US government, rarely funds perioperative anesthetic research. Indeed, there is no specific institute within the NIH for anesthesiology. Further, the NIH cannot possibly bear the full burden of anesthesia-based research because of its priorities to primarily fund basic science research. Also, until very recently, industry was also unwilling to mount pediatric clinical trials because the pediatric market was viewed as too small to justify the return on investment, particularly because, as we will discuss shortly, most drugs used in pediatrics are used off-label anyway.

There is no easy answer to the lack of funding conundrum in pediatric perioperative anesthetic and analgesic trials. Despite the difficulties, it is essential to try. Giving up without a significant effort only assures failure. It has been our experience that if the project is worth doing, funding will be found either from traditional sources like the government and industry or from not so traditional sources like private and public foundations or local philanthropists. Often overlooked, there are anesthesia-specific foundations and societies that fund both novice and well-established investigators. These include the Foundation for Anesthesia Education Research (FAER), the Anesthesia Patient Safety Foundation (APSF), the International Anesthesia Research Society (IARS), and the subspecialty anesthesia societies, such as the Society for Pediatric Anesthesia (SPA). Additionally, many public foundations, such as the Mayday Fund and the Bill and Melinda Gates Foundation, provide research funding for pediatric clinical trials, particularly pain trials.

Another funding source that is closer to home, and one that is often poorly mined by anesthesiologists, requires raising funds from within the community in which the trial will take place. Within every locality there are philanthropists, corporations, and community organizations that can be recruited to support anesthetic research, education, and patient care. Although hospitals in general and children's hospitals in particular are very good at this, anesthesia departments are notoriously poor at it.

Developing and raising money for research endowments or endowed chairs specifically designed to provide seed money for young and established investigators is essential for clinical trials and for our specialty. Finally, regardless of how one obtains funding, the funding source(s) must always be disclosed to the IRB, the institutional conflict of interest office, and the public when patients are being recruited to enter into the trial and when the data and conclusions generated by the trial are presented in public forums or published in the lay or scientific press.

Phases of testing a new drug

A considerable proportion of anesthesia research involves testing of drugs. All US studies involving investigational new drugs require an Investigational New Drug (IND) application issued by the US FDA before testing can move from animals to humans. The first stage of testing a new drug is called phase I (Fig. 4.2). Phase I trials generate preliminary information on the absorption, distribution, metabolism, elimination, and safety of a drug. Phase I studies typically involve 20–80 subjects and are usually first conducted in healthy adult human volunteers. However, some phase I trials, for example chemotherapeutics targeted to pediatric cancer, may need to be conducted in children. In contrast to phase I studies in adults, pediatric participants must have the target disease or condition. Phase I studies are rarely if ever done with a comparison group; if one is included, it is typically the study drug at a different dose.

After phase I studies have established the basic pharmacology and safety profile for the new drug, testing proceeds to phase II. Phase II trials can be further subdivided into two basic types [55]. Phase IIa are generally smaller pilot clinical trials to explore efficacy (and safety) in selected populations with the disease or condition to be treated, diagnosed, or prevented. Phase IIb are well-controlled trials to evaluate efficacy (and safety) in subjects with the disease or condition to be treated, diagnosed, or prevented. These clinical trials usually represent a more rigorous demonstration of a medicine's

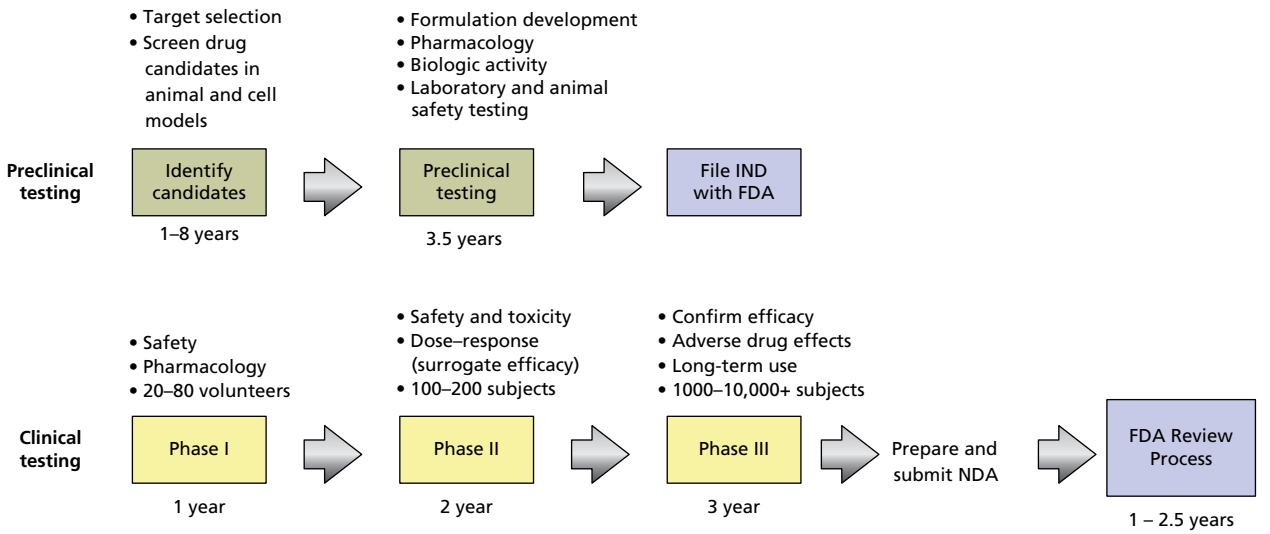

Figure 4.2 All studies investigating new drugs go through a process of preclinical testing in animals, several phases of human clinical trials, and culminate in a new drug application and approval by the FDA. The process takes years, with failure possible all along the way. FDA, US Food and Drug Administration; IND, Investigational New Drug; NDA, New Drug Application.

efficacy. These trials explore the efficacy in individuals with the disease or condition of interest, usually using surrogate measures of efficacy (e.g. decrease in blood pressure or reduction in tumor size rather than mortality). These are well-controlled trials designed to provide preliminary evidence of efficacy, explore the useful dosage range of the drug, and supplement the data about the safety profile of the drug. They often include additional pharmacokinetic testing during repeat dosing and at the anticipated therapeutic dose. Phase II trials frequently involve a few hundred individuals.

Phase I and II studies frequently explore the relationship between the dose administered and the physiological response. Typically, five or six doses are needed to establish the complete range of responses – ranging from the highest no-response dose, the lowest dose with a meaningful response, and up to the dose beyond which either no further effect or undue side-effects are seen. When only two or three doses are studied, then the trial is more appropriately termed a dose-ranging trial. Given the expected intra-individual variation, dose-ranging trials generally require dosages that are a factor of 3–4 to clearly distinguish one dose from the other. Failure to establish the correct dose prior to conducting efficacy studies can result in failed efficacy trials or unnecessary toxicity. At the end of phase II testing, preliminary evidence of efficacy and safety has either been established sufficiently to proceed to confirmatory trials or development ends. For chemotherapeutic drugs, it is also necessary to identify the maximal tolerated dose (MTD). Based on dose–response studies, the dosage for confirmatory trials of efficacy is selected. At the end of phase II testing, the sponsor and the FDA meet to establish the endpoints to be used for the phase III or pivotal trials.

Phase III trials, or confirmatory trials, are the final stage of new drug development and are designed to enable drug approval and labeling by the FDA. The drug label, distributed as a package insert, is the document approved by the FDA and furnished by the manufacturer of a drug for use when dispensing the drug. It lists a summary of the basic information about the pharmacology of the drug, its approved uses (conditions, populations, recommended dosage), contraindications, and potential side-effects. Phase III trials are usually large, randomized, controlled clinical trials designed to confirm both the efficacy and safety of the drug. It is a given that all drugs provide a trade-off between their benefits and their side-effects. The results must be generalizable to the wider population. Surrogate measures of efficacy are no longer sufficient to support a labeling indication. For a cancer chemotherapy drug, improved survival would need to be established rather than simply reduction in tumor size. A new pain medication would need to not only demonstrate a statistically significant difference in pain score between groups, the difference would need to be large enough to be considered clinically important.

When the sponsor believes that they have established the efficacy and safety of the drug for a specific indication, they submit a New Drug Application (NDA) to the FDA to label and market the drug to the public. Of every 1000 drugs that enter preclinical testing, only 100 drugs enter phase I testing in humans, approximately 70 go on to phase II testing, and 30–40 make it into phase III testing. Only about 12–15 result in an NDA submission and, of those, only nine or 10 are approved (see Fig. 4.2).

Once a drug is approved, the sponsor must continue to conduct postmarket surveillance. Many serious adverse drug effects and interactions are only discovered after a drug has been approved for use and released into the marketplace. In reality this should not be surprising since at the time of initial approval most newly approved drugs have only been tested in 1000–5000 people. Although to investigators and sponsors this is a considerable number of people, in reality it is too small to detect rare but potentially important side-effects. Most rare but serious side-effects occur in less than 1:10,000 individuals. Obviously, adverse drug effects this infrequent will not be reliably detected at the time of drug approval if less than 5000 people were exposed to the drug. This underscores the importance of postmarketing surveillance and explains the headline-making news accompanying the withdrawal of an approved drug, a process that occurs in approximately 1.5–5% of all newly approved drugs, depending on the epoch [56].

Some of the recently withdrawn drugs include: oxymorphone, a long-acting μ_1-receptor agonist removed for higher than expected abuse potential; rofecoxib, a COX-II inhibitor removed because of an increased risk of myocardial infarction; rapacuronium, a short-acting muscle relaxant, removed because of severe or fatal bronchospasm; hydromorphone extended-release, removed because of the risk of accidental overdose; and ximelagatran, removed because of hepatotoxicity. Rare cases of idiosyncratic hepatotoxicity and increased risk of myocardial infarction may be difficult to detect in phase III trials.

None of the risks associated with these drugs was detected during initial testing and the risks came to light from postmarketing surveillance rather than as the result of phase IV trials. However, when common patterns emerge, the FDA and its European counterpart the European Medicines Agency (EMA) can impose additional requirements for the approval of all new drugs. For example, as the result of several drugs (e.g. astemizole, terfenadine, and cisapride) being withdrawn due to cardiac arrhythmias in the 1990s, all new drugs are now tested for possible effects on prolonging the QTc interval.

To ensure and evaluate the long-term safety and efficacy of the newly approved drug following FDA approval and drug licensure, the FDA may require phase IV trials [57]. The pharmaceutical sponsor may also choose to explore additional indications for the drug or to study the drug in wider populations than studied in the phase III trials. Unfortunately, many phase IV studies do not have sound scientific designs and are funded by the pharmaceutical sponsor as seeding trials to increase interest in the drug and to generate sales.

Timing of pediatric clinical trials

Ideally, all new therapeutic interventions would be rigorously tested before introduction into clinical practice. The reality is far different, with clinical adoption of new therapies far outstripping a solid evidence base on which to make these therapeutic judgments. As stated previously, there is often a very narrow window of time during which it is feasible to test a new therapy, particularly for children. After introduction into practice, interventions approved for adults become "standard of care" for children, even without the benefit of adequate evidence of their efficacy or safety in children. Indeed, this is one

of the ongoing conundrums of small case reports, case series, and other forms of uncontrolled trials that flood the medical literature. The recent mandate to conduct clinical trials in children has clearly demonstrated that trials are not only feasible but also essential. Children have been shown to experience unique adverse effects (e.g. growth impairment and suicidality), require different dosage levels or formulations, and may fail to respond to a drug in the same way that adults do, even when the disease is the same (e.g. triptans for migraine headache and SSRIs for depression) [7,58]. Clearly, the adage that "children are not small adults" has been proven true over and over again. Therefore, the ideal time to start pediatric trials is before or just after a new treatment is first approved, before preconceived notions regarding its merit develop. Unfortunately, this is rarely the case because, as we will describe, the planning, organization, and structure of a proper trial take a fair amount of time, patience, discipline, and money – qualities that many investigators unfortunately lack.

Anesthetic and pharmacological research in pediatrics

Although most children cannot swallow pills, few drugs are available in liquid formulations [59]. While pharmacies can make extemporaneous formulations, these must be used without information about bio-availability or palatability. Changes in formulation and route of administration affect uptake, distribution, and ultimately efficacy in unpredictable ways. Inadequate information exposes children to age-specific adverse reactions, ineffective treatment due to inappropriate dosing, and lack of access to new drugs because physicians tend to prescribe less effective known medications. Additionally, insurance companies and other third-party payers may refuse payment for off-label use of medications. Indeed, in the past, so little pharmacokinetic and pharmacodynamic testing was performed in children that by 1968 they were termed "therapeutic orphans" [60].

To remedy the lack of appropriate labeling in children and in pediatric subpopulations (newborns, infants, school age, and adolescents), the US Congress enacted the FDA Modernization and Accountability Act (FDAMA) of 1997, its successor, the Best Pharmaceuticals for Children Act (BPCA, 2002) and the Pediatric Research Equity Act (PREA, 2003). Taken together, these laws were intended to promote standards and requirements for the use and labeling of drugs in children. The FDAMA and BPCA offered pharmaceutical companies incentives to study pediatric indications for approved drugs while the PREA required that all new drugs and biologics, all new formulations and indications for approved drugs be tested and studied in children. The PREA and BPCA were reauthorized into a single law as part of the FDA Amendments Act (FDAAA, 2007). These programs have been tremendously successful, with labeling changes to more than 750 pharmaceutical package inserts to date [61–64].

Despite the major advances in labeling drugs for children made since 1997, most of the drugs used in infants, children, and adolescents during the perioperative period are still administered off-label, that is, they have not been thoroughly tested for efficacy or safety in pediatric trials. One of the main reasons for this is that most anesthetic and pain management drugs are older and had no patent life or exclusivity remaining at the time the FDAMA was signed into law. However, some drugs, including desflurane, ondansetron, midazolam, milrinone, oxycodone, tramadol, and sevoflurane, have been studied under the FDAMA or BPCA. Looking forward, all new drugs must be studied under the PREA. Unfortunately, off-label administration of older medications to pediatric patients often goes beyond the indications on the approved label and by routes of administration neither tested nor approved even in adults. It is hard to extrapolate the data available from the relatively healthy adult participants in most phase III trials to chronically ill adults, the aged, pregnant women, infants, children, adolescents, and both adult and pediatric critically ill patients without consideration of the maturation of drug-metabolizing enzymes or alterations in sites of action over the normal course of aging. To deal with the issue of older drugs, the BPCA included funding for off-patent drugs under a partnership between the NIH and the FDA. These studies are currently being managed through a large grant by the Duke Clinical Research Institute (DCRI) via the Pediatric Trials Network (PTN).

Ethical aspects of clinical trials

Overview

There is a long history of shame involving human research, from the Nazi war crimes in which lethal medical experiments were conducted on Jews and other subjugated people, to the Tuskegee syphilis study, which was conducted by the US Public Health Service from 1932 to 1972, in which minority men with syphilis were enrolled to study natural disease progression without being informed that they had the disease and without being treated after penicillin became available.

In the United States, the Belmont Report written by the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research identified beneficence, respect for persons, and justice as the essential ethical principles that should underpin research involving human subjects. These principles are not merely ideals; they have been translated into the federal research regulations known as the Common Rule (45 CFR 46) and into the FDA research regulations (21 CFR 50 and 56). An excellent review has proposed that there are seven requirements for ensuring the ethical conduct of clinical research, referring back to the fundamental principles articulated in the Belmont Report. Despite considerable progress, the death of Jesse Gelsinger in a gene transfer trial at the University of Pennsylvania in 1999 served to increase the attention on compliance with federal regulations, conflicts of interest in research, and clinical trials oversight by institutions. For more information concerning federal regulations, we refer the reader to the FDA website [65].

Investigational review board review and approval

All institutions in the United States who receive federal funding for research must have a Federal Wide Assurance (FWA) issued by the Office for Human Research Protections (OHRP). The FWA is the institution's assurance to the government that it will follow the federal regulations guiding human research. Worldwide, the Declaration of Helsinki

first adopted by the World Medical Association in 1964 and amended repeatedly (most recently in 2008) serves as an important expression of clinical research ethics worldwide. The Declaration is important for international trials but does not supersede American law and federal regulations. The FDA has recently adopted the International Conference on Harmonisation Guidelines on Good Clinical Practice to supplant the Declaration [66]. Other organizations with important clinical research ethics statements include the Council of International Organization and Medical Sciences (CIOMS) guidelines on the ethical conduct of clinical trials and the World Health Organization (WHO) operational guidelines for ethics committees that review biomedical research. Some organizations have produced more specific guidelines for pediatric clinical trials, including the EMA. All these organizations share a common ethical perspective, namely, that the well-being of the individual research subject must take precedence over all other interests.

A fundamental principle of all clinical research mandated by US federal regulations (as well as by the CIOMS, WHO, EMA, and the Declaration of Helsinki internationally) is the requirement for independent review and approval by a research ethics committee prior to initiation of any research protocol involving human subjects. In the United States these ethics committees are known as institutional review boards (IRBs) and consist of five or more individuals with diverse backgrounds in clinical research, medicine, law, research ethics, biostatistics, nursing, and, when children are involved, pediatrics [67]. To ensure independence and outside perspectives, at least one member of the IRB must be unaffiliated with the institution in which the research takes place and at least one member must be a non-scientific person, who preferentially is representative of the community surrounding the trial site's institution. Research that is no more than minimal risk (Box 4.1) can be expedited with just the review of the chair of the IRB. Most clinical trials are greater than minimal risk and require review by the convened board of the IRB. IRBs generally have a very formal application process that requires extensive documentation of the elements of the trial. Assembling and preparing this documentation is laborious, time consuming, and expensive, with many IRBs charging a fee for submission that can run into thousands of dollars. This cost and the cost of preparing the documentation for submission are often overlooked in trial design and implementation.

Typically, the documentation required by the IRB includes copies of the protocol, the informed consent form and assent documents, copies of any advertisements and brochures that will be used to recruit study participants, study data collection instruments, the investigational drug Investigators' Brochure, funding sources, and revelation of any conflicts of interest by the study investigators. Increasingly, many IRBs also require a detailed plan for data management, genetic specimen security, and for how protection of subject privacy and confidentiality of data will be maintained. Finally, many institutions require documentation confirming that participating investigators have taken and passed institutionally mandated courses (through national programs such as the online CITI Program, Miami FL, https://support.citiprogram.org) in research ethics, patient safety, billing, and confidentiality protection.

For multicenter research studies, a "central" IRB offers many potential time-saving, organizational efficiencies, and cost advantages [68]. A central IRB acts on behalf of a local IRB by reviewing and approving a trial proposal. Its organizational composition and process of review are identical to a local IRB. However, unlike a local IRB, the central IRB can simultaneously serve as the IRB of record for numerous sites. Central IRBs can be located either in an academic center or, as is most common, in one of many for-profit centers. Although the cost of submission and processing is often higher than a local institution's IRB, it is both much cheaper in the short and long term because of its center-by-center cost and much more time efficient. Some have even advocated that the ethical oversight is superior when just one IRB takes responsibility for the trial [69]. Indeed, nothing is more expensive in a trial than not being able to start and enroll patients while awaiting IRB approval. Because of this, central IRBs are a favored review oversight method of the pharmaceutical industry. To facilitate government funded research, the NIH is also now requiring a single IRB (sIRB) for all of its new multicenter trials. In addition, a new provision has been added to the Common Rule at 45 CFR §46.114 which requires use of a single IRB for all cooperative research conducted at US institutions. This new regulatory requirement took effect as of 20 January 2018 [70].

Regardless of how a proposal is reviewed, the process often takes 3 months or more. For many investigators and sponsors, this delay becomes a source of friction and frustration. Although this is understandable, it can be made significantly more onerous if the IRB submission itself is inadequate or poorly conceived and written. It is our experience that delays

Box 4.1: Waiver or alteration of consent for minimal risk research

To approve such a waiver or alteration, the IRB must find and document that:

- the research involves no more than minimal risk to the subjects
- the waiver or alteration will not adversely affect the rights and welfare of the subjects
- the research could not practically be carried out without the waiver or alteration
- whenever appropriate, the subjects will be provided with additional pertinent information after participation.

Source: US Department of Health and Human Services Regulations: 45 CFR 46.116(d)

Examples of minimal risk research not requiring informed consent from patient, parent, or guardian:

- retrospective medical record review of anesthetic techniques for several hundred patients, where the process of finding patients and obtaining consent would prevent the study from being done
- retrospective medical record review of hundreds or thousands of anesthetics for complications, e.g. laryngospasm
- research from already existing large databases, i.e. state Medicaid databases, University Health Consortium, U.S. Agency for Healthcare Research and Quality Kids' Inpatient Database (KID), Child Health Corporation of America (CHCA) Database
- research involving only materials (data, documents, records, or specimens) that have been collected, or will be collected solely for non-research purposes (such as medical treatment or diagnosis). Examples: excess waste blood or urine for a novel biomarker assay technique; height and weight data from a large population of children to determine incidence of obesity in a given population presenting for anesthesia.

in IRB approval are often prolonged by sponsor or investigator revisions, amendments, and the rush to complete the submission. Our mantra in protocol development and submission is to "measure twice and cut once." The trial planning process should ensure that there is sufficient time for both the initial IRB review as well the review of the IRB's requested modifications to the application, protocol, and consent documents. Finally, contracting issues also take time and are more frequently the rate-limiting step in getting a trial started. Again, it is our experience that it is far better and more efficient to do these in tandem than sequentially.

Special considerations when children are participants

The principle of respect for persons, which encompasses the right of the individual to self-determination, requires that investigators obtain the informed consent of participants prior to enrolling them in a clinical trial. Since children cannot legally give their consent and may be unable to comprehend the information about the trial, they are considered a vulnerable population in clinical research. Subpart D of both the Common Rule (45 CFR 46) and the FDA research regulations (21 CFR 50 and 56) contain additional protections for children. Extraordinary risk of harm is permissible when those risks are outweighed by the prospect for direct benefit, such as in an oncology trial. When the research offers no prospect of direct benefit, Subpart D limits the amount of risk to which the child can be exposed. It also delineates the requirements for parental permission and child assent. There are four ascending categories of risk/benefit that have corresponding increased levels of scrutiny (Box 4.2) (45 CFR 46 and 21 CFR 50: Subpart D).

Informed consent is not simply a document that requires a signature; it is a process that involves detailed ongoing explanations regarding the purpose of the trial, the nature of the procedures, the risks and potential benefits, and the alternatives to the research intervention and procedures. Components of the informed consent process include an assessment by the physician of the competence and decision-making capacity of the subject, disclosure, and the assurance, as much as is possible, that the individual has the freedom to choose the medical alternatives without coercion or manipulation. Further, subjects must be told explicitly that they can withdraw their consent and discontinue trial participation at any time without affecting the quality of their care and by whom and where it is provided. Since children cannot legally or developmentally provide consent, the child's parents or guardians serve as surrogate decision makers and provide permission for their child to participate. Just as in clinical care, there is an expectation that parents will make their decision for research participation based on the best interests of their child. Studies that have greater than minimal risk (see Box 4.2) without prospect for direct benefit to the child must be approved under the provisions of the Common Rule (45 CFR §46.406 or §407) or the FDA's Protection of Human Subjects (21 CFR §50.53 or §54). These regulations require an added protection: the need to get the permission of both parents (when it is practical to do so).

The assent of the child is required whenever the child is deemed capable of comprehending the required information [71,72]. Assent must be active and affirmative; failure to disagree does not constitute assent. In contradistinction to the requirements for consent, assent does not require the child to make a risk/benefit assessment. The assent process should disclose the purpose of the research, the nature of the procedures, and the right to withdraw assent at any time. Obtaining the assent of child participants requires an awareness of the child's cognitive abilities and the investigator's ability to describe the therapy, procedure, and trial objectives in terms that the child or adolescent can understand in age-appropriate language. In general, children less than 7 years of age are thought to be incapable of decision-making capacity and of providing assent. Children between 7 and 14 are in a gray zone and IRBs are quite variable in their requirements. In practice, we try to obtain assent for research trials in all mentally competent children older than 7 years of age. Above age 14, assent is required by most all IRBs in developmentally capable children. When assent is required, the requirement for documentation will be determined by the local IRB. Some require a separate written assent form and others just documentation of assent on the consent form [73,74].

Box 4.2: Federal classification for pediatric research

§46.404 and §50.51: Research not involving greater than minimal risk

- IRB determines minimal risk
- Adequate provisions are made for soliciting assent from the child and consent from the parent or guardian
- In the State of Maryland, even this level of study must be of direct benefit to the patient

§46.405 and §50.52: Research involving greater than minimal risk but presenting the prospect of direct benefit to the child

- IRB justifies the risk by anticipated benefit to the child
- The anticipated benefit-to-risk ratio is at least as favorable as the current available alternative therapy
- Adequate provisions are made for soliciting assent from the child and consent from the parent or guardian

§46.406 and §50.53: Research involving greater than minimal risk and no prospect of direct benefit to the child but likely to yield generalizable knowledge about the disorder or condition

- IRB determines that the risk represents a minor increase over minimal risk
- The intervention or procedure presents experiences to subjects that are reasonably commensurate with those inherent in their actual or expected medical, dental, psychological, social or educational situations
- The intervention or procedure is likely to yield generalizable knowledge which is of vital importance for understanding or amelioration of the subject's disorder or condition
- Adequate provisions are made for soliciting assent from the child and consent from the parent or guardian

§46.407 and §50.54: Research not otherwise approvable that presents an opportunity to understand, prevent or alleviate problems affecting the health and welfare of children

Level of acceptable risk

Perhaps the unique aspect of pediatrics clinical research concerns the limits of acceptable risk. The definitions of minimal risk and a minor increase over minimal risk are key to

understanding when research is approvable. When a clinical trial has risks that are no greater than minimal, any child can take part (§46.404 and §50.51). However, if the risks are more than a minor increase above minimal, then the trial is not possible unless there is a prospect for direct benefit to the child (§46.405 and §50.52) that "is at least as favorable to the subjects as that presented by available alternative approaches." The definition of minimal risk is inherently confusing because embedded in it are two separate standards: the routine examination standard and the daily life standard. While the risks of routine examination are essentially trivial, the risks of daily life are considerable [75]. Almost all IRBs will consider a clinical trial involving administration of an investigational drug, no matter how innocuous, to be at least a minor increase above minimal risk.

The risk of death or serious injury in childhood is not zero. The risk of death from a car ride (adult driver) varies from 0.06 to 0.6 per million car trips depending on the age of the driver, the time of day, and road conditions. The daily cumulative likelihood of death, predominantly from car accidents and drowning, is 1.5 per million children per day. The likelihood of hospitalization and an emergency department visit varies between 1.0–2.1 and 6.4–64 per million children per day depending on the age of the child [75]. American Society of Anesthesiologists physical status I or II children undergoing general anesthesia currently have an estimated risk of death of approximately 4–5 per million (1:200,000). Thus, riding in a car, which is part of the risks of daily life, would be considered minimal risk, whereas receiving a general anesthetic, which is riskier, is at least a minor increase above minimal risk. Different IRBs and ethicists will come to different conclusions about the level of risk associated with some procedures. In 2016, the FDA Pediatric Advisory Committee could not come to a consensus regarding the risks of general anesthesia for procedures, such as MRI. The committee was divided seven (minor increase) to nine (more than a minor increase) [76]. To avoid the possibility of exposing children to too high a level of risk, some within the research ethics community believe that there should be just a single standard for risk and generally they favor risks closer to the routine examination standard [77]. Adoption of this unified standard would have a chilling effect on pediatric research. Part of the discrepancy between various IRBs in their decision making is due to the difference in their threshold for these two definitions.

Benefits

Benefits in clinical research can be direct, indirect, or both. Research offers a prospect for direct benefit when there is a reasonable and plausible expectation, based on prior research, preclinical data, or other basis, that participants will receive a meaningful clinical benefit [77]. Clinical trials that have greater than a minor increase above minimal risk are only permissible if they offer a prospect for direct benefit. As long as the prospects for benefit outweigh the risks and are at least as good as the alternatives available outside the research, the IRB can approve the research (§46.405 and §50.52).

If the research or a component of the research is purely for research purposes and is not for the participants' direct benefit, the IRB can only approve the research if the risks are limited to a minor increase above minimal risk (§46.406 or §50.53). Since the definition of minimal risk is controversial, it should be expected that the definition of minor increase is controversial too. Rid et al have proposed a rubric for assessing risk which requires that all the probabilities for all negligible, small, moderate, significant, major, severe, and catastrophic harms be defined for each intervention and then compared to the risks of daily life [78]. Investigators know much more about the procedures proposed than the IRB. It is their responsibility to provide the IRB with as much data as possible about the probability and magnitude of all possible harms from the procedure or intervention to assist the IRB in making its determination.

Coercion and undue inducements

Recruiting subjects can create or cross a very real line between persuasion and coercion. Coercion of subjects can include manipulating or misusing information, or instilling fear that non-participation will result in withdrawal of or inferior medical care. Many institutions consider it coercive to be both the principal investigator and also the individual's primary physician. Coercion is a threat and should be distinguished from undue inducement, a reward so generous that subjects ignore their better judgment and assume risks that they would not otherwise be willing to endure.

Undue inducement means payment or rewards so excessive that it makes it hard for subjects with limited means (economically vulnerable subjects) to decline participation. Examples of inducements can include indirect benefits of participation such as increased access to care or excessive financial remuneration. Indirect benefits of participation such as access to clinical experts, reduced waiting time for clinic visits, door-to-door transportation, and free care including study drugs during and after the trial can be quite persuasive incentives. The provision of free care and drugs and shortened wait times can be very powerful incentives indeed to participate. There can be a fine line between fair subject payment and undue inducement. Reasonable compensation is ethical and provides all individuals the opportunity to take part in research without experiencing financial hardship. There is no evidence that moderate payment negatively affects subjects' judgment [79,80]. The object in designing a budget should be to try to make payment neutral so that it offsets the costs and burdens of participation.

Payments can be broken down into four components: reimbursement for expenses, compensation for time and effort, gifts of appreciation, and incentives [80,81]. Incentives are almost universally forbidden by IRBs. Appreciation gifts to subjects should be of nominal value. If participation imposes no travel or other burdens, then it may be inappropriate to include any payment. When subjects must return to the hospital or clinic for follow-up, payment of travel costs (reimbursement) and lost work time of the parents (compensation) is absolutely fair and expected. When the child participant has to complete procedures, such as diaries, or must forego leisure activities, it is fair to compensate them for their time and effort as well as their parents [82,83]. Payments to children need to be age appropriate; children less than 9 years generally do not understand the relationship between the amount of effort and size of payment and should be paid with a fixed-size payment.

Operational planning and trial execution

As with any large-scale project, a clinical trial has several stages that must be managed for the trial to be run and completed successfully. Each has specific features and timelines for completion and each is associated with pitfalls that, if not dealt with, will lead to failure and frustration. For most clinical trials, the stages include initial design, feasibility assessment, protocol development, data management and document preparation, subject recruitment/screening and enrollment, study treatment and follow-up, close-out and study termination, and an optional post-trial follow-up (Fig. 4.3). Once the enrollment and follow-up are complete, the data must be checked to ensure that they are accurate (data cleaning) and only then can analysis commence. Obviously, there is overlap across each of these stages.

Initial design stage

The initial design stage specifies the rationale, purpose, and objectives of the clinical trial. A literature review is essential to identify pertinent background information about the target disease or condition and the proposed study intervention. Pharmaceutical trials compile this information in an Investigators' Brochure but it is up to the investigators to establish what is already known about the safety and efficacy of the intervention. Although confirmation of previous results has some value, it is usually a waste of time and resources to repeat work that has been done previously. Exposing subjects to risk when the answer to the research question is known is also unethical [78].

In our experience, the best approach is to start by creating a synopsis or concept protocol. This is a 2–4-page document that outlines the PICOT questions for the trial as well as the method of assignment to the various study arms and the methods for concealing treatment allocation. The primary and secondary endpoints should be formalized, the required sample size estimated, and the statistical plan for the analysis of the primary endpoint specified. Only when all members of the protocol development team have agreed on the synopsis should the study planning proceed. As the details of the concept protocol are being finalized, the details of the recruitment plan should also be considered to determine how many sites would be needed for the study. A preliminary timetable for the trial, the organizational structure, subject safety, and plans to ensure data integrity, quality, and security all need to be developed and implemented. Finally, it is at this point that funding proposals are sought, written, and submitted.

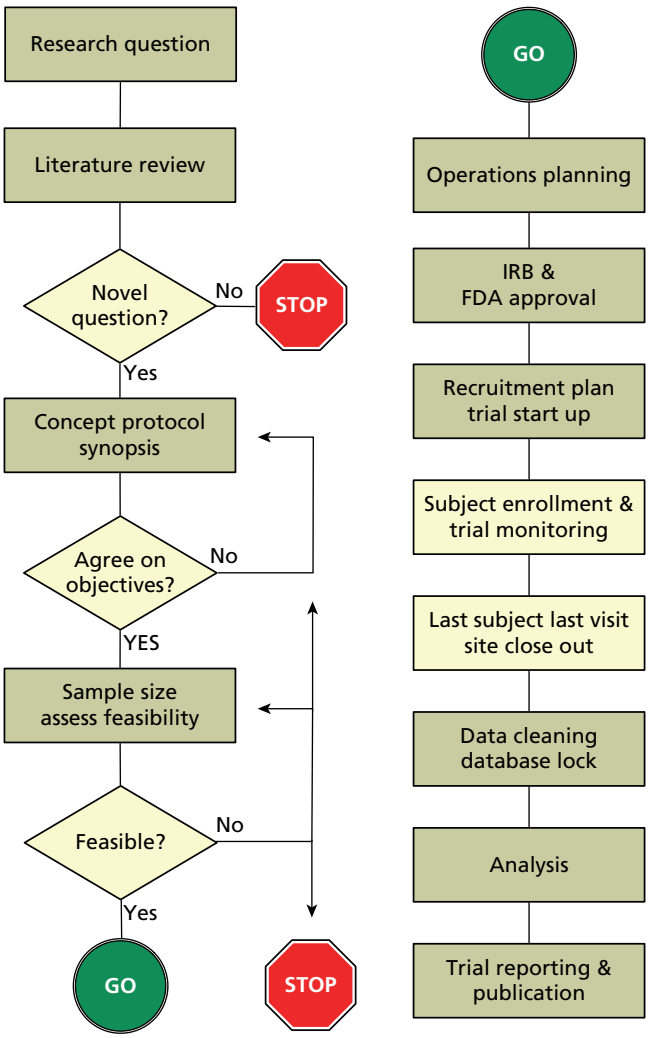

Figure 4.3 The primary stages of a clinical trial. Each major phase shown as a diamond has components shown as rectangles that are shared across the clinical trial. FDA, US Food and Drug Administration; IRB, investigational review board.

Feasibility and recruitment planning

With the protocol synopsis in hand, the principal investigators next need to assess whether the plans are operationally feasible. A realistic appraisal of the likely number of available subjects will determine whether or not the study can be conducted at a single site or whether other institutions will be needed to increase the pool of available subjects. Starting a clinical trial is a time-consuming process and unless the proposed study is feasible, it should not be started. Most ethicists consider underpowered or unfeasible studies unethical and many IRBs will not approve a study that has no hope of being completed [84].

If it has not already been done, it is at this moment of protocol planning that the principal and co-investigators must include and obtain the advice of experienced study clinical coordinators for managing many study-associated activities. Having a study coordinator assist in project planning can help ensure that pre-established work scope, study protocol, and regulatory requirements will be feasible and pragmatic. Study coordinators often assist in the recruitment of subjects and are often delegated to ensure the study team adheres to the study protocol. They can serve as the principal administrative liaison between the study's administrative coordinating center and the local site. Finally, the study coordinator often oversees and coordinates the provision of administrative and staff services to the site investigators and maintains record-keeping systems, regulatory binders, and procedures.

Recruitment planning requires the input and planning of each study site and is often a collaborative effort between the study investigator and coordinator. The first step is to review the potential available population, keeping in mind the inclusion and exclusion criteria. If it appears that there will be

insufficient numbers of potential participants, then the options are to loosen the inclusion/exclusion criteria to increase the available pool of subjects, increase the number of sites participating, or plan for an advertising campaign to widen the potential audience (see Fig. 4.3). In general, investigators greatly overestimate their ability to enroll subjects and the majority of trials fail to complete enrollment on time. In our experience of coordinating multicenter trials, a quarter to a third of sites fail to enroll even a single subject while the best 25% of the sites enroll 75–90% of the subjects. Since it is very difficult to predict which sites will successfully enroll subjects, it is usual to recruit more sites than would be expected to ensure study completion. During the actual recruitment process, the study coordinator should track all subjects from screening to completion. The 2010 CONSORT guidelines provide an excellent resource on how and why patients should be tracked through the recruitment process and include a recruitment table that should be provided in any randomized controlled trial for publication [85–87] (Fig. 4.4). The nature of the study will determine how, when, and by whom prospective subjects will be approached. For anesthesia and pain trials, this could include review of the operating room schedule, solicitation in surgeons' offices, or one or more publicity schemes, such as advertising in print or on the internet or radio.

Protocol development and operational planning

If the planned study appears feasible without modification, the next step is to flesh out the synopsis or concept into a complete protocol. It is at this stage that the nuts and bolts of the protocol are elaborated and put into writing ("cast in stone"). The objectives, endpoints, and inclusion and exclusion criteria will come from the study synopsis. However, many other items need to be specified, such as the time windows for screening and follow-up examinations, procedures for management of known or suspected complications related to the disease or therapy, and treatment algorithms for how the individual patient is to be monitored and treated if complications arise. The SPIRIT 2013 statement includes all of the elements that need to be specified in a clinical trial protocol [88–90]. Box 4.3 presents an example of a protocol table of contents for a clinical trial.

Most protocols provide very detailed scientific background sections but are left wanting when it comes to detailing the actual study procedures. The mark of a well-written protocol is that the study coordinator can read it and know which procedures to perform and when, and how to perform them for each study visit, the data manager can design the requisite case report forms, the biostatistician can perform the study analyses,

Box 4.3: An example of a protocol table of contents for a clinical trial

1 Background information and rationale
- 1.1 Introduction
- 1.2 Name and description of investigational product or description of intervention
- 1.3 Findings from non-clinical and clinical studies
  - 1.3.1 Non-clinical studies
  - 1.3.2 Clinical studies
- 1.4 Selection of drugs and dosages
- 1.5 Compliance statement
- 1.6 Discussion of relevant literature and data

2 Study objectives
- 2.1 Primary objective
- 2.2 Secondary objectives

3 Investigational plan
- 3.1 General schema of study design (overview)
  - 3.1.1 Screening phase
  - 3.1.2 Treatment phase
  - 3.1.3 Follow-up phase (if applicable)
- 3.2 Randomization and blinding
- 3.3 Study duration, enrollment and number of sites
  - 3.3.1 Duration of study
  - 3.3.2 Total number of study sites/total number of subjects projected
- 3.4 Study population
  - 3.4.1 Inclusion criteria
  - 3.4.2 Exclusion criteria

4 Study procedures
- 4.1 Screening visit
- 4.2 Treatment phase
  - 4.2.1 Visit 1
  - 4.2.2 Visit 2 (etc.)

and another group of investigators could replicate the clinical trial. The study procedures section should contain a visit schedule listing each and every measurement that is to be made during that encounter. Often, a simple bullet point list will do and usually a summary table is created as well. Having a complete list of visit-by-visit procedures is key to ensuring that all measurements are made as required at each time point. For clinical trials that take place in the operating room, the visits might be separated by minutes or hours rather than by days. To assist with this, the study evaluations and measures section should specify how each evaluation will be performed. Continuing with our previous example of a clinical trial of an antihypertensive drug, it is not enough to state that systolic blood pressure will be measured. Rather, the protocol must describe exactly how it will be measured (which arm, which device, whether the subject is to be seated, lying, or standing, after how minutes of rest, and how many measurements will be averaged).

When completed, the protocol becomes the blueprint for the study execution and, once put into place, its recipe must be followed to the letter if the trial is to be successful. Indeed, it is this "cast in stone" rigidity that so befuddles many clinicians and represents the fundamental difference between a clinical trial and routine clinical care [91]. In routine clinical care, physicians use their best judgment to make treatment decisions. On the other hand, in a clinical trial, the investigator's responsibility is strict adherence to the protocol, not to their own judgment, and this is absolutely essential to ensure the fidelity of the trial. For example, if a 6-year-old postoperative patient has an oxygen saturation of 92% in the postanesthesia care unit (PACU), some clinicians might decide to watch and wait, whereas others may prescribe and administer supplemental oxygen. However, if a study protocol treatment algorithm requires a subject to receive oxygen if their oxygen saturation decreases below 94%, then oxygen must be administered even if this is not the investigator's individual clinical practice. Put another way, if a study protocol requires that subjects eat green jello, the clinician/investigator must provide green jello, even if they would prefer red.

Data management and document preparation

When the protocol is finalized, the informed consent and assent forms and the case report forms (CRF), paper or electronic, can be developed. Data should be recorded first in the source document – the medical chart, anesthesia record, or data collection form – and then transferred to the CRFs. If data collection forms will be used, they should be tested for usability. The data management team should be organized and must develop the data storage, back-up, and security plans. In multicenter trials, the data team will produce the randomization and treatment allocation schedules and develop protocols for data transfer from each site to the data center. All clinical trials need a data quality control plan. If the study is conducted at a single site, the principal investigator will be responsible. For a multicenter trial, the overall study principal investigator, study sponsor or contract research organization (CRO) will be responsible for site monitoring and for reviewing performance and outcomes during the course of the trial. These procedures establish the plan for collecting, processing, and verifying study data accuracy and for on-site monitoring to ensure that the protocol is being adhered to and that the data forms actually are being completed correctly. Finally, the data monitoring group must develop guidelines for data security and access to study data by investigators within and outside the study and this access must be weighed by the rights of patients to privacy and confidentiality. The coordinating center may also be responsible for ancillary documents for the study staff to help ensure that the study procedures are followed precisely as well as to prepare any diaries or instructions for participants.

The Standards for Privacy of Individually Identifiable Health Information (the Privacy Rule) established, for the first time, a set of national standards for the protection of certain health information. The US Department of Health and Human Services (HHS) issued the Privacy Rule to implement the requirement of the Health Insurance Portability and Accountability Act of 1996 (HIPAA). The Privacy Rule standards addressed the use and disclosure of individuals' health information (called "protected health information") by organizations subject to the Privacy Rule (called "covered entities"), as well as standards for individuals' rights to understand and control how their health information is used. Within HHS, the Office for Civil Rights (OCR) has responsibility for implementing and enforcing the Privacy Rule with respect to voluntary compliance activities and civil money penalties. The effect of the Privacy Rule on the conduct of clinical trials has not been major and largely involves expansion of the mandated confidentiality language in the informed consent document.

Informed consent document

The principal investigator is usually responsible for the development of the informed consent template document. However, for multicenter trials, the study sponsor usually provides a model consent form as a service to the site investigators. The consent form must follow the federal regulatory required elements of informed consent (45 CFR §46.116(a) and 21 CFR §50.25). The document should be written in plain language, with a target reading level of 6–8th grade (the average reading level for US adult trial participants). Approximately 12% of Americans have a below Basic health literacy proficiency and 22% are at the Basic level. Thus, if the informed consent form is written at greater than 8th-grade level, over a third of the participants will be unable to comprehend what they are reading [92].

Safety monitoring plan

All clinical trials require monitoring of unanticipated problems involving risks to subjects or others, including serious adverse events (SAEs). In multicenter studies, SAEs are usually reported promptly to the study sponsor. The sponsor is responsible for reporting these events to the regulatory agency overseeing the study. However, not all SAEs have to be reported to the IRB. Both the FDA and the OHRP have published guidelines on reporting of adverse events to the IRB. These require that unanticipated problems involving risks to subjects or others – events that are serious, related to the study intervention(s) and unexpected – require prompt reporting to the IRB. Regardless of the guidelines, investigators need to adhere to the policies in place at their local institution.

Safety monitoring should be tailored to the complexity of the study and the potential for harm to subjects. For a single-center study with a relatively low level of risk, the principal investigator's oversight should suffice. For a single-center trial with a moderate level of inherent risk, an internal data safety monitoring committee (DSMC) made up of the principal investigator and other knowledgeable individuals unassociated with the study would be advisable. Multicenter trials involving life-threatening conditions or interventions that have inherent risks should have an independent DSMC [93,94].

For all drug trials enrolling pediatric subjects, the American Academy of Pediatrics strongly recommends a DSMC for monitoring [95]. When the intervention has a track record of safety in adults and the condition of interest is not life-threatening, this level of oversight can be an unnecessary burden and can add substantially to the overhead costs of the study. Regardless of the oversight mechanism, meeting schedules and endpoints for interim analyses (if any) need to be defined and agreed upon. For trials involving life-threatening conditions, the protocol should contain stopping rules and procedures for early termination of the trial if serious unanticipated risks emerge. Only rarely should a trial be stopped for benefit and then only when one arm demonstrates a large margin of superiority [96,97].

Authorship and registration

Deciding exactly how the results of the study will be disseminated and by whom is a step often overlooked in the pretrial planning process. In our experience, failure to make this decision before embarking on a trial often leads to bad blood and ill will amongst the study investigators. As stated previously, for many investigators, authorship is essential for academic promotion. The order of authorship for study papers (and for ancillary studies) should be established and agreed upon by all investigators before starting a study. Ideally, a formal steering committee should be charged and entrusted with acting impartially on behalf of all the investigators early in a study design. The steering committee should establish procedures for review and approval of all publications and

presentations made by members of the investigative group before professional and lay scientific committees. At this stage it is also important to clarify trial roles. Some journals now request the exact role of each investigator at the time of publication. Finally, it is also important to establish safeguards that protect against premature disclosure of study results or the publication of the study results by a "minority" within the study group.

The final step within the protocol development stage is establishing the budget and staffing requirements for the trial. Does each prospective participating center have the manpower and skills to safely, effectively, and efficiently conduct the trial? Do they have enough potential participants to enroll in a timely manner? How will oversight be performed and by whom? How will study drugs be packaged, labeled, distributed, and safeguarded? How will the study be funded and by whom? Who will do all the regulatory work required for the trial? Funding and projected budgets are the keys to successful and unsuccessful trials. Inadequate funding, just like undercapitalization of a business, leads to failure. Indeed, it has been our experience that the real costs of conducting a study, including protocol development and site approval, are often underbudgeted, which often results in contract delays and misadventures.

Because many of the studies conducted by pediatric anesthesiologists involve drugs, and most if not all have invariably not been approved for use in children, approval by the FDA and its European counterpart the EMA may be required. It is beyond the scope of this chapter to discuss the process of obtaining an IND Application from the FDA but several useful sources are available at the FDA website (www.FDA.gov/CDER) including a guidance entitled Investigational New Drug Applications (INDs)— Determining Whether Human Research Studies Can Be Conducted Without an IND. Finally, all phase II, III, and IV trials require prospective registration in a national trial registry, such as www.clinicaltrials.gov in the United States. These registries are often funded by government entities and are designed to keep investigators from manipulating study endpoints by prespecifying the study objectives, intervention, subject population, sample size, and analysis plan of a trial before a trial is started. The databases are publicly available and are searchable. Most journals use and require trial registration for any trial submitted for publication.

Trial execution: treatment and follow-up

It is only after all the preliminary development, feasibility assessments, protocol development, and regulatory approval have been organized that the investigators are ready for subject recruitment and actually conducting the trial. For all multicenter trials there is usually an investigators' meeting held before the first subject is enrolled at which required training, standard operating procedures, and data management are finalized. For most perioperative pediatric anesthesia trials, the local investigator or their study coordinator recruits subjects from an in- and an outpatient operative list. The recruitment plan, including viewing and accessing these lists, should be included as part of the initial submission to the IRB. Advertising and liaisons with medical and lay societies that are so important in other adult and pediatric trials are often unnecessary. On the other hand, it is essential to inform the surgeons and the local referring pediatricians whose patients could be enrolled about the study and to get their tacit approval prior to recruiting subjects into the trial.

When it will be difficult to obtain consent and assent on the day of surgery, one approach is to screen the operative schedule and send letters to prospective study participants to inform them in general terms of the study objectives and procedures and to send a copy of the consent form to those who express an interest. Recruitment letters must be approved by the IRB prior to use and copies should be maintained in the study records. Without this prescreening and notification, there can be insufficient time to allow prospective participants to consider the risks, benefits, and alternatives to more complicated studies, making an informed decision difficult if not impossible. Thus, a successful recruitment plan often requires the investigator and study coordinator to screen and recruit in the surgeon's or pediatrician's office.

Before agreeing to take part in a clinical trial, both the investigator and the prospective participant need to understand that care provided during research is different from usual clinical care. The investigator's obligation is to adhere to the protocol and not to individualize care to the participant's need. It is not known whether or not the participant will benefit directly from their participation; to promise benefit is to presuppose the outcome from the trial. Failure to understand the difference between clinical care and research is termed "therapeutic misconception" [98–100]. The investigator must ensure that the prospective participant understands the difference so that expectations are aligned with reality. The data quality review, site monitoring visits, and meetings of the study steering committee, DSMC, and other study committees take place at regularly scheduled intervals. At these meetings, recruitment progress and projected time lines for completion of the study are reviewed to ensure that the study is meeting its goals.

Close-out and termination stage

Once the last subject has had their last visit and the final data queries issued by the data management team are resolved, sites can be closed. In practice, low-enrolling sites are closed well before this point so that there are sufficient monitoring resources to rapidly lock the study database. The site monitoring team will direct the disposition of equipment, supplies, drugs, and other stored materials. Once all data queries are resolved, the database can be locked, which means that no further changes will be made, even if small errors are discovered. As long as subject identifiers remain in the database used for analysis, the study must remain open and be approved by the IRB. For multicenter trials, most sites can submit a request for study closure once the sponsor has conducted the close-out visit.

The study statistician might or might not conduct the planned analyses blinded to treatment assignment. The statistician prepares results summarized in tables and figures. A formal study report is usually prepared and investigators and participants can be informed of the study's findings. The results of the study are submitted for publication and to regulatory agencies. Finally, if indicated, this is the time to plan for follow-up studies.

Other clinical research study designs

This chapter has focused on the prospective, randomized, blinded, placebo-controlled trial as the accepted highest standard of evidence to decide whether a therapeutic intervention (drug or other treatment) is efficacious in improving a specified outcome. Because of the complexity and cost of these trials, they are often not feasible, and other clinical research approaches are necessary to provide data to help determine effectiveness of an intervention, or to follow a cohort of patients with a particular condition to determine risk factors for particular outcomes. The principles of planning and conducting a randomized controlled trial are very useful when designing these types of clinical research; observational studies will be briefly described here. The reader is referred to several excellent reviews and texts summarizing the various approaches to clinical research [101–104].

Observational studies

Observational research studies include cohort, case–control, cross-sectional, and descriptive research. Depending on the nature of the study, the research could be exempt from the research regulations or require IRB approval. For research requiring IRB approval, informed consent is required unless the research qualifies for waiver of informed consent. For the research to be eligible for a waiver of consent, the research can be no more than minimal risk, it cannot violate the rights or welfare of the subjects, and it could not be practicable to conduct the research without the waiver. If the study involves additional research procedures – imaging studies, additional study visits, blood tests – it is unlikely to qualify for a waiver. If the study involves more than minimal risk, the study would be approvable only if the risks were limited to no more than a minor increase above minimal and would require two parents' signatures.

While observational studies are cheaper and faster to perform, they suffer from weaknesses. Compared to the clinical trials where assignment is based on randomization, there is no assurance that groups being compared were equivalent at baseline. Confounding variables that influence the outcome can be adjusted for but it cannot be assumed that all factors were accounted for. In addition, since blinding to treatment assignment is not present, bias can influence the investigator's assessments. It is therefore possible that differences in the populations at baseline are responsible for the differences in outcome rather than exposure to a risk factor(s). Compared to a clinical trial, it is not possible to establish, with certainty, cause and effect.

Cohort studies

A cohort study follows one or more groups of individuals over time. The groups or cohorts are defined by a risk factor or exposure – type of anesthetic, age, ASA physical status, anesthesiologist experience, etc. – rather than by treatment assignment and are then followed over time for outcome. Cohort studies can either be prospective – starting with an inception cohort in the present and followed forward in time – or retrospective where the inception cohort is defined in the past and followed up to the present or further into the future.

As an example, a cohort of neonates undergoing congenital complex open heart surgery could be divided by a risk factor of interest such as circulatory arrest versus no circulatory arrest. The cohort could be followed for a period of months to years, to assess neurodevelopmental outcome. The data collected would include demographic and clinical data, such as the details of the surgery and bypass, circulatory arrest, comorbid conditions and complications, monitoring and neuroimaging data, and anesthetic and sedative drug exposure. Outcome measures could involve information from the subject's usual clinical care or procedures performed only for the research, such as neuroimaging and neurodevelopmental outcome testing [105]. The usual method analysis of involves estimation of relative risks and their 95% confidence interval. Logistic regression can be used to simultaneously assess the association of two or more risk factors on outcome.

Just like a clinical trial, cohort studies should have defined objectives (e.g. low cerebral oxygen saturation as measured by near-infrared spectroscopy is associated with lower neurodevelopmental outcome scores at age 12 months) in a formal protocol. Cohort studies can identify possible risk factors and preliminary data that can be used to design a controlled trial of a therapeutic intervention (e.g. using a treatment algorithm for low cerebral oxygen saturation vs. standard care, and determining effect on neurodevelopmental outcome). All cohort studies should have a pre-defined analysis plan that can be as detailed as for a clinical trial [106] and the protocol should include all of the details required to meet reporting guidelines [107–109].

Another example of a prospective cohort study is the recently published APRICOT study, where 261 hospitals in 33 European countries prospectively collected very detailed adverse outcome data for a 2-week period and combined results for an analysis of over 31,000 anesthetics [110].

Case–control studies

Whereas a cohort study assigns subjects to groups based on the subject's exposure to a risk factor and then follows the subjects forward in time to identify the outcome, a case–control study starts with the outcome and moves backwards in time to identify risk factors. The choice of control group is key; an inappropriate choice can lead to spurious results [111]. Since the number of cases is usually limited, it is usual to assign more than one control to each case to increase the power of the study. Since the number of control subjects is chosen arbitrarily it is not possible to calculate relative risks. Instead, the method of analysis involves calculation of the odds ratio and its 95% confidence interval, which can approximate the relative risk when the frequency of the outcome is low.

Case–control studies can be performed rapidly but are one step further down the strength of evidence chain compared to cohort studies. However, when the strength of association is high and there is a strong physiological rationale, they can be persuasive. For example, the link between aspirin administration and Reye syndrome was established by a case–control study. A more recent example demonstrated that patients who developed bronchospasm were at a 3.3-fold risk of having received rapacuronium instead of vecuronium [112]. Notice that with a case–control study, the attribution of the risk factor to the outcome is the reverse of that for a cohort study; those

with the outcome of interest are at risk of having been exposed to the risk factor.

Database registries

In the last several decades there has been a large increase in the number of prospective single or multicenter databases relevant to pediatric anesthesia. These include adverse event registries, such as the Pediatric Perioperative Cardiac Arrest registry and Wake Up Safe registry [113,114]. Data from registries can be used to perform cohort studies and case–control studies or to provide benchmark data back to institutions.

Adverse events are identified, and along with the other data about the patient and the clinical scenario, are entered into the data collection forms. Causation for adverse events may be adjudicated by a panel of expert reviewers. Periodic analyses of these data have resulted in important new information about, for example, the higher risk of cardiac arrest in patients with congenital heart disease, the prevalence of medication errors, and the risk of hyperkalemic cardiac arrest with massive blood transfusion. Alternatively, a larger more comprehensive dataset can be collected about a population of interest with or without complications, e.g. Pediatric Regional Anesthesia Network, Congenital Cardiac Anesthesia Database [115,116]. With the considerable expense and complexity of prospective clinical trials, large databases may afford an opportunity for a "trial within a database," i.e. a hypothesis that an outcome is improved with vs. without a particular drug, allowing the data already collected to inform the study design, often at a much lower cost and with faster "enrollment" [117].

With the widespread adoption of electronic anesthesia records, automated digital data collection and submission to larger multicenter databases is possible. These "big data" sets can be analyzed for outcomes of interest, or to define the characteristics of a population, e.g. blood pressure ranges in anesthetized children [118].

Although the level of evidence for database research is not usually considered as high as for the prospective clinical trial, hypotheses can be generated for prospective studies, and the large number of patients often included in databases can at least partially overcome some of the weaknesses, such as incomplete data collection, incomplete set of variables, and not having an exact study hypothesis and primary outcome measure pre-specified when the database was designed. Additional discussion of database research is presented in Chapter 48.

Levels of evidence for clinical research studies

There are a number of schema to classify the quality or level of evidence and strength of recommendations when determining whether a particular drug or therapeutic intervention, or diagnostic test, is associated with a better outcome. One such approach is from the American Heart Association; it has been widely adopted and can provide a framework to understand the many other approaches to assessing levels of evidence, and the strength of recommendation for a particular treatment, drug, strategy, or diagnostic test [119]. The prospective, randomized, controlled trial is considered the highest level of evidence, and if there is more than one trial addressing a particular issue with the same result after a combined or meta-analysis, the evidence is considered strong for that particular intervention. Very few drugs or interventions in pediatric anesthesia have been subjected to a single, let alone multiple, randomized trials. One exception would be the recently published GAS trial comparing spinal vs. general anesthesia for infant inguinal hernia repair, and association with neurodevelopmental outcomes [120]. In this very well designed and adequately powered trial, outcomes at 2 years (the secondary outcome as the 5-year neurodevelopmental testing is primary) were almost identical, and as such a trial is unlikely to be repeated, this constitutes strong evidence for the neurodevelopmental equivalence of spinal vs. general anesthesia for a relatively short procedure. Most of the other clinical data in the field of anesthetic neurotoxicity are wholly or partly retrospective in nature, indicating a lower level of evidence for association of anesthetic exposure with lower neurodevelopmental outcomes.

Conclusion

The randomized, blinded, placebo-controlled clinical trial is the indispensable "gold standard" in determining the efficacy of therapeutics. Trials are time-consuming, maddeningly difficult, and often very expensive to perform, and can be frustrating from inception to execution to completion. However, the failure to properly perform a trial results in perpetual uncertainty. Performing a proper trial takes time to develop a protocol, create and test the data collection forms, obtain support and funding, and establish the structure for data intake and analysis. For complicated studies, it may be best to pilot the protocol before embarking on the trial. Once completed, the results of the trial must be published and made available to the public and regulatory agencies. Finally, above all else, all aspects of trial conduct must adhere to accepted ethical standards. Other study designs including prospective observational, retrospective cohort and case–control, and database research, can provide important data, although usually at a lower level of evidence than the prospective randomized controlled trial.

Introduction

Congenital heart disease (CHD) represents the most common birth defect, affecting approximately 1% of liveborns. The anomalies within this disease spectrum account for almost one-third of all major congenital malformations [1,2]. The etiology and mechanisms of congenital cardiovascular defects are incompletely understood [3]. Our current knowledge and understanding of the pathogenesis of CHD originates mostly from research in non-human species and progress in genomics, proteomics, transgenesis, imaging, and integrative systems biology [4].

Although cardiac anomalies have genetic and non-genetic causes, the multifactorial mode of inheritance of some defects is likely due to the interactions between several genes and modulating environmental factors [5–8]. Developmental mechanisms that may impact cardiac development include genetic and epigenetic molecular events, signaling pathways, cell migration, differentiation, proliferation, and death, and hemodynamic and contractile forces [9–15].

A segmental anatomical approach will be used in this chapter to describe the development of the cardiovascular system and demonstrate the relationships between abnormal development and specific congenital cardiac defects. It should be recognized, however, that cardiovascular development is a three-dimensional, spatiotemporal process with many elements occurring simultaneously.

Development of the cardiovascular system

Changing view of cardiac development

For many years the classic teaching in cardiac embryology was founded on the *segmental model*. It was theorized that the primordiums or earliest recognizable components of all the future cardiac segments were present in the linear heart tube [16]. The model assumed that the straight heart tube would eventually give rise to the atria, ventricles, bulbus cordis, and truncus arteriosus. Over the last several decades, however, many of these concepts have been challenged as more information has become available from scientific advancements (Fig. 5.1) [9]. Although early studies suggested that cells were added to the poles of the heart from the surrounding mesoderm [17–19], later investigations showed that cells are added to the heart after the initial stage of looping [20–22]. The current concept is that the primitive heart tube contains little more than the precursors for the left ventricle (LV) and that the precursor cells of the other cardiac components are added to both the venous and arterial poles from a second heart field outside the initial heart tube [16].

KEY POINTS: CHANGING VIEW OF CARDIAC DEVELOPMENT

- The classic concept in cardiac development that all cardiac chambers were derived from segments in the primordial heart tube has been challenged by ongoing research
- In the revised view of cardiac development it is considered that only precursors of the future left ventricle are present in the straight heart tube

Normal and abnormal cardiovascular development

During the first 2 weeks of development the human embryo relies on diffusion from the utero-placental circulation as it is lacking a heart and vascular system. At the end of the second week, the embryo is a bilaminar disk made up of the epiblast and the hypoblast (Fig. 5.2). In vertebrates, *the cardiovascular system is the first organ system to develop and function,* beginning during the third week of life. By the process of gastrulation,

Gregory's Pediatric Anesthesia, Sixth Edition. Edited by Dean B. Andropoulos and George A. Gregory.

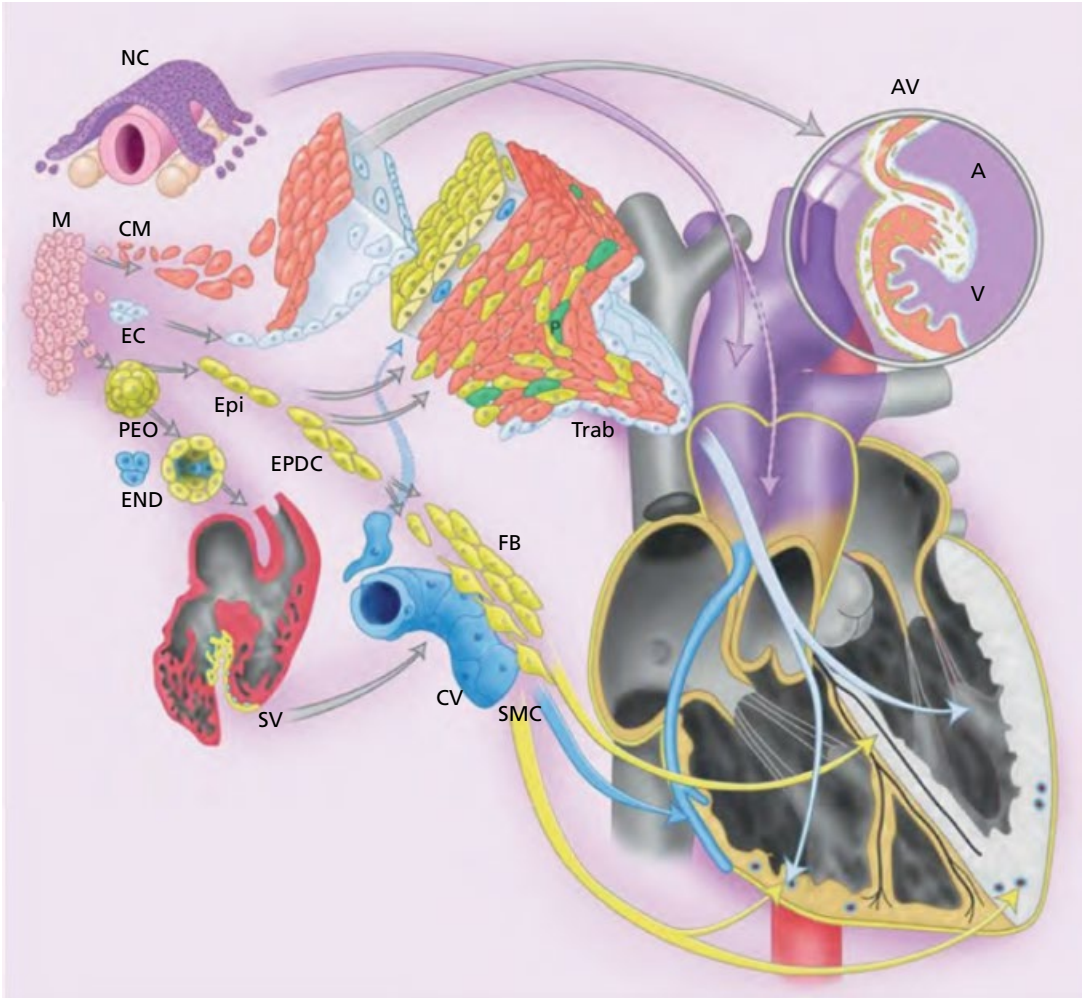

Figure 5.1 Cardiogenesis in a condensed form starts with mesoderm (pink) and neural crest (NC, purple) precursors. The primary and second heart field precursors are taken together. They develop into the cardiomyocyte (CM) line (dark pink), endocardium (EC, light blue), PEO-derived epicardium (Epi, yellow), and vascular endothelium (END, dark blue). The cardiomyocyte precursors give rise to the compact and trabeculated (Trab) myocardium of the ventricles (PHF-derived left ventricle, silver), SHF-derived right ventricle (gold), and atria (also SHF-derived, gold), including the interventricular septum (silver and gold), and part of the atrial septum (not depicted). The endocardium lining the myocardial wall at the inside gives rise to endocardial cushions, consisting of mixed cell populations (EC, NC, EPDC), and subsequently AV (inset) and semilunar valves. The cushions are also instrumental in septation processes (not depicted). The epicardium (Epi, yellow) covers the myocardial wall and develops into EPDC that differentiate into e.g. interstitial fibroblasts (FB) and coronary smooth muscle cells (SMC). EPDC probably are instrumental in induction of cardiomyocytes into peripheral Purkinje cells (P, dark green). Endothelial cells (dark blue) of the coronary system mostly arise from the sinus venosus/liver region (red), entering the subepicardial space and developing into the coronary microvascular network. At the arterial pole endothelial tubes invade the aortic wall to form the coronary ostia and become enveloped by EPDC-derived SMC to form the coronary arteries. Cardiac neural crest cells (purple) migrate around the pharynx, join the SHF, and find their way in the outflow tract and large arteries including semilunar valves, and probably also into the venous pole of the heart (not depicted). Finally, elements are depicted of the conduction system, e.g. sinus node, and bundle branches (black). A, atrium; AV, atrioventricular canal; CM, cardiomyocytes; CV, coronary vasculature; EC, endocardium; END, endothelium; EPDC, epicardial derived cells; FB, fibroblasts; M, mesoderm; NC, neural crest; P, Purkinje cell; PEO, proepicardal organ; SMC, smooth muscle cells; SV, sinus venosus; Trab, trabeculations; V, ventricle. *Source:* Reproduced from Poelmann and Gittenberger-de Groot [9] with permission of Elsevier.

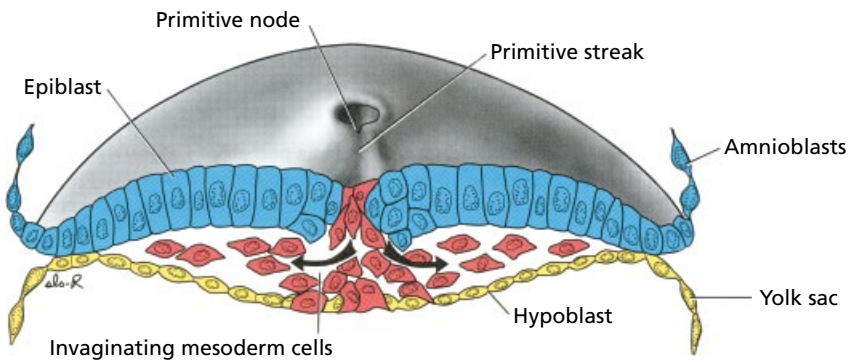

Figure 5.2 Formation of three cell layers. Cross-section through the cranial region of the primitive streak at 15 days showing invagination of epiblast cells. The first cells to move inward displace the hypoblast to create the definitive endoderm. Once definitive endoderm is established, inwardly moving epiblast forms mesoderm. *Source:* Reproduced from Sadler [33] with permission of Wolters Kluwer.

the embryo develops into a trilaminar disk, thereby establishing all three germ layers (ectoderm, mesoderm, and endoderm) [23].

Cardiogenic fields

After gastrulation, cardiac progenitor cells, located in the epiblast, migrate via the primitive streak laterally and cranially to the lateral plate mesoderm. The lateral plate mesoderm is split by the pericardial coelom into two layers: somatic (dorsal) mesoderm and splanchnic (ventral) mesoderm (Fig. 5.3). Cells in the somatic mesoderm will give rise to the pericardium, while cells in the splanchnic mesoderm form the bilateral *cardiogenic* or *heart fields* that will give rise to the myocardium [24]. The cardiogenic fields fuse in the midline to form the *cardiac crescent* (Fig. 5.4A and B). At least two distinct lineages of cells are present within the cardiac crescent: one referred to as the "*first (or primary) heart field*" (FHF), and the other as the "*second heart field*" (SHF) [12]. The FHF will give rise to the linear heart tube, and cells from the SHF will contribute at the inflow (venous) and outflow (arterial) poles during cardiac looping. As discussed later in the chapter, *the embryonic cells that contribute to cardiac development arise not only from the mesoderm in the heart fields but also from cardiac neural crest* [25] *and the proepicardium* [26].

KEY POINTS: CARDIOGENIC FIELDS

- Myocardial cells are derived from the bilateral cardiogenic or heart fields in the splanchnic mesoderm
- The cardiogenic fields merge to form a cardiac crescent, giving rise to two cell lineages, also known as first and second heart fields
- Cells contributing to cardiac development originate from heart field mesoderm, cardiac neural crest, and the proepicardium

Heart tube

The primitive heart tube is formed at the beginning of the fourth week of development. As the embryo folds, the lateral portions of the cardiac crescent come close together, forming the ventral aspect of the heart tube [27] (Fig. 5.4 C–G). The medial portions of the cardiac crescent form the dorsal part of the heart tube, suspended from the foregut by the dorsal mesocardium. The heart tube has two caudolateral inlets (venous pole) and one craniomedial outlet (arterial pole) [27,28]. It should be noted that the schematic drawings in embryology educational resources illustrating the presence of all cardiac segments in the primitive heart tube represent hypothetical constructions as most of the segments are added to the linear heart tube during the stages of cardiac looping [29].

The initial heart tube consists of an inner endocardial layer, a middle layer of cardiac jelly, and an outer myocardial layer. The *endocardium* is composed of a specialized endothelial cell type derived from the splanchnic mesoderm and develops simultaneously with the myocardium in the cardiac crescent. The *myocardium* is considered primitive or primary because the myocytes of the heart tube have few contractile elements, a poorly developed sarcoplasmic reticulum, a low density of gap junctions, and high automaticity [16].

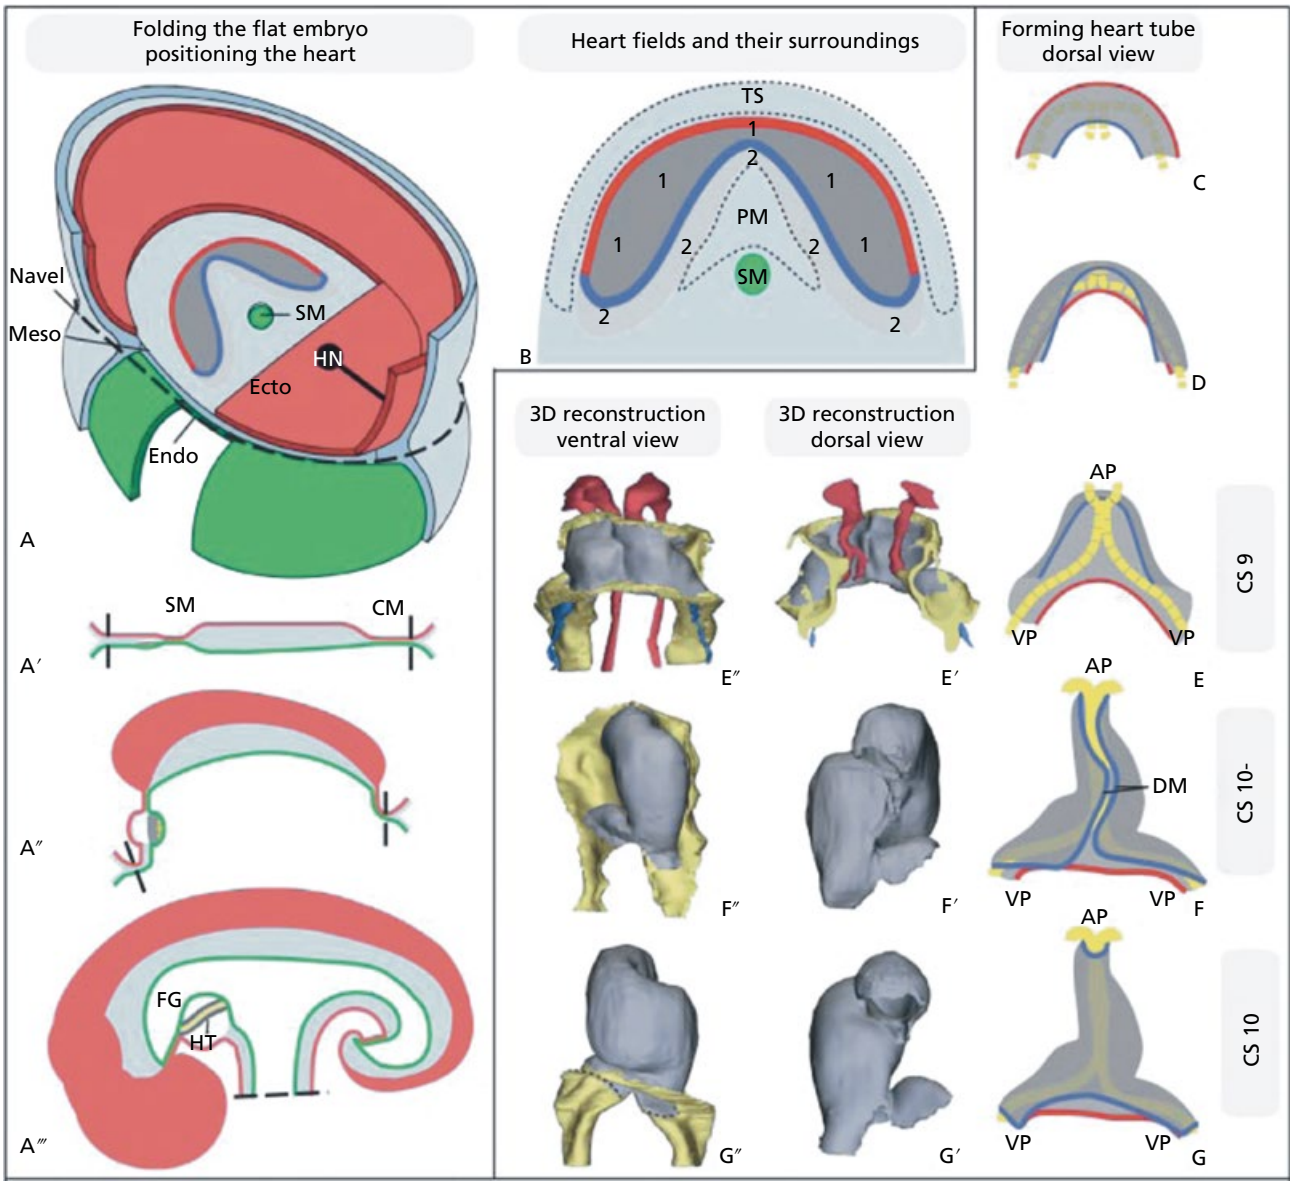

Figure 5.4 Folding of the embryo and formation of the heart tube. (A) The embryo starts as a flat disc containing the three germ layers, the ectoderm (Ecto), mesoderm (Meso), and endoderm (Endo). (A–A‴) With ongoing folding of the embryo the embryonic gut that runs from the stomatopharyngeal membrane (SM) to the cloacal membrane (CM) is formed. The heart (HT) becomes positioned ventrally to the foregut (FG), caudally to the head, and cranially to the umbilical cord and transverse septum (TS). HN, Hensen's node or primitive node. (B) Division of the heart-forming field into the first heart field (1), which will give rise to the linear heart tube, and the second heart field (2), which will remain in continuity with the first heart field during subsequent development and from which cardiomyocytes are added to the developing heart. In reality, the strict borders drawn here are gradual. PM, pharyngeal mesoderm. (C–G) Formation of the heart tube from a flat horseshoe-shaped cardiac crescent to a tube. Folding of the embryo brings the lateral portions of the cardiac crescent (red line) together to form the ventral part of the heart tube, while the medial portions of the cardiac crescent (blue line) will form the dorsal part of the heart tube, which is suspended from the foregut by the dorsal mesocardium (DM). After the DM closes and the suspension from the foregut is lost, cells of the second heart field can only be added to the heart via the arterial and venous poles (AP and VP). *Source:* Reproduced from Sylva et al [27] with permission of John Wiley and Sons.

Cardiac contractions begin around the third week of gestation in the human, and circulation through the embryo begins shortly thereafter. Given that the highest automaticity is found at the venous pole of the heart tube, a slow peristaltic contraction propels the blood from the venous to the arterial pole (unidirectional flow).

Abnormalities of heart tube formation

Failure of the heart tube to develop (*acardia*) results in fetal demise.

KEY POINTS: FORMATION OF THE HEART TUBE

- The primitive heart tube forms at the beginning of the fourth week of development
- Contractile activity commences and circulation through the embryo begins with formation of the heart tube
- Failure of the heart tube to develop results in fetal demise

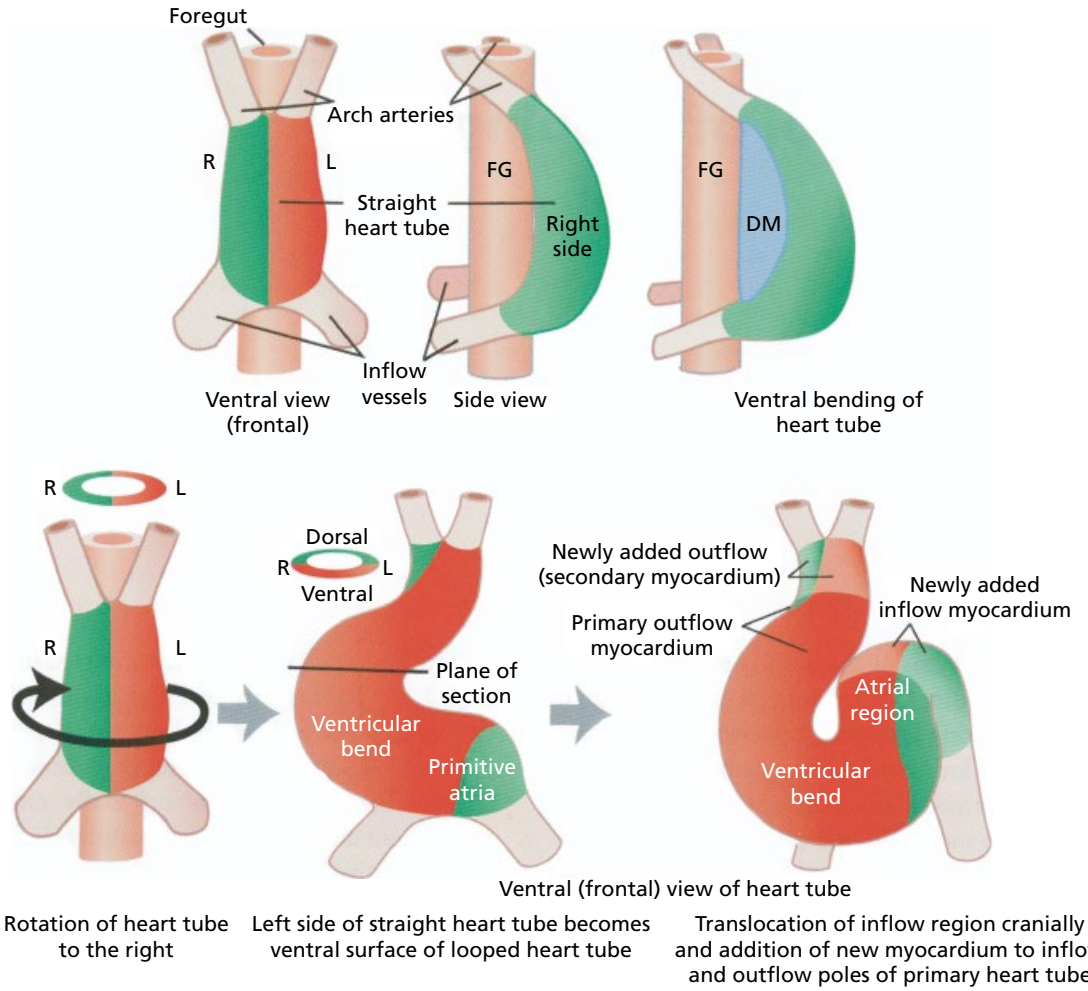

Figure 5.5 Steps in looping of the heart tube. The heart tube forms ventral to the foregut and is open to it at first. Then the heart tube is suspended at its nascent inner curvature from the ventral foregut by the dorsal mesocardium which quickly disappears. Ventral bending occurs first, followed by rotation to the right which brings the left side of the tube to the front and the inner curvature to the left side. Subsequent looping to form the S-shaped loop involves addition of cells at the inflow and outflow poles. DM, dorsal mesocardium; FG, foregut. *Source:* Reproduced from Kirby [34] with permission of Oxford University Press.

Cardiac looping

Cardiac loop formation brings the linear configuration of the primitive heart tube into the correct conformation for chamber specification, septation, and the creation of systemic and pulmonary pathways [29,30]. *The heart is not only the first organ to function, but it is also the first to develop a bilateral asymmetrical form through the process of looping*.

Cardiac looping begins with ventral bending and the loss of the dorsal mesocardium which, as described, suspends the heart tube from the foregut; this is followed by rotation to the right along a craniocaudal axis (*dextro- or D-looping*), bringing the left side of the tube to the front and the inner curvature to the left. These changes transform the straight heart tube into a C-shaped loop (Fig. 5.5) [29]. Subsequent conformational changes result in a two-dimensional, S-shaped loop. When looping is complete, the segments of the heart might be referred to (extremely variable between authors) as the sinus venosus, common atrium, atrioventricular canal (AVC), presumptive LV, presumptive right ventricle (RV), conus arteriosus, and truncus arteriosus (frequently referred to as the conotruncus) [31].

In the normal heart, cardiac looping to the right (*D-loop)* positions the RV towards the right side (Fig. 5.6, left panel) and leaves the heart lying predominantly in the left hemithorax with a leftward apex (*levocardia*). The normal heart is characterized by visceroatrial *situs solitus*, referring to the usual position of the thoraco-abdominal organs and the atria, as well as D-loop ventricles as described.

Abnormalities of cardiac looping

Abnormalities in left-right patterning are associated with cardiac malformations in both D- and L-loop hearts, as seen for example in heterotaxy syndromes, atrial isomerism, mirror image arrangements, and discordant connections [32].

Rotation of the heart tube around the craniocaudal axis to the left, instead of the right, results in a *levo-loop (L-loop)* heart (Fig. 5.6, right panel). In this setting, the RV is positioned towards the left side relative to the LV which is located towards the right.

Congenitally corrected transposition of the great arteries (CCTGA) results when the atria and outflow receive correct left-right signals but the ventricular segment loops abnormally to the left (L-loop ventricles), resulting in discordant atrioventricular (AV) and ventriculoarterial (VA) connections. This can be found within the context of visceroatrial situs

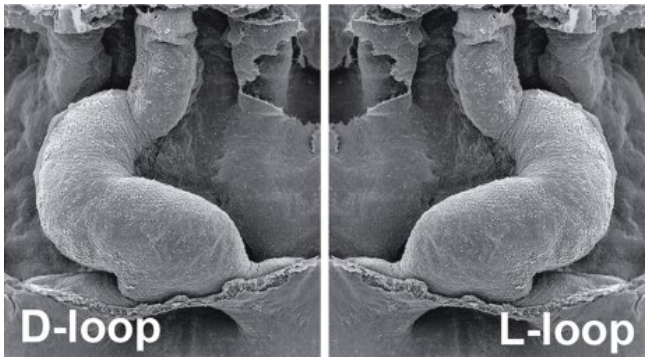

Figure 5.6 Handedness of the cardiac loop. Scanning electron micrographs of embryonic chick hearts, viewed from the front, showing the so-called D-loop (dextral-loop) and L-loop (levo-loop) configurations ("C-shaped" loops; HH-stage 12). *Source:* Reproduced from Männer [114] with permission of Elsevier.

solitus or in *situs inversus* where there is mirror-image reversal of organs such as the liver, stomach, and spleen.

In *dextrocardia* the heart lies predominantly in the right hemithorax, usually with a rightward pointing apex, while *mesocardia* refers to a midline heart with the apex pointing inferiorly or anteriorly. Mesocardia and dextrocardia can be associated with normal or abnormal arrangement of cardiac structures. *Atrial isomerism* refers to a bilaterally symmetrical pattern of the atrial appendages (i.e. bilateral left or right sidedness) and is usually associated with complex cardiac malformations [30]. *Mixed situs* occurs when some organs, or components thereof, have normal situs and others have situs inversus. This usually results in complex heart disease referred to as *heterotaxia* or *heterotaxy* syndromes.

KEY POINTS: CARDIAC LOOPING

- The heart is the first functional organ to develop in the embryo
- Looping represents a crucial process in cardiac morphogenesis that determines the shape of the heart and results in right-left asymmetry in the embryo
- Dextro- or D-looping refers to normal cardiac looping to the right; abnormal looping to the left results in levo- or L-looping

Cardiac septation

After looping of the heart tube cardiac septation occurs and consists of various processes that begin in the fourth week and continue into the seventh week of gestation [27]. These events divide the heart into four chambers and create separate systemic and pulmonary circulations [33].

Atrial septation

Atrial septation takes place in phases to maintain necessary atrial right-to-left shunting in the fetal heart. The *primary atrial septum*, known as the septum primum, emerges from the roof of the atrium and gradually extends inferiorly towards the endocardial cushions in the AV junction (Fig. 5.7) [34]. The leading edge is covered by a mesenchymal cap that is continuous with the dorsal mesenchymal protrusion. The communication between the leading edge of the septum primum and the AV cushions is known as the *primary atrial foramen* (ostium primum). This foramen closes when the septum primum becomes contiguous with the fused AV endocardial cushions. Communication between the left and right atria is maintained by the detachment of the septum primum from the roof of the atrial cavity to produce a secondary atrial foramen (ostium secundum) [35]. The *secondary atrial septum* (septum secundum) originates by folding of the dorsal wall between the primary atrial septum and the left leaflet of the sinoatrial valve. The foramen ovale arises because the septum secundum is crescent-shaped and does not form a complete partition of the atrial cavity. This structure acts as a one-way valve in fetal life, allowing the better-oxygenated blood from the inferior vena cava to course from the right atrium (RA) into the left atrium (LA).

The *venous pole* of the heart has two channels early in development, the left and right horns of the sinus venosus, which return blood from the embryo (via the cardinal, vitelline, and umbilical veins) to the sinus venosus and common atrium. The sinus venosus, including its right horn, and the sinoatrial junction become incorporated into the dorsal (back) wall of the RA (Fig. 5.8). The left horn of the sinus venosus is incorporated into the developing AV groove to become the coronary sinus. The dorsal (back) wall of the LA is also formed by incorporation of the pulmonary vein and its surrounding myocardium [34,36].

Defects in atrial septation

A *secundum atrial septal defect* (ASD) is the most common communication resulting in an atrial level shunt. The defect is located within the region of the fossa ovalis and in most cases is due to a deficiency of the septum primum [37].

A *patent foramen ovale* (PFO) represents failure of complete fusion of the septum primum and septum secundum. The foramen remains functionally closed if the flap valve is large enough and the LA pressure exceeds the RA pressure (probe-patent foramen).

An *ostium primum ASD* results from failure of the septum primum to fuse with the endocardial cushions. The defect extends from the inferior limbus of the fossa ovalis to the crest of the interventricular septum. This type of defect is part of the spectrum of AVC defects, also referred to as AV septal and endocardial cushion defects, and may occur in isolation or in association with other abnormalities of the AV junction.

A *sinus venosus ASD* occurs in the area derived from the embryological sinus venosus (posterior aspect of the RA) and represents an interatrial communication associated with anomalous entry of the right pulmonary veins to the heart [38]. The most common defect is the superior vena cava type located between the cardiac end of the superior vena cava and the right upper pulmonary vein. Less commonly, an inferior vena cava type can be found where the more caudal atrial wall is involved at the entrance of the right lower and/or middle pulmonary veins [37].

A *coronary sinus ASD* occurs when the tissue between the coronary sinus and the LA is either partially or completely absent (unroofed), resulting in a communication between the atria via the coronary sinus orifice.

A *common atrium* is caused by the absence of the septum primum, septum secundum, and atrial portion of the AVC septum, and is usually associated with heterotaxy syndrome [37].

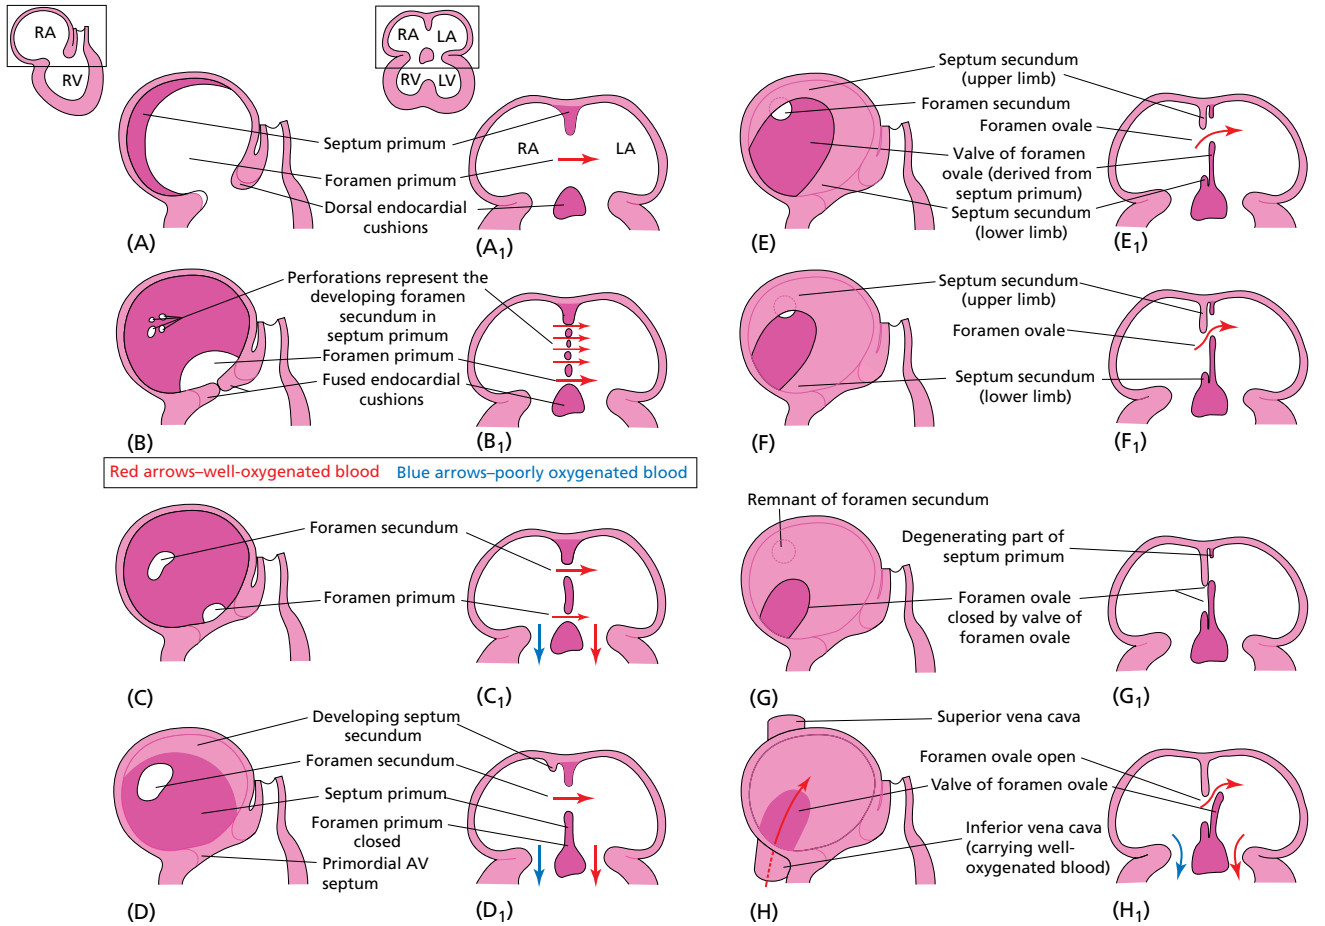

Figure 5.7 Atrial septation. Diagrammatic sketches illustrating progressive stages in partitioning of the primordial atrium. (A–H) Sketches of the developing interatrial septum as viewed from the right side. (A1–H1) Coronal sections of the developing interatrial septum. Note that as the septum secundum grows, it overlaps the opening in the septum primum, the foramen secundum. Observe the valve of the foramen ovale in G1 and H1. When pressure in the right atrium (RA) exceeds that in the left atrium (LA), blood passes from the right to the left side of the heart. When the pressures are equal or higher in the left atrium, the valve closes the foramen ovale (G1). Ventricular septation

After looping of the heart tube, differentiation and re-initiation of cell division by the primary myocardium of the outer curvature causes the ventricles to expand caudally in a pouch-like fashion on either side of the bulboventricular groove (Fig. 5.9). Disappearance of the cardiac jelly results in the formation of trabeculations on the luminal side, producing a spongy-type myocardium. The myocardium becomes compacted when epicardially-derived fibroblasts infiltrate the epicardial side, at which time proliferation in the trabeculations ceases.

Ventricular septation begins in the fifth week and continues into the seventh week of gestation [27]. The *muscular* portion of the interventricular septum is formed by apposition and merging of the medial walls of the expanding ventricles, with cells added mainly from the adjacent LV free wall [27,33]. The space between the free rim of the muscular septum and the fused AV cushions is the *primary interventricular foramen*. Although the primary interventricular foramen allows for communication between the primitive ventricles, initially, blood from the primitive atrium can only reach the primitive RV via the interventricular foramen. It is only after the AV junction develops that the RA will communicate directly with the RV. Closure of the interventricular foramen occurs by fusion of the superior and inferior endocardial cushions, the muscular interventricular septum, and the endocardial cushions of the outflow tract (conal cushions). The site of fusion represents the *membranous* portion of the ventricular septum.

Defects in ventricular septation

Ventricular septal defects (VSDs) can be found in isolation or can coexist with other congenital cardiovascular malformations. These can result from a deficiency of one or more structures, namely the components of the ventricular septum (muscular, AVC endocardial cushion, and outflow tract (conal) cushion), and/or from their malalignment.

Muscular VSDs, the most common types, are those that occur in the *muscular* portion of the interventricular septum. These defects are completely surrounded by a muscular rim. They can be multiple and can be located anywhere along the muscular trabecular septum.

The *membranous* portion of the ventricular septum is adjacent to the anteroseptal commissure of the tricuspid valve (TV) and below the non-coronary leaflet of the aortic valve (AoV). Small defects can close spontaneously by surrounding aneurysmal fibrous tissue. Defects that extend beyond the

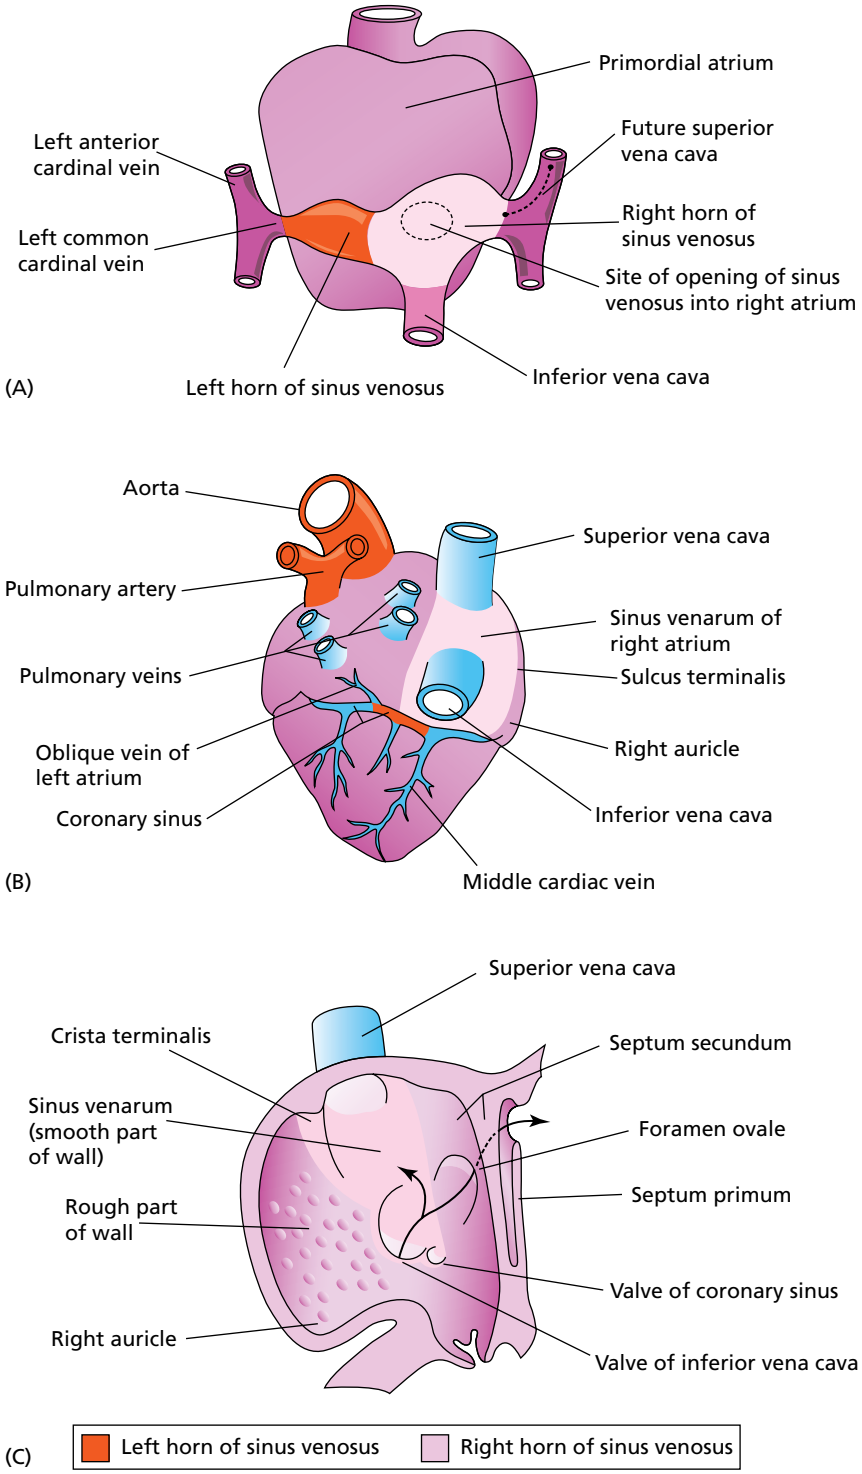

Figure 5.8 Fate of the sinus venosus. (A) Dorsal view of the heart (approximately 26 days) showing the primordial atrium and sinus venosus. (B) Dorsal view at 8 weeks after incorporation of the right horn of the sinus venosus into the right atrium. The left horn of the sinus horn becomes the coronary sinus. (C) Internal view of the fetal right atrium showing: (1) the smooth part of the wall of the right atrium (sinus venarum) derived from the right horn of the sinus venosus and (2) the crista terminalis and valves of the inferior vena cava and coronary sinus that are derived from the right sinuatrial valve. The primordial right atrium becomes the right auricle, a conical muscular pouch. The *arrows* indicate the flow of blood. *Source:* Reproduced from Moore et al [115] with permission of Elsevier.

region of the membranous septum are called *para- or perimembranous VSDs*.

A *conoventricular* or *subaortic VSD* is situated between the conal and muscular portions of the ventricular septum [39]. These defects are often related to malalignment of the muscular and conal regions of the ventricular septum.

A *subpulmonary, conal, supracristal*, or *doubly committed subarterial VSD* is located in the outflow tract (conal septum) just underneath the pulmonary valve (PV). The AoV can prolapse into the defect resulting in aortic regurgitation.

A defect that opens to the *inlet* portion of the RV can be perimembranous, muscular, or AVC-type [40]. The location of

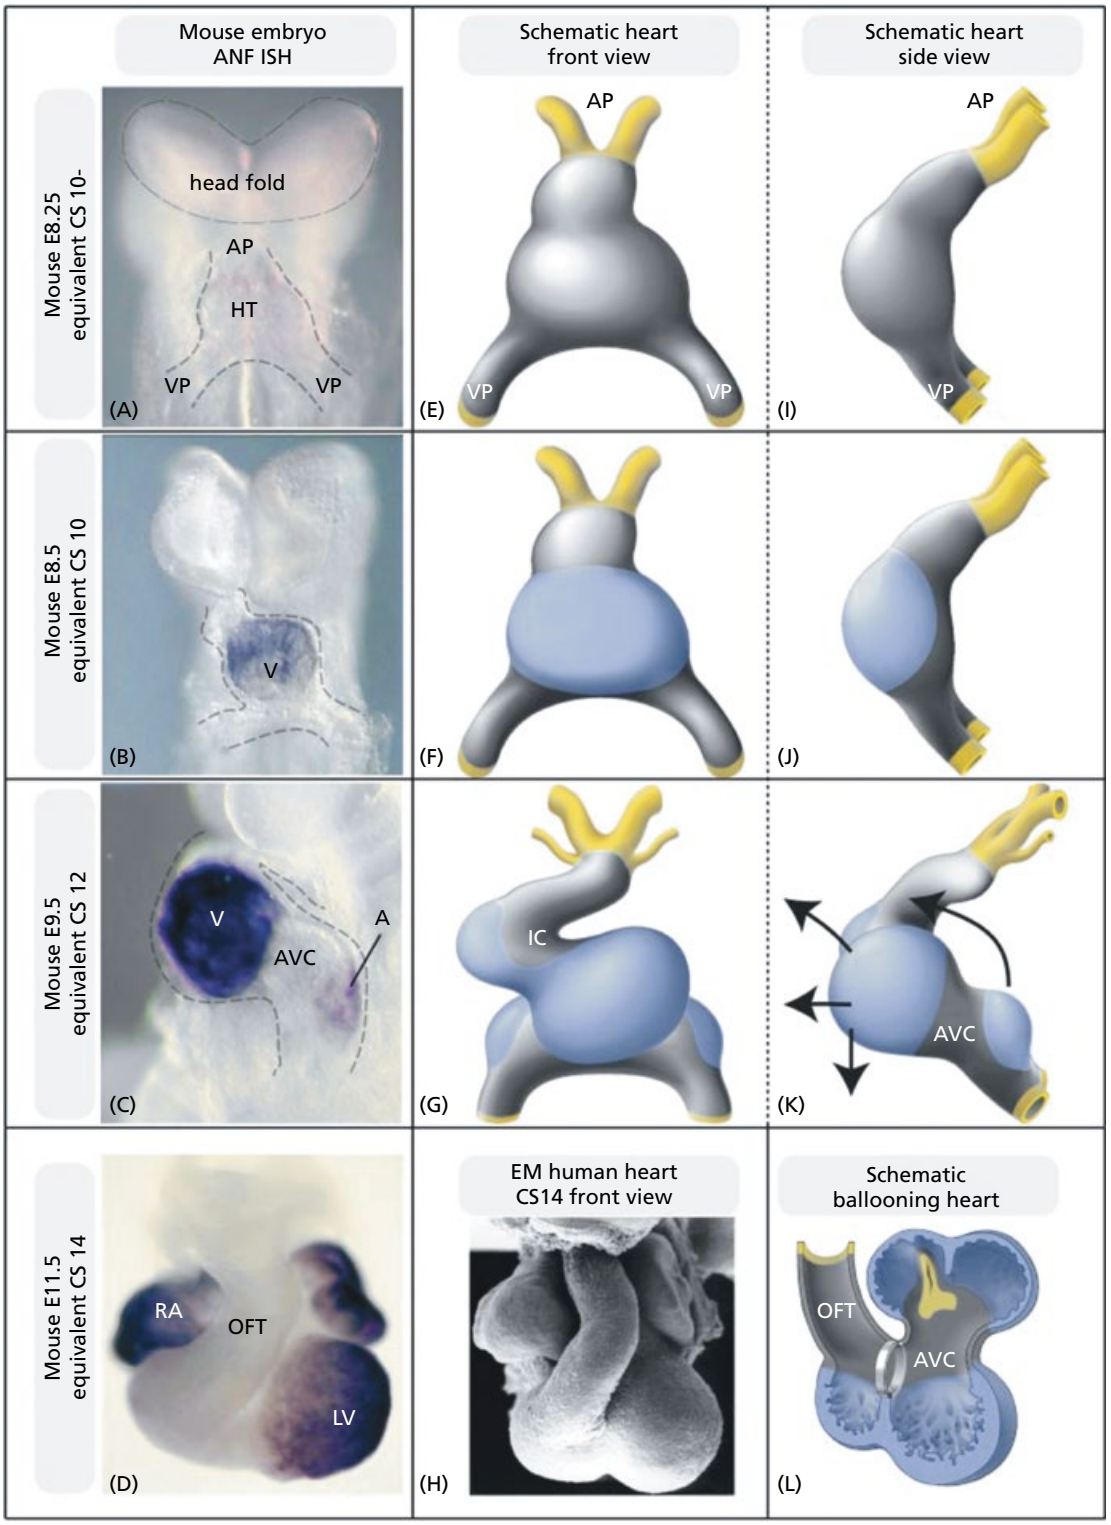

Figure 5.9 Formation of the cardiac chambers. (A–D) Developmental series of mouse embryos. Whole mount RNA *in situ* hybridization for the embryonic chamber marker atrial natriuretic factor (ANF) is used as a marker for differentiation into chamber myocardium. the AV node and the course of the bundle of His differ for these types of VSDs, having implications for surgical repair.

A *common* or *single* ventricle, characterized by the presence of two AV valves with one ventricular chamber or a large dominant ventricle with a diminutive or hypoplastic opposing ventricle, can result from different mechanisms. The pathology can be due to the arrest of or a defect in interventricular septation or poor alignment of the common AV valve with the ventricles [41]. A wide spectrum of functional single ventricles is recognized.

Septation of the atrioventricular canal and development of the atrioventricular valves

The endocardial cushions arise from cells of the endocardium that undergo endocardial-to-mesenchymal transformation [42]. The endocardial cushions and underlying myocardium prevent the backflow of blood prior to valve formation. Central fusion of the inferior and superior cushions forms the AV septum, thereby separating the AVC into the left (mitral) and right (tricuspid) components [43]. The *atrial portion of the AV septum* extends from the primary atrial septum to the level of the valve annuli, whereas the *ventricular portion of the AV septum* extends from the level of the valve annuli to the muscular component and forms the inlet portion of the interventricular septum.

The AV valves and subvalvar apparatus are formed by cavitation and remodeling of the cushions and excavation of the underlying ventricular myocardium to form leaflets and chordal structures (Fig. 5.10) [44,45]. The primitive leaflets undergo lengthening and delamination with the disappearance of the myocardial layer late in development.

After fusion of the endocardial cushions, the fibroblast-like cells of the cushions are replaced by myocardial cells in a process called myocardialization. Fusion of the non-myocardial mesenchymal cushions and myocardialization create portions of the atrial septum, ventricular septum, and conal septum, as well as the substrate for the crux of the heart [46].

Defects of the atrioventricular canal and the atrioventricular valves

Abnormalities in the structures derived from the endocardial cushions can produce a spectrum of malformations referred to as endocardial cushion defects (as previously noted, they are also termed AVC or AV septal defects).

An isolated *cleft in the anterior mitral valve (MV) leaflet represents the mildest form of pathology*. An *ostium primum ASD* is the result of incomplete fusion of the septum primum with the superior endocardial cushion, and is frequently associated with a MV cleft. The combination of these defects is referred to as a *partial AVC defect*. An *inlet* or *AVC-type* VSD occurs when the inferior endocardial cushion does not fuse with the muscular component of the ventricular septum. A *transitional AVC defect* consists of an ostium primum ASD with a very small to moderate (restrictive) inlet VSD, often occluded by AV valve tissue. A *complete AV canal defect (CAVC)* comprises an ostium primum ASD, an inlet VSD, and a common AV valve. In an *unbalanced CAVC defect*, usually one ventricle is hypoplastic and the other receives most of the AV valve tissue. Approximately 40% of patients with trisomy 21 (Down syndrome) have AVC defects [45].

Ebstein anomaly is characterized by displacement of the septal and posterior TV leaflets into the RV. This anomaly is considered the most important cause of congenital tricuspid regurgitation. The pathology is thought to be due to abnormal delamination of the inlet portion of the RV [47]. The portion of the RV that extends from the true TV annulus to the level where the septal and posterior leaflets attach is thin due to partial absence of myocardium and termed the "atrialized" portion, whereas the trabecular and outlet portions make up the functional RV.

Tricuspid atresia is characterized by agenesis of the TV and associated RV hypoplasia. The pathology can be found within the context of normally related great arteries or transposition of the great arteries, and with an intact ventricular septum or a VSD. Isolated *tricuspid stenosis* is exceedingly rare.

Mitral stenosis is commonly associated with other left-sided obstructive lesions. The disease spectrum of the obstructive pathology is quite variable. *Congenital mitral regurgitation* is more common than mitral stenosis.

Septation of the outflow tract and development of the semilunar valves

Cardiac neural crest cells are critical for normal cardiovascular development [25]. These cells contribute to outflow tract septation, semilunar valvulogenesis, development of cardiac neuronal tissue, insulation of the cardiac conduction system, and remodeling of the aortic arch arteries [48].

The outflow tract has been traditionally divided into three sections: the conus (proximal), the truncus (middle), and the aortic sac (distal) [49]. Outflow tract septation begins with the formation of a shelf of mesenchyme (the aorticopulmonary septum) in the dorsal wall of the aortic sac in the area between the fourth and sixth pairs of aortic arch arteries [50]. This shelf elongates towards the truncus, thereby dividing the lumen of the aortic sac into the future portions of the aorta and pulmonary trunk. Cardiac neural crest cells migrate into the pharyngeal arches (arches 3, 4, and 6) and a subset of these cells migrates into the outflow tract (Fig. 5.11). The outflow endocardial cushions are ridges of mesenchyme, formed by endocardial-to-mesenchymal transformation of the underlying endocardium, that spiral into the outflow tract. Mesenchymal cells from the pharynx, followed by neural crest cells, invade the truncal cushions to form two centrally placed columns or prongs (Fig. 5.12) [51]. These prongs eventually fuse with the conal cushions proximally and the aorticopulmonary septum distally. Rotation of the developing PV is associated with spiraling of the aorticopulmonary septum and prongs in such a fashion that the developing aorta will connect with the rightward and cranial component of the aortic sac and the developing pulmonary trunk will connect with the leftward and caudal component of the aortic sac [52].

The convergence of the inflow and outflow poles during cardiac looping, combined with the processes of rotation and wedging, brings the atria and outflow vessels into appropriate alignment with the AV valves and ventricles (Fig. 5.13) [49,51]. In the conus, myocardial cells invade the cushions, which then bulge further into the lumen and subsequently meet and fuse in the midline. These conal cushions fuse most proximally with the AV cushion tissue and the crest of the muscular ventricular septum.

Early in development, both a subpulmonary conus and a subaortic conus can be found above the RV. Subsequent regression and shortening cause the AoV to sink inferiorly

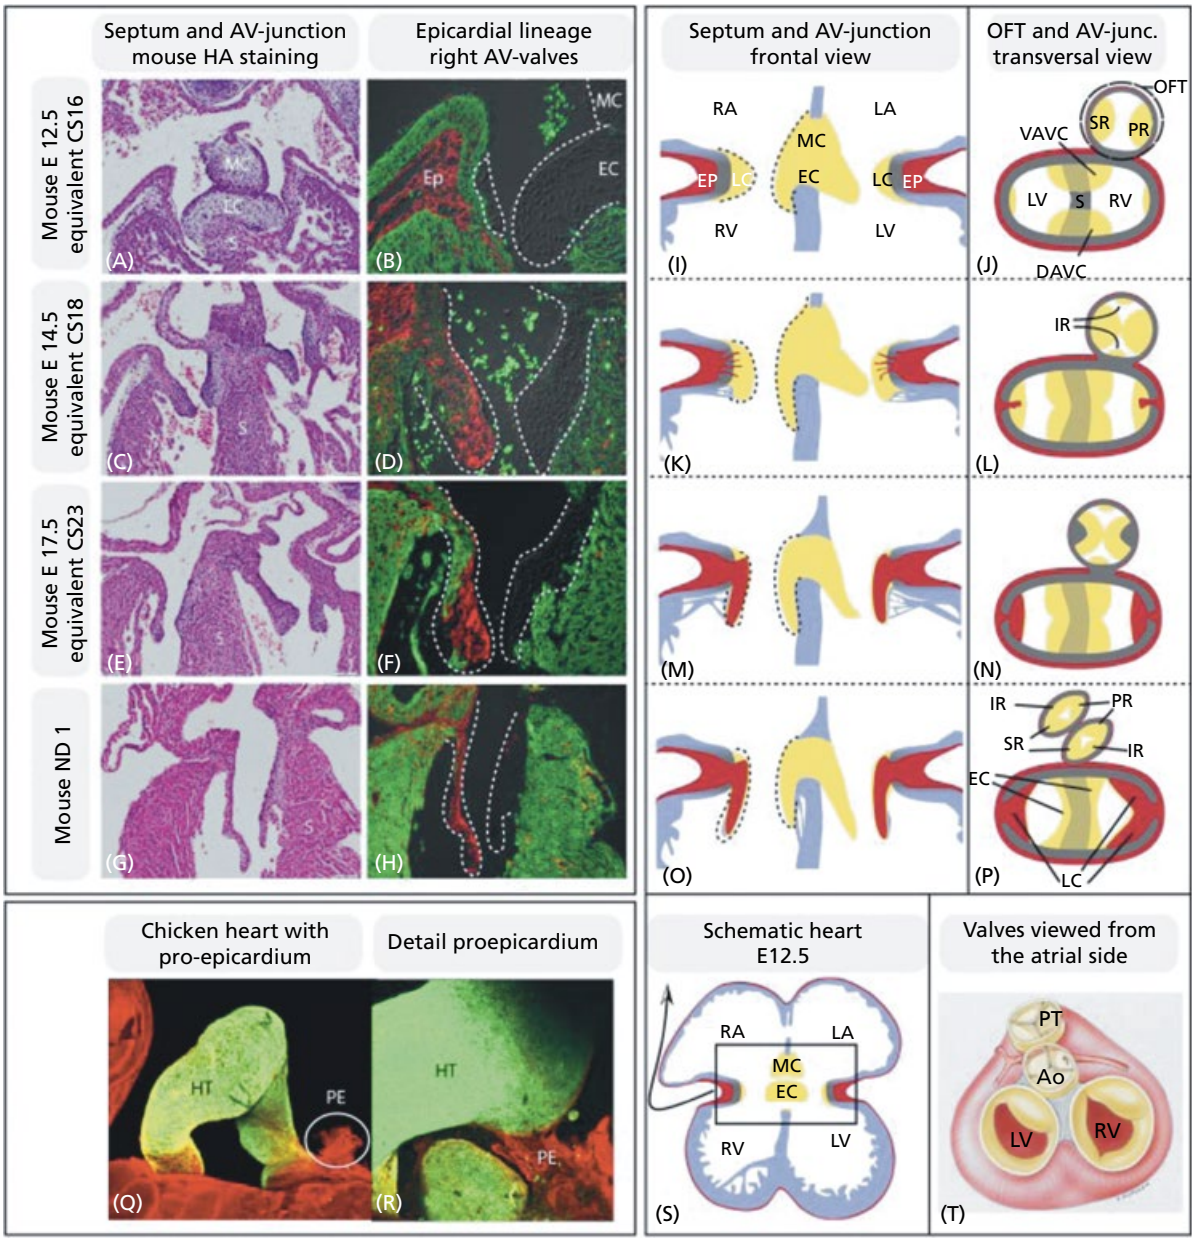

Figure 5.10 Development of the atrioventricular (AV) and outflow tract (OFT) valves and their contributing tissues. (A–H) Sections through mouse hearts in a plane comparable to the schematic heart in (S). (B, D, F, and H) The lineage contributions of the epicardium are displayed at different developmental stages. The epicardial lineage marker WT1 was used; epicardial lineage is depicted in red, myocardium in green. (I–P) Schematic drawings of valve development in both the atrioventricular canal and outflow tract. Red, epicardium (Ep); gray, primary myocardium; and yellow, endocardial cushion tissue (EC). Note that in the outflow tract the cells are primarily neural crest derived and not endocardial derived as in the atrioventricular canal. (P) The contribution of the different cushions and ridges to the eventual valves (T) is depicted. (Q and R) The proepicardium (PE) in a 3-day-old chick embryo. (R) The PE is attached to the heart tube (HT) and spreading out to form the epicardium. and posteriorly so that it comes to lie directly over the LV and in fibrous continuity with the MV [53]. The transition from the primitive, single in-series circulation to the double in-series circulation begins during the fifth week of development.

After outflow tract septation, the semilunar valves are formed as the mesenchyme in the outflow cushions is remodeled into the trileaflet aortic and pulmonary valves. Cells from the endocardium are the primary source of semilunar and AV valve fibroblasts, but fibroblasts derived from the epicardium also contribute to valve formation [50]. Although neural crest cells are found in the tips of the leaflets, their contribution to valve formation is not completely understood.

Abnormalities of outflow tract septation

The loss or dysfunction of cardiac neural crest cells produces a wide spectrum of conotruncal abnormalities that are associated with syndromes linking defects in the heart, face, thymus, parathyroids, and brain [49,51]. These include 22q11 deletion syndromes, such as DiGeorge and velocardiofacial syndromes, CHARGE syndrome, fetal alcohol syndrome,

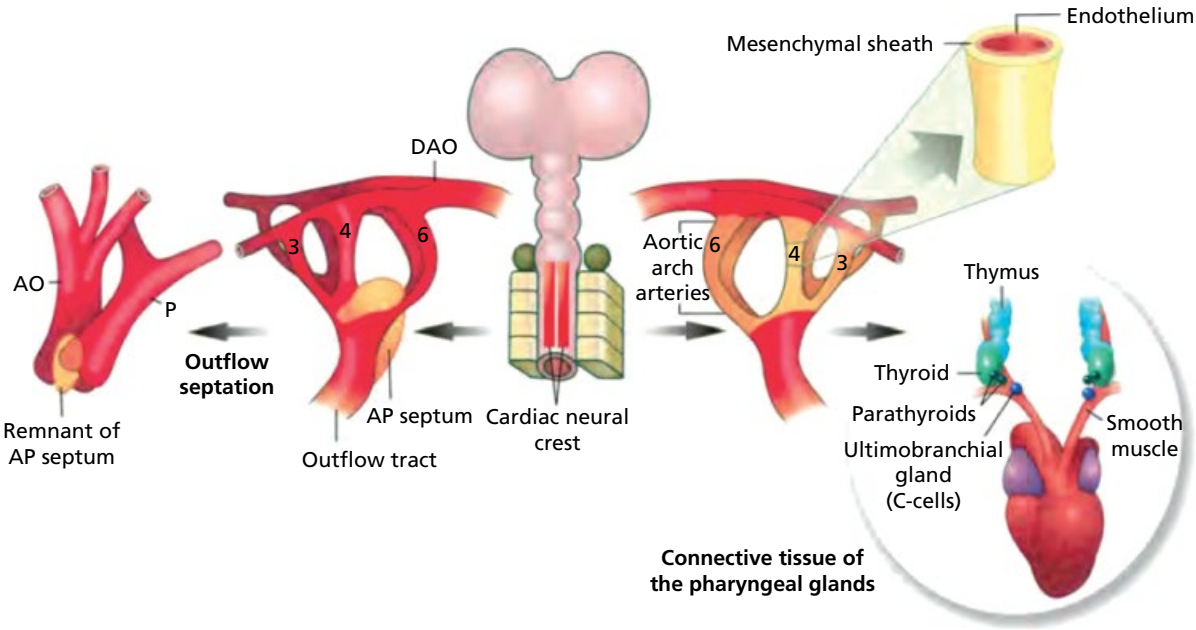

Figure 5.11 Derivatives of the cardiac neural crest cells. Cardiac neural crest cells support development of and patterning of the persisting aortic arch arteries into the great arteries of the thorax and form smooth muscle tunics. In addition, the cells contribute to the development of the thymus, parathyroids, and thyroid glands, and provide stromal cells after gland development. *Source:* Reproduced from Keyte and Hutson [49] with permission of Elsevier.

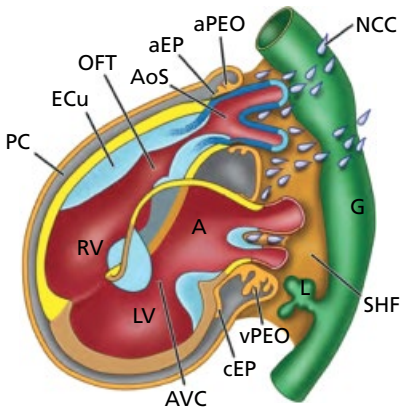

Figure 5.12 Schematic representation of the looped heart tube. The second heart field (SHF: ocher) has contributed new myocardium (yellow) to the right ventricle (RV) and the atrium (A). The first heart field derived myocardium of the left ventricle (LV) and atrioventricular canal (AVC) is brown. Neural crest cells (NCC) mainly contribute a population to the arterial pole including the wall of the aortic sac (AoS) and the endocardial cushions (ECu) of the outflow tract (OFT). At the venous pole also some NCCs are found in the area of the AVC endocardial cushions. In the pericardial cavity (PC) a proepicardial organ protrudes at the venous pole (vPEO) as well as a homologous organ at the arterial pole (aPEO). Arterial epicardium (aEP) spreads over the AoS while the epicardium from the venous pole will eventually cover the complete cardiac myocardium (cEP). Figure 5.13 Steps in aortic wedging. The aortic side of the outflow tract nestles between the mitral and tricuspid valves as the outflow myocardium is remodeled. AVC, atrioventricular canal. *Source:* Reproduced from Kirby [34] with permission of Oxford University Press.

retinoic acid embryopathy, Alagille syndrome, Noonan, and LEOPARD syndromes [49].

Persistent truncus arteriosus results from failure in outflow tract septation (conotruncus and aorticopulmonary septum) combined with the absence of the subpulmonary infundibulum and, thus, a VSD [54]. In this defect, the aortic and pulmonary valves are fused forming a single semilunar truncal valve. The pulmonary arteries (PAs) originate from the truncal root in variable fashion, dependent on the extent of the septation deficiency. An *aortopulmonary window* is the result of incomplete outflow tract septation. An *aortoventricular tunnel* is thought to be due to abnormal excavation and maturation of the outflow cushions during the formation of the semilunar valves [52]. *Aorta or PA hypoplasia* can result from unequal outflow tract septation.

Tetralogy of Fallot is thought to result from underdevelopment of the subpulmonary infundibulum (conus) [55]. The smaller infundibulum causes anterior deviation of the conal septum and malalignment between the conal and muscular septa. This leads to RV outflow tract obstruction and a subaortic VSD [56]. The PV is usually abnormal, and the reduced blood flow contributes to PA underdevelopment. Variants of tetralogy include *pulmonary atresia* associated with varying degrees of PA hypoplasia.

Transposition of the great arteries (TGA) is thought to be the result, among other theories, of either resorption of the subpulmonary conus, causing the PV to move inferiorly and posteriorly to lie above the LV [57], or failure of spiraling of the aorticopulmonary septum [58]. In D-TGA, the most common form of transposition, there is AV concordance and VA discordance. *Congenitally or physiologically corrected transposition of the great arteries* is characterized by TGA and AV discordance (i.e. double discordance). The malformation is also referred to as L-transposition, as in most cases it is characterized by L-looping of the heart with levocardia and situs solitus of the atria.

Double outlet RV is associated with persistence of both the subpulmonary and subaortic coni, whereas *double outlet LV* (very rare) is linked to a deficiency of both. A VSD is almost always present in these anomalies.

Pulmonary valve stenosis in most cases is characterized by fused or absent valve commissures. *Critical pulmonary stenosis* in the neonate is a ductal-dependent lesion because pulmonary blood flow relies on patency of the ductus arteriosus (PDA).

Obstruction of the LV outflow tract can also occur at the valvar, subvalvar, or supravalvar levels. The most common AoV anomaly is a *bicuspid AoV*, which is the most common congenital cardiac defect (occurring in 1–2% of the population) [1]. There are several phenotypes, the most prevalent being characterized by commissural fusion. *Critical AoV stenosis* in the neonate is a ductal-dependent lesion in that a PDA is necessary to provide systemic blood flow. The AoV usually exhibits dysplastic features and may be unicommissural or bicommissural, with thickened, redundant, and rolled edges and leaflets [59]. *Severe aortic stenosis* or *aortic atresia* can be part of a spectrum of left-sided obstructive lesions associated with hypoplasia of the LV, ascending aorta, and/or aortic arch, MV stenosis or atresia, and endocardial fibroelastosis of the LV (i.e. hypoplastic left heart syndrome) [60].

Subvalvar aortic stenosis has several embryological etiologies. *Malalignment* of the conal septum posteriorly relative to the muscular septum can result in LV outflow tract obstruction. This pathology along with a VSD can be seen in an *interrupted aortic arch*. *Familial hypertrophic cardiomyopathy* is an autosomal dominant disorder most commonly resulting from mutations in the contractile protein genes [61]. A discrete *subaortic fibromuscular ridge or membrane* can also cause subaortic stenosis.

Congenital supravalvar aortic stenosis (SVAS) is associated with deletions of or a loss of function in the elastin gene (chromosome 7). In the majority of cases, SVAS occurs in association with Williams-Beuren or Williams syndrome [62,63]. This condition is frequently characterized by developmental disabilities, elfin facies, distinctive behavioral traits, and neonatal hypocalcemia. Non-syndromic SVAS can also be inherited as an autosomal dominant disorder or can result from sporadic mutations [64]. The arterial media in these children has a reduced elastin content, pathological alignment of the elastin fibers, increased collagen content, and an increased number of hypertrophied smooth muscle cells. The clinical manifestations can also be the result of the arteriopathy that can involve the aorta, renal, and/or pulmonary arteries.

KEY POINTS: CARDIAC SEPTATION

- Cardiac septation begins after looping with the eventual creation of four chambers and two distinct circulations
- The process of cardiac septation involves the muscular septa in the atrial and ventricular chambers, the AV and outflow tract endocardial cushions, and the dorsal mesenchymal protrusion.
- Abnormalities in cardiac septation can result in defects at the atrial and/or ventricular levels, altered AV valve development, abnormalities of outflow tracts, and semilunar valve pathology

Development of the endocardium

Endocardial cells develop from a pre-specified or multipotent population of cardiac progenitor cells that undergo vasculogenesis during cardiac tube formation. Morphologically, these specialized endothelial cells line the inner myocardium and connect with the vascular network [65]. Epithelial to mesenchymal transformation of endocardial cells overlying the AV and outflow tract cushions is essential for formation of the cardiac valves and for completion of cardiac septation [66]. Endocardial cells also sense hemodynamic forces induced by blood flow (shear stress) and radial wall stretching and contraction (mechanical stress) that via mechanosensitive pathways contribute to cardiac morphogenesis and physiology [65]. Endocardial progenitor cells also contribute to the development of coronary arteries and veins [67]. Finally, some endocardial cells constitute a stem cell niche and angiocrine signaling center that contribute to cardiac repair and regeneration [68].

Development of the epicardium and coronary arteries

The epicardium develops after looping to invest the heart and roots of the great arteries. In the pericardial cavity, a *proepicardial organ* (PEO) derived from splanchnic mesoderm of the ventral pharynx protrudes at the venous pole (vPEO) and arterial pole (aPEO) (see Fig. 5.12) [26,69]. The epicardium originating from the vPEO will cover the atria, AVC, and ventricles, and that from the aPEO will cover the outflow tract. Gittenberger-de Groot and colleagues have shown that after the epicardium has invested the myocardium, a subset of cells undergoes epithelial-to-mesenchymal transformation and migrates into the subepicardial space [70]. These epicardially derived cells (EPDCs) invade the myocardium and endocardial cushions and differentiate into fibroblasts, coronary smooth muscle cells, and endothelial and hematopoietic cells. The epicardially-derived fibroblasts become the interstitial fibroblasts, the annulus fibrosus, and the adventitial coronary fibroblasts. The epicardium is necessary for myocardial growth, and interstitial fibroblasts are crucial to the formation of the thick compact myocardium.

Nutrient delivery to the myocardium occurs in three sequential and overlapping phases [46]. Although the early myocardium is avascular, the inner trabecular zone of the myocardial wall has venous sinusoids (trabecular channels) lined by endocardium through which nutrients diffuse. The coronary vessels are derived from the epicardium, sinus

venosus, and endocardium. With the formation of the epicardium, a subepicardial endothelial plexus forms from the EPDCs and undergoes vasculogenesis, angiogenesis, and arteriogenesis (coating of the initial coronary plexus by smooth muscle cells and pericytes) [71]. The contribution of the epicardium to coronary vessel development is smaller than was previously proposed [72]. Venous endothelial cells of the sinus venosus sprout, dedifferentiate, and migrate to the subepicardial space on the dorsal side of the heart [67,73]. These cells then penetrate the myocardial wall and differentiate into arterial and venous endothelial cells. On the ventral side of the heart and ventricular septum, endocardial endothelial cells give rise to the coronary plexus. Some channels of the coronary plexus will communicate with the intertrabecular venous sinusoids. The density of the coronary plexus is not uniform across the myocardial wall, being higher on the outer epicardial than on the inner endocardial side [69]. The subepicardial vascular network later undergoes remodeling to produce the coronary arteries and veins with adult branching characteristics. The final step in the development of the coronary circulation is ingrowth of the peritruncal coronary capillary plexus into the base of the aorta (Fig. 5.14) [71,74]. Each coronary sinus has an ostium, which receives multiple small vessels. In the right and left aortic sinuses, the multiple channels coalesce to form the main stems of the right and left coronary arteries, whereas the channels in the remaining (non-coronary) sinus regress.

Abnormalities of epicardial development and the coronary arteries

Normal development of the compact myocardium requires a trophic interaction between the cardiomyocytes and EPDCs [26,75]. *Ventricular non-compaction,* a cardiomyopathy characterized by a spongy myocardium with a predilection for the LV, is the result of abnormal EPDC function.

Coronary artery fistulae may arise from the coronary arteries and frequently terminate in the right heart. Fistulae can occur in isolation or in association with other lesions. Flow into a lower pressure chamber can produce ventricular volume overload and myocardial ischemia (coronary steal).

Anomalous origin of the left coronary artery from the pulmonary artery (ALCAPA) results from penetration of vascular channels from the peritruncal ring into the PA instead of the aortic sinuses [76]. In this setting, coronary steal can occur, in which the direction of blood flow is reversed in the anomalous vessel because of drainage into the lower vascular resistance and pressure of the PA and/or the higher pressure of a collateral coronary circulation from the normal right coronary artery.

Anomalous aortic origin of a coronary artery from the opposite sinus of Valsalva and *congenital atresia of the left coronary artery* are relatively rare anomalies, but have been associated with sudden death [76].

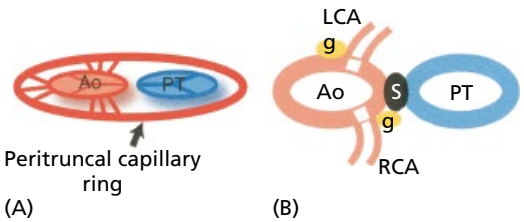

Figure 5.14 Left (LCA) and right (RCA) coronary artery development. (A) Multiple channels penetrate the aortic (Ao) wall in all of the aortic sinuses from the peritruncal ring. (B) Only the ones in the right and left sinuses survive and coalesce to form the main stems of the LCA and RCA. KEY POINTS: EPICARDIUM AND CORONARY ARTERY DEVELOPMENT

- The coronary vessels are derived from the epicardium, sinus venosus, and endocardium
- The development of the coronary circulation involves various steps, culminating in ingrowth of the peritruncal coronary capillary plexus into the base of the aorta
- Abnormal epicardial development can result in certain types of cardiomyopathies and coronary artery anomalies

Development of the conduction system

The primitive cardiac pacemaker is located at the junction of the sinus venosus and the primitive atrium. Prior to valve formation, a unidirectional, slowly transmitted, depolarizing wave generates a peristaltic contraction that allows the blood to move in the heart tube from the venous pole to the arterial pole. With elongation of the heart tube, the myocardial cells differentiate into a *working* myocardial phenotype characterized by fast-conducting gap junctions, well-developed sarcomere components, and low automaticity [77]. Myocardial cells at the venous pole, AVC, and outflow tract differentiate into specialized *conductive* myocardium with high automaticity, poorly developed sarcomeres, and slow transmission. With differentiation of myocytes into working and conductive myocardium, the electrocardiogram resembles that of the formed heart [78].

The *sinoatrial node* (SAN), detectable at approximately 32 days of gestation, develops from myocardial cells located at the junction of the right common cardinal vein and the RA [79]. The *atrioventricular node* (AVN), detectable at approximately 33 days of gestation, develops from slow-conducting myocardium within the AVC, and retains its primary phenotype of slow conduction. The *AV bundle, left and right bundle branches*, and *Purkinje fibers* develop from fast-conducting ventricular myocardium. The AV conduction system provides the only myocardial continuity between the atria and ventricles.

Abnormalities of the conduction system

Normal development of the conduction system is dependent upon a concordant relation between the atrial and ventricular chambers, correct alignment of the atrial and ventricular septa, and complete closure of the ventricular septum [80]. Anomalies known to be or that can be associated with an abnormal location of the conduction system, and therefore potential vulnerability, include corrected TGA, AVC defects, perimembranous VSDs, and single ventricles.

Accessory pathways are bundles of cardiomyocytes that electrically connect the atria and ventricles, providing the substrate for supraventricular arrhythmias (e.g. Wolff-Parkinson-White

syndrome) [81]. Ebstein anomaly is frequently associated with Wolff-Parkinson-White syndrome and other accessory connections.

Atrial conduction disturbances and arrhythmias are frequently related to sinus venosus myocardium and, thus, tend to take place at specific anatomical sites [81]. The structure of the AVN is complex and in many normal hearts it provides the substrate for dual AVN physiology (two pathways with different electrophysiological characteristics) and *AV nodal reentry tachycardia*.

At the molecular level, gene mutations that affect ion channels give rise to the *cardiac channelopathies*; the most important of these are long QT syndrome, Brugada syndrome, catecholaminergic polymorphic ventricular tachycardia, and short QT syndrome [82].

KEY POINTS: DEVELOPMENT OF THE CONDUCTION SYSTEM

- The primitive cardiac pacemaker is located at the junction of the sinus venosus and the primitive atrium
- The AV node retains its primary phenotype of slow conduction allowing for appropriate AV delay, whereas the AV bundle, left and right bundle branches, and Purkinje fibers develop from fast-conducting ventricular myocardium
- Abnormalities of the conduction system are expected in defects that alter AV concordance, proper alignment of the atrial and ventricular septa, and complete closure of the ventricular septum

Development of the aortic arches

The dorsal aortae are bilateral, parallel channels that form in the mesoderm on either side of the notochord, adjacent to the ventral pharyngeal endoderm. The aortic sac is connected to the paired dorsal aortae by the artery of each pharyngeal arch, referred to as the pharyngeal arch arteries (PAAs) or the aortic arch arteries [15]. Cardiac neural crest cells migrate into the mesoderm of the pharyngeal arches and surround the endothelial cells to form the smooth muscle of the PAAs [25,83–85]. The PAAs form over time in a symmetrical pattern cranially to caudally. The neural crest cells are critical for remodeling, whereby some segments of the aortic arch apparatus and dorsal aortae regress, whereas other segments transform and persist to produce the mature asymmetrical pattern (Fig. 5.15).

The dorsal aortae fuse, starting caudally, up to the seventh somite. The seventh somite is supplied by the seventh intersegmental artery, which forms the left subclavian artery and contributes to formation of the right subclavian artery. The dorsal aortae give off dorsal intersegmental arteries, which supply the spinal cord and developing somites. Longitudinal anastomoses form between the intersegmental arteries, with those from the first to the seventh forming the vertebral artery. The first six intersegmental arteries regress after the vertebral artery is formed, and the vertebral artery arises from the seventh intersegmental artery.

Abnormalities of the aortic arches

Abnormalities of the aortic arch can be regarded as variations in regression of segments in the primitive double aortic arch as explained using Edwards' hypothetical double aortic arch model (Fig. 5.16) [86]. The aortic arch is referred to as left- or right-sided to indicate which mainstem bronchus is crossed by the arch [87]. The normal left aortic arch (LAA) results from regression of the segment of the right aortic arch between the right subclavian artery and the descending aorta. Conversely, a *right aortic arch (RAA) with mirror-image branching* occurs when the left aortic arch regresses between the left subclavian artery and the descending aorta. An RAA with mirror-image branching is frequently associated with CHD. An *LAA with an aberrant right subclavian artery* arises from regression of the segment between the right subclavian and right carotid arteries, whereas regression of the segment between the left carotid and left subclavian arteries results in an *RAA with an aberrant left subclavian artery*. A *double aortic arch* results from the persistence of both fourth aortic arches. An *interrupted aortic arch* (IAA) is considered to be due to the regression of both the right and left fourth aortic arches. The most common type of IAA is type B, in which there is interruption between the left carotid and left subclavian arteries and normal regression of the RAA. In a *vascular ring* the trachea and esophagus are completely encircled by vascular structures, which may be patent or consist of fibrous remnants such as the ligamentum arteriosum. When the trachea and esophagus are not completely encircled, the abnormality is referred to as a *vascular sling*. Aortic arch anomalies can result in tracheobronchial and/or esophageal compression. A PA sling, in which the left PA arises from the right PA and passes to the left between the trachea and esophagus, can be associated with airway malformations [88].

Coarctation of the aorta is an obstructive pathology to systemic blood flow that may take the form of a focal narrowing of the descending aorta opposite to the insertion of the ductus arteriosus (juxtaductal) or tubular arch hypoplasia. The malformation is thought to be due to ductal tissue extending into the wall of the aorta and/or an abnormal blood flow pattern in the presence of associated anomalies that lead to decreased flow into the ascending aorta.

Isolated *patent ductus arteriosus* in full-term infants is most likely a malformation with a genetic origin, with the persistent vascular structure having different histological features than the normal ductus arteriosus [89]. A PDA may occur in isolation, particularly with prematurity, or in association with almost any congenital cardiac anomaly. It is required for survival in some forms of CHD.

KEY POINTS: DEVELOPMENT OF THE AORTIC ARCHES

- The initial pattern of the aortic arches becomes modified throughout development allowing for the definitive vascular pattern present at birth
- Neural crest cells play a critical role in the development of the aortic arches
- Abnormalities of the aortic arch occur when segments of the primitive double aortic arch fail to regress or regression occurs at an abnormal site

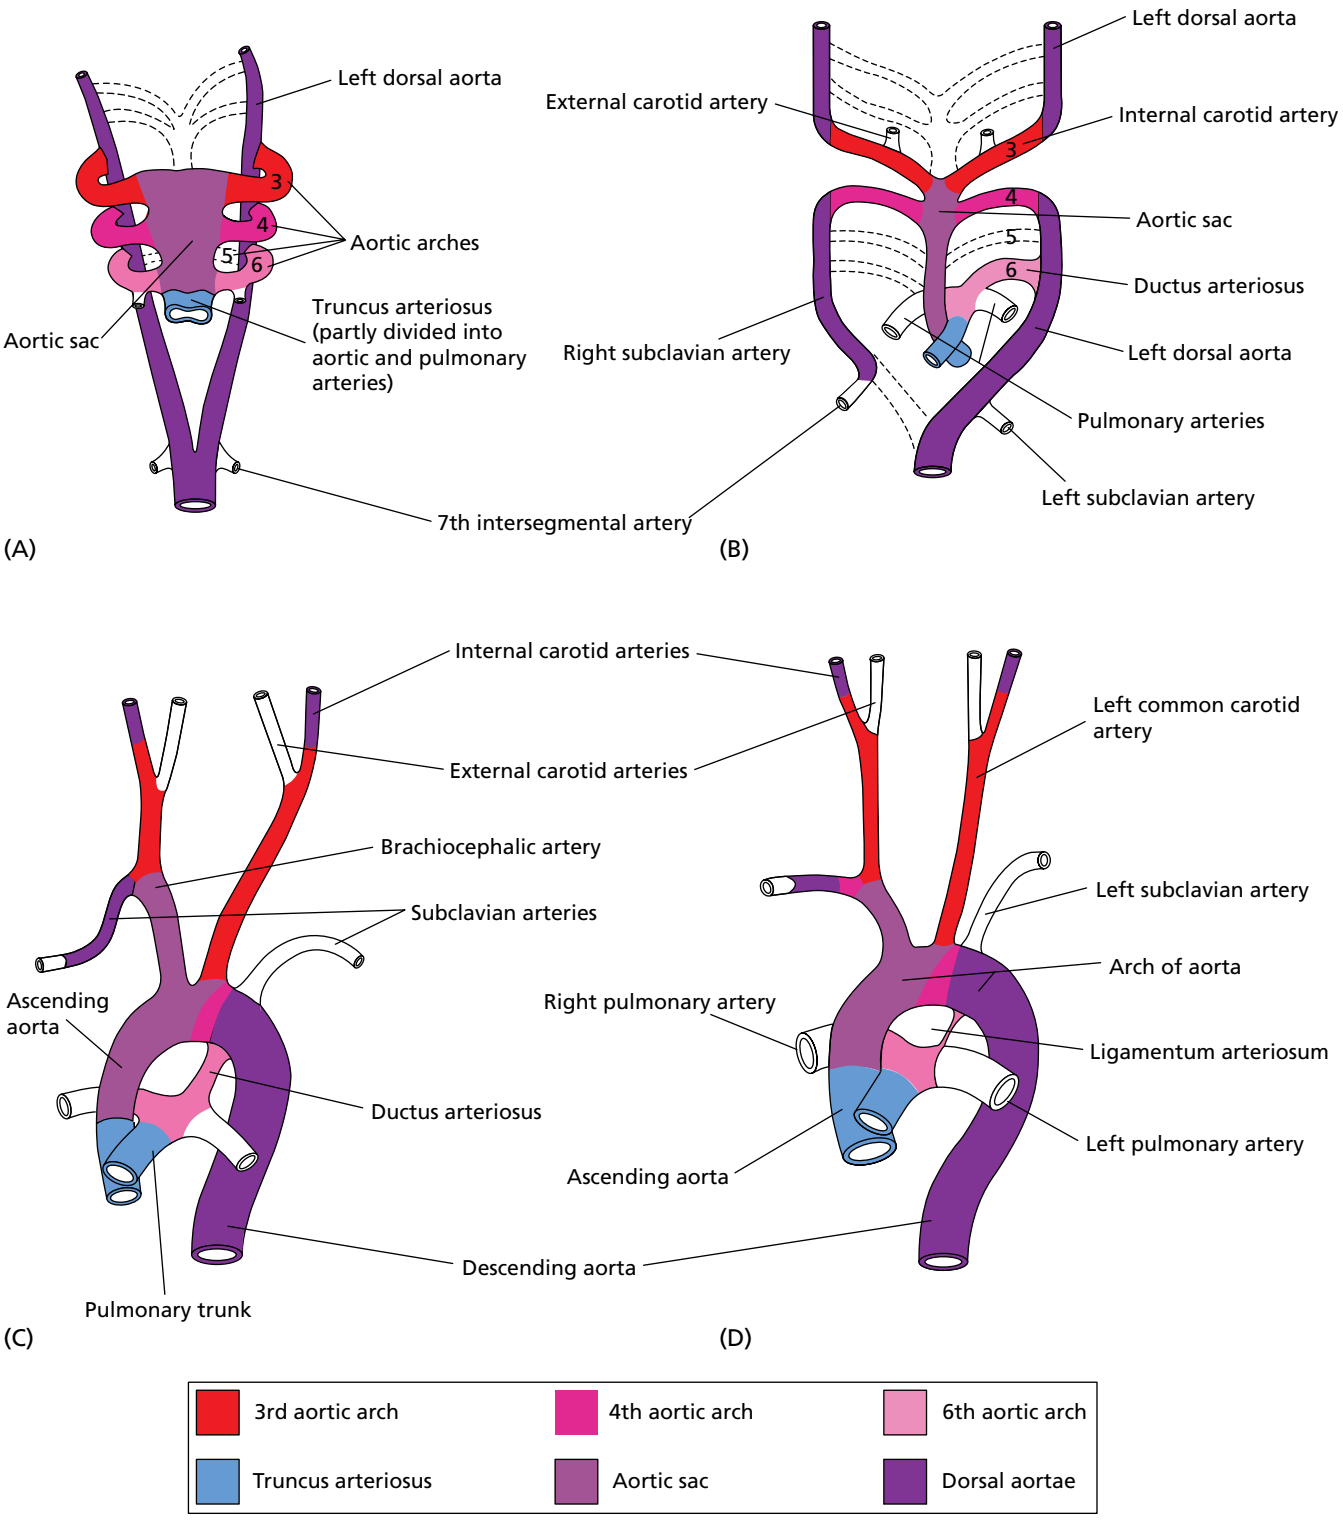

Figure 5.15 Schematic drawings illustrating the arterial changes that result during transformation of the truncus arteriosus, aortic sac, pharyngeal arch arteries, and dorsal aortae into the adult arterial pattern. The vessels that are not colored are not derived from these structures. (A) Pharyngeal arch arteries at 6 weeks; by this stage, the first two pairs of arteries have largely disappeared. (B) Pharyngeal arch arteries at 7 weeks; the parts of the dorsal aortae and pharyngeal arch arteries that normally disappear are indicated with *broken lines*. (C) Arterial arrangement at 8 weeks. (D) Sketch of the arterial vessels of a 6-month-old infant. Note that the ascending aorta and pulmonary arteries are considerably smaller in (C) than in (D). This represents the relative flow through these vessels at the different stages of development. Observe the large size of the ductus arteriosus in (C) and that it is essentially a direct continuation of the pulmonary trunk. The ductus arteriosus normally becomes functionally closed within the first few days after birth. Eventually the ductus arteriosus becomes the ligamentum arteriosum, as shown in (D). *Source:* Reproduced from Moore et al [115] with permission of Elsevier.

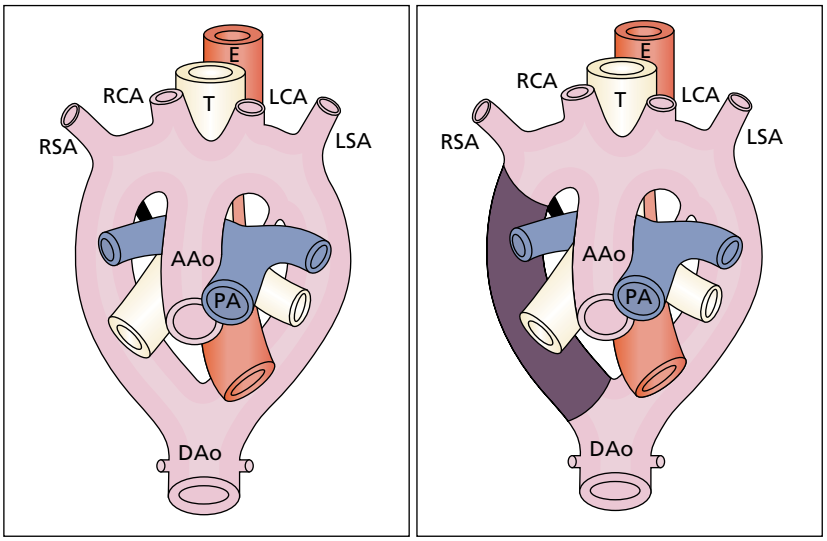

Figure 5.16 Diagram of Edwards' developmental model of the aortic arch. (A) Hypothetical double aortic arch system in which there is an aortic arch and ductus arteriosus on each side encircling the trachea (T) and esophagus (E), with the carotid and subclavian arteries arising bilaterally from the respective arches. The descending aorta is in the midline. (B) Normal arch branching results from interruption of the dorsal segment of the right arch between the right subclavian artery and descending aorta with regression of the right ductus arteriosus. AAo, ascending aorta; DAo, descending aorta; LCA, left carotid artery; LSA, left subclavian artery; PA, pulmonary artery; RCA, right carotid artery; RSA, right subclavian artery. *Source:* Reproduced from Türkvatan A, Büyükbayraktar F.G, Ölçer T, and Cumhur T. Development of the pulmonary and systemic veins

Pulmonary veins

The tracheobronchial tree and lungs develop from a ventral outgrowth from the foregut referred to as the respiratory diverticulum. Early in development, the lungs have the same venous drainage as the foregut, namely via the splanchnic plexus into the cardinal and umbilicovitelline (systemic) veins (Fig. 5.17).

The primary pulmonary vein develops by canalization within the dorsal mesocardium to form a channel [36]. Further canalization of the primary pulmonary vein brings it into continuity with developing LA, and by the end of the first month of gestation the primary pulmonary vein has established a connection between the pulmonary venous plexus of the lung bud and the sinoatrial portion of the heart. Once this occurs, the pulmonary venous plexus loses its connections with the systemic veins; thereafter the common pulmonary vein incorporates into the LA so that the individual pulmonary veins connect separately and directly to the LA.

Abnormalities of the pulmonary veins

Total anomalous pulmonary venous connection (TAPVC) results from a failure to establish the normal connection between the common pulmonary vein and the pulmonary venous plexus before the connections with the splanchnic venous system regress. In most cases, all the pulmonary veins join a confluence behind the LA, which can drain via the supracardiac, cardiac, or infracardiac (infradiaphragmatic) route into the right heart circulation. *Partial anomalous pulmonary venous connection* (PAPVC) results from atresia of only the right or left portions of the common pulmonary vein before regression of connections with the splanchnic venous system, leading to drainage into derivatives of the left or right cardinal systems. Both TAPVC and PAPVC produce a left-to-right shunt and can be associated with pulmonary venous obstruction. Pulmonary veins can also be *hypoplastic* or *atretic*, with the most common variation in the number of pulmonary veins being a *single pulmonary vein* on either the right or left side [90]. *Cor triatriatum* is an oblique fibromuscular membrane that divides the LA into two chambers: a posterosuperior chamber that receives the pulmonary veins, and an anteroinferior chamber that communicates with the MV and LA appendage [91]. The malformation is thought to arise from incomplete incorporation of the common pulmonary vein into the primitive LA. *Sinus venosus atrial septal defects* are associated with drainage of some, and less frequently, of all the right pulmonary veins into the right superior vena cava or RA with normal connection of the pulmonary veins to the LA (superior vena cava type defect). In rare cases, the defect is by the entrance of the inferior vena cava (inferior vena cava type defect) and the right pulmonary veins drain near this region. Congenital *pulmonary vein stenosis* typically occurs at the pulmonary vein–LA junction but can be progressive in its length, degree of stenosis, and number of pulmonary veins affected. The basis for this anomaly appears to be abnormal incorporation of the common pulmonary vein into the LA [92].

KEY POINTS: DEVELOPMENT OF THE PULMONARY VEINS

- The lungs and tracheobronchial tree develop from a ventral outgrowth of the foregut
- Establishment of a normal connection between the primary pulmonary vein and the left atrium is associated with the loss of the initial connection of the pulmonary venous plexus to the systemic veins
- Abnormalities of pulmonary vein development result from failure of normal connections between rudimentary pulmonary venous structures to be established before the connections with the splanchnic venous system regress

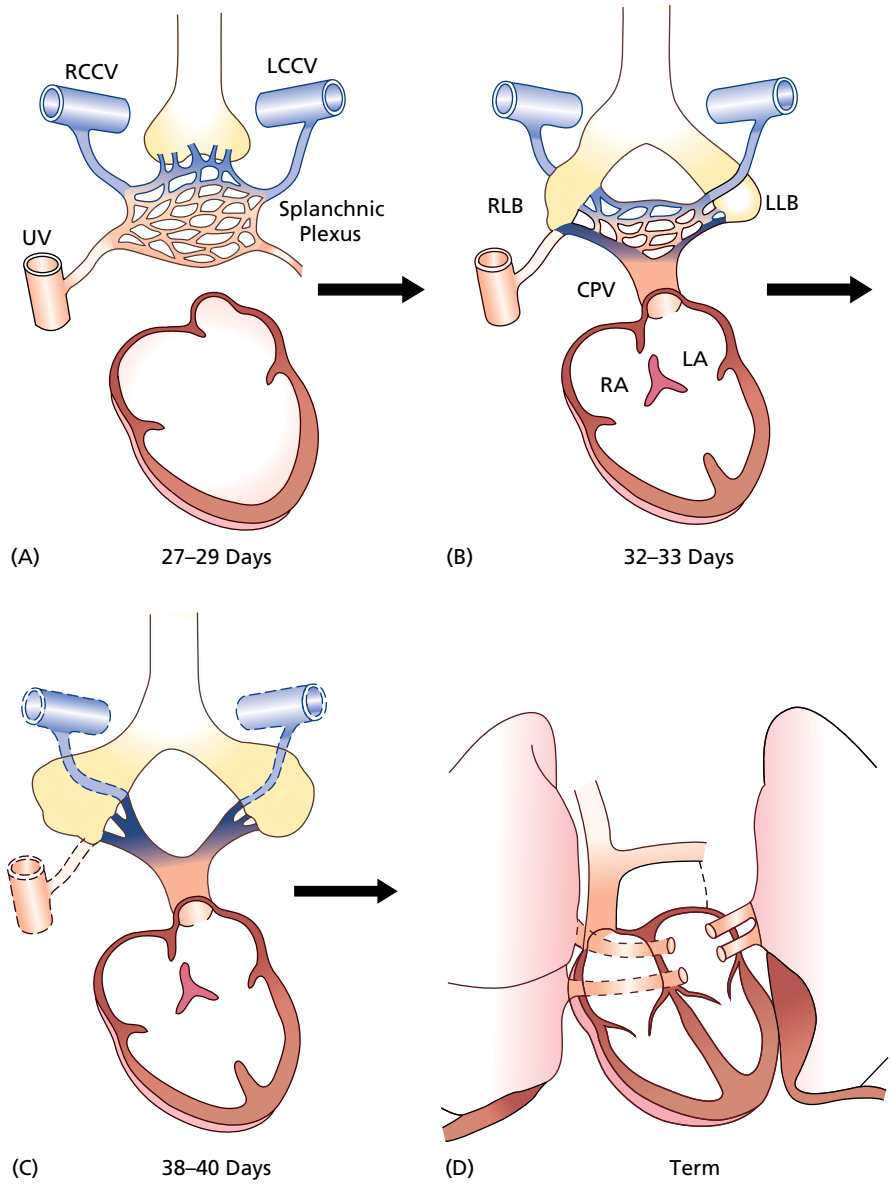

Figure 5.17 Development of the pulmonary veins. (A) At 27–29 days of gestation, the primordial lung buds are enmeshed by the vascular plexus of the foregut (splanchnic plexus). At this stage, there is no direct connection to the heart. Instead, there are multiple connections to the umbilicovitelline and cardinal venous systems. A small evagination can be seen in the posterior wall of the left atrium to the left of the developing septum secundum. (B) By the end of the first month of gestation, the common pulmonary vein establishes a connection between the pulmonary venous plexus and the sinoatrial portion of the heart. At this time, the connections between the pulmonary venous plexus and the splanchnic venous plexus are still patent. (C) Next, the connections between the pulmonary venous plexus and the splanchnic venous plexus involute. (D) The common pulmonary vein (CPV) incorporates into the left atrium, so that the individual pulmonary veins connect separately and directly to the left atrium. LA, left atrium; LCCV, left common cardinal vein; LLB, left lung bud; RA, right atrium; RCCV, right common cardinal vein; RLB, right lung bud; UV, umbilical vein. *Source:* Reproduced from Brown and Geva [92] with permission of Wolters Kluwer.

Systemic veins

By the end of the fourth week of development, the primitive venous system consists of three bilaterally symmetrical systems that each drain into the right and left horns of the sinus venosus: the *vitelline* veins, the *umbilical* veins, and the *cardinal* veins. The vitelline veins drain the yolk sac and gastrointestinal derivatives, and develop into the portal system; the *umbilical* veins, which carry oxygenated blood from the placenta, regress during the second month of gestation (right) and after birth (left); and the *cardinal* veins, which drain the head, neck, and body wall, develop into the caval system (Fig. 5.18). The shift of the systemic venous return to the RA is associated with regression and remodeling to yield the adult asymmetrical venous pattern (Fig. 5.19) [93].

Abnormalities of systemic veins

The complex development of the venous system results in a wide spectrum of systemic venous anomalies [94]. A *persistent left superior vena cava* (LSVC) results from failure of the left anterior and left common cardinal veins to regress. It may be found in association with a right SVC (*bilateral SVCs*) or may be the only SVC if the right anterior and right common cardinal veins have regressed. In the majority of cases, an LSVC will drain via the coronary sinus into the RA, but in other

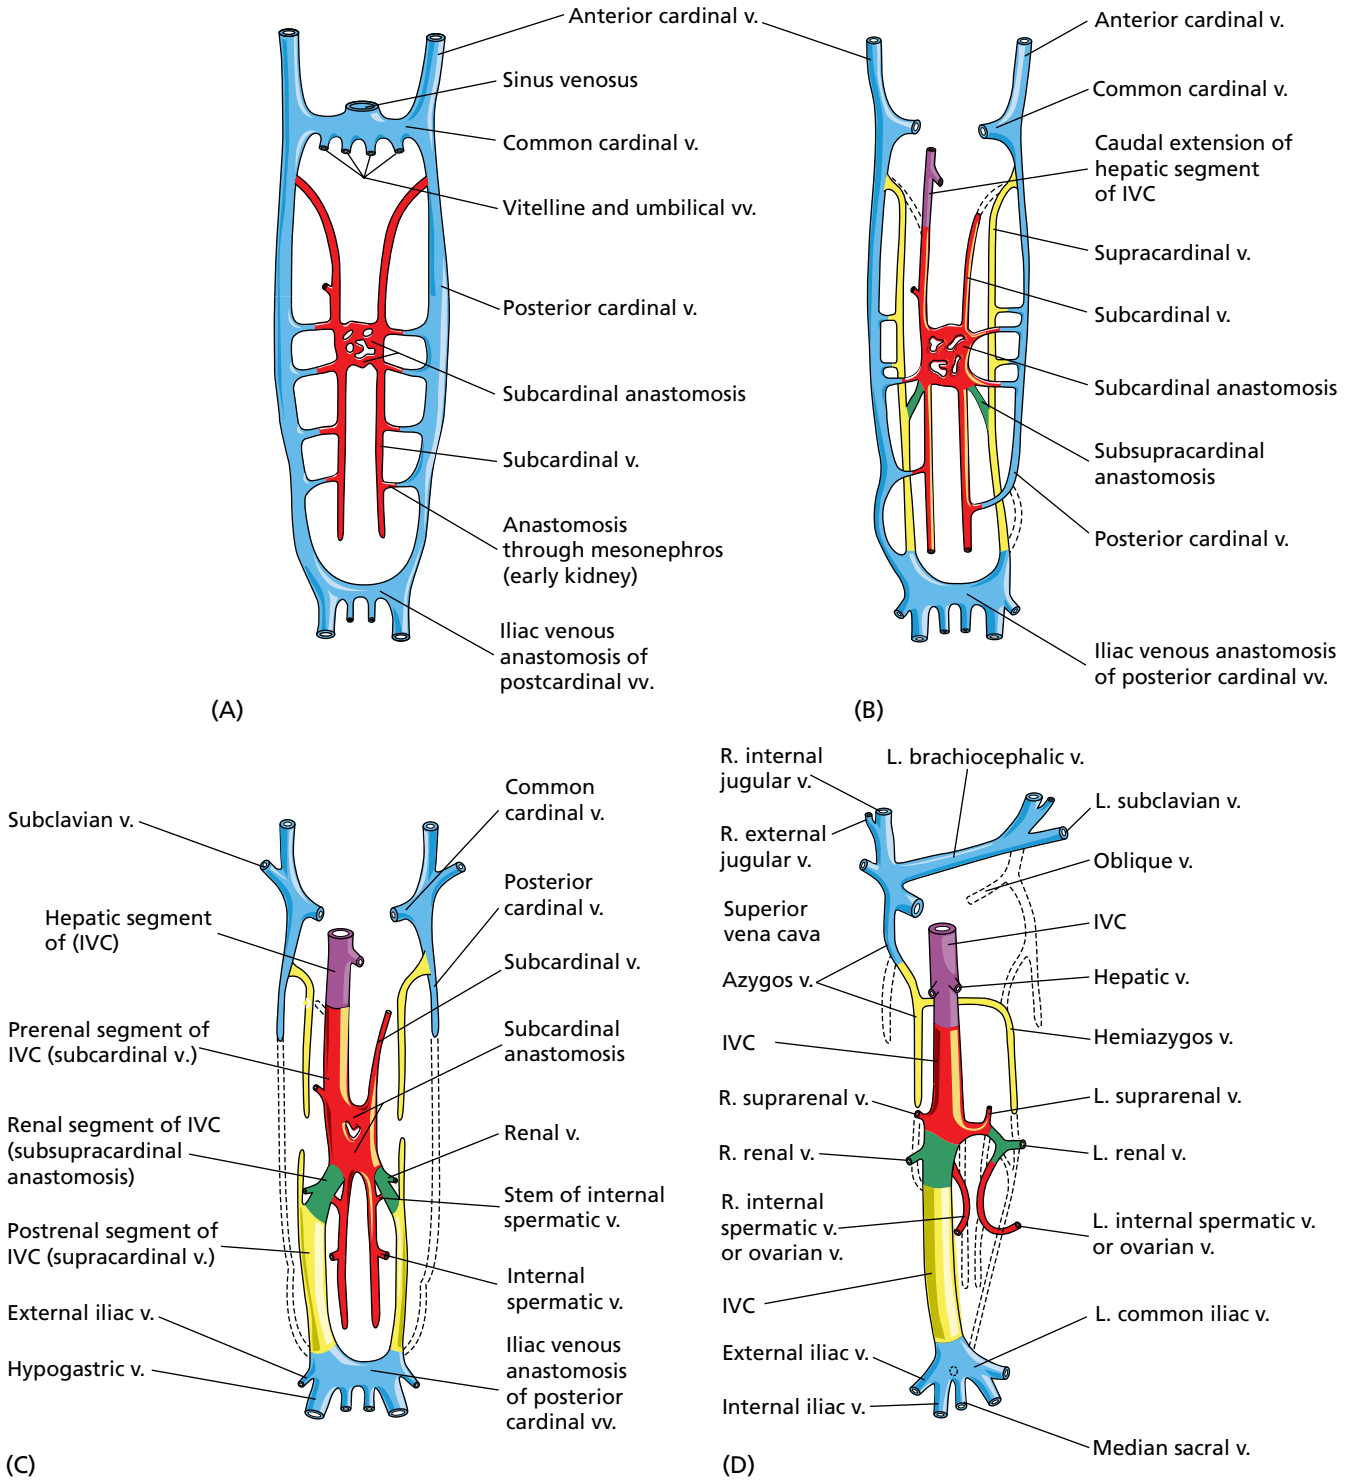

Figure 5.18 Illustrations of the primordial veins of bodies (trunks) of embryos (ventral views). Initially, three systems of veins are present: the umbilical veins from the chorion, vitelline veins from the umbilical vesicle, and cardinal veins from the body of the embryos. Next the subcardinal veins appear, and finally the supracardinal veins develop. (A) At 6 weeks. (B) At 7 weeks. (C) At 8 weeks. (D) Adult. This drawing illustrates the transformations that produce the adult venous pattern. Figure 5.19 Development of the venous system. Dorsal views of the developing heart. (A) During the fourth week (approximately 24 days), showing the primordial atrium and sinus venosus and the veins draining into them. (B) At 7 weeks, showing the enlarged right sinus horn and venous circulation through the liver. The organs are not drawn to scale. (C) At 8 weeks, indicating the adult derivatives of the cardinal veins shown in A and B. *Source:* Reproduced from Moore et al [115] with permission of Elsevier.

instances it can drain into the LA if the coronary sinus is partially or completely unroofed [95]. Bilateral SVCs with an unroofed coronary sinus usually occur in association with other congenital heart defects. Heterotaxy syndrome results from disorders of left-right axis determination during early embryonic development and is frequently associated with systemic venous abnormalities.

An *interrupted inferior vena cava* with azygos/hemiazygous continuation into the right or left SVC is due to failure of formation of the hepatic segment of the IVC; in this setting, the hepatic veins drain directly into the RA. Multiple variations of *bilateral inferior venae cavae* can occur.

KEY POINTS: DEVELOPMENT OF THE SYSTEMIC VEINS

- The primitive systemic venous circulation consists of three bilaterally symmetrical systems: the vitelline veins, the umbilical veins, and the cardinal veins
- The shift of the systemic venous return to the right atrium is associated with regression and remodeling of vascular structures throughout development resulting in the asymmetrical venous pattern seen at birth
- Alterations in the complex development of the venous system lead to a wide spectrum of systemic venous anomalies

Innervation of the developing heart

The heart has both sensory (afferent) and motor (efferent) innervation that is derived from neural crest (Fig. 5.20) [96,97]. Sensory afferents relay information from the heart to the brain via both parasympathetic and sympathetic pathways. The motor (efferent) pathways are part of the autonomic nervous system, and both the parasympathetic and sympathetic pathways use preganglionic to postganglionic relays.

The cardiac nervous system develops and matures slowly, becoming fully functional well after birth [97]. Parasympathetic innervation precedes sympathetic and sensory innervation, so the parasympathetic–cholinergic system becomes functional before the sympathetic–adrenergic system [98]. Autonomic receptor-mediated effector mechanisms are present before functional innervation, thereby allowing a cardiac response to circulating catecholamines to mitigate the effects of hypoxia and bradycardia [99]. The primary neurotransmitter of the parasympathetic neurons is acetylcholine, whereas that of the sympathetic neurons is norepinephrine.

Abnormalities of cardiac innervation

Dysautonomias result from impaired autonomic interactions due to inadequate development, migration, survival, and function of sensory and autonomic neurons; in this regard, the sympathetic system is affected more often than the parasympathetic system [100]. *Familial dysautonomia* (Riley–Day syndrome), the best known of the hereditary sensory and autonomic neuropathies, is associated with orthostatic hypotension and an increased risk of sudden death. Abnormal autonomic nervous system control in patients with CHD contributes to the pathophysiology of long-term sequelae [101].

Sudden infant death syndrome has been linked to abnormal development of the autonomic nervous system, resulting in immature cardiorespiratory autonomic control and failure of the arousal responsiveness from sleep [102]. Two of the brainstem nuclei with frequent abnormalities are the dorsal motor nucleus of the vagus and the nucleus of the solitary tract, both playing a role in cardiac innervation [101].

Autonomic dysfunction likely plays a role in Down syndrome given that the heart rate and blood pressure responses to exercise are reduced [103,104] and the risk of bradycardia is increased during induction of anesthesia [105].

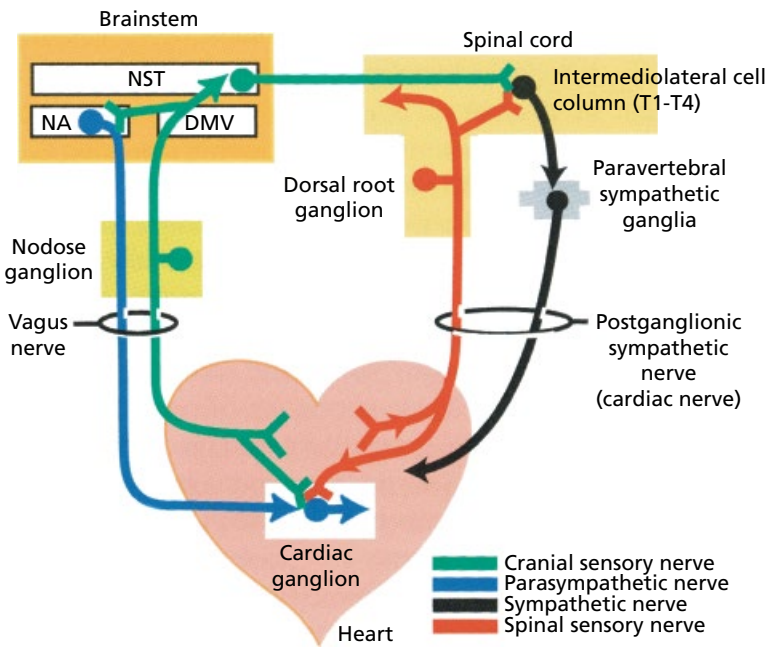

Figure 5.20 Schematic of the general plan of the innervation of the heart. Direction of the impulse is indicated by the arrow. DMV, dorsal motor nucleus of vagus; NA, nucleus ambiguus; NST, nucleus of the solitary tract. *Source:* Reproduced from Kirby [34] with permission of Oxford University Press.

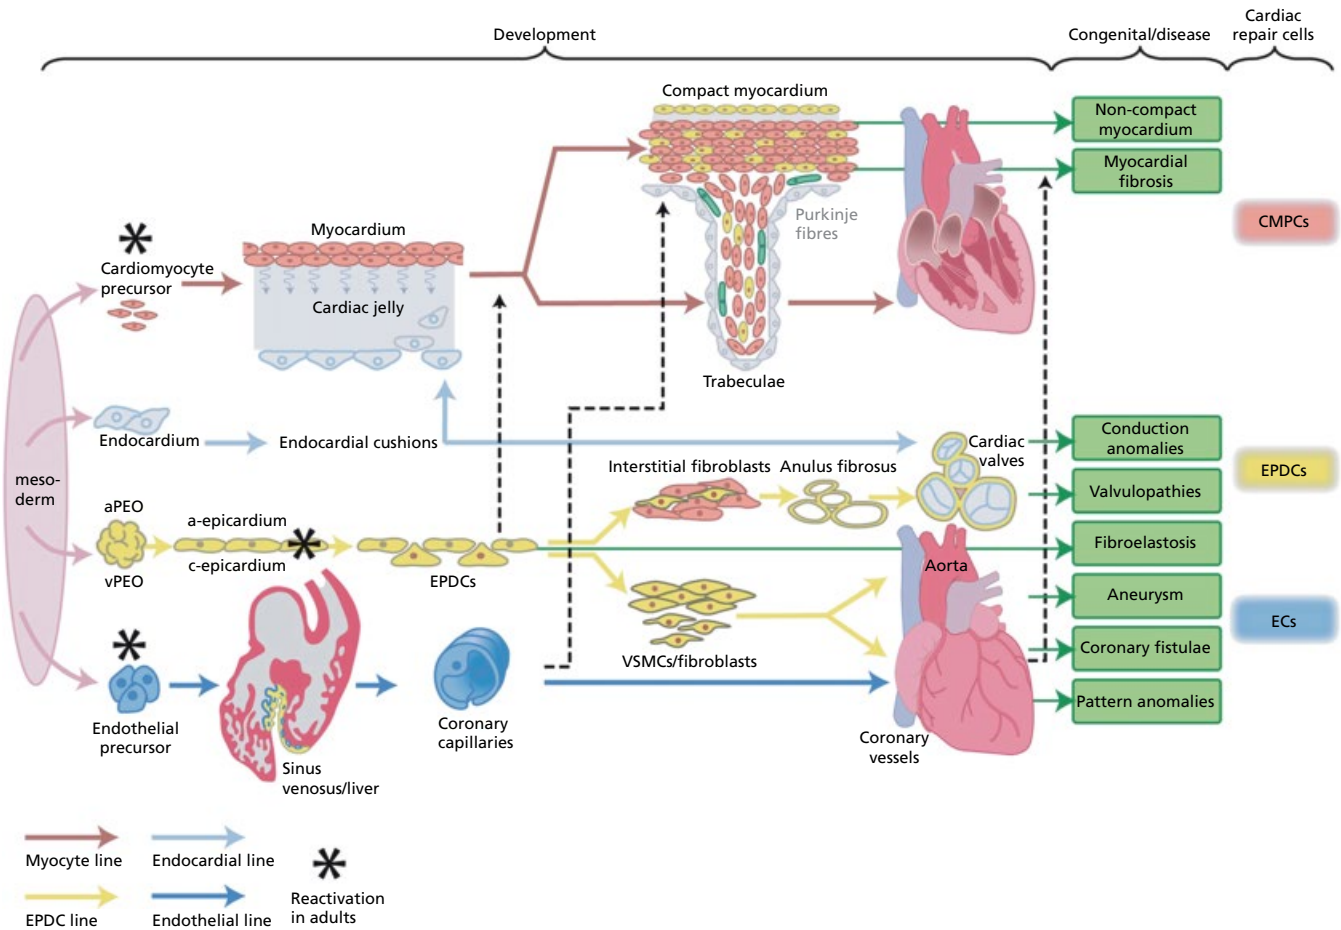

Figure 5.21 Schematic presentation of cellular contribution to heart development with special focus on role of epicardium and epicardium-derived cells during normal development, disease, and repair processes. Four mesodermal cell lines (cardiomyocytes, endocardium, epicardium, and endothelium) are considered to form the main building blocks of the heart. The differentiation of each line is depicted together with the main interactions with the other cell lines. The most frequent epicardium-derived cells (EPDCs)-related congenital malformations and (acquired) disease processes are boxed in green, while three cardiac (stem) cell populations that may become reactivated are presented on the far right side. *Source:* Reproduced from Gittenberger-de Groot et al [26] with permission of Elsevier.

KEY POINTS: INNERVATION OF THE DEVELOPING HEART

- The heart has both sensory (afferent) and motor (efferent) innervation
- The cardiac nervous system develops and matures slowly, and is not fully functional until well after birth
- Parasympathetic innervation precedes sympathetic innervation
- Abnormalities in cardiac innervation may result from impaired autonomic interactions and abnormal development of the autonomic nervous system

Cardiac stem cell therapy and heart regeneration

A resident pool of cardiac stem cells that are multipotent, clonogenic, and self-renewing exists in the normal human heart [106]. Although research has predominantly focused on recovery or regeneration of ischemic myocardium in adults, stem cell therapy is now emerging as a novel treatment modality for CHD [107–109] and has the potential to be more successful than in adults [110]. The heart is not a terminally differentiated, post-mitotic organ [106] and cardiac regeneration has been demonstrated in humans [111]. Possible mechanisms for cardiomyocyte regeneration after injury include: (1) activation, proliferation, and differentiation of resident cardiac progenitor cells; (2) dedifferentiation of mature cardiomyocytes that reenter the cell cycle; (3) activation of the epicardium with new blood vessel growth and/or new cardiomyocyte proliferation; and (4) release of paracrine factors by non-cardiomyocyte cells to promote proliferation of existing cardiomyocytes [112]. Reactivation of cardiac stem cells has opened the door for using regenerative medicine and novel therapies for treating congenital and acquired heart disease [113].

Conclusion

The heart is the first functional organ to develop in the embryo. Recent insights into the process of cardiac development have challenged many prior paradigms in classic embryology and morphogenesis, including the segmental model of heart development. It is now well established that not all cardiac chamber progenitors are derived from the early heart tube. The current concept is that only precursors of the LV are present in the straight heart tube and multiple heart-forming surrounding fields contribute to cardiac development.

The heart originates from mesoderm and neural crest precursors. The mesoderm gives rise to four cell lines (cardiomyocytes, endocardium, epicardium, and endothelium) to form the building blocks of the heart and vascular system (Fig. 5.21) [26]. Cardiac neural crest cells are critical to the formation and remodeling of the aortic arch arteries, outflow tract septation, semilunar valvulogenesis, cardiac neuronal tissue, and the insulation of the conduction system [48]. The progressive stages of human development along with a timeline of the corresponding events in the development of the cardiovascular system, as discussed in this chapter, are depicted in Table 5.1 [27].

Table 5.1 Stages of human development with corresponding events in cardiac development

Carnegie stage	Human DPC	Mouse DPC	
CS8	17–19	7	The cardiac crescent forms
CS9	19–21	7.5	The embryo folds, the pericardial cavity is placed in its final position, gully of myocardium forms, the endocardial plexus forms, cardiac jelly forms
CS10	22–23	8	The heart beats, the endocardial tubes fuse, the mesocardium perforates, looping starts, the ventricle starts ballooning
CS11	23–26	8.5	The atria balloon, the proepicardium forms
CS12	26–30	9.5	The septum primum appears, the right venous valve appears, the muscular part of the ventricular septum forms, cells appear in the cardiac jelly, epicardial growth starts
CS13	28–32	10.5	The atrioventricular cushions form, the pulmonary vein attaches to the atrium, the left venous valve appears, epicardial mesenchyme appears first in the atrioventricular sulcus
CS14	31–35	11.5	The atrioventricular cushions approach one another, the outflow ridges become apparent, capillaries form in the epicardial mesenchyme
CS15	35–38	12	The atrioventricular cushions oppose one another, the secondary foramen forms, the distal outflow tract septates, the outflow tract ridges reach the primary foramen
CS16	37–42	12.5	The primary atrial septum closes, the outflow tract ridges approach the interventricular septum. The entire heart is covered in epicardium
CS17	42–44	13.5	Secondary atrial septum appears, the sinus node becomes discernible, the left and right atrioventricular connection becomes separate, the proximal outflow tract becomes septated, the semilunar valves develop
CS18	44–48	14.5	Papillary muscles appear, the atrioventricular valves start to form
CS19	48–51	15	The left venous valve fuses with the secondary septum, the mural leaflets of the mitral and tricuspid valve are released
CS21	53–54	16	The main branches of the coronary artery become apparent
CS22	54–56	16.5	The chordae tendineae form
CS23	56–60	17.5	The septal leaflet of the tricuspid valve delaminates

Ongoing scientific work into cellular and molecular mechanisms involved in the development of the cardiovascular system has shown that this is a complex process. The availability of sophisticated research techniques over the last several decades continues to unravel many aspects of normal and abnormal cardiovascular development. Although it is well established that abnormal cardiac development leads to CHD, our understanding of important factors and mechanisms underlying congenital cardiovascular malformations continues to evolve.

Introduction

The circulatory system in congenital heart disease continually changes and develops in response to both normal and pathological stimuli. Response to anesthetic and surgical interventions must be understood in this framework, and is often radically different from the usual, expected pediatric and adult situations with a "normal" cardiovascular system. This chapter will review developmental changes of the cardiovascular system from fetal life through adulthood, in both the normal and pathophysiological states associated with congenital heart disease. Not much is known about the development of the normal and diseased human heart. Much of the information discussed in this chapter was derived from animal models, and undoubtedly new information will be discovered as human myocardial tissue is studied.

Development from fetus to neonate

Circulatory pathways

The fetus receives oxygenated and nutrient-rich blood from the placenta via the umbilical vein, and ejects desaturated blood through the umbilical arteries to the placenta; thus it is the placenta, not the lung, that serves as the organ of respiration. Blood flow thus largely bypasses the lungs *in utero*, accounting for only about 7% of the fetal combined ventricular output [1]. Pulmonary vascular resistance is high, and the lungs collapsed and filled with amniotic fluid. This is the basis for the fetal circulation, which is a parallel circulation, rather than the series circulation seen postnatally. Three fetal circulatory shunts exist to carry better-oxygenated blood from the umbilical vein to the systemic circulation: the ductus venosus, ductus arteriosus, and foramen ovale (Fig. 6.1A) [2]. Approximately 50% of the umbilical venous blood, with an oxygen tension of about 30–35 mmHg, passes through the ductus venosus, and then into the right atrium. There it streams preferentially across the foramen ovale, guided by the valves of the sinus venosus and Chiari network into the left atrium. Thus the brain and upper body preferentially receive this relatively well-oxygenated blood, which accounts for 20–30% of the combined ventricular output. Blood returning in the inferior vena cava represents about 70% of the total venous return to the heart, and two-thirds of this deoxygenated blood passes into the right atrium and ventricle. About 90% of the blood flows through the ductus arteriosus to supply the lower fetal body.

After birth, there is a dramatic fall in pulmonary vascular resistance and increase in pulmonary blood flow, with inflation and oxygenation of the lungs (Fig. 6.2) [3]. The placental circulation is removed, and all of these changes lead to closure of the ductus venosus, constriction of the ductus arteriosus, and reversal of pressure gradients in the left and right atria, leading to closure of the foramen ovale. This leads to a state called the transitional circulation (Fig. 6.1B), characterized by

high pulmonary artery pressures and resistance (much lower than *in utero*, however), and a small amount of left-to-right flow through the ductus arteriosus. This is a labile state, and failure to maintain lower pulmonary vascular resistance can rapidly lead to reversion to fetal circulatory pathways and right-to-left shunting at the ductus arteriosus and foramen ovale. This maintenance of fetal circulatory pathways is necessary for survival in many congenital heart diseases, particularly those dependent on a patent ductus arteriosus for all or a significant portion of systemic or pulmonary blood flow, or atresia of atrioventricular valves. Maintenance of ductal patency with PGE1 is crucial in these lesions. In the two-ventricle heart with large intracardiac shunts, maintenance of the fetal circulation leads to right-to-left shunting at the foramen and ductal levels, and thus hypoxia. Conversion to the mature circulation (Fig. 6.1C) in the normal heart occurs over a period of several weeks, as pulmonary vascular resistance falls further, and the ductus arteriosus closes permanently by thrombosis, intimal proliferation, and fibrosis. Factors favoring the transition from fetal to mature circulation include normal oxygen tensions and physical expansion of the lungs, normal pH, nitric oxide, and prostacyclin. Factors favoring reversion to fetal circulation include low oxygen tension, acidotic pH, lung collapse, and inflammatory mediators (leukotrienes, thromboxane A2, platelet activating factor) as seen in sepsis and other related conditions, and endothelin A receptor activators [4].

Myocardial contractility

The fetal myocardium is characterized by poorly organized cellular arrangements, and fewer myofibrils with a random orientation, in contrast to the parallel, well-organized myofibrillar arrangement of the adult myocardium [5]. Fetal hearts develop less tension per gram than adult hearts because of increased water content and fewer contractile elements. Calcium cycling and excitation contraction coupling are also very different, with poorly organized T-tubules and immature sarcoplasmic reticulum, leading to more dependence on free cytosolic ionized calcium for normal contractility. Despite this immature state, the fetal heart can increase its stroke volume in a limited fashion up to left atrial pressures of 10–12 mmHg according to the Frank–Starling relationship, as long as afterload (i.e. arterial pressure) is kept low [6]. These features continue throughout the neonatal and early infancy period.

KEY POINTS: DEVELOPMENT FROM FETUS TO NEONATE

- Transition from fetus to neonate involves decrease in pulmonary vascular resistance, elevation of left heart pressures, and closure of shunts at the ductus arteriosus, foramen ovale, and ductus venosus
- The transitional circulation is an intermediate state between fetal and adult circulation and may revert to fetal circulation with persistence of hypoxemia, acidosis, or congenital heart disease or other conditions with elevated pulmonary pressures
- The fetal heart develops less tension per gram of resistance than mature hearts and has limited ability to increase stroke volume up to left atrial pressure of only 10–12 mmHg

Development from neonate to older infant and child

At birth the neonatal heart must suddenly change from a parallel circulation to a series circulation, and the left ventricle in particular must adapt immediately to dramatically increased preload from blood returning from the lungs, and increased afterload as the placental circulation is removed. The very high oxygen consumption of the newborn necessitates a high cardiac output for the first few months of life. However, animal models have demonstrated that the fetal and newborn myocardium develops less tension in response to increasing preload (sarcomere length), and that cardiac output increases less to the same degree of volume loading [7,8] (Fig. 6.3). Resting tension, however, is greater in the newborn compared to the mature heart. This information suggests that the newborn heart is operating near the top of its Frank–Starling curve, and that there is less reserve in response to both increased afterload and preload. This observation is borne out clinically in newborns after complex heart surgery, who are often intolerant of even small increases in left atrial pressure or mean arterial pressure. The newborn myocardium also has only a limited ability to increase its inotropic state in response to exogenous catecholamines, and is much more dependent on heart rate to maintain cardiac output than is the mature heart. One reason for this is the high levels of circulating endogenous catecholamines that appear after birth, necessary to make the transition to extrauterine life [9]. As these levels decrease in the weeks after birth, contractile reserve increases.

The neonatal myocardium is less compliant than the mature myocardium, with increased resting tension as noted above, and a significantly greater increase in ventricular pressure with volume loading [10]. This implies that diastolic function of the neonatal heart is also impaired compared to the mature heart [11]. The myofibrils of the newborn heart also appear to have a greater sensitivity to calcium, developing a greater tension than adult myofibrils when exposed to the same free Ca^{2+} concentration *in vitro* [12].

It must again be emphasized that nearly all of these data were obtained from animal models, and although the information appears to agree with what is observed clinically, there exists a need for non-invasive studies of normal human hearts from the neonatal period through adulthood to confirm these impressions of cardiac development.

Gene expression in cardiac development

Progress has recently been made in understanding the genetic aspects of human cardiac development, and in contrast to the physiological studies that are almost exclusively performed in animal models, small amounts of human cardiac tissue obtained from biopsy or autopsy specimens can be used for these studies. Some aspects of these developmental changes will be reviewed.

Myosin is the major protein component of the thick filaments of the cardiac myofibril, and differences in the expression of this protein may play a significant role in myocardial contractility. Chromosome 14 has the genetic material responsible for producing the myosin heavy chain that makes up the backbone of the thick filaments, and two major isoforms, α and β, exist. The β isoform predominates and does not change significantly with maturation [13]. The myosin light chain has multiple isoforms; the relative proportions of these isoforms change with development, and also in response to pressure loading of the heart. The isoforms that predominate in the newborn myocardium appear to confer a greater sensitivity to Ca^{2+} than those seen in the mature heart [14] and may contribute to the increased sensitivity of the neonatal myocardium to Ca^{2+}.

Troponins I, C, and T are critical proteins that bind Ca^{2+} and regulate the interaction between myosin and actin, directly affecting the force of contraction. Troponin C, the Ca^{2+} binding portion of the troponin moiety, does not change with development. Troponin I, however, has two major isoforms, a slow skeletal muscle type that predominates in the heart in fetal and neonatal life, and the cardiac isoform, which is the only isoform expressed in the mature heart [15]. Only the cardiac (mature) isoform responds to β-adrenergic stimulation, producing a faster twitch development and greater twitch tension. However, contractility in the neonatal myofibrils containing the immature myosin light chain isoform is more resistant to acidosis. Four isoforms of troponin T are expressed in the fetal and neonatal heart, but only one in the mature heart. These isoforms exhibit different levels of ATPase activity and Ca^{2+} sensitivity, with greater ATPase activity and Ca^{2+} sensitivity seen in the immature forms [12]. Tropomyosin [16] has two and actin [17] has three isoforms which are expressed in different proportions as developmental changes occur, but the functional significance of these changes has yet to be elucidated.

Some enzymes are affected by the loading conditions of the heart. Protein kinase C (PKC) is an enzyme with a major role in transmembrane signal transduction through phosphorylation of a number of downstream intracellular components (see section "Calcium cycling in the normal heart") [18]. There are six isoforms of this enzyme, and they are not affected during development. However, in aortic stenosis producing left ventricular hypertrophy, all isoforms except PKC-β are dramatically upregulated, and in dilated cardiomyopathy there is a dramatic upregulation of PKC-β. Phosphodiesterase (PDE) is an enzyme involved in the termination of the action of cyclic AMP, which regulates the contractile state of the myocardium. Expression of the isoform PDE-5 is dramatically increased in the hypertrophied human right ventricle in patients with pulmonary hypertension, and inhibition of this enzyme improves ventricular contractility [19].

New information is available about the molecular and cellular basis for normal cardiac development and the causes of congenital heart disease [20]. A missense mutation in the myocardial protein actin has been discovered to be the cause of isolated secundum ASD in some patients [21]. Pluripotent cardiac progenitor cells reside in the human neonatal myocardium in relatively high numbers during the first month of life [22]. This knowledge has given rise to the exciting notion that these stem cells could potentially be used to facilitate recovery from cardiac morbidity, or to enhance surgical repair.

The extracellular matrix

The extracellular matrix of the heart is important in translating the force generated from shortening of sarcomere length to the cardiac chambers, resulting in stroke volume. The major components of the extracellular matrix are collagen types I and II, glycoproteins, and proteoglycans, and the expression of these elements changes with development. The neonatal heart has a higher content of both total and type I collagen (which is stiffer and less compliant than type III collagen) when compared to the total protein content of the heart [23]. The collagen to total protein ratio reaches mature levels by about 5 months of life. This change, along with greater water content of the immature myocardium, may partially explain the diminished diastolic function. Also, this relative lack of contractile elements reduces the ability of the neonatal myocardium to increase its inotropic state. A network of collagen-based connections, called the weave network, develops rapidly after birth, connecting myocytes and capillaries and allowing greater functional integrity to develop in response to the greater afterload stress on the heart [24]. This development of the extracellular matrix appears to be complete by approximately 6 months of age, and results in a much more efficient transfer of force generated by sarcomere shortening to the cardiac chambers (Fig. 6.4) [12].

The connection of the cardiac myocyte to the extracellular matrix is maintained by two specialized complexes that together are comprised of over 20 proteins, the costameres, and the dystrophin-associated glycoprotein complexes [25,26] (Fig. 6.5). The costameres produce a physical connection between the sarcomeres at the Z disk and the extracellular matrix. Transmembrane proteins called integrins connect the sarcolemma to the extracellular matrix. Integrins are receptors which are specific for collagen and fibronectin and cause the attachment of the extracellular matrix to the myocytes, allowing force transduction to occur [27]. Collagen and vinculin, another cytoskeletal protein, are attached to the sarcomere at the Z disk. The integrins have two subunits, α and β, which express several isoforms, the relative proportions of which change during development to those that afford greater adherence of the cytoskeletal proteins to the myocytes, resulting in greater structural integrity.

Dystrophin-associated glycoprotein complexes also contribute to a substantial mechanical linkage from the extracellular matrix to the cardiac cytoskeleton, and contribute to force transduction [25,26]. The proteins dystrophin, sarcoglycans, dystroglycan, and dystrobrevins are included in these complexes. These complexes play an integral role in cardiac function, and mutations in these proteins can be associated with cardiomyopathies, especially the muscular dystrophy

Figure 6.4 Longitudinal sections through an adult rabbit cardiac myocyte (A), and a 3-week-old rabbit cardiac myocyte (B). Note the differences between myofibril organization and structure, as well as cell size. *Source:* Reproduced from Nassar et al [12] with permission of Wolters Kluwer.

associated cardiomyopathies. Reduction of dystrophin activity results in dilatation of all four cardiac chambers and reduced ventricular function. Mutations in dystrobrevins have been associated with left ventricular non-compaction.

Cell-to-cell connectivity

The intercalated disks mediate the cell-to-cell interactions that coordinate cardiac myocyte activity resulting in synchronous contraction and maintaining the structural integrity of cardiac tissue [28] (Fig. 6.6). These disks are situated between cardiac myocytes at the longitudinal ends of the cells and consist of three types of connections: desmosomes, fascia adherens junctions, and gap junctions. The desmosomes have both intracellular and intercellular components. This structure serves to integrate signals from both cell-to-matrix and cell-to-cell interactions, ensuring force transmission, cell membrane integrity, and biochemical signaling. The fascia adherens junctions are responsible for holding the cardiac myocytes tightly together, and they anchor myofibrils and ensure transmission of contractile forces from cell to cell. Finally, the gap junctions form the electrical coupling apparatus between individual myocytes, ensuring rapid propagation of the electrical impulse, forming and electrical syncytium and thus triggering the coordinated contraction of cardiac myocytes. Mutations in intercalated disk proteins have recently been found to be associated with cardiac disorders. These include adherens junctions mutations associated with heart failure and dilated cardiomyopathy, and desmosome complex mutations associated with some forms of arrhythmogenic right ventricular cardiomyopathy.

The preceding short review is meant to give the reader an idea of some of the aspects of the cellular biology of the developing circulation. The explosion of new information in this area, and especially new data from human tissue, will lead to a more thorough understanding of the pathophysiology of disease states and suggest avenues for future treatment. For a more complete treatment of this area, the reader is referred to several excellent reviews [29–31].

Innervation of the heart

Clinical observations in newborn infants have led to the hypothesis that the sympathetic innervation and control of the cardiovascular system is incomplete in the newborn infant compared to older children and adults, and that the parasympathetic innervation is intact [5]. Examples of this include the frequency of bradycardia in the newborn in response to a number of stimuli, including vagal, and vagotonic agents, and the relative lack of sensitivity in the newborn to sympathomimetic agents. Histological studies in animal models have demonstrated incomplete sympathetic innervation in the neonatal heart when compared to the adult, but no differences in the number or density of parasympathetic nerves [32,33].

Autonomic cardiovascular control of cardiac activity can be evaluated by measuring heart rate variability in response to both respiration and beat-to-beat variability in systolic blood pressure [34]. The sympathetic and parasympathetic input into sinoatrial node activity contribute to heart rate variability changes with greater heart rate variability resulting from greater parasympathetic input into sinoatrial node activity [35]. Studies using these methodologies for normal infants during sleep suggest that the parasympathetic predominance gradually diminishes until approximately 6 months of age, coinciding with greater sympathetic innervation of the heart similar to adult levels [36].

KEY POINTS: DEVELOPMENT FROM NEONATE TO OLDER INFANT AND CHILD

- The neonatal heart exhibits heart rate dependence, limited ability to increase contractile state, and limited tolerance for excessive afterload and preload
- The costameres and dystrophin-associated glycoprotein complexes play central roles in connection of the cardiac myocyte to the extracellular matrix and thus force transduction in the heart
- The intercalated disks maintain cell-to-cell connectivity between cardiac myocytes, allowing tight adhesion and electrical impulse transition to facilitate coordinated cardiac contraction

Development from child to adult

Beyond the transition period from fetal to newborn life and into the first few months of postnatal life, there is not much

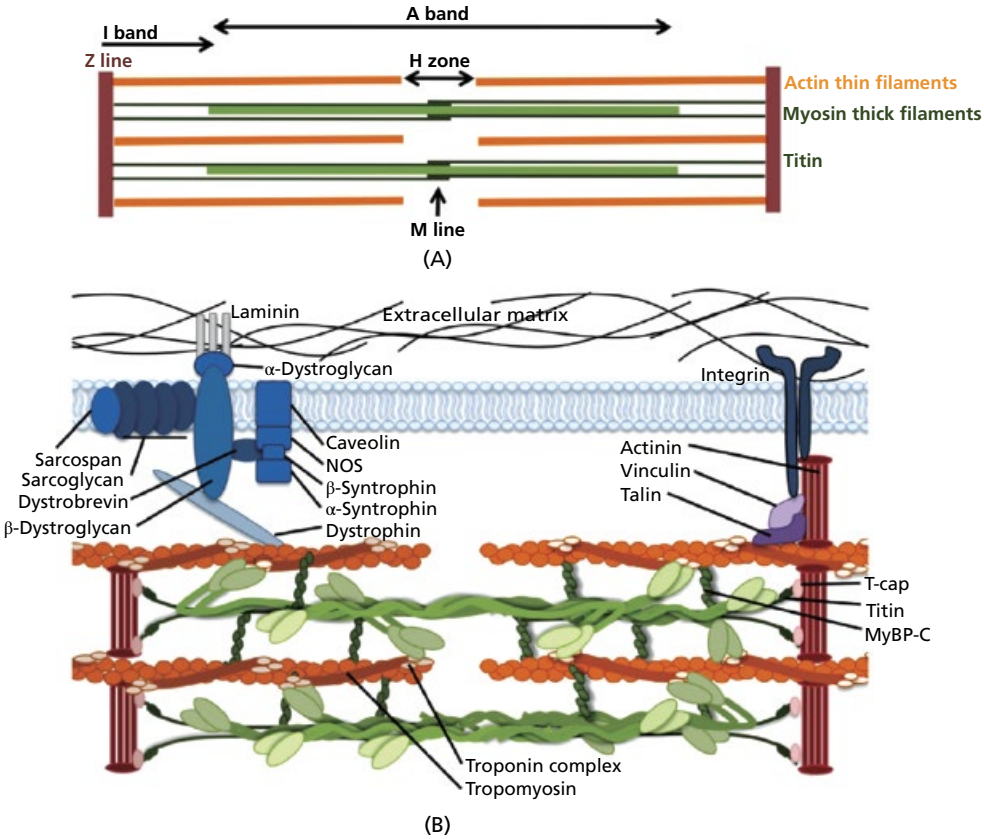

Figure 6.5 Anatomy of the cardiac sarcomere. (A) Basic organization of the sarcomere. The sarcomere forms the basic contractile unit. Thin filaments composed of actin are anchored at the Z line and form transient sliding interactions with thick filaments composed of myosin molecules. The M line, I band, and A band are anatomical features defined by their components (actin, myosin, and cytoskeletal proteins) and appearance in polarized light. Titin connects the Z line with the M line and contributes to the elastic properties and force production of the sarcomere through its extensible region in the I band. Coordinated shortening of the sarcomere creates contraction of the cardiomyocyte. (B) Major proteins of the sarcomere. Attachment to the extracellular matrix is mediated by costameres composed of the dystroglycan–glycoprotein complex and the integrin complex. Force transduction and intracellular signaling are coordinated through the costamere. The unique roles of each of these proteins are critical to appropriate function of the heart. human or animal information concerning the exact nature and extent of cardiac development at the cellular level. Most studies compare newborn or fetal to adult animals [37]. Cardiac chamber development is assumed to be influenced by blood flow [38]. Large flow or volume load in a ventricle results in ventricular enlargement. Small competent atrioventricular valves, as in tricuspid stenosis, result in lower blood flow and a small ventricle. Increases in myocardial mass with normal growth, as well as in ventricular outflow obstruction, are mainly due to hypertrophy of myocytes. Late gestational increases in blood cortisol are responsible for this growth pattern, and there is concern that antenatal glucocorticoids to induce lung maturity may inhibit cardiac myocyte proliferation. In the human infant, it is assumed that the cellular elements of the cardiac myocyte, i.e. adrenergic receptors, intracellular receptors and signaling, calcium cycling and regulation and interaction of the contractile proteins, are similar to the adult by approximately 6 months of age. Similarly, cardiac depression by volatile agents is greater in the newborn, changing to adult levels by approximately 6 months of age [39].

Normal values for physiological variables by age

It is useful for the anesthesiologist to be aware of normal ranges for physiological variables in premature and full-term newborns of all sizes, and in infants and children of all ages (Table 6.1, Fig. 6.7) [40]. Obviously, acceptable ranges for these variables are highly dependent on the individual patient's pathophysiology, but the wide range of "normal" values may reassure the practitioner to accept "low" blood pressure, for example, if other indices of cardiac function and tissue oxygen delivery are acceptable. Values for awake, healthy infants and children are often significantly different than in anesthetized patients and those with significant cardiac disease undergoing invasive procedures, especially with regard to the higher resting blood pressure values [41–43].

A very important study of over 116,000 ASA I and II patients from 10 centers undergoing non-cardiac procedures with mostly sevoflurane anesthesia reported the range of blood pressure values in the preparation (presurgical) phase and the surgical phase in patients from 0 to 18 years of age, measured by non-invasive oscillometric method (NIBP) [44] (Fig. 6.8). The data were reported from electronic anesthesia medical records and were carefully refined to remove artifacts. Age- and gender-specific reference curves were calculated which specified the systolic, diastolic, and mean blood pressures. The range at each age from +2 to –2 standard deviations (SD), representing 95% of all blood pressure values and thus

Table 6.1 Normal heart rates and systolic blood pressure as a function of age

Age	Range of normal heart rates (beats/minute)	Range of normal systolic blood pressures, measured by oscillometric blood pressure device (mmHg)
Neonate (<30 days)	120–160	60–75
1–6 months	110–140	65–85
6–12 months	100–140	70–90
1–2 years	90–130	75–95
3–5 years	80–120	80–100
6–8 years	75–115	85–105
9–12 years	70–110	90–115
13–16 years	60–110	95–120
>16 years	60–100	100–125

Blood pressure data are from references [40–43].

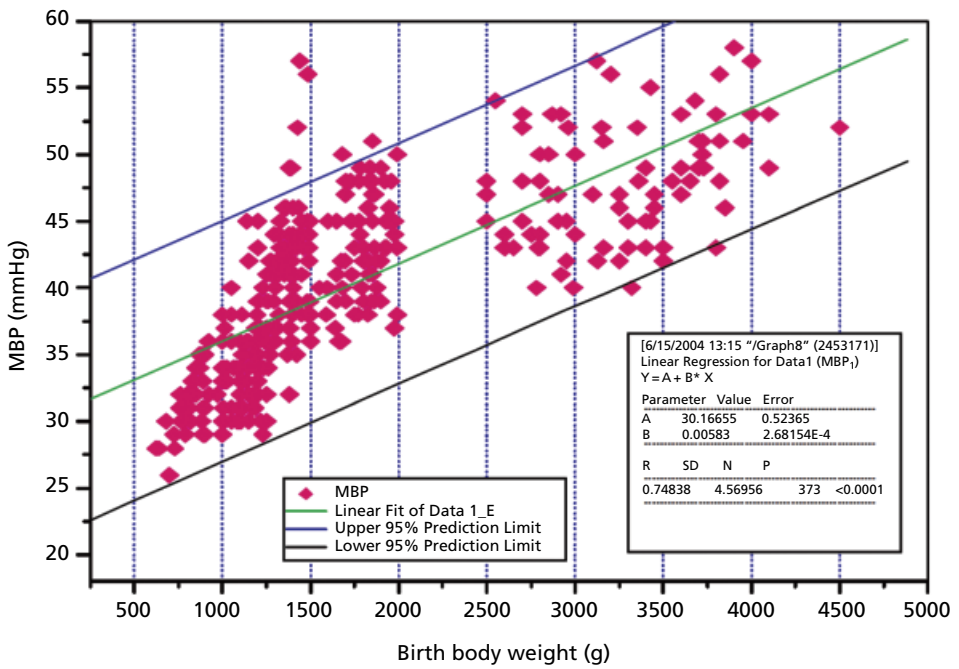

Figure 6.7 Linear regression of mean arterial pressure in 1-day-old neonates free of cardiopulmonary disease, measured by oscillometric methods in the awake state; 292 were premature and 81 full-term neonates. Middle green line is 50th percentile, upper blue line 95th percentile, and lower black line 5th percentile. Note that in the 3.0 kg full-term neonate, normal mean arterial pressure can range from 37 to 56 mmHg. *Source:* Reproduced from Pejovic et al [40] with permission of Springer Nature.

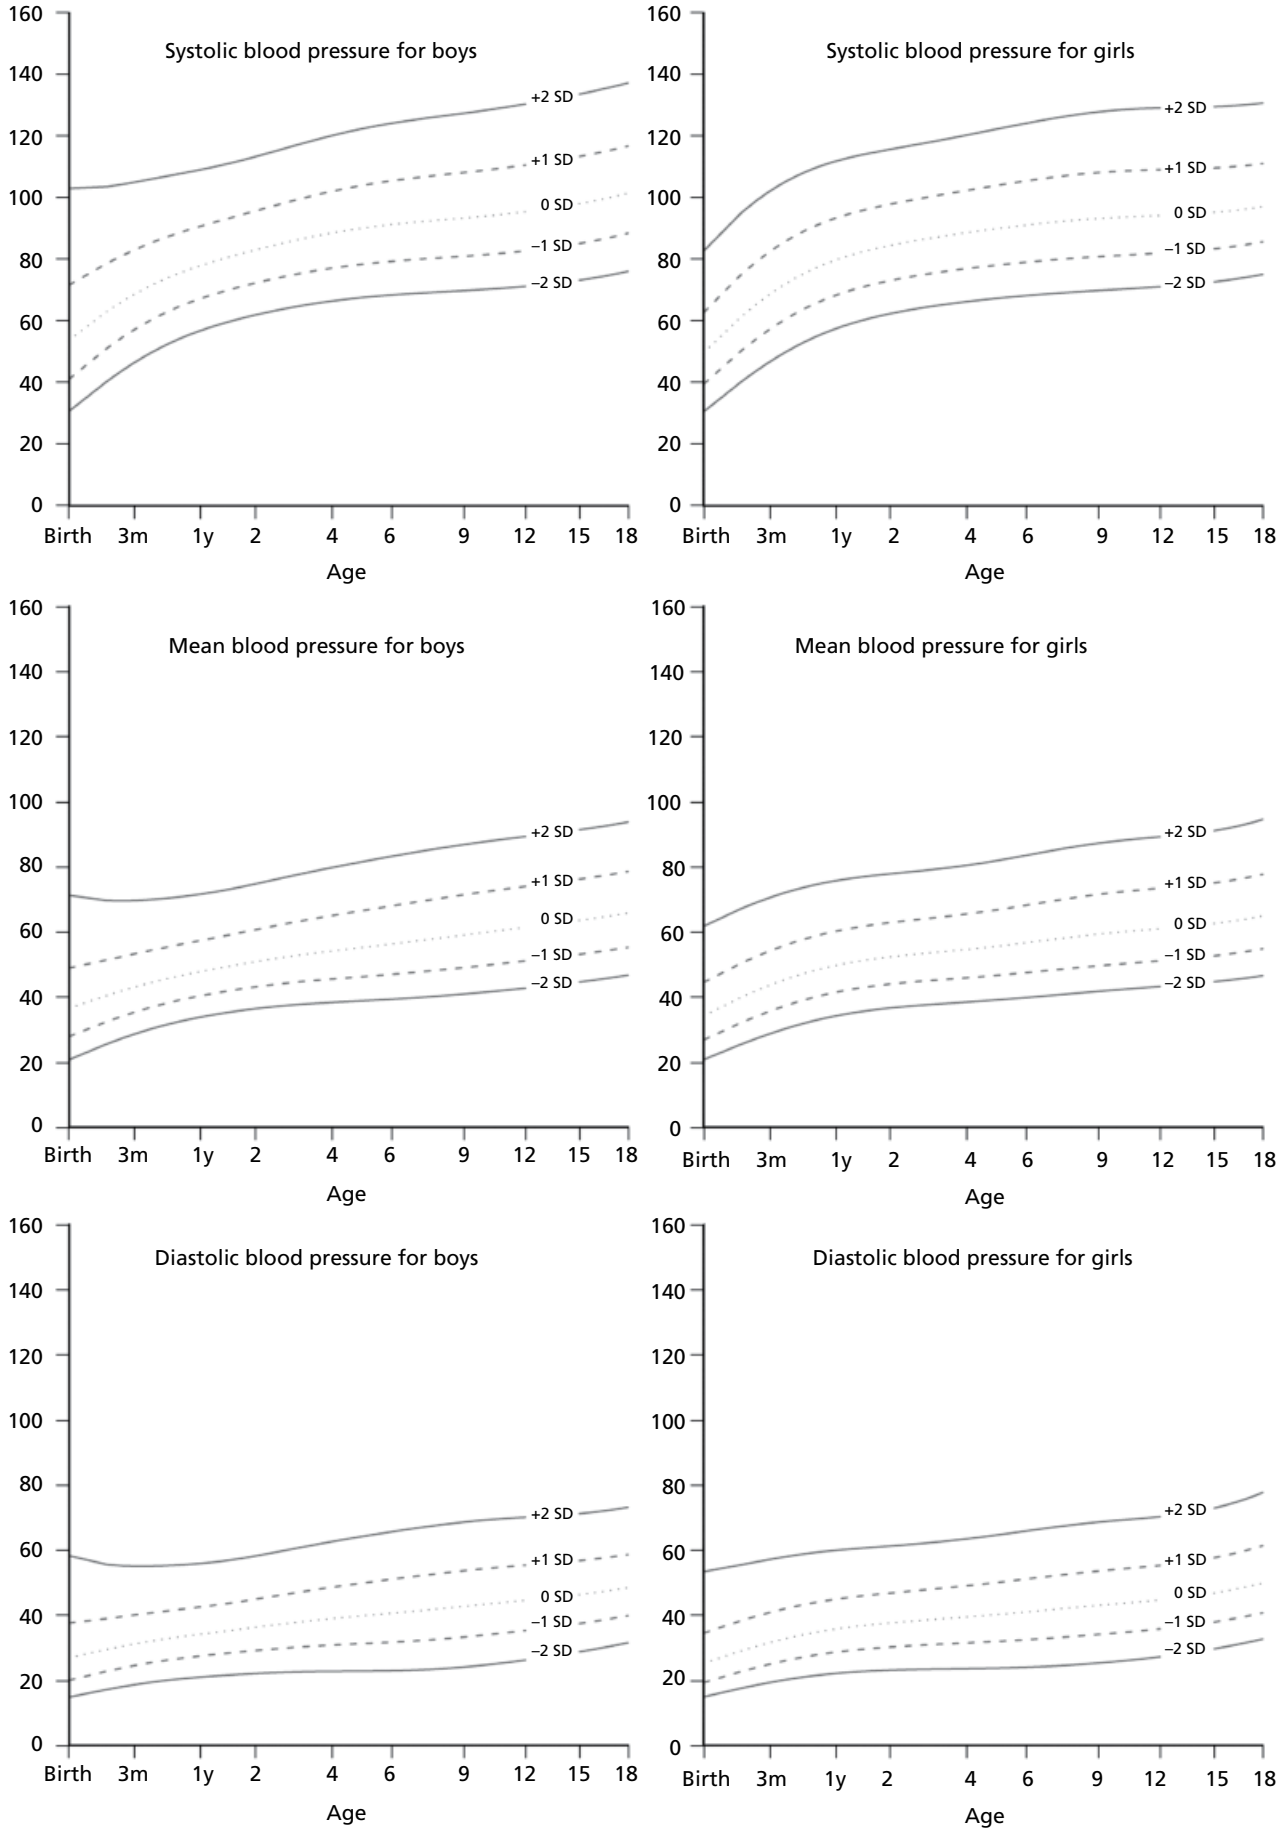

Figure 6.8 Reference curves for noninvasive blood pressure for boys and girls during anesthesia during the surgical phase in relation to age. *Source:* Reproduced from de Graaff et al [44] with permission of Wolters Kluwer.

constituting the range of "normal" blood pressures, was included. For example, the 50th percentile (0 SD) of mean arterial pressure ranged from 33 mmHg at birth to 66 mmHg at age 18 years in boys. The –2 SD (2.5th percentile) values for mean blood pressure ranged from 17 mmHg at birth to 47 mmHg at 18 years. The lowest reference ranges for anesthetized children are much lower (approximately 20 mmHg) than those for awake children; the 2.5th percentiles (–2 SD) of the systolic and mean NIBP of a 4-year-old boy are 85 and 60 mmHg, respectively, when non-anesthetized, and 68 and 38 mmHg, respectively, when anesthetized.

Myocardial sequelae of long-standing congenital heart disease

Hypertrophy of the cardiac chambers is a common response to a number of different chronic pathophysiological states. Wall thickness increases through hypertrophy of the cardiac myocytes and non-contractile elements. The hypertrophy reduces wall stress in the dilated heart, but also serves to reduce ventricular function, particularly diastolic function. This reduction in function serves to reduce myocardial oxygen consumption in response to a wide variety of chronic stresses, both in pressure and volume overloaded ventricles [45].

Pressure overload hypertrophy results in altered gene expression in the cardiomyocyte. Myosin isoform expression changes from the faster-reacting α-myosin to the slower β-myosin, reducing myocardial function [46]. Integrin-linked kinase expression is increased in patients with hypertrophic cardiomyopathy and induces hypertrophy in an animal model [47]. Altered expression or mutations of other genes that regulate production of cardiac cytoskeletal proteins, such as dystrophin, occur in patients with end-stage cardiomyopathy [48,49].

Cardiomyocyte receptor function in normal and diseased hearts

The adrenergic receptor

The adrenergic receptors (AR) are part of a large superfamily of receptors that mediate their biological responses through the coupling of a specific guanine nucleotide regulatory protein or G protein [50]. This superfamily of receptors shares a common structural motif, characterized by seven hydrophobic domains spanning the lipid bilayer. The seven domains are attached by three internal loops and three external loops between the amine terminus and the cytoplasmic carboxy terminus. The function of this receptor family is dependent on a specific agonist (or ligand) binding to the receptor, which causes a conformational change in the receptor. This structural change permits the interaction between the intracellular portion of the receptor and guanine nucleotide regulatory protein (or G protein). This interaction, also referred to as coupling, inevitably links the activated receptor to a specific biological response. The regulation of the biological response is initiated by the specificity of the receptor for a particular extracellular agonist and the coupling of a specific G protein to that activated receptor.

Once an extracellular ligand (or agonist) is specifically recognized by a cell surface receptor, the receptor goes through a conformational change that exposes a specific region of the receptor complex to the intracellular side of the plasma membrane [51] (Fig. 6.9). This conformation change triggers the interaction of the G protein with the amino acids of the third intracellular loop of the receptor and hence leads to G protein activation. There are three different G proteins: stimulatory G protein (Gs), inhibitory G protein (Gi), and Gq. Under normal conditions, all of the β receptors interact with Gs, the α_1 interacts with Gq, and α_2 interacts with Gi. Each G protein is a heterotrimer made up of three subunits: α, β, and γ. The activation of the G protein-coupled receptor causes an exchange of bound guanosine diphosphate (GDP) for guanosine triphosphate (GTP) within the α subunit and initiates the disassociation of the β-γ subunit from the α subunit. The GTP-activated α subunit modulates the activity of a specific effector enzyme within a specific signaling pathway by catalyzing the hydrolysis of GTP to GDP and inorganic phosphate. This causes the transference of a high-energy phosphate group to an enzyme and in turn causes the deactivation of the α subunit. This process will eventually lead to the deactivation of the α subunit and the reassociation with the β-γ complex. This cycle is continuously repeated until the agonist becomes unbound from the receptor. Downstream of enzyme activation, the production of a second messenger regulates the biological response.

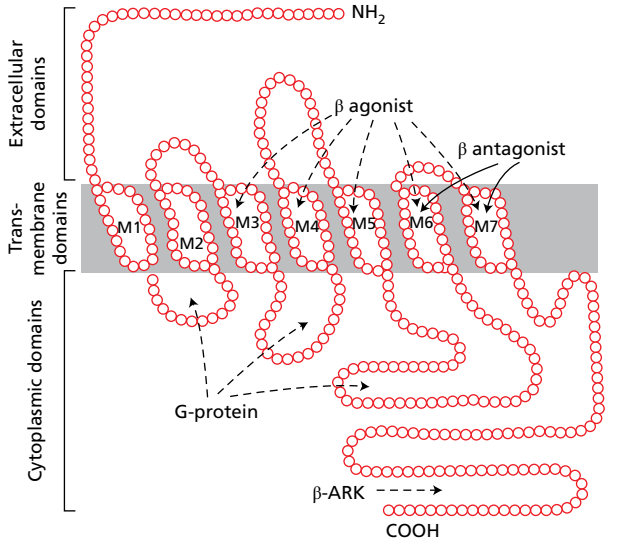

Figure 6.9 Molecular structure of the β-adrenergic receptor, demonstrating its three domains. The transmembrane domains serve as ligand-binding pockets for agonists (dashed arrows) and antagonists (solid arrows). The cytoplasmic domains interact with G proteins and β-adrenergic receptor kinases. *Source:* Reproduced from Moss and Renz [50] with permission of Elsevier.

Adrenergic receptors (AR) have been subdivided into two groups of receptors based on the results of binding studies using a series of selective agonists and antagonists. In 1948 Ahlquist used the difference in rank orders of potency of a series of agonists to separate the ARs into two principal receptor groups, the α and β receptor group [52]. These findings have been confirmed repeatedly with the development of drugs that function to selectively antagonize the α receptor with no effect on the β receptor. Soon after the distinction between the α and β receptor type was understood, it became more evident that the separation of α and β receptors was not sufficient to explain pharmacological studies using rank order

of potency for an antagonist, differing from an agonist because it blocks the biological response. With the advent of radioligand-labeled antagonists and new molecular cloning techniques examining receptor gene expression, it became clear that the two principal receptor groups could be further subdivided into additional subtypes.

To date, within the β-adrenergic group four different subtypes have been identified: β_1, β_2, β_3, and β_4. Pharmacologically, β_1 and β_2 are differentiated by their affinities to different catecholamines: epinephrine, norepinephrine, and isoproterenol. β_1 has similar affinity for epinephrine and norepinephrine, while β_2 has a higher affinity for epinephrine than for norepinephrine. Both β_1 and β_2 have the same affinity for isoproterenol. The β_3 and β_4 receptors have minor roles in cardiovascular function and will not be further discussed.

The expression and distribution of each subtype is highly dependent on the organ, which adds another level of specificity. Distribution of a particular receptor in two different tissue types may result in two different functions. When examining cardiovascular response to adrenergic stimulation, the β_1 receptor is predominantly expressed in heart tissue. The stimulation of the receptor subtype leads to both inotropic and chronotropic effects on cardiac function, resulting in an increase in the myocardial contractile force and a shortening of contractile timing, respectively. While β_2 can also be found in the heart, it is mostly expressed in vascular smooth muscle tissue. The distribution and functional relevance of this receptor subtype in the heart is controversial and may change with alterations in cardiac function. The percentage of β_2 receptors in the non-failing heart averages about 20% in the ventricle [53] and 30% in the atrium. The percentage of β_1 to β_2 receptors is approximately 75%:25% in the ventricles of younger hearts [54,55].

Each signaling pathway is specific to each adrenergic receptor. Once the agonist binds to the β_1 receptor causing the coupling of the G protein, the G protein α-subunit becomes activated followed by an increase in adenylate cyclase (AC) activity, which induces the conversion of ATP to cAMP. The second messenger, cAMP, phosphorylates protein kinase A (or PKA). The function of a kinase is to phosphorylate other target proteins, which initiates a biological response. PKA phosphorylates many intracellular targets including calcium channels, troponin I, and ryanodine receptors. PKA also plays a central role in regulating calcium sensitivity [56].

The β_2 receptor also been shown to function through the cAMP signaling pathway causing the activation of PKA, but not nearly to the extent of $\beta_{1\,in}$ cardiomyocytes [57]. The response of this stimulation appears to have a larger effect on smooth muscle, for example the vascular smooth muscle. In this tissue type, the stimulation of β_2 and the subsequent increase in cAMP promotes the vasodilation of vascular smooth muscle and may lead to alterations in blood pressure. In these tissues, the effect of β_1 stimulation appears to be minimal, due to lack of β_1 receptors in the smooth muscle.

Similar to the β receptor, the α receptors can be pharmacologically subdivided into α_1 and α_2. The α1 receptor is distributed in most vascular smooth muscle and to a lesser extent in the heart. The α_2 receptor has been found in some vascular smooth muscle; however its major functional importance is as a presynaptic receptor in the central and peripheral nervous systems. The use of molecular techniques has identified three additional subtypes of the α_1 receptor (α_{1A}, α_{1B}, and α_{1D}) and three additional subtypes of the α_2 receptor [50]. Binding of an agonist to an α_1 receptor in the heart or vascular smooth muscle results in activation of the Gq subunit of the G protein, which activates phospholipase C, producing diacylglycerol and inositol-1,4,5-triphosphate, which releases Ca^{2+} from the sarcoplasmic reticulum and increases vascular smooth muscle tone or cardiac contractility. A schematic classification of adrenergic receptors incorporating recent knowledge of molecular pharmacology and signal transduction is presented in Figure 6.10 [50].

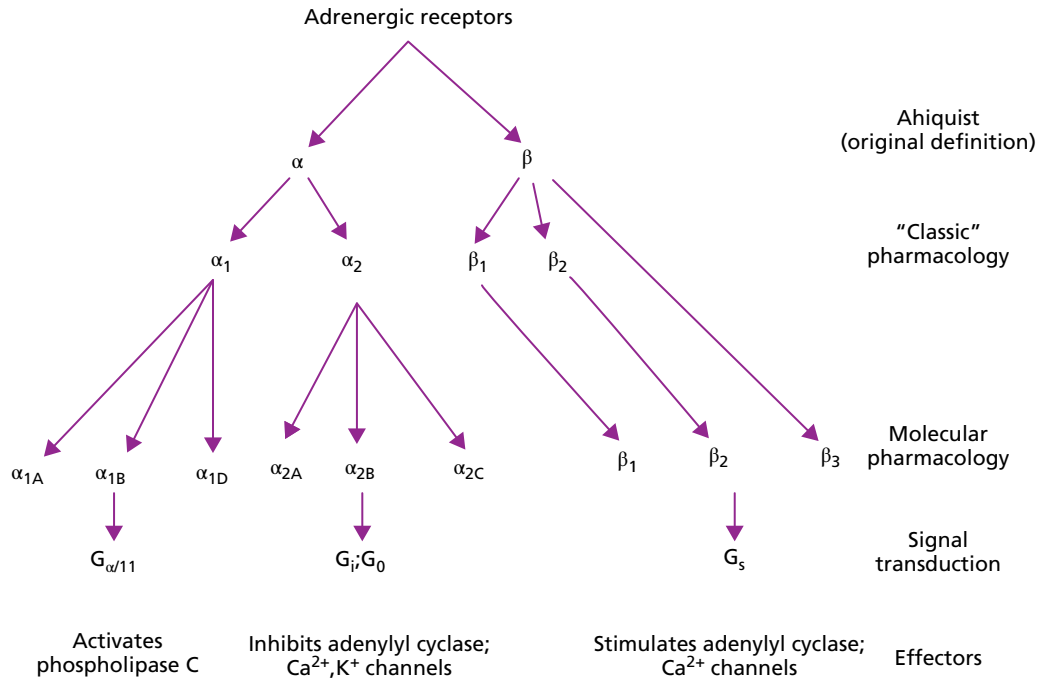

Figure 6.10 A schematic classification of adrenergic receptors. *Source:* Reproduced from Moss and Renz [50] with permission of Elsevier.

The adrenergic receptor concentration in cardiac tissue is very small and measured as femtomoles per milligram of protein. However, the response to stimulation of the receptor is greatly amplified by the signal that occurs downstream of the receptor. In rat ventricular myocytes, the ratio between the β receptors and the next two downstream signaling components (β receptor: G protein: adenylate cyclase) is 1:200:3 [58]. This demonstrates how a large response can be initiated by the activation of a small number of receptors. In addition, it also shows that the rate-limiting component that ultimately regulates intracellular production of cAMP is receptor density and the enzyme concentration of adenylate cyclase.

Developmental changes in adrenergic receptor signaling

Information concerning changes in adrenergic receptor function during the transition from neonatal to more mature myocardial development is limited to a few animal studies. As noted previously, the neonatal heart has a limited inotropic response to catecholamine administration.

β-Adrenergic receptor density is higher in the ventricular myocardium of neonatal versus adult rabbits, but the inotropic response to the same concentration of isoproterenol is significantly greater in adult tissue [59]. In the neonatal rat, the mechanism of β-adrenergic mediated increase in contractility is entirely due to β_2 stimulation, whereas in the adult rat it is due solely to β1 receptor activation. Coupling of the β_2 receptor to Gi protein action is apparently defective in the neonatal rat, because the ratio of Gi to Gs subunits is much higher in the neonate. The relative proportion of β_1 and β_2 receptors is the same in neonatal versus adult hearts (17% β_2) and approximates the ratio measured in children with simple acyanotic congenital heart disease, which is about 22% [60].

There is animal and human evidence that α-adrenergic receptor-mediated chronotropic and inotropic effects on the cardiac myocyte change with development. In the neonatal animal model, α stimulation produces positive inotropic and chronotropic effects, whereas in the adult it produces negative effects [60,61]. The chronotropic response to α_1 stimulation diminished with increasing age in children being evaluated for autonomic dysfunction after vagal and sympathetic blockade [62].

Calcium cycling in the normal heart

Calcium assumes a central role in the process of myocardial contraction and relaxation, serving as the second messenger between depolarization of the cardiac myocyte and its contraction mediated by the actin–myosin system. Calcium's role in this excitation–contraction coupling in the normal mature heart will be reviewed briefly before discussion of developmental changes and changes with heart failure [63].

Cardiac muscle cell contraction depends on an increase in intracellular Ca^{2+} above a certain threshold, and relaxation ensues when intracellular Ca^{2+} falls below this threshold. Two major regions of Ca^{2+} flux occur: across the sarcolemmal membrane (slow response), and release from internal stores–the sarcoplasmic reticulum (rapid release and reuptake) [64,65] (Fig. 6.11). The primary site of entry of Ca^{2+} through the sarcolemmal membrane is through the L-type, or low-voltage-dependent Ca^{2+} channels, which occurs in two types: a low-threshold, rapidly inactivating channel; and a higher threshold, more slowly inactivating channel [66]. Depolarization of the sarcolemmal membrane triggers opening of these channels, resulting in the release of large amounts of Ca^{2+} from the sarcoplasmic reticulum (SR), the major internal Ca^{2+} storage organelle. Ca^{2+} entry through the slowly inactivating channels serves to fill the SR with adequate Ca^{2+} stores. Removal of Ca^{2+} from the cytoplasm to the exterior of the cell occurs via two major mechanisms: the sodium–calcium (NaO–Ca^{2+}) exchanger, and the calcium ATPase pump. The NaO–Ca^{2+} exchanger usually serves to exchange three sodium ions (moving into the cell) for one Ca^{2+} (moving out of the cell), although the reverse action, as well as a 1:1 exchange, is possible [67]. The Ca^{2+}-ATPase pump actively transports Ca^{2+} (in a 1:1 Ca^{2+}-ATP ratio) out of the cell in an energy-dependent high-affinity but low-capacity manner [68]. The affinity of the sarcolemmal Ca^{2+}-ATPase pump is enhanced by calmodulin, which binds free cytoplasmic Ca^{2+}. Although the calcium movement through the sarcolemma plays an important role in balancing internal and external Ca^{2+} concentrations and in supplying Ca^{2+} to replenish SR Ca^{2+} stores, and in initiating the Ca^{2+}-induced release of Ca^{2+} from the SR, it is important to recognize that the amount of Ca^{2+} flux is far less than across the SR, the far more important mechanism for excitation–contraction coupling in the mature heart [69]. The sarcolemmal Ca^{2+} flux mechanisms play a much more important role in the excitation–contraction coupling of the neonatal (immature) heart.

The massive release and reuptake of Ca^{2+} responsible for activation and deactivation of the actin–myosin complex and cardiocyte contraction and relaxation occurs at the level of the SR. The SR is a closed, intracellular membranous network that is intimately related to the myofilaments responsible for contraction [70,71] (Fig. 6.12). The SR is connected to the sarcolemmal membrane via the transverse tubule (T-tubule) system. Depolarization of the sarcolemmal membrane results in transfer of charge down the T-tubules to the SR, resulting in the opening of SR Ca^{2+} channels and the release of large amounts of Ca^{2+} into the cytoplasm, where it can then bind to troponin and initiate the actin–myosin interaction. The SR is divided into longitudinal SR and terminal cisternae; the latter connect to the T-tubules. The terminal cisternae are primarily involved in the release of Ca^{2+}, and the longitudinal SR in its reuptake [72].

The primary Ca^{2+} release mechanism of the SR is the ligand-gated Ca^{2+} release channels (also known as the ryanodine receptors) that bind to the drug ryanodine. The channels are activated by two primary mechanisms: depolarization via the T-tubules, and binding of intracellular Ca^{2+} itself; the predominance of one mechanism over the other differs in cardiac versus skeletal muscle. The close proximity of the L-type sarcolemmal Ca^{2+} channels in the T-tubules to the ligand-gated Ca^{2+} release channels allows the depolarization to rapidly allow Ca^{2+} into the cell and open the SR Ca^{2+} channels. These ligand-gated Ca^{2+} release channels close when the cytosolic Ca^{2+} concentration increases; normally they open at 0.6 μM Ca^{2+} and close at 3.0 μM Ca^{2+}.

The reuptake and sequestration of Ca^{2+} leads to relaxation of the cardiac myocyte and is an active transport mechanism, primarily involving hydrolysis of ATP by the SR Ca^{2+}-ATPase

(SERCA), located in the longitudinal SR [73]. It binds two Ca^{2+} ions with high affinity and rapidly transports them to the inside of the SR. This transport system differs from the sarcolemmal membrane: it has higher affinity, allows for more rapid transport, and is not sensitive to calmodulin. Ca^{2+} is stored in the SR by calsequestrin, a high-capacity, low-affinity protein that acts as a Ca^{2+} sink.

There are two other proteins with essential roles in the regulation of Ca^{2+} flux: phospholamban and calmodulin [74,75]. Phospholamban is associated with the SERCA and can be phosphorylated by at least four different protein kinases: cAMP-dependent, Ca^{2+}/calmodulin dependent, cGMP-dependent, or protein kinase C. When phosphorylated, phospholamban increases the affinity of the SERCA for Ca^{2+}, facilitating Ca^{2+} flux back into the SR, thus affecting the inotropic and lusitropic state of the heart. Phospholamban plays an important role in the β-adrenergic mediated increase in inotropic state of the heart. Calmodulin is a Ca^{2+} storage protein with four binding sites, found in the cytoplasm, which interacts with the sarcolemmal Ca^{2+}-ATPase (increasing its affinity for Ca^{2+}) and the SR ligand-gated Ca^{2+} release channel (inhibiting its activity at optimal cytoplasmic Ca^{2+}), and binds to the Ca^{2+}/calmodulin dependent protein kinase [75]. Mutations in the phospholamban gene have been described, and may be a rare cause of dilated cardiomyopathy [76].

The increase in intracellular cytoplasmic Ca^{2+} initiates the contractile process. Myosin is the major component of the thick filaments, which make up the microscopic structure of the myofibril, and its interaction with actin (the major component of the thin filaments) provides the mechanical basis of cardiac muscle cell contraction [77]. Actin and myosin make up approximately 80% of the contractile apparatus and are arranged in a parallel, longitudinal fashion, projecting from a Z-line or band (Fig. 6.13) to form the basic contractile unit called the sarcomere [78]. A three-dimensional lattice consisting of interdigitated thick and thin filaments in a hexagonal array with three thin filaments in close proximity to each thick filament is formed. The actin and myosin are linked by projections on the myosin protein called S1 cross-bridges, which bind to actin and, via an energy-dependent hinge-like mechanism, produce the sliding filament cross-bridge action that is thought to produce sarcomere shortening and lengthening. The lattice is held together by connecting proteins such as titin, nebulin, and α-actinin [79]. The actin–myosin interaction is initiated when Ca^{2+} binds to troponin, a protein closely connected to actin which consists of three subunits: a Ca^{2+} binding subunit (TNC), a tropomyosin binding unit (TNT), and an inhibitory subunit (TNI). TNC can bind up to four Ca^{2+} ions, and this produces a conformational change on the thin filament, which allows the S1 myosin head cross-bridges to attach [80]. This also changes the TNI subunit's conformation and allows tropomyosin, another protein integral in filament interaction, to move aside and expose the binding sites on actin, allowing strong binding to the S1 cross-bridges. With Ca^{2+} present, actin causes myosin ATPase to hydrolyze one ATP molecule, providing energy that results in the S1 myosin head pulling on the thin filament, resulting in sarcomere shortening. Troponin C is the most important aspect of the regulation of cardiocyte contraction, and has a steep response curve to local levels of Ca^{2+}. The reuptake of Ca^{2+} into the SR causes Ca^{2+} levels to decline rapidly and the inhibitory form of the troponin, tropomyosin, actin complex returns, resulting in the reversal of the cross-bridge binding and thus sarcomere relaxation.

Besides calcium, many other regulatory mechanisms exist to influence the interaction and sensitivity of Ca^{2+} binding to troponin. These mechanisms include β-adrenergic stimulation, thyroid hormone, and phosphorylation by cAMP-dependent protein kinases.

Developmental changes in calcium cycling

Several aspects of the excitation–contraction system are different in the immature heart. The T-tubule is not fully formed [81]. The sarcoplasmic reticulum has less storage capacity and less structural organization [82], less mRNA expression [83,84], and less responsiveness to chemical blockade [85,86].

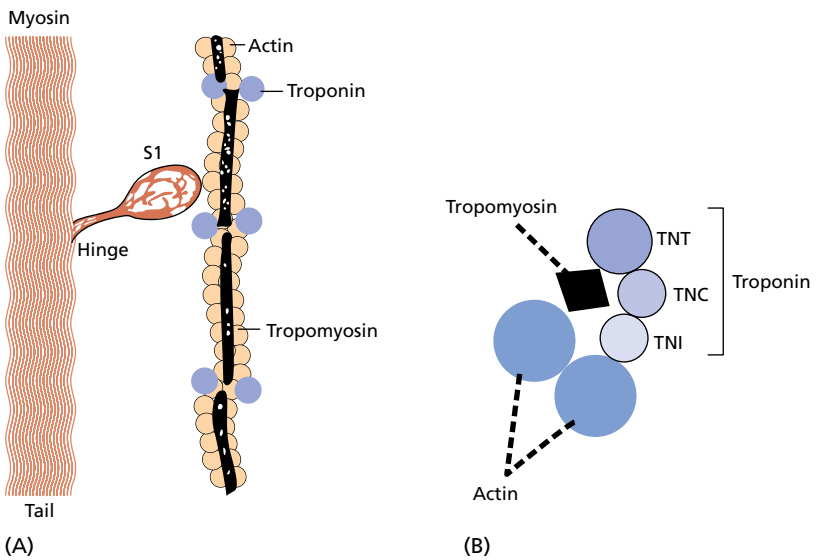

Figure 6.13 (A) Single thick and thin filament showing the S1 cross-bridge and hinge mechanism. (B) Relationship of actin to tropomyosin and the three troponin subunits. See text for explanation. *Source:* Reproduced from Michael [78] with permission of Wolters Kluwer.

The inhibitory subunit of troponin (TNI) changes from a predominately cAMP-insensitive form to a cAMP-responsive form by 9 months of age, an additional factor contributing to the increased responsiveness seen with β-adrenergic stimulation after the neonatal period [86]. All of this information has led to the theory that the neonatal cardiac myocyte is more dependent on free cytosolic Ca^{2+} fluxes than is the mature heart, and more susceptible to blockade of the L-type Ca^{2+} sarcolemmal channels as a mechanism of myocardial depression. The latter is thought to be the mechanism producing greater myocardial depression observed with halothane in neonatal rat models compared with sevoflurane, and the same phenomenon seen clinically [87]. A summary of the major differences in cardiac development and function between the neonatal and mature heart is presented in Table 6.2.

Thyroid hormone

Tri-iodothyronine (T3) has a critical role in both the development of the cardiovascular system and also acute regulation and performance. Normal T3 levels are essential for normal maturation and development of the heart through expression of genes responsible for the production of the cardiac contractile proteins, elements of the calcium cycling apparatus, and development and density of β-adrenergic receptors [88]. There are cell nucleus mediated effects from exogenous T3 that occur from an increase in protein synthesis and require at least 8 h to develop. These include an upregulation of β-adrenergic receptors, increase in cardiac contractile protein synthesis, increase in mitochondrial density, volume, and respiration, increase in SR Ca^{2+}-ATPase mRNA, and changes in myosin heavy chain isoforms. However, there are acute effects of T3 on cardiac myocytes that occur in minutes from interactions with specific sarcolemmal receptors, and include stimulation of L-type Ca^{2+} pump activity, stimulation of SR Ca^{2+}-ATPase activity, increased protein kinase activity, and decrease in phospholamban [89]. Cardiac surgery and cardiopulmonary bypass interfere with the conversion of thyroxine (T4) to T3, and serum levels decrease significantly after cardiac surgery in infants and children [90]. T3 infusions improve myocardial function in children after cardiac surgery and reduce intensive care unit stay [91].

KEY POINTS: CARDIOMYOCYTE RECEPTOR FUNCTION IN NORMAL AND DISEASED HEARTS

- The adrenergic receptor system, particularly the β-receptor system, plays a central role in regulating cardiac contractility through G protein and adenylate cyclase coupling
- Calcium cycling in the neonatal heart is characterized as immature, with underdeveloped T-tubules and sarcoplasmic reticulum, not reaching the mature state until an estimated 6–12 months of age
- Thyroid hormone is essential for normal gene expression for production of cardiac contractile proteins, calcium cycling apparatus, and adrenergic receptor density, as well as acute effects to increase sensitivity of adrenergic receptors and efficiency of calcium cycling

Regulation of vascular tone in systemic and pulmonary circulations

The regulation of vascular tone is an important consideration in the understanding and treatment of congenital heart disease. Both the systemic and pulmonary circulations have complex systems to maintain a delicate balance between vasodilating and vasoconstricting mediators in normal patients. Abnormal responses may develop which lead to pulmonary or systemic hypertension or, conversely, vasodilation. A schematic representation of some of these mediators is shown in Figure 6.14 [92]. To some extent, the control mechanisms reviewed are present in both the systemic and pulmonary circulations; however certain mechanisms are more important in one circulation. For example, the endothelial-mediated systems (nitric oxide–cGMP pathways, etc.) predominate in the pulmonary

Table 6.2 Summary of major differences between neonatal and mature hearts

	Neonatal	Mature
Physiology		
Contractility	Limited	Normal
Heart rate dependence	High	Low
Contractile reserve	Low	High
Afterload tolerance	Low	Higher
Preload tolerance	Limited	Better
Ventricular interdependence	Significant	Less
Ca^{2+} cycling		
Predominant site of Ca^{2+} flux	Sarcolemma	SR
Dependence on normal Ca^{2+}	High	Lower
Circulating catecholamines	High	Lower
Adrenergic receptors	Down-regulated, insensitive	Normal
	β_2, α_1 predominant	β_1 predominant
Innervation	Parasympathetic predominates; sympathetic incomplete	Complete
Cytoskeleton	High collagen and water content	Lower collagen and water content
Cellular elements	Incomplete SR, disorganized myofibrils	Mature SR, organized myofibrils

SR, sarcoplasmic reticulum.

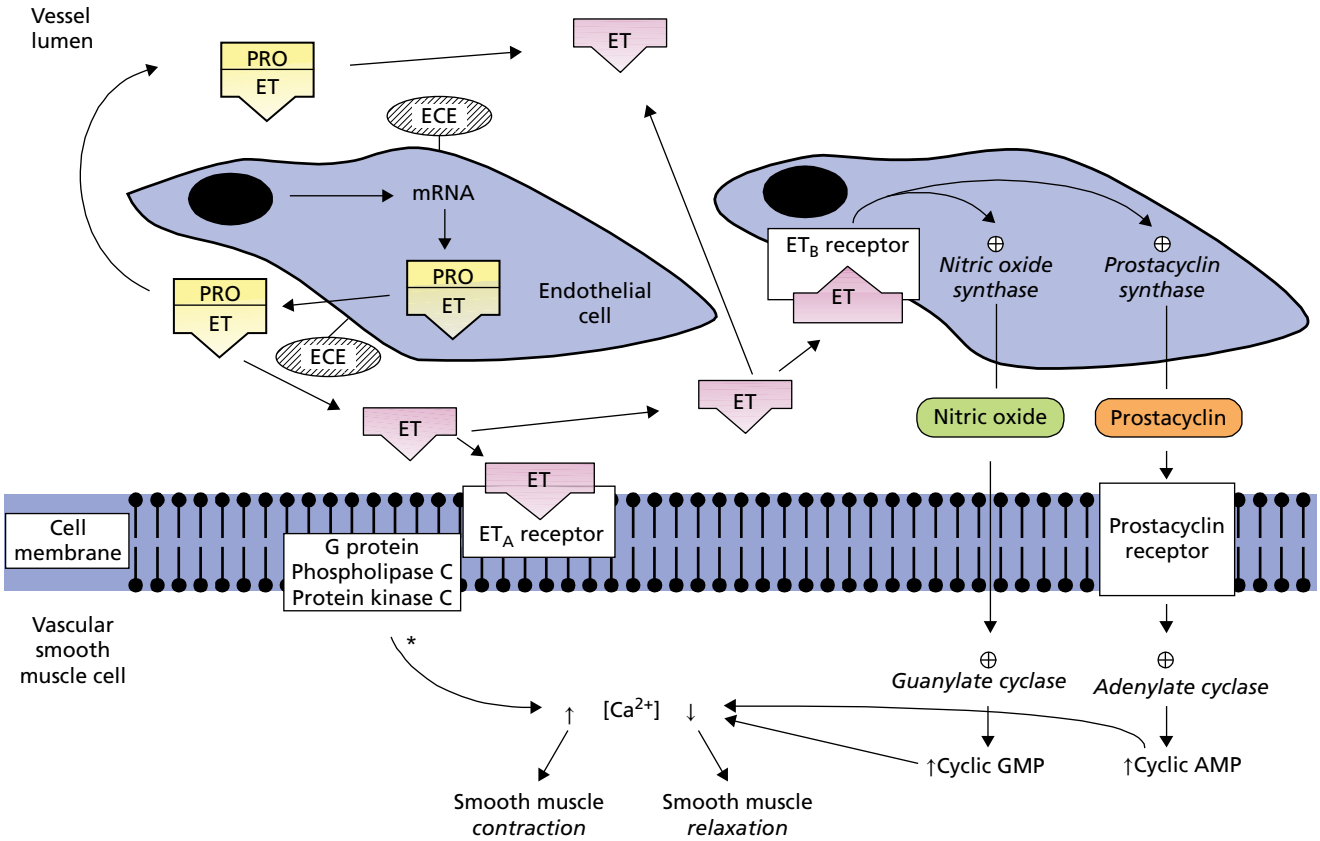

Figure 6.14 Schematic of some major mediators of vascular tone in the pulmonary circulation. ET, endothelin-1; PROET, proendothelin-1; ECE, endothelin-converting enzyme. See text for explanation. *Source:* Reproduced from Haynes and Webb [92] with permission of Portland Press.

circulation (low-resistance circulation), whereas the phospholipase systems predominate in the systemic circulation (high-resistance circulation). The endothelium-dependent control of vascular tone plays a significant role in the transition from fetal to postnatal circulation, with pathological persistence of fetal endothelial milieu contributing to the transitional circulation and pulmonary hypertension, both of which may influence the pathophysiology of congenital heart disease [93].

Pulmonary circulation

Vasoactive metabolites of arachidonic acid, called eicosanoids, are produced in cell membranes. Eicosanoids metabolized via the lipoxygenase pathway will form leukotrienes, and those metabolized via the cyclo-oxygenase pathway form the prostaglandins. Important vasodilating prostaglandins include PGE_1, which also promotes and maintains patency of the ductus arteriosus. Prostacyclin, PGI_2, is a potent pulmonary vasodilator [94]. Prostaglandins act in vascular smooth muscle of the systemic and pulmonary circulations by binding to receptors in the smooth muscle cell membrane, activating adenylate cyclase and increasing cAMP concentrations, which lead to lower Ca^{2+} levels and a reduction of vascular tone. Thromboxane A2 is a potent leukotriene that has the opposite effects of the prostaglandins, producing vasoconstriction and platelet aggregation. Imbalance in this system caused by chronic hypoxia can lead to chronic pulmonary hypertension [95–97].

Nitric oxide (NO) is an endothelium-derived relaxant factor that causes relaxation of vascular smooth muscle cells after diffusing into the cell and activating guanylate cyclase, increasing the concentration of cGMP, leading to a reduction in the local concentration of Ca^{2+} and thus reducing vascular tone [96]. Calcium-sensitive potassium channels contribute to the vasodilatation caused by NO via a cGMP-dependent protein kinase [98]. NO is formed from L-arginine by NO synthase, and is almost immediately inactivated by binding to hemoglobin. Phosphodiesterase V breaks down cGMP, so the phosphodiesterase-inhibiting drugs, like sildenafil, potentiate NO-mediated vasodilation [99].

Endothelins are powerful endothelium-derived vasoactive peptides, and endothelin-1 (ET-1) is the best characterized. ET-1 is produced from proendothelin-1 by endothelin-converting enzymes in the endothelial cells of the systemic and pulmonary vasculature. Increased pressure, shear stress, and hypoxia can lead to increased production of ET-1 in the pulmonary circulation. Two ET-1 receptors, ETA and ETB, mediate effects on smooth muscle vascular tone [100]. The ETA receptor is found on the smooth muscle cell membrane and mediates vasoconstriction, while the ETB receptor is located on the endothelial cell itself, and results in increased NO synthase activity, producing vasodilation. The primary activity of ET-1 appears to be to stimulate the ETA receptor, and indeed increased levels of ET-1 are found in many pulmonary hypertensive states such as Eisenmenger syndrome and primary pulmonary hypertension [101]. ET-1 increases in response to shear stress, hypoxia, or ischemia, and results in elevated intracellular Ca^{2+} and increased sensitivity to Ca^{2+}, increasing pulmonary vascular tone and pressure [95].

Systemic circulation

There are multiple levels of control over the peripheral circulation. Neural control by the sympathetic and parasympathetic nervous systems is produced from stimulation of receptors on the afferent limb such as stretch receptors within the walls of the heart, and baroreceptors in the walls of arteries, such as the aortic arch and carotid sinuses. Stretch in the arterial wall stimulates the baroreceptors producing vasodilation and heart rate slowing, mediated by the vasomotor centers of the medulla [102]. Atrial stretch receptors inhibit secretion of vasopressin from the hypothalamus. The efferent limb of the autonomic nervous system consists of sympathetic and parasympathetic nerve fibers. The sympathetic nerves can be divided into vasoconstrictor and vasodilator fibers. When stimulated, the vasoconstrictor fibers release norepinephrine-activating α-adrenergic receptors producing vasoconstriction. The vasodilator fibers release acetylcholine or epinephrine, and are mainly present in skeletal muscle. Parasympathetic fibers are vital in control of heart rate and function, but have only a minor role in controlling the peripheral circulation [103].

Hormonal control and receptor-mediated intracellular signaling are other important mechanisms. Norepinephrine primarily stimulates peripheral α receptors and causes vasoconstriction. It is secreted by the adrenal medulla and by sympathetic nerves in proximity to the systemic blood vessels. Epinephrine is also secreted by the adrenal medulla, but its primary action is to stimulate the β_2 receptors in the peripheral circulation, causing vasodilation through cAMP-mediated reductions in intracellular Ca^{2+} concentrations.

Angiotensin II is produced by activation of the renin–angiotensin–aldosterone axis in response to reduced flow and pressure sensed by the juxtaglomerular apparatus in the kidney. Renin produces angiotensin I by cleaving angiotensinogen, and angiotensin II is produced when angiotensin I passes through the lung by angiotensin-converting enzyme. Angiotensin II is a potent vasoconstrictor, and also induces the hypothalamus to secrete vasopressin (antidiuretic hormone), which also has vasoconstrictor properties.

Atrial natriuretic factor (ANF) is released from atrial myocytes in response to stretch (elevation of right or left atrial pressure) on the atrium. It has vasodilatory and cardioinhibitory effects, and acts to retain sodium by decreasing tubular reabsorption of sodium in the kidney [104]. B-type natriuretic peptide is released by ventricular myocardium, also in response to stretch, and causes an increase in cGMP, leading to vasodilatation in both arterial and venous systems. In addition, it increases urinary sodium and water excretion [105].

Second messenger systems affect the activation of receptors on systemic vascular cell membranes leading to changes in vascular tone. The phosphoinositide signaling system is the common pathway for many of these agonists [102] (Fig. 6.15). Membrane kinases phosphorylate phosphatidylinositol, which is an inositol lipid located mainly in the inner lamella of the plasma membrane, producing phosphatidylinositol 4,5 biphosphate. The second

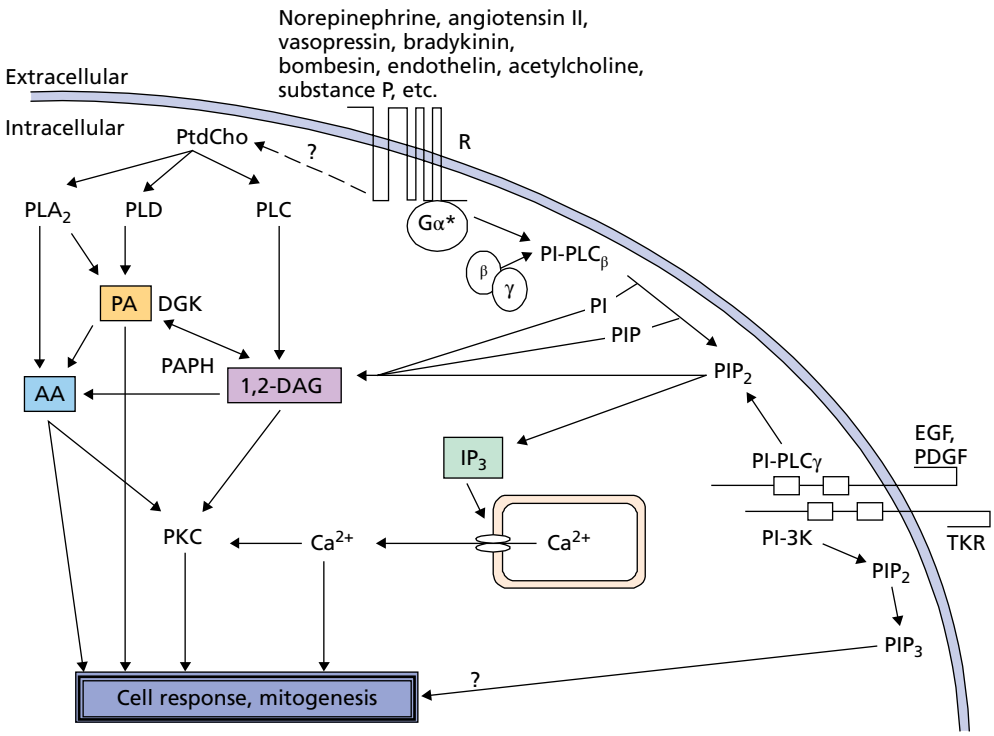

Figure 6.15 Phospholipase C system. Diagram summarizing the major receptor-activated pathways for production of inositol 1,4,5-triphosphate (IP3) and 1,2-diacyglycerol (1,2-DAG). The binding of an agonist to a receptor (R) with seven membrane-spanning domains results in the activation of the phosphatidylinositol-specific phospholipase Cβ (PI-PLCβ), whereas the stimulation of tyrosine kinase receptors (TKR) by polypeptide growth factors will activate phosphatidylinositol-specific phospholipase Cγ (PI-PLCγ). Both pathways will result in the hydrolysis of phosphatidylinositol 4,5-biphosphate (PIP2) and the formation of IP3 and 1,2-DAG. In addition, agonists that act on the heterotrimeric receptors may stimulate phosphatidylcholine (PtdCho) hydrolysis, and activation of tyrosine kinase receptors will stimulate the production of phosphatidylinositol 3,4,5-triphosphate (PIP3). DGK, diacylglycerol kinase; PAPH, phosphatidic acid phosphohydrolase; G*, activated G protein subunit; β, β-adrenergic receptor subunits; γ, γ-adrenergic subunits; PLD, phospholipase D; PKC, protein kinase C; PI-3K, phosphatidylinositol 3-kinase; PI, phosphatidylinositol; PIP, phosphatidylinositol 4-phosphate; EGF, epidermal growth factor; PDGF, platelet-derived growth factor; PLA2, phospholipase A2; AA, arachidonic acid. *Source:* Reproduced from Izzard et al [102] with permission of Elsevier.

messenger, inositol 1,4,5-triphosphate, is produced from this compound by the action of the enzyme phospholipase C (PLC) [106]. The sequence begins with the binding of an agonist, such as angiotensin II, vasopressin, norepinephrine, or endothelin to a receptor with seven membrane spanning domains. This receptor is linked to activated Gq protein subunit, which in turn stimulates phosphatidylinositol-specific phospholipase C (PI-PLC) to produce inositol 1,4,5,-triphosphate, which acts to cause release of Ca^{2+} from the sarcoplasmic reticulum, activating the actin–myosin system in the smooth muscle cells and producing vasoconstriction. Another second messenger, 1,2-diacylglycerol, is also produced, which goes on to activate protein kinase C, which in turn has a role in mitogenesis and thus proliferation of smooth muscle cells. There are many isozymes of phospholipase C; the form implicated in this series of events is the PLCβ form. The PLCγ isoform is activated when cell growth factors such as platelet-derived growth factor bind to their receptors on the cell surface and active tyrosine kinases. This results in the production of phosphatidylinositol 3,4,5-triphosphate, which is also implicated in mitogenesis.

Vasodilatation of the systemic circulation results from the formation of NO by nitrovasodilators, or by activation of β_2-adrenergic receptors in the peripheral vasculature, both of which result in the activation of guanylate cyclase and the production of cGMP, which reduces intracellular Ca^{2+} concentrations, producing vasodilation [107].

The vascular beds in various peripheral tissues differ in the amount of local metabolic control of vascular tone. For example, pH has much more influence on the pulmonary circuit, with low pH leading to vasoconstriction and higher pH leading to vasodilatation, than in the vascular tone of other tissues. Local CO_2 concentration is much more important to central nervous system vasculature, with high levels leading to vasodilatation. Decrease in oxygen tension will often lead to vasodilatation, as adenosine is released in response to the decreased oxygen delivery; however decreased oxygen tension increases tone in the pulmonary circulation. Autoregulation, or maintaining relatively constant blood flow over a wide range of arterial pressures, predominates in the cerebral circulation but is not as critical in other tissue beds. Autoregulation and CO_2 responsiveness are both blunted in the fetal and immature brain [108].

KEY POINTS: REGULATION OF VASCULAR TONE IN SYSTEMIC AND PULMONARY CIRCULATIONS

- The pulmonary vascular endothelium exerts major control of vascular tone and resistance, maintaining low resistance through complex pathways including nitric oxide, prostaglandins, and cyclic GMP
- Systemic vascular tone and resistance are maintained in a higher resistance state than the pulmonary vascular circulation with more neurohormonal activation that includes the sympathoadrenal, renin–angiotensin–aldosterone, and phospholipase C systems
- Pathophysiological derangements in vascular tone of pulmonary and systemic circulations have led to therapeutic approaches such as inhaled nitric oxide and endothelin receptor antagonists

Receptor signaling in myocardial dysfunction, congenital heart disease, and heart failure

A discussion of receptor signaling and calcium cycling in myocardial dysfunction is useful to serve as the basis for understanding many of the therapies discussed later in this text, and this section will focus on receptor physiology and calcium flux in three settings: acute myocardial dysfunction as seen after cardiac surgery and cardiopulmonary bypass; changes seen as responses to chronic cyanotic heart disease; and changes seen with chronic congestive heart failure and cardiomyopathy.

Receptor signaling in acute myocardial dysfunction

Acute myocardial dysfunction, such as that sometimes seen after cardiopulmonary bypass, is often treated with catecholamines. These drugs are sometimes ineffective, especially when used in escalating doses. In children, the number and subtype distribution of β-adrenergic receptors in atrial tissue is not affected by cardiac surgery with bypass; however, the activation of adenylate cyclase by isoproterenol is significantly reduced after bypass [109]. There is an uncoupling of β receptors from the Gs–protein–adenylate cyclase complex. Desensitization to moderate or high doses of catecholamines may occur after only a few minutes of administration, because increased cAMP concentrations result in uncoupling from the Gs protein [110].

After only a few minutes of high-dose catecholamine administration there may be inactivation of the phosphorylated adrenergic receptors from sequestration. These receptors can be sequestered by endocytosis, in a process involving a protein called β-arrestin, which binds to the receptor and a sarcolemmal protein called clathrin (Fig. 6.16) [51]. These sequestered receptors may either be recycled back to the cell membrane surface, or be destroyed by lysosomes [111]. This permanent destruction and degradation of receptors occurs after hours of exposure to catecholamines, and is accompanied by decreased mRNA and receptor protein synthesis, resulting in prolonged decrease in adrenergic receptor concentrations, which is reversed by decreasing exogenous catecholamines, but only as fast as new receptors can be synthesized.

Neonatal hearts may exhibit a different response to the acute or prolonged administration of catecholamines. Instead of desensitization, neonatal animal models demonstrate an enhanced β-adrenergic receptor response, accompanied by an increase in adenylate cyclase activity [112]. Desensitization occurs later in development. The exact translation of these data to humans is not clear.

Treatment with catecholamines may also increase the concentration of Gi protein subunits, decreasing the sensitivity of the β-adrenergic receptor. This relative decrease in the ratio of Gs to Gi protein subunits has been demonstrated in rat and dog models [113,114]. Another possible mechanism of catecholamine-induced desensitization of the neonatal myocyte was demonstrated in a rat model, where prolonged exposure to norepinephrine caused an initial increase in functional L-type Ca^{2+} channels on the sarcolemmal membrane. Continued

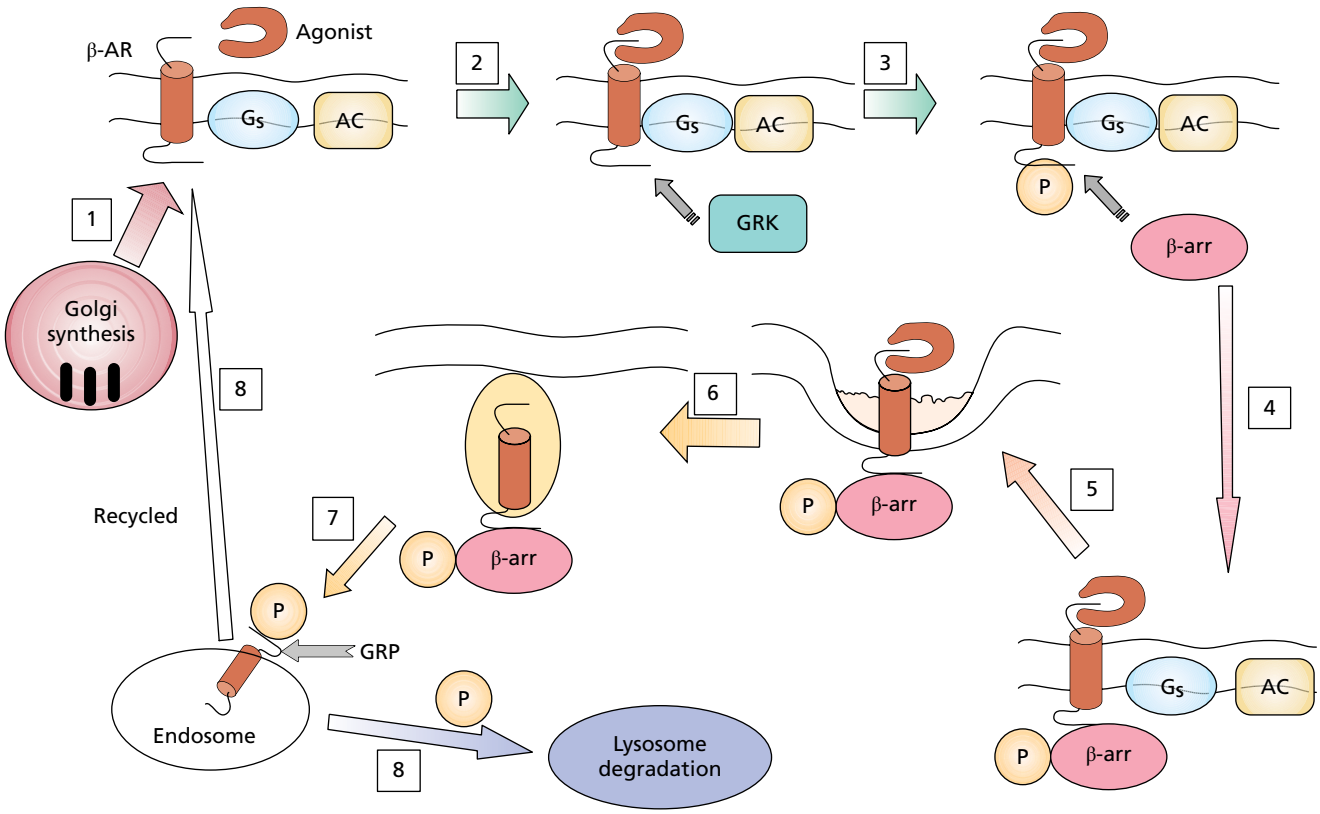

Figure 6.16 Desensitization and downregulation of the β-adrenoreceptor (β-AR). (1) Agonist binding. (2) Phosphorylation of the β-AR by G-protein coupled receptor kinases (GRK). (3) β-Arrestin binds to the GRK-phosphorylated β-AR, which is bound to the Gs protein. The receptor is then sequestrated to the endosomal compartment (4–7), to be dephosphorylated, and then either recycled back to the sarcolemma (8) or translocated to lysosomes for further degradation (8). AC, adenylate cyclase; GRP, G protein-coupled receptor phosphatase; P, inorganic phosphate groups; β-arr, β-arrestin. *Source:* Reproduced from Booker [51] with permission of John Wiley and Sons.

exposure caused a decrease in L-type Ca^{2+} channel mRNA to 50% of control values [115]. Sarcoplasmic reticulum Ca^{2+}-ATPase concentrations are reduced with chronic norepinephrine administration in the dog [116]. Finally, exposing adult or neonatal rat myocytes to high concentrations of catecholamines for 24 h leads to increased apoptosis of myocardial cells, a genetically programmed energy-dependent mechanism for cell death and removal [117,118]. This effect was mediated through β-adrenergic receptors in the adult model and α-receptors in the neonatal model.

All of these studies provide the theoretical basis for the argument that administration of catecholamines to patients with acute myocardial dysfunction should be limited in dose and duration. Obviously, this is difficult to accomplish in the setting of weaning a hemodynamically unstable patient from cardiopulmonary bypass. Strategies that may limit catecholamine dose include administering low doses of catecholamines together with phosphodiesterase inhibitors, as well as adding corticosteroids, tri-iodothyronine, and vasopressin [119].

Receptor signaling in congenital heart disease

In the past decade new information has become available concerning adrenergic receptor signaling in patients with congenital heart disease. A study of 71 infants and children undergoing cardiac surgery used tissue from the right atrial appendage to study β-adrenergic receptor density, distribution of β_1 and β_2 receptor subtypes, and coupling to adenylate cyclase [120]. This study found that patients with severe or poorly compensated acyanotic (e.g. congestive heart failure) or cyanotic (e.g. severe cyanosis) heart disease had significantly reduced β-adrenergic receptor densities. Outside of the newborn period, this downregulation was β_1 selective, but in newborns with critical aortic stenosis or transposition of the great arteries there was additional significant downregulation of the β_2 subtype. In tetralogy of Fallot patients, those treated with propranolol had a significant increase in the number and density of β-adrenergic receptors, when compared with untreated patients. β-Adrenergic receptor downregulation correlated with increased circulating norepinephrine levels. Finally, in severely affected patients, adenylate cyclase activity was reduced, demonstrating a partial decoupling, as noted previously. Other studies have determined that symptomatic tetralogy of Fallot patients, i.e. those with cyanotic spells, have a significantly greater number of β-adrenergic receptors in their right ventricular outflow tract muscle, and their adenylate cyclase activity was greater when compared to patients without cyanotic spells [121]. α_1-Adrenergic receptors are also affected by congenital heart disease. A study of atrial tissue excised at surgery in 17 children evaluated α- versus β-adrenergic receptor stimulation with pharmacological agents. The α component was responsible for 0–44% of the inotropic response, and β stimulation for 56–100% of the response, with the degree of right ventricular hypertrophy and pressure load correlating with the amount of α stimulation found [122].

A study of the myocellular changes and adaptation of the β-adrenergic receptor system that occur in the systemic RV of children with hypoplastic left heart syndrome (HLHS) compared 14 patients listed for transplant with normal RV function and no heart failure or inotropic therapy (compensated) with 12 HLHS patients listed for transplant with RV failure (decompensated) [123]. The control group was 12 organ donors whose hearts could not be matched due to size or blood type mismatch. Compared with non-failing control RVs, the HLHS RV demonstrated decreased sarcoplasmic reticulum calcium-adenosine triphosphatase 2α and α-myosin heavy chain gene expression, decreased total β-adrenergic receptors due to downregulation of β_1 receptors, preserved cyclic adenosine monophosphate levels, and increased calcium/calmodulin-dependent protein kinase II activity. There was increased atrial natriuretic peptide expression only in the HLHS group. There was myosin isoform switching, increased adenylyl cyclase 5, and increased phosphorylation of phospholamban threonine 17 only in the decompensated HLHS group; this signifies unique adaptation occurring only in these failing ventricles.

Receptor signaling in congestive heart failure and cardiomyopathy

Like adults with heart failure, children with congestive heart failure due to chronic left-to-right shunting and volume overload of the heart have elevated levels of circulating norepinephrine. This leads to a downregulation in β-adrenergic receptor density [124]. The degree of elevation of pulmonary artery pressure and amount of left-to-right shunting correlates with the plasma catecholamine levels, and is inversely correlated with β-adrenergic receptor density. All of these abnormalities return to normal levels after corrective surgery. The degree of receptor downregulation in congestive heart failure correlates with postoperative morbidity in infants and children. Children with an intensive care unit stay of greater than 7 days or those who died during the early postoperative period (9 of the 26) had significantly less β_1 and β_2 mRNA gene expression than those who had better outcomes [125]. In addition, the children receiving propranolol for treatment of their congestive heart failure had higher β-adrenergic receptor mRNA levels and tended to have improved outcomes. Finally, children with dilated cardiomyopathy also have a reduced response to catecholamines with one study showing no significant increase in ejection fraction during dobutamine stress test, with infusion of dobutamine at 5 and then 10 μg/kg/min [126]. Generally, studies in excised right atrial tissue in infants and children with congenital heart disease or cardiomyopathy demonstrate decreased density of β_1 and β_2 receptors, and decreased downstream adenylate cyclase function, with larger decreases associated with worse ventricular function [127]. A recent study of adrenergic receptor genetic variations assessed by single-nucleotide polymorphism analysis in 135 children with heart failure assessed α_2 receptor genotypes associated with increased norepinephrine (NE) release, and β_1 receptor genotypes associated with greater NE sensitivity [128]. In addition, β_2 receptor genotypes associated with receptor downregulation and impaired vasorelaxation were assayed. Patients with higher numbers of these abnormal genotypes had a linear increase in central venous pressure, pulmonary capillary wedge pressure, indexed pulmonary vascular resistance, and systemic vascular resistance. Patients with abnormal genotypes had much better response to β-blockers in preserving cardiac function.

An increasing number of children with heart failure are receiving therapy with left ventricular assist devices (LVAD), and in many the devices serve as a bridge to cardiac transplantation. In a very interesting study of hearts explanted for transplant, 11 hearts from transplanted LVAD children were compared with 20 heart failure patients transplanted without LVAD, and 16 control hearts explanted from donors which could not be transplanted for technical reasons [129]. Failing hearts without LVAD had a downregulation in total and β_1 receptors which was restored to normal non-failing levels with LVAD therapy. Other signaling pathways that were abnormal in failing hearts were also restored to normal non-failing levels, including G protein-coupled receptor kinase 2, indicative of reverse remodeling and suggesting that the use of LVAD more frequently as a bridge to recovery may be feasible in children.

The preceding has been a brief discussion of receptor signaling in pediatric heart disease. This emerging field has many implications for treatment strategies, and the reader is referred to excellent reviews for more detailed information on this subject [130].

KEY POINTS: RECEPTOR SIGNALING IN MYOCARDIAL DYSFUNCTION, CONGENITAL HEART DISEASE, AND HEART FAILURE

- High catecholamine doses in acute myocardial dysfunction can desensitize the myocardium through uncoupling of G protein adenylate cyclase complex and sequestration of β-adrenergic receptors
- Significant cyanotic or acyanotic congenital heart disease with heart failure can result in downregulation of β-adrenergic receptors in neonatal or infant myocardium
- Long-standing decreased ventricular function is often associated with decreased density of β-adrenergic receptors and decreased adenylate cyclase function

Myocardial preconditioning

Myocardial preconditioning refers to the finding that repeated, brief exposures of the myocardium to ischemia, volatile anesthetics, or other stresses induces a protective effect to a later (i.e. 12–24 h), more prolonged ischemic insult resulting in decreased myocardial infarction size and improved myocardial function after the insult [131]. Chronic cyanosis also induces a similar protective effect in the myocardium, although the effect size is smaller and more long-lasting, i.e. beyond 24 h. Another mechanism is remote ischemic preconditioning (RIPC), in which ischemia is produced in a tissue bed remote to the myocardium, for example skeletal muscle of the arm or leg, by repeated inflation of a blood pressure cuff which is thought to liberate as yet uncharacterized neurohumoral or hormonal substances that can protect the myocardium [132]. The mechanisms of myocardial preconditioning are complex but are thought to involve

release of various neurohormonal agents and peptides such as adenosine, bradykinin, and nitric oxide via a cGMP-dependent mechanism, which then triggers a series of signal transduction events within the cardiomyocyte that confer a "memory" effect that protects the myocardium from future ischemic insults. The signal transduction effects include protein kinase C, tyrosine kinases, mitogen-activated protein kinases, glycogen synthase kinase 3β, and other enzymes [133]. This series of events allows activation of mitochondrial and sacrolemmal K-ATP channels, which leads to the preconditioning by elusive mechanisms. One recently discovered candidate for this end effector is the mitochondrial permeability transition pore (MPTP) [133]. This is a nonspecific channel that spans both mitochondrial membranes; when opened for a prolonged period the result is a dissipation of mitochondrial electrical potential, inhibition of ATP synthesis, and ultimately mitochondrial swelling, rupture, failure of cellular energy metabolism, and cell death. Agents and stimuli that confer myocardial preconditioning have been found to keep the MPTP closed, thus possibly elucidating further the subcellular mechanisms involved.

KEY POINTS: MYOCARDIAL PRECONDITIONING

- Myocardial preconditioning is a complex phenomenon by which repeated brief exposure of the myocardium to ischemia or other stresses induces a protective effect to later ischemic insults
- The mitochondrial permeability transition pore is a common pathway for the various forms of ischemic preconditioning, staying closed and preventing mitochondrial failure
- Remote ischemic preconditioning produced by inflation of a blood pressure cuff on a limb before cardiopulmonary bypass will reduce some inflammatory and ischemic cell death markers, but as yet has not improved clinical outcomes.

Introduction

Aerobic cellular respiration is critical for survival and requires the efficient exchange of oxygen for carbon dioxide at the alveolar surface. The alveolar surface area must be able to accommodate the tremendous range in oxygen consumption – from 250 mL/min at rest to 5500 mL/min at peak exercise [1]. As a result, the gas exchange surface area of the adult lung will attain 50–100 m^2 with a final total lung capacity of 2.5–3.0 L. Lung organogenesis has to expand the lung surface area to meet these needs. This chapter will discuss the development of lung, chest wall, and diaphragm structure, development of the pulmonary vasculature, lung fluid physiology, transition in pulmonary function and circulation at the time of birth, and the postnatal development of lung structure and pulmonary function. Then the developmental pathophysiology of three diseases commonly encountered by the anesthesiologist will be presented: asthma, bronchopulmonary dysplasia, and cystic fibrosis.

Embryology of the lungs, chest wall, and diaphragm

Lung formation begins early in human gestation and growth extends well into childhood [2,3]. Although lung development is organized into stages (embryonic, pseudoglandular, canalicular, saccular, and alveolar), there is considerable temporal overlap of each stage that can be modified by prenatal and postnatal events (Fig. 7.1).

Embryological phase

This phase of lung development is marked by the formation of the lung bud and initial branches of the airways. The primordial lung is a foregut derivative, first recognizable at 25 days in the human fetus as a laryngotracheal groove in the ventral foregut. The more distal aspect of the groove closes, resulting in the only remaining connection between foregut in the region of the developing hypopharynx and larynx. Failure of closure results in a spectrum of tracheoesophageal fistulae, from the most common proximal esophageal pouch with a distal fistula between trachea and esophagus typically at the level of the carina (87%) to the less common isolated esophageal atresia (8%), H-type fistula (4%), and esophageal atresia with either proximal (1%) or proximal plus distal (1%) fistula [4]. Upon closure of the laryngotracheal groove, the lung bud begins a series of dichotomous divisions that give rise to the conducting airways and five primordial lung lobes (two left and three right). Failure of the lung bud to divide can result in pulmonary agenesis, most typically of the right lung.

Gregory's Pediatric Anesthesia, Sixth Edition. Edited by Dean B. Andropoulos and George A. Gregory.

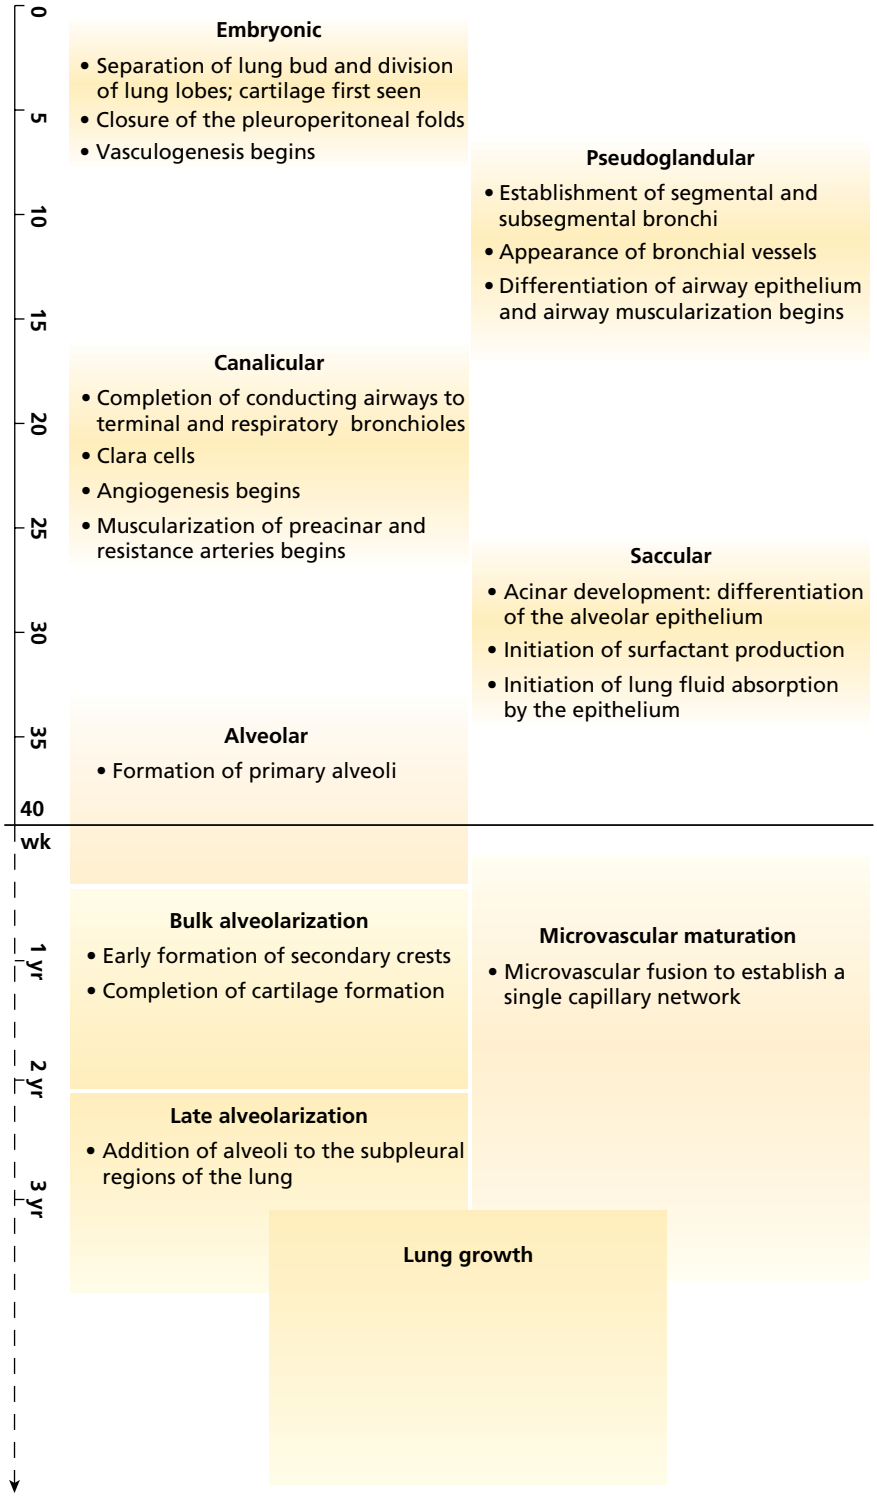

Figure 7.1 Schematic diagram of the fetal and postnatal stages of lung development.

Pseudoglandular phase

This stage of lung development marks the establishment of the large conducting airways of the lung. Divisions that establish the tracheaand segmental and subsegmental bronchi are completed by 7 weeks in the human fetus, and all bronchial divisions are completed by 16 weeks. It is important to remember that although the conducting airways will enlarge as the fetus and newborn grow (airway diameter and length increase 2- to 3-fold between birth and adulthood), large airway branching ceases after 16 weeks of gestation.

Canalicular phase

The canalicular phase of lung development is marked by completion of the small conducting airways through the

level of the terminal bronchioles, the last airways with cartilaginous support. Respiratory bronchioles no longer invested with cartilage mark the beginning of the gas exchange region of the lung. A respiratory bronchiole and all of its associated alveolar ducts and alveoli constitutes an acinus, and is the basic gas exchange unit of the lung. A terminal bronchiole with all its associated acinar structures constitutes a lobule. Branching of the terminal and respiratory bronchioles during the canalicular phase will ultimately result in a total of 23 airway subdivisions and completes the branching of the airways.

Saccular phase

This phase of lung development begins at roughly 24 weeks of human gestation and continues until just prior to term gestation. During this phase there is evolution of the relationships between the airspaces, capillaries, and mesenchyme, although the alveolocapillary membrane (the distance from the luminal surface of the airspace/alveolus to the luminal surface of the capillary) is sufficient to participate in gas exchange (0.6 μm) by approximately 24 weeks. Beyond this point, the efficiency of gas exchange is determined by the available surface area, not by the width of the alveolocapillary membrane. Lengthening and widening of the smooth-walled airspaces of terminal sacs expands the gas exchange surface area, which remains invested with a double capillary network.

Alveolar phase

This phase of lung development is the final stage that is initiated during fetal lung development, but alveolarization will not be completed until much later (see section "Lung development after birth"). While branching morphogenesis establishes the conducting airways of the lung, alveolarization will establish the large surface area involved in gas exchange [5]. This process will result in a 20-fold increase in surface area between birth (with between 0 and 50 million alveoli) and adulthood (>300 million alveoli). Primitive saccules develop low ridges (primary septa) that subdivide the saccule into an alveolar duct containing primary alveoli, and outpouchings between the ridges (secondary septa) that establish secondary alveoli. Regions destined for secondary septation exhibit increased elastin deposition [6], and elastin localizes to the tips of the secondary crests as they form. The septa contain a connective tissue core separating two capillary membranes, suggesting that the septum is formed by the folding of a capillary on itself. Septation also leads to the development of the pores of Kohn, allowing gaseous continuity between acini. Formation of secondary crests and the maturation of the microvasculature are critical elements of this stage of lung development, which only begins at roughly 36 weeks gestation in the human. Thus, the human lung is not fully mature structurally, even at term delivery. The completion of alveolar development is discussed in the section "Development of the pulmonary vasculature and its relationship to alveoli."

Development of the chest wall and diaphragm

Formation of the ventral body wall is initiated in the fourth week post fertilization with the formation of the lateral body wall folds. The folds consist of lateral plate mesoderm and overlying ectoderm, and the folds will move ventrally to meet in the midline of the developing embryo [7]. Failure of closure may occur anywhere along the midline, resulting in congenital malformations of the thoracic body wall (ectopia cordis, sternal cleft), and abdominal body wall (omphalocele, bladder exstrophy). The sternum arises from parallel bands of condensed mesenchyme in the 6th week and will fuse in the 10th week [8]. Formation of cartilage appears in the sternum immediately but ossification will not begin until the 6th month. Ossification of the ribs begins in the 7th week of gestation and will be completed by early adulthood. The diaphragm is critical for separating the developing lung within the thorax from the abdominal cavity with the developing gut and solid organs of the abdomen. Closure of the pleuroperitoneal folds is initiated in the pseudoglandular phase, and is completed by 7 weeks in the human fetus. During this time, the midgut resides within the umbilical cord and returns to the peritoneal cavity at 10 weeks. Thus, failure of diaphragm formation results in continuity between thoracic and peritoneal cavities, allowing peritoneal contents (stomach, intestine, and/or liver) to migrate into the thoracic cavity. This restricts the space into which the lung grows, leading to pulmonary hypoplasia of the lung ipsilateral to the diaphragmatic defect. Pulmonary hypoplasia can also extend to the contralateral lung due to shifting of the mediastinum as abdominal viscera accumulate within the thorax.

KEY POINTS: EMBRYOLOGY OF LUNGS, CHEST WALL, AND DIAPHRAGM

- Lung development passes through five phases that somewhat overlap
- Each developmental phase extends the structure of the lung and eventually produces a lung that is capable of oxygenation and carbon dioxide removal without the placenta
- Alveolarization, while incomplete at birth, is mostly complete by about 3 years of age
- The chest wall is mostly cartilage at birth and therefore very compliant. This chest wall plasticity is necessary to allow vaginal birth

Development of the pulmonary vasculature and its relationship to alveoli

The pulmonary vasculature consists of the vascular supply to the acini and the bronchial circulation [9]. During early fetal life, the airways act as a template for pulmonary blood vessel development. Early pulmonary blood vessels form by vasculogenesis, which is *de novo* differentiation of mesenchymal cells into endothelial cells and then capillaries. As each new airway buds into the mesenchyme, a new plexus forms and

adds to the pulmonary circulation. By 5 weeks of human gestation, a capillary network surrounds each bronchus and circulation of blood between the right ventricle and the left atrium via this network is evident. By the canalicular stage of lung development, new blood vessels form from pre-existing vessels via *angiogenesis* in which endothelial cells proliferate and sprout from established vessels. *Vasculogenesis* is the primary mode of pulmonary vascular development until the 17th week of gestation when all preacinar airways are complete, whereas angiogenesis becomes the predominant mode in the later stages of lung development. Interconnections between vascular networks arising from both angiogenesis and vasculogenesis increase in the saccular phase of lung development.

In the human lung, a second circulatory system, the bronchial circulation, arises from the dorsal aorta supplying systemic blood. The bronchial vasculature develops after the pulmonary circulation, with bronchial vessels first apparent by 8 weeks. The network of bronchial vessels is extensive, with bronchial arteries demonstrated as distal as the alveolar ducts in the adult respiratory tree. The inappropriate branching of bronchial vessels from the dorsal aorta is implicated in the formation of bronchopulmonary sequestration, a space-occupying lung malformation that can result in hypoplasia of the ipsilateral lung.

Vasculogenesis and angiogenesis are the primary mechanisms of vascular development throughout intrauterine life. The human lung at term contains only a small portion of the adult number of alveoli, and the airspace walls are represented by a thick "primary septum" consisting of a central layer of connective tissue surrounded by two capillary beds, each of them facing one alveolar surface [3]. This double capillary network is not present in the adult lung. As alveolar architecture changes with the appearance of secondary septa, folding of one of the two capillary layers occurs within the secondary septa. Microvascular maturation involves fusion of the double capillary network into a single capillary system. The expansion of surface area and luminal volume compresses the interstitium, bringing the capillary networks in close proximity to potential airspaces and thereby promoting both alveolar surface area expansion and capillary bed fusion. By the third postnatal week, lung volume increases by 25% and there is a 27% decrease of the interstitial tissue volume that is believed to promote microvascular fusions. Subsequently, there is preferential growth of fused areas that continues until ~3 years of age. Lung volume increases about 23-fold between birth and young adulthood, while capillary volume expands 35-fold. It has been recently shown that this increase in capillary volume occurs by insertion of capillaries in the absence of capillary sprouting. This new concept in capillary network growth has been named *intussusceptive microvascular growth*, and involves the formation of transluminal tissue pillars within existing vessels that then expand to increase capillary surface area [3].

Muscularization can be detected early in development of the pulmonary arteries [9]. Initially the muscular investment of the vasculature is derived from the migration of bronchial smooth muscle cells from adjacent airways. Muscularization of preacinar and resistance arteries of the pulmonary vasculature begins in the canalicular stage and continues through the remainder of gestation. This second phase of smooth muscle cells investing pulmonary vessels develops from the surrounding mesenchyme. A third phase of vascular muscularization has been described, largely in the very distal lung, in which capillary endothelial cells undergo a process of endothelial–mesenchymal transition that encompasses endothelial cell division, separation and migration from the endothelial layer, and expression of smooth muscle cell markers. Normal muscularization of pulmonary arteries extends down to the level of the terminal bronchiole and is minimal to absent in vessels surrounding respiratory bronchioles. Abnormal extension of smooth muscle along arterioles supplying acinar structures occurs in infants dying from persistent pulmonary hypertension of the newborn and in severe bronchopulmonary dysplasia.

Recent evidence suggests that the pulmonary capillary bed actively promotes normal alveolar development and contributes to the maintenance of alveolar structures throughout life [10]. The observation that combined abnormalities in the airways and vasculature occur in bronchopulmonary dysplasia supports this hypothesis. Intra-acinar arteries and veins continue to develop after birth by angiogenesis as long as alveoli continue to increase in number and size. This may well be a reciprocal process because vascular growth around the distal airspaces suggests an inductive influence from the alveolar epithelial cells.

KEY POINTS: DEVELOPMENT OF THE PULMONARY VASCULATURE

- Development of pulmonary vasculature generally follows development of the airways
- There is a dual system of vessels in the alveoli at birth that disappears with further extrauterine lung growth
- From birth to young adulthood the lung volume increases 23-fold and the capillary volume increases 35-fold
- The pulmonary capillary bed probably actively promotes normal alveolar development and contributes to the maintenance of alveolar structures throughout life

Physiology and anatomy of the upper and lower airways in infants and children

Some aspects of this topic are also covered in Chapter 16. The airway of infants and young children has several anatomical and physiological differences compared to that of older children and adults. Nasal breathing is strongly preferred over oral breathing in the neonatal period. Newborn infants with obstruction of the nasal passage, i.e. with choanal atresia, can present with severe episodes of cyanosis. However, infants can breathe through their mouth in the case of nasal obstruction [11]. Reasons for the preferred nasal route in newborn infants are the relatively large tongue and the more cranially positioned epiglottis which can be in contact with the soft palate and therefore impede oral breathing [12]. The highly positioned epiglottis and larynx move down over the first years of life. The upper airway, including pharynx, larynx, trachea,

and bronchi, shows also a much higher compliance in infants compared to older children and adults. This is due to a decreased upper airway muscle tone and a higher flaccidity of the supporting laryngeal, tracheal, and bronchial cartilage. Infants and young children are therefore at higher risk of upper airway collapse [13]. This can be observed in infants with upper airway obstruction, who can aggravate their obstruction by forceful inspirations leading to upper airway collapse and further obstruction. In lower airway obstruction, forceful expiration can lead to airway collapse due to compressive forces of the thorax and respiratory muscles. This phenomenon of dynamic airway collapse can be observed in agitated and crying infants and young children. It also explains why sedatives can improve their respiratory function, especially by preventing airway collapse due to forceful inspirations and expirations [14].

Airway resistance (R_{aw}) is much higher in newborn infants compared to older children and adults, and small reductions of their airway diameter lead to a much higher increase in R_{aw} than in airways with larger diameters. This is one of the reasons why infants and young children are much more affected by small airway diseases, e.g. bronchiolitis, compared to adults, as up to 50% of R_{aw} in infancy is contributed by the small airways [15,16].

KEY POINTS: PHYSIOLOGY OF THE UPPER AIRWAY IN NEONATES

- Neonates prefer nasal breathing
- The large tongue and more cranial epiglottis make contact with soft palate and make difficult breathing more likely
- Structures of the upper airway are more compliant and, therefore, more prone to collapse during upper airway obstruction
- Airway resistance is higher in neonates and infants due to the small airway. Edema of these airways has a much more profound effect than in older patients

Chest wall and respiratory muscles

Breathing is the result of cycling changes of pressures in the lung and airways generated by a complex interplay between chest wall, diaphragm, airways, and lung parenchyma. Besides developmental changes of lung parenchyma and airways, respiratory muscles and chest wall also undergo specific changes during infancy and childhood.

Diaphragm and intercostal muscles

The diaphragm is a dome-shaped musculo-fibrous septum between thorax and abdomen. It represents the most important respiratory muscle. In infancy, the insertion of the diaphragm is more horizontal, i.e. the costo-diaphragmatic angle is more shallow compared with later in life [17]. This reduces the efficiency of breathing and limits the ability of the diaphragm to increase tidal volumes when required. In young children with high chest compliance and less efficient intercostal muscles, maximal diaphragmatic activity during inspiration can lead to an indrawing of the lower costal margin. This so-called Hoover sign is a common symptom in infants and young children with respiratory distress. The relative muscle mass of the diaphragm in infancy is also lower and contains fewer fatigue-resistant type I muscle fibers than in older children and adults. The external intercostal muscles raise the rib cage upward and outward but contribute little to inspiration in early infancy due to the horizontally placed ribs. Additionally, the external intercostal muscles contribute to stabilization of the ribcage. Anesthetic agents can impair their function and can lead to a loss of functional residual capacity. At the end of the first year of life the contribution of ribcage muscles to tidal breathing has reached characteristics of older children and adults [18].

Chest wall

The configuration of the chest differs markedly in infants compared to older children. The cross-sectional area of the thorax in infants shows a relatively square rather than an elliptic shape as in older children. The ribs in infants are more horizontally placed, which limits the function of the intercostal muscles and thoracic respiration. During childhood and adolescence, the ribs become more downward sloping so that by age 10 years they have reached the adult configuration. This enables older children to increase their thoracic diameter more than younger children. As a result, the contraction of the diaphragm and intercostal muscles, lifting the ribs like a bucket handle, is more effective in increasing intrathoracic volume, and thus negative pressure, in adulthood than it is in infancy. Furthermore, the chest wall in infants is highly compliant and shows a higher deformability than in older children [19]. Respiratory distress in young children can lead to thoracic distortion with waste of energy and reduced efficiency of breathing. During the first years of life, chest configuration gradually changes and chest wall compliance decreases continuously with progressive ossification of the ribs.

KEY POINTS: DIAPHRAGM AND CHEST WALL OF NEONATES AND INFANTS

- The diaphragm of infants inserts more horizontally, which decreases the efficiency of breathing
- The decreased efficiency of the diaphragm decreases the infant's ability to increase tidal volume when needed
- The diaphragm of neonates and young infants has fewer fatigue-resistant type I fibers
- Anesthesia decreases the function of the external intercostal muscles, which reduces functional residual capacity
- The very compliant chest wall of neonates is distorted during airway obstruction, which wastes energy and decreases breathing efficiency

Lung fluid physiology

Fetal lung fluid is a product of the epithelial cells lining the developing lung [20], and averages 4–6 mL/kg/h. Laryngeal abduction creates resistance to passage of lung fluid out into

Table 7.1 Composition of human fetal lung fluid compared to other body fluids

Component	Lung fluid	Interstitial fluid	Plasma	Amniotic fluid
Sodium (mEq/L)	150	147	150	113
Potassium (mEq/L)	6.3	4.8	4.8	7.6
Chloride (mEq/L)	157	107	107	87
Bicarbonate (mEq/L)	3	25	24	19
pH	6.27	7.31	7.34	7.02
Protein (g/dL)	0.03	3.27	4.09	0.10

the amniotic fluid, providing an end-expiratory pressure of approximately 2–4 cmH_2O. As a result, fetal lung fluid accumulates to a total volume of 20–30 mL/kg during gestation. The composition of fetal lung fluid is distinct from both amniotic fluid and plasma, as illustrated in Table 7.1. The increased chloride content of fetal lung fluid, as compared to serum, is the result of active chloride secretion by the tracheal and distal pulmonary epithelium. Fetal lung fluid secretion can be enhanced by prolactin, keratinocyte growth factor, and prostaglandins E2 and F2, while it is inhibited by a variety of mediators, including β-adrenergic agonists, vasopressin, serotonin, and glucagon.

While fetal lung fluid is an essential component of lung development, it presents a significant obstacle to the transition to air breathing upon delivery. Three important events must occur to decrease the amount of fetal lung fluid and its potential impact on alveolar surface tension: absorption, bulk removal, and maturation of pulmonary surfactant. Conversion of the epithelial surface from secretory to absorptive is largely due to enhanced sodium transport across the alveolar epithelium during the third trimester [20]. Much evidence suggests that induction of components of the epithelial sodium channels (ENaC) around the time of birth is a major factor in promoting sodium transport with water passively following the movement of sodium. Induction of ENaC components occurs at a transcriptional level in response to changes in extracellular matrix components, glucocorticoids, aldosterone, and oxygen. By comparison, agents that increase intracellular cyclic adenosine monophosphate (cAMP) levels (i.e. β-agonists, phosphodiesterase inhibitors, and cAMP analogs), while not increasing the number of sodium channels, increase the probability of a channel being open to sodium transport. Glucocorticoids and thyroid hormones play an important role in priming the lung epithelium to the actions of β-adrenergic agonists on sodium transport across lung epithelia near term. Water channels consisting of aquaporins are also induced during the late fetal period to facilitate fluid movement, but their importance remains unclear.

Conversion to an absorptive surface is not sufficient to minimize the fetal lung fluid at the time of term delivery. The absence of uterine contractions is associated with an increased incidence of retained fetal lung fluid in infants delivered by cesarean section without the benefit of labor. Upon delivery of the head and neck, continued uterine contractions on the fetal thorax promote expulsion of bulk fluid from the fetal lung. However, animal studies have shown that the magnitude of the benefit of thoracic compression during labor is only modest [21]. The primary mechanism by which labor facilitates clearance of lung fluid is through hormonal effects on fluid clearance, especially through catecholamine-induced changes in the open probability of ENaC. The onset of air breathing with increased intrathoracic negative pressure assists in the clearance of residual fetal lung fluid into the loose interstitial tissues surrounding alveoli. Fluid is then reabsorbed via lymphatics and pulmonary blood vessels. The amount of residual liquid in the lung after transition is approximately 0.37 mL/kg bodyweight.

KEY POINTS: LUNG FLUID PHYSIOLOGY

- The lungs of fetuses produce 4–6 mL/kg/h of fluid, which is necessary for lung growth
- Near birth the volume of fluid in the lungs is 20–30 mL/kg, similar to the functional residual capacity after birth
- Fetal lung fluid is removed at or near birth by absorption, bulk removal, and maturation of surfactant

Pulmonary cell types, development, and release of surfactant

Proximal airways

The proximal airway epithelium is tall and columnar, decreasing to a more cuboidal appearance distally [22,23]. The endodermal epithelial lining cells of the trachea and bronchi partition into four cell types: undifferentiated columnar, ciliated, secretory/goblet, and basal cells. Ciliated cells critical to the process of mucous clearance are first apparent between 11 and 16 weeks of human gestation and become less prevalent in more distal airways. Three types of secretory cells – those with largely mucous granules, those with serous granules, and some with both types of granules – can be seen as early as 13 weeks. The number of mucin-producing goblet cells in airways peaks at mid-gestation in the fetus and declines into adulthood. Finally, immature basal cells expressing epidermal keratin have been noted as early as 12 weeks of gestation.

Cartilaginous support of the tracheobronchial tree proceeds in a centrifugal fashion beginning in the primitive trachea at 4 weeks of human gestation, reaching the main bronchi by 10 weeks, and proceeding to the most distal terminal bronchioles by approximately 25 weeks of gestation. Cartilaginous investment of airways is complete by the second month postnatally. Submucosal glands are found in the interstitium between the cartilaginous tissue and surface epithelium, and play a major role in airway host defense. The airways of infants and children contain relatively more submucous glands than adults. The glands are lined by mucous cells proximally and serous cells more distally, the latter comprising 60% of the total epithelial cell content of the glands. Serous cells secrete water, electrolytes, and proteins with antimicrobial, anti-inflammatory, and antioxidant properties, while the mucous cells produce primarily mucins. In addition to this host defense role, submucosal glands also contain a population of basal cells that respond to injury of the airway by replenishing the airway epithelium.

Muscular investment of the airways begins as early as 6–8 weeks of gestation as smooth muscle cells are identifiable around the trachea and large airways. Fetal airway smooth muscle is innervated and able to contract during the first trimester. It is also responsive to methacholine challenge that is reversible with β-adrenergic agonists. Muscularization increases through fetal life and childhood such that there is an increase in the amount of smooth muscle relative to airway size compared to adults. Furthermore, there is a rapid increase in bronchial smooth muscle immediately after birth, whether at term or prematurely.

Pulmonary neuroendocrine cells (PNEC) are found throughout the airways, often in innervated clusters known as pulmonary neuroendocrine bodies (NEB) located at branch points in the bronchial tree [24]. Solitary PNEC are sensitive to stretch- and hypoxia-mediated secretion, producing both amines (i.e. serotonin) and peptides (i.e. bombesin) that are important in regulating bronchial tone. Pathological conditions recently associated with PNEC/NEB, most often characterized by hyperplasia, include bronchopulmonary dysplasia, disorders of respiratory control (congenital central hypoventilation syndrome and sudden infant death syndrome), cystic fibrosis, and pulmonary hypertension. Neuroendocrine hyperplasia of infancy (NEHI) is a rare form of interstitial lung disease of infancy associated with expansion of the number of PNEC and NEB, yet little is known about the mechanism of disease.

Distal airways

The bronchiolar epithelium differs from the more proximal airway epithelium. The bronchiolar epithelium contains progressively fewer ciliated cells and goblet cells, which are ultimately absent from the terminal bronchioles. Clara cells are found in increasing numbers and density down the conducting airways, such that it is the most abundant cell of the terminal bronchiole [22]. Clara cells are first evident by 16–17 weeks of human gestation, initially exhibiting large glycogen stores that are replaced by secretory granules. Between 23 and 34 weeks there is a dramatic increase in Clara cell numbers in distal bronchioles. Clara cells play an important role in host defense and in the detoxification of gaseous components of the air we breathe. This specialized cell produces the highest levels of cytochrome P450 and flavin mono-oxygenases in the lung. While critically important in detoxification, these enzymes participate in the bioactivation of procarcinogens as well, placing the Clara cell at risk as a target of toxic metabolites. The Clara cell also plays an important role in immunoregulation in the distal airways. Important host defense products of the Clara cell include Clara cell secretory protein (CCSP or CC10), surfactant proteins A and D, leukocyte protease inhibitor, and a trypsin-like protease. The secretion of antiproteases from Clara cells suggests that they modulate the protease–antiprotease balance in the distal lung.

Alveoli

During the 4th through 6th months of gestation the epithelial cells lining the acini begin to differentiate further [25]. The cuboidal epithelial cells accumulate large glycogen stores and develop small vesicles containing loose lamellae. The large glycogen pools provide a ready source of substrate required for the production of increasing amounts of surfactant phospholipids, and they decrease in size as surfactant production advances in the fetal lung. In cells destined to become type 2 cells, lamellar bodies become larger, more numerous, and more densely packed with surfactant phospholipids and proteins, whereas those cells destined to become type 1 cells, upon losing their relationship to mesenchymal fibroblasts, lose the prelamellar vesicles and become progressively thinner, thereby adopting a phenotype more suitable for gas exchange. Alveolar type 1 and 2 cells are readily identified early in the saccular stage of fetal lung development. There remains considerable controversy regarding the origin of type 1 cells. In culture these cells demonstrate very slow turnover, with a doubling time estimated to be between 40 and 120 days, suggesting that *in vivo* they are functionally terminally differentiated. In response to epithelial damage, type 2 cells proliferate to re-establish epithelial continuity, and then lose phenotypic features such as lamellar bodies while acquiring markers of type 1 cells, suggesting that rapid repopulation of type 1 cells requires a type 2 cell intermediary.

There is increasing appreciation for the alveolar type 1 cell as more than a passive membrane for gas exchange [26]. The large surface area and small cytoplasm:nucleus ratio provides for a thin alveolocapillary membrane to facilitate gas exchange. However, this large surface area also provides a large absorptive surface in the lung. The presence of water and ion channels, some distinct from those in type 2 cells, helps to ensure that the alveolus remains relatively dry. Type 1 cells may also regulate cell proliferation locally, signal macrophage accumulation, and modulate the functions of local peptides, proteases, and growth factors.

While most notable for its role in surfactant production, the alveolar type 2 cell provides additional important functions in the alveolus [27]. Alveolar type 2 cells are local progenitor cells, as mentioned previously. Like type 1 cells, alveolar type 2 cells contain specialized ion and water channels as well as ion pumps in both the apical and basal membranes that contribute to the movement of water and ions across the epithelium. Type 2 cells also produce important antioxidants (SOD-1, -2, -3, glutathione) and molecules of innate host defense (SP-A, SP-D, lysozyme) to participate in detoxification and sterilization of the alveolar microenvironment.

More recently, it is becoming clear that alveolar type 2 cells may also play a part in exacerbating alveolar pathology. The type 2 cell participates in the coagulation–fibrinolysis cascade through the production of fibrinogen, urokinase-type plasminogen activator, and tissue factor, especially under pathological circumstances. Type 2 cells are increasingly recognized as a source of cytokine and chemokine production in the lung, as well as growth factors that can promote fibrosis. Finally, crosstalk between epithelial cells, cell matrix, interstitial cells, and local inflammatory cells can foster the resolution of injury and inflammation, or prolong lung remodeling after injury with detrimental effects, such as lung destruction and fibrosis. Therefore, while previously heralded as the defender of the alveolus, the alveolar type 2 cell plays a much more complex role in alveolar health and disease.

KEY POINTS: PULMONARY CELL TYPES AND SURFACTANT RELEASE

- Ciliated epithelial cells are present by 10–16 weeks of gestation and are important for clearing mucus from the lung
- Mucus-producing goblet cells are present by 13 weeks of gestation and are important for proteting the lung from foreign material
- Cartilage is found early in the trachea and is in the distal terminal bronchioles by 25 weeks of gestation
- Clara cells in the distal airways are important for host defenses
- Type 2 cells are the eventual source of surfactant but also produce cytokines and chemokines

Surfactant

Pulmonary surfactant is essential to alveolar health. A thin layer of liquid is constantly secreted into the alveolar lumen to protect the delicate alveolar epithelium. The surface tension generated by this aqueous layer opposes alveolar inflation and promotes alveolar collapse at the end of expiration owing to the law of Laplace, which states that the collapsing pressure on the alveolus is directly proportional to the surface tension while inversely proportional to the radius of curvature of the alveolus. The presence of pulmonary surfactant at the air–liquid interface lowers surface tension as alveolar surface area decreases, thereby preventing end-expiratory atelectasis, maintaining functional residual capacity, and lowering the force required for subsequent alveolar inflations.

Pulmonary surfactant is a complex mixture of phospholipids (80% by weight), neutral lipids (10%), and proteins (10%) that is synthesized, packaged, and secreted by alveolar type 2 cells [28]. Storage of surfactant occurs in the lamellar body, a lysosome-derived membrane-bound organelle that undergoes regulated secretion in response to a variety of stimuli, including stretch. In the alveolus, surfactant phospholipids transition through an extracellular storage form, tubular myelin. Phospholipid and protein components are recycled out of the surfactant monolayer at the air–liquid interface and taken back into the alveolar type 2 cell where they can be repackaged into lamellar bodies. Alveolar macrophages engulf and degrade surfactant components as well.

Saturated phosphatidylcholine makes up 45% of surfactant by weight, with unsaturated phospholipids accounting for 25%, and other phospholipids (most notably phosphatidylglycerol at 5%) contributing 10%. The predominant saturated surfactant phospholipid is dipalmitoyl phosphatidylcholine, or DPPC. DPPC is the only surface-active component of lung surfactant, capable of lowering surface tension to nearly zero. The presence of unsaturated phospholipids and other lipid components like cholesterol enables the monolayer to remain fluid at body temperature during the respiratory cycle. The phospholipid content of the developing fetal lung increases with advancing gestation due to increased activity of enzymes responsible for phospholipid synthesis within alveolar type 2 cells. The expression and activity of enzymes of the choline incorporation pathway, the predominant pathway for surfactant phospholipid synthesis, are not only developmentally regulated but are also induced by hormones. The inductive hormones that have direct clinical relevance are glucocorticoids and agents that increase intracellular cAMP, such as the β-adrenergic agonist (and tocolytic) terbutaline.

Surfactant contains a group of specific proteins with importance to surfactant function and host defense that contribute up to 5% of surfactant by weight; the remaining 5% of the protein content of surfactant comes largely from serum proteins. The four surfactant proteins, SP-A, -B, -C, and -D, are subdivided based upon their physical characteristics into either hydrophobic (SP-B and -C) or hydrophilic (SP-A and -D) proteins. The hydrophobic surfactant proteins play a major role in the surface-active properties of surfactant, whereas the primary roles of the hydrophilic surfactant proteins are in host defense, immunomodulation, and surfactant clearance and metabolism.

Together, the hydrophobic proteins facilitate the mobilization of surfactant phospholipid from tubular myelin to the surface monolayer, promote spreading of phospholipids in the surfactant film, and assist in film stability at end-expiration [28]. SP-B plays a central role in alveolar health due to its critical function in surfactant homeostasis. It is a secretory protein that exhibits strong association with membranes, unlike SP-C which contains a membrane-spanning domain and covalently attached fatty acids (palmitate) that render it integral to phospholipid membranes [29]. Both SP-B and SP-C are synthesized as large precursor proproteins that undergo extensive post-translational processing as they pass through the secretory pathway, ultimately reaching the lamellar body. SP-B is essential for the process of lamellar body formation, and the alveolar type 2 cells of infants with inherited deficiency of SP-B are devoid of lamellar bodies. Because the lamellar body is where SP-C processing is completed, infants with inherited deficiency of SP-B are also deficient in mature SP-C, instead accumulating a larger, non-functional precursor of SP-C. Thus, patients with inherited deficiency of SP-B, despite having relatively normal surfactant phospholipid profiles, make a pulmonary surfactant with very poor surface tension properties due to the absence of both SP-B and SP-C. Conversely, because SP-C does not play either a direct or indirect role in SP-B protein processing, animals with SP-C deficiency have normal SP-B, normal lamellar bodies, relatively normal surfactant function, and exhibit no perinatal lethality due to surfactant dysfunction.

Like the enzymes of surfactant phospholipid production, SP-B and SP-C exhibit developmental and hormonal regulation of expression [30]. In human fetuses, SP-C mRNA is detected as early as 12 weeks of gestation and SP-B mRNA by 14 weeks, yet the mature proteins are not detectable in fetal lung tissue until after 24 weeks. SP-B protein is not detectable in amniotic fluid until after 30 weeks of gestation, increasing towards term [31]. This is due to developmental regulation of post-translational events in the proteolytic processing of proSP-B and proSP-C [32]. Consequently, infants delivered prematurely have reduced levels of both surface-active components of surfactant, phospholipid and hydrophobic surfactant proteins, due to the developmental regulation of surfactant proteins and the enzymes of phospholipid production in alveolar type 2 cells. The rate of type

2 cell differentiation, and secondarily surfactant production by the fetal lung, is modulated by levels of endogenous corticosteroids and is accelerated by administration of antenatal glucocorticoid to women in preterm labor. The response of the surfactant system to glucocorticoid involves all the lipid and protein components, and occurs primarily through increased gene expression, thus representing precocious maturation mimicking the normal developmental pattern. Endogenous thyroid hormones, prostaglandins, and catecholamines also have stimulatory effects on type 2 cell maturation as well as on clearance of lung fluid at birth. Certain proinflammatory cytokines (e.g. tumor necrosis factor and TGF-β) inhibit surfactant production in experimental systems and may downregulate surfactant in conditions such as sepsis and inflammation.

KEY POINTS: SURFACTANT

- Surface-active material improves lung function by lowering the surface tension of alveoli at end-expiration and preventing alveolar collapse
- Surface-active material is made up of phospholipids, lipids, and proteins
- Surfactant proteins are important for surfactant function and for host defenses
- The rate of type 2 cell differentiation is modulated by levels of endogenous corticosteroids and is accelerated by administration of antenatal glucocorticoid to women in preterm labor

Physiological changes in lung liquid and pulmonary blood flow at birth

Two critical events in fetal development play a major role in the adaptation to air breathing that occurs at birth: removal of fetal lung liquid and changes in fetal circulation. Each is considered separately here but they are interdependent in the process of neonatal transition.

While fetal lung fluid is critical for early lung development, it is essential that fluid is cleared in preparation for the onset of air breathing [33]. Because fluid reabsorption depends largely upon regulation of the sodium channel, management options during labor and delivery that impair the catecholamine-induced maturation of ENaC (i.e. cesarean section without the benefit of labor) can impair lung fluid clearance, resulting in retention of fetal lung fluid, known as transient tachypnea of the newborn. Transient tachypnea of the newborn is a relatively benign condition generally requiring supportive care in the form of supplemental oxygen to allow for drainage of the excess fluid via lymphatics, or continuous positive airway pressure (CPAP) to facilitate clearance of lung fluid from the alveoli. It is important to recognize that retained fetal lung fluid can complicate other neonatal respiratory conditions such as meconium aspiration syndrome and bacterial and viral pneumonias. Furthermore, retained fetal lung fluid may complicate the transition from fetal to adult circulatory physiology and thereby contribute to the development of persistant pulmonary hypertension of the newborn.

The other critical event during neonatal transition is the adaptation of the circulatory pattern. During fetal life, the organ of gas exchange is the placenta. Thus, the circulatory pattern of the fetus is adapted to optimize blood flow to/from the placenta and minimize blood flowing to/from the lungs to between 5% and 10% of cardiac output. This is achieved through the low resistance/high capacitance of the placenta, the high resistance of the pulmonary vasculature, and the ductus arteriosus. The large surface area and lacunar structure of the placenta contribute to the low resistance/high capacitance of this organ. The low partial pressure of oxygen in the fetal lung and circulating vasoconstrictors, such as endothelin-1, leukotrienes, and Rho kinase, in the face of low production of vasodilators, including nitric oxide and prostacyclin, contribute to high pulmonary vascular tone [34]. As a result, pulmonary and systemic pressures are roughly equivalent. The high pulmonary vascular resistance and equivalent pulmonary and systemic pressures together favor the flow of oxygenated blood returning from the placenta (via the umbilical vein and ductus venosus) to the right atrium across the foramen ovale to the left atrium and out to the systemic circulation. The ductus arteriosus, a blood vessel developing from the 6th aortic arches, bridges between the pulmonary artery and the aorta at the bifurcation of the left pulmonary artery, and approximately at the level of the left subclavian artery as it branches from the aortic arch. The high pulmonary vascular resistance and low systemic vascular resistance *in utero* favor flow of oxygenated blood passing from right atrium to right ventricle and pulmonary artery, through the ductus arteriosus, and into the aortic arch to supply the systemic circulation. In addition to optimizing flow of oxygenated blood systemically, the combination of atrial and ductal level shunts allows for sufficient blood flow to all of the chambers of the heart facilitating their development during fetal life, and this explains the greater muscularization of the right ventricle in the newborn period relative to the left ventricle.

In the transition to air breathing, the circulatory pattern must undergo change to establish the lung as the organ of gas exchange [35]. Clamping and transection of the umbilical cord at delivery removes the placenta from the systemic circulation, resulting in a precipitous increase in systemic vascular resistance. This has at best a modest effect on changing blood flow centrally, instead improving blood flow to the lower body. Initiation of air breathing inflates the lungs and increases oxygen tension across the alveolar capillary bed, facilitating a precipitous drop in pulmonary vascular resistance. Pulmonary stretch receptors elicit reflex dilatation of the pulmonary vasculature independently of the effects of enhanced oxygen tension. The net effect of these events is that left atrial pressure becomes higher than right atrial pressure, leading to functional closure of the foramen ovale. These changes also reduce flow through the ductus arteriosus by 24% soon after birth, but are not sufficient to eliminate ductal flow for 48 hours after birth. Cessation of ductal blood flow and ultimately scarring of this structure, which becomes the ligamentum arteriosum, occurs over the first 2–3 weeks of life. Increasing hypoxemia of the muscle media of the ductus due to reduced blood flow through the ductal lumen promotes

vasoconstriction of the ductus. Ductal constriction enhances muscle media hypoxia by collapsing the vasa vasorum, the other source of oxygen to the ductus. Together, these adaptations lead to the adult circulatory pattern with the lung in series with the systemic circulation, enabling efficient oxygenation.

These physiological changes are dynamic and capable of reverting to a fetal pattern over the first days of life. While pulmonary vascular resistance decreases precipitously in the first minutes to hours of life, it does not achieve adult levels for weeks to months postnatally, and the pulmonary vasculature is prone to vasoconstriction in response to hypoxia and acidosis during that time. In addition, events associated with reduced systemic vascular resistance, such as septicemia, can lower systemic vascular resistance to the extent that even the normal pulmonary vascular tone in the first days of life can lead to pulmonary pressures becoming suprasystemic, leading to enhanced right-to-left blood flow.

Persistent pulmonary hypertension of the newborn (PPHN), also known as persistent fetal circulation, can occur in association with other neonatal diseases such as septicemia or meconium aspiration, or can be idiopathic in nature [34]. The disorder is characterized by suprasystemic right ventricular pressure, right-to-left flow of deoxygenated blood through the ductus arteriosus, and severe hypoxemia. PPHN can result from lung parenchymal disease leading to pulmonary vasoconstriction, from pulmonary vascular remodeling in the absence of lung parenchymal disease, or from primary or secondary pulmonary hypoplasia. Animal studies have elucidated pathways for targeted therapies such as nitric oxide/cGMP, prostacyclin/cAMP, and endothelin to lower pulmonary vascular resistance. Optimization of oxygenation and ventilation while providing specific pulmonary vasodilatation with nitric oxide has lowered the morbidity and mortality of this disorder and reduced the need for more aggressive therapies such as extracorporeal membrane oxygenation (ECMO).

Ductal patency can also complicate the management of prematurely born infants [36,37]. The ductus arteriosus of premature infants is thin-walled and thus depends only on luminal blood flow for oxygenation. As a consequence, the ductal muscle media does not become as hypoxic with constriction of the premature ductus, thus contributing to a prolonged delay in anatomical closure. As pulmonary vascular resistance decreases in preterm infants in response to lung inflation and surfactant administration, the high systemic vascular resistance favors left-to-right flow across a patent ductus arteriosus, resulting in pulmonary edema. Both are responsive acutely to elevated positive end-expiratory pressure. The pulmonary overcirculation can also be associated with vascular steal from the cerebral and mesenteric vasculatures, increasing the risk of intraventricular hemorrhage and intestinal ischemia. Closure of a patent ductus arteriosus can be achieved by treatment with agents that reduce prostaglandin synthesis, such as indomethacin and ibuprofen, but success is inversely related to gestational age. When repeated indomethacin therapy fails and the patent ductus arteriosus is felt to be a major factor in pulmonary symptoms, surgical ligation through a left thoracotomy approach is possible. There is some controversy regarding the long-term morbidity of surgical ligation of a patent ductus arteriosus.

KEY POINTS: LUNG FLUID AND PULMONARY CIRCULATION CHANGES AT BIRTH

- Critical events at birth include exchange of lung fluid for air and conversion of the parallel fetal circulation to the adult series circulation
- Retained lung fluid (as with cesarean section) causes transient tachypnea of the newborn and a need for additional oxygen and occasionally for nasal CPAP (nCPAP)
- Fetal type circulation (right-to-left shunting) can be re-established in the first few days of life with resultant hypoxemia
- The right heart pressures of patients with persistent pulmonary hypertension can re-establish fetal type circulation and cause severe hypoxemia
- The ductus arteriosus of premature infants often remains open, worsening lung disease

Lung development after birth

As with fetal lung development, postnatal lung development can be subdivided into several stages, also illustrated in Figure 7.1 [3]. True alveoli containing secondary septa (described previously) become evident as early as 36 weeks in the human fetus, initiating the alveolar phase of fetal lung development that extends to 1–2 years of age. Postnatal alveolarization begins with a phase of bulk alveolarization occurring within the first 6 months, with a more modest addition of secondary alveoli through the remainder of this period. The alveoli of the infant lung are different from adult alveoli. These immature secondary alveoli contain a double capillary bed, whereas adult alveoli are invested by a single capillary bed. Microvascular maturation, the next phase of postnatal lung development, occurs from the first few postnatal months of life through 3 years of age (discussed previously). Alveolar addition continues throughout childhood well into adolescence. It has been even observed that alveolar expansion can occur in response to pneumonectomy in adult animals and humans. The acquisition of alveoli after the maturation of the microvasculature has been termed late alveolarization. This activity has been most often demonstrated in subpleural regions of the lung and likely invokes mechanisms similar to the formation of secondary alveoli. Alveolarization is accompanied by increasing content of elastic fibers in the alveolar septa that prevents alveolar and small airways from collapsing by increasing the elastic recoil properties of the lung parenchyma. Interalveolar pores of Kohn and bronchoalveolar canals of Lambert develop at 3–4 years of age during the process of thinning of alveolar septa. Absence of these connections in newborn infants predisposes them to lung atelectasis.

The addition of alveoli is not the only means of expanding the surface area of the lung. While alveolarization wanes over the first 3 years of life in the human, growth of the lung continues to expand the gas exchange surface. Between

2 years of age and adulthood, lung tissue expands with lung volume roughly proportionately to the increase in bodyweight of the child. Alveolar diameter increases from 50–100 µm in newborn infants to 200–300 µm in adults. Thus, owing to the combined processes of prenatal lung development, postnatal lung development, and lung growth, there is tremendous potential for expansion of the gas exchange surface area that is developmentally programmed into the fetal lung to account for the growing needs of the infant, child, and adult for aerobic cellular respiration. The extent to which these developmental mechanisms can be harnessed after premature birth, with or without superimposed lung injury, is a topic of active investigation.

KEY POINTS: LUNG DEVELOPMENT AFTER BIRTH

- The alveolar phase of lung development extends to the first 2 years of life but continues to a lesser extent into teenage years
- Bulk alveolarization occurs during the first 6 months of extrauterine life
- Microvascular maturation continues up to 3 years of age
- After 3 years of age, the increase in lung surface area is due to increase in size of the alveoli

Control of breathing

The development of respiratory control starts prenatally but continues to mature for several weeks and months after birth [38]. Preterm and term infants can present with immature breathing patterns characterized by irregular and periodic breathing. Several components of the respiratory control system can still be immature including peripheral and central chemoreceptor responses, brainstem respiratory rhythmogenesis, and other parts of the network. The risk of severe and life-threatening apneas is therefore increased in young infants compared to older children. The ventilatory response to carbon dioxide and oxygen is impaired in newborn infants [39]. Whereas hypercapnia leads to increased tidal volumes and respiratory rates in term infants, children, and adults, the response is often diminished in preterm neonates. Preterm infants show a biphasic response to hypoxia. After an initial period of increased ventilation for approximately 1 minute, ventilation subsequently decreases with an increased risk of apneas. Other important mechanisms contributing to apneas in neonates are an exaggerated inhibitory response to either an afferent laryngeal stimulation or excessive lung inflation. Apneic response to the latter due to stimulation of pulmonary stretch receptors is also known as the Hering–Breuer inflation reflex, which is more pronounced in infants compared with older children. Apneas are defined periods of absence of airflow for more than 20 s and classified as either central apneas in the absence of breathing efforts or obstructive apneas in the presence of breathing efforts. Clinically, in infants most apneas occur as mixed apneas, i.e. a combination of absent respiratory drive (central apnea) and failure to maintain a patent airway (obstructive apnea). Central apneas as well as obstructive apneas result from a decreased respiratory center output due to the immaturity of the respiratory control system. The predominant site of airway obstruction in obstructive apneas is the pharynx, which shows reduced muscle tone during this period [40]. Poor respiratory control, especially in very preterm infants, might require the use of respiratory stimulants (e.g. caffeine), CPAP, or mechanical ventilation.

KEY POINTS: CONTROL OF BREATHING

- Respiratory control starts prenatally and continues to mature for several weeks and months after birth
- Preterm infants continue to have immature breathing patterns characterized by irregular and periodic breathing
- Peripheral and central chemoreceptor responses and brainstem respiratory rhythmogenesis are still immature, making neonates prone to apnea
- The Hering–Breuer inflation reflex is more pronounced in infants compared with older children
- Preterm infants are prone to both central and obstructive apnea

Normal values for pulmonary function with age

In neonates and children, the developmental changes discussed previously lead to rapid transformations in the mechanical properties of the respiratory system and influence pulmonary function. Unlike many physiological parameters that do not vary with age (i.e. arterial pH), predicted values of pulmonary function depend upon age, height, gender, and race [41]. Consistent normalization of pulmonary function test results – based on weight or height – is important to the interpretation of results and for comparison to reference values. When tests rely on the subjective effort of an infant or young child, technique can have profound effects on measurements and efforts to standardize pulmonary function testing. For example, several studies have compared compliance measurements from preterm infants with and without bronchopulmonary dysplasia (BPD) to term infants to determine their diagnostic or prognostic value. However, there was a large overlap between the groups, with the majority of infants with BPD having compliance measurements within the 95% confidence interval of the control group [42]. This observation suggests that in particular single point measurements in individual infants are of limited value as a diagnostic or prognostic tool. In a research setting, consistency can best be obtained in a pulmonary function laboratory, although infant and pediatric ventilators now provide opportunities to make measurements in the intensive care setting. The discussion that follows presents an outline of basic parameters and descriptions of how pulmonary function changes with age where applicable, including normal references only where they are considered consistent standards (Table 7.2).

KEY POINTS: NORMAL VALUES FOR PULMONARY FUNCTION WITH AGE

- Predicted values of pulmonary function depend upon age, height, gender, and race
- Tests that rely on the subjective effort of an infant or young child can have profound effects on measurements because the child cannot perform them effectively
- Single point measurements in individual infants are of limited value as a diagnostic or prognostic tool

Compliance

The elastic properties of the lung are described by the changes in volume (V) per unitary change in transpulmonary pressure (P_L) under the conditions of zero flow, or lung compliance ($C_L = \Delta V/\Delta P_L$). The systematic change in both pressure and volume during inflation and deflation allows a static pressure–volume curve of the lungs to be plotted. Compliance of the respiratory system is the combination of lung (C_L) and chest wall compliance (C_W) and changes throughout childhood and adolescence. It ranges from 1.5 to 2 mL/cmH_2O/kg in newborns to 2.5–3 mL/cmH_2O/kg in children and adults [43]. Both chest wall and lung tissue are characterized by specific elastic properties. Whereas the chest wall tends to expand, especially at low lung volumes, the lung tissue has the tendency to recoil and collapse due to its elastic fibers and the surface tension at the alveolar air–fluid interface.

Compliance of the lung

Lung compliance is proportional to its volume and increases with growth throughout childhood. However, specific compliance, which is the lung compliance divided by functional residual volume (C_L/FRC), remains relatively constant in children and adults. The elastic recoil properties of the lung tissue increase from birth into adolescence before they decline in adulthood; they seem to be mainly associated with the pulmonary content of elastic fibers. The compliance of the lung is also dependent on the content and quality of pulmonary surfactant. The function of surfactant is to stabilize alveoli in their size and to prevent them from collapse.

Compliance of the chest wall

Chest wall compliance (C_W) is high in infants and can contribute to ineffective breathing in the presence of lung disease, visible by ribcage recessions. C_w progressively decreases as the ribcage gradually ossifies throughout infancy and childhood into adulthood.

Closing volume and dynamic elevation of functional residual capacity

C_W in infants is 2–6 times higher than the compliance of the lung tissue, even more so in preterm infants, but will decrease to nearly equal to lung tissue compliance in childhood and adulthood. FRC is determined by the tendency of the chest wall to expand and the lungs to collapse and reflects the elastic equilibrium of C_W and C_L. The chest wall in newborns and infants is less stiff than in older children and adults and has therefore a higher C_W which results in a lower FRC.

The increased compliance in infants leads to an FRC that is near the infant's closing capacity, the volume in the lungs at which alveoli and small airways can collapse [44]. Infants can counteract the collapse by dynamically elevating their FRC. Several mechanisms contribute to increase of the FRC:

- Activation of the respiratory muscles: in inspiration as well as in expiration there is an activation of the respiratory muscles including the diaphragm, which brakes at expiration.
- High breathing frequency: less time for expiration and lung emptying.
- Vocal cord adduction: especially in expiration, vocal cord adduction leads to a higher respiratory resistance and a lower expiratory flow. Expiratory grunting can be observed in newborn infants with lung disease.

These mechanisms are being used mainly in the first year of life. As the chest wall gradually stiffens, C_W decreases and matches C_L at resting volume of the respiratory system.

KEY POINTS: LUNG AND CHEST WALL COMPLIANCE

- The elastic properties of the lung are described by the changes in volume (V) per unitary change in transpulmonary pressure
- Compliance of the respiratory system is the combination of lung (C_L) and chest wall compliance (C_W) and changes throughout childhood and adolescence
- The specific compliance (lung compliance divided by functional residual volume (C_L/FRC)) remains relatively constant in children and adults
- Chest wall compliance (C_W) is high in infants and can contribute to ineffective breathing in the presence of lung disease, visible by ribcage recessions
- Increased chest wall compliance in infants leads to an FRC that is near the infant's closing capacity, the volume in the lungs at which alveoli and small airways can collapse

Resistance

Airway resistance (R_{aw}) reflects the non-elastic airway and tissue forces resisting gas flow. Lung resistance is determined predominantly by frictional resistance to inspiratory and expiratory airflow in the larger airways (80%), while tissue resistance (19%) and inertial forces (1%) also contribute [43]. By definition, resistance to airflow is equal to the resistive component of driving pressure (ΔP) divided by the airflow (Q), $R_{aw} = \Delta P/Q$ with units of cmH_2O/L/s. Poiseuille's law states that resistance to flow increases by a power of 4 with any decrease in airway diameter ($R_{aw} = 8\eta L/\pi r^4$, where η is the gas viscosity, L is length, and r the radius of the airway). Compared to an adult the airways in children are relatively large. However, in actual size the diameter of airways in infants and children is much smaller than that in adults, resulting in increased R_{aw}. Therefore, minor changes in the

Table 7.2 Standards for lung mechanics and pulmonary function in infants, children, and adults

	Infant	Child	Adult
Compliance	1.5–2.0 mL/cmH_2O/kg	2.5–3.0 mL/cmH_2O/kg	0.1 L/cmH_2O *note different units
Resistance	20–40 cmH_2O/L/s	20–40 cmH_2O/L/s *up to 2 years	1–2 cmH_2O/L/s
Functional residual capacity	20–25 mL/kg	20–25 mL/kg *up to 18 months	1.9–2.4 L *note different units
Tidal volume	4–8 mL/kg *preterm 3–5 mL/kg	4–8 mL/kg	6–8 mL/kg
Respiratory rate	20–60 breaths/min	20–30 breaths/min	12–20 breaths/min
Minute ventilation	240–480 mL/kg/min		5–8 L/min *note different units

airway diameter lead to much larger increases in R_{aw} in infants compared to adults [45]. Resistance is also dependent on the number of airways, lung volume, and respiratory rate. In adults about 80% of R_{aw} is attributed to airways larger than 2 mm in diameter and only about 20% to small peripheral airways as the cross-sectional area is much larger than in infants. In infants the small peripheral airways account for up to 50% of R_{aw} which explains their vulnerability to small airway diseases, e.g. bronchiolitis [16]. Airway resistance in normal healthy infants up to 2 years of age ranges from 20 to 40 cmH_2O/L/s, whereas R_{aw} in adults is 1–2 cmH_2O/L/s.

KEY POINTS: AIRWAY RESISTANCE

- Airway resistance (R_{aw}) reflects the non-elastic airway and tissue forces resisting gas flow
- The diameter of the airways in infants and children is much smaller than in adults, resulting in increased airways resistance

Tidal volume

Tidal volume is the volume of each breath and is measured during inhalation or exhalation, or averaged for the entire respiratory cycle. The value should be normalized to bodyweight or length. Very small preterm infants may have spontaneous breathing tidal volumes as low as 3–5 mL/kg. During spontaneous breathing, normal values in healthy infants are approximately 7–8 mL/kg (range from 4.3 to 11.8 mL/kg) [46] and are similar to the tidal volumes in older children and adults.

Gas exchange

The pulmonary gas exchange takes place in the terminal respiratory units of the lung, i.e. alveoli, by diffusion. The diffusion process of oxygen and carbon dioxide across the alveolar–capillary membrane is similar in infants and older subjects. The thickness of the alveolar–capillary membrane is similar for all ages but its surface area increases markedly throughout childhood. The increasing surface area is also associated with an increase of the diffusion capacity. The reserve of diffusion capacity seems therefore to be lower in newborn infants compared to older children and adults. The development of interalveolar (pores of Kohn) and bronchoalveolar connections (canals of Lambert) in the first years of life improves gas exchange within the lungs. Its absence predisposes infants to lung atelectasis, ventilation–perfusion mismatch, and intrapulmonary shunting. Gas exchange depends on the amount of gas that reaches the alveolar–capillary membrane. A certain amount of gas does not reach the alveolar–capillary membrane but remains in the conducting airways and therefore does not participate in gas exchange. This is referred to as anatomical dead space. Another portion of the inspired gas might reach alveoli that are not perfused or poorly perfused, which is referred to as alveolar dead space. Dead space in infants is markedly higher than that in older children and adults. This is mainly due to the relatively larger extrathoracic component of the anatomical dead space in infants, which is 50% greater than in older subjects [47]. The dead space to tidal volume ratio (V_D/V_T) in adults is considerably lower than in newborn infants (approximately 0.2–0.3 versus 0.4–0.5 respectively). This explains to some degree the need for a higher minute ventilation/kg bodyweight in infants compared to older children and adults as some portion of the inspired gas is "wasted" and does not participate in alveolar ventilation [48].

Minute ventilation

Minute ventilation is the product of tidal volume and respiratory rate. Respiratory rates of most preterm and term infants are 20–60 breaths/min, and the normal range for minute ventilation is from 240 to 480 mL/kg/min [49].

KEY POINTS: TIDAL VOLUME, DEAD SPACE, AND MINUTE VENTILATION

- Normal values for tidal volume in healthy spontaneously breathing infants are approximately 7–8 mL/kg, similar to those of older patients
- The thickness of the alveolar–capillary membrane is similar for all ages, but its surface area increases markedly throughout childhood
- The increasing surface area is also associated with an increase of the diffusion capacity
- Absence of the pores of Kohn and the canals of Lambert predisposes infants to lung atelectasis, ventilation–perfusion mismatch, and intrapulmonary shunting
- The dead space in infants (0.4–0.5) is markedly higher than that of older children and adults (0.2–0.3)

Pathophysiology of important respiratory diseases affecting infants and children

Asthma

Asthma is a chronic, recurrent disease; its prevalence is 1–20% and is higher in countries with a Western lifestyle and higher rates of obesity (e.g. Scotland 18%, Australia 15%, USA and Brazil 11%) [50]. The characteristics of bronchial asthma include a variable and often reversible airflow obstruction and bronchial hyperreactivity. Patients with bronchial hyperreactivity have an increased tendency for and higher degree of airway narrowing in response to stimulation. This makes children with asthma or other diseases associated with airway inflammation (e.g. upper respiratory tract infection) more prone to the development of respiratory adverse events in the perioperative setting, particularly with regards to the incidence of bronchospasm and laryngospasm. Asthmatic patients have varying degrees of airway inflammation, bronchial hyperreactivity, wheeze, and remodeling [51], which can also be found in children with recurrent respiratory tract infections, cystic fibrosis, and BPD.

Asthma is characterized by reversible bronchoconstriction, wheezing, and cough accompanied by inflammation and increased and more viscous mucus production in the small airways that can lead to airway plugging. A child's smaller airway diameter causes increased airflow obstruction and puts it at a significantly increased risk for asthma-related morbidity and mortality [50].

Hypoxemia during an acute asthma exacerbation is mainly caused by the perfusion of hypoventilated airways leading to a ventilation–perfusion (V/Q) mismatch [52]. Children with mild airflow obstruction will hyperventilate to improve gas exchange while at the same time increasing their risk of lung hyperinflation, placing the diaphragm at a mechanical disadvantage and leading to an increased work of breathing [53].

While expiration in healthy children is usually passive, increased airflow obstruction forces the child to actively support expiratory efforts by using accessory respiratory and abdominal muscles, which may lead to fatigue, particularly in young infants, causing carbon dioxide retention. In addition, greater inspiratory effort will be required to overcome the positive intrathoracic pressures as a result of trapped gas. Hypercapnia is a warning sign that the child may require ventilatory support.

Many infants are labeled "asthmatic" in infancy because of wheeze with viral upper and lower respiratory tract infections, particularly with respiratory syncytial virus (RSV) and rhinovirus. Many of these children will only wheeze during their preschool years, and thus do not develop chronic asthma. In some children, RSV infection is felt to increase the risk of developing chronic asthma, through a combination of genetic, environmental, and immune response mechanisms that are not clearly elucidated. Those who have recurrent bronchospasm events after age 6 years are diagnosed with asthma; many of these patients will have their disease resolve completely or greatly diminish after adolescence. Those with asthma persisting into adolescence often have an atopic/allergic component to their disease. Up to 75% of young children who wheeze with viral respiratory tract infections will have complete resolution of symptoms by adulthood [54–57].

The inciting events for an episode of bronchospasm are myriad. As noted previously, viral respiratory infections, especially with RSV, are a frequent inciting event in children. Other viruses known to be associated with asthma exacerbations include rhinovirus, influenza, parainfluenza, and coronavirus. Allergic sensitization and innate immune response to the virus exposure play a role in these exacerbations [54]. Other infections, such as chlamydia, mycoplasma, and bacterial infections of the respiratory tract, can provoke asthma exacerbations. Allergic responses with antigen-specific IgE antibodies to aeroallergens are another important mechanism that usually does not occur until at least 2–3 years of age. This mechanism increases during later childhood and adolescence and peaks in the second decade of life. Dust mites, animal dander, tree and grass pollens are among the most frequent underlying factors for allergic asthma. Another very important risk factor for childhood asthma is exposure to tobacco smoke, which is thought to be the single most important environmental factor for asthma exacerbation in infants and children [57]. Other factors for asthma exacerbation, particularly in older children, include exercise, gastroesophageal reflux, and psychosocial stressors. The genetic components of asthma are complex and multifactorial, and although the atopic phenotype has a familial component, recent genomewide association studies and other gene candidate studies have had limited success in elucidating the genetic origins of asthma. Several groups have reported markers on chromosome 17q21 that were reproducibly associated with childhood-onset asthma in families from the UK and Germany and other populations. This association appears to be strongest in young children with tobacco smoke exposure. There are several candidates identified, but as yet no definitive asthma genes have been designated [58].

The pathophysiology of an asthma exacerbation is complex, keeping in mind that it is an acute episode superimposed upon an abnormal airway with chronic changes of inflammation, increased airway smooth muscle that results in airway remodeling and chronic loss of lung function, and increased mucus production. In addition, the asthma phenotype has been divided into a number of subphenotypes. Airway inflammation is a fundamental abnormality in asthma pathogenesis, with mast cells, eosinophils, neutrophils, and $CD4^+$ T lymphocytes all playing a role. In allergic asthma, antigen exposure in the airway to IgE specific antibodies incites a T-helper cell 2 (Th2) type lymphocyte response, which in turn generates a cytokine response. The cytokine response attracts mast cells, eosinophils, and basophils, which in turn are activated and release mediators of airway smooth muscle tone, including histamine, leukotrienes (including slow-reacting substance of anaphylaxis), and prostaglandins, resulting in acute bronchospasm [59]. The effects of chronic inflammation on the airway epithelium are known to be crucially important to asthma pathogenesis. Bronchial biopsies in moderate to severe asthma show areas of epithelial metaplasia, thickening of the subepithelial basal membranes, increased numbers of myofibroblasts, and evidence of airway remodeling, including hypertrophy and hyperplasia of airway smooth muscle, mucous gland hyperplasia, angiogenesis, and an altered deposition and composition of extracellular matrix proteins

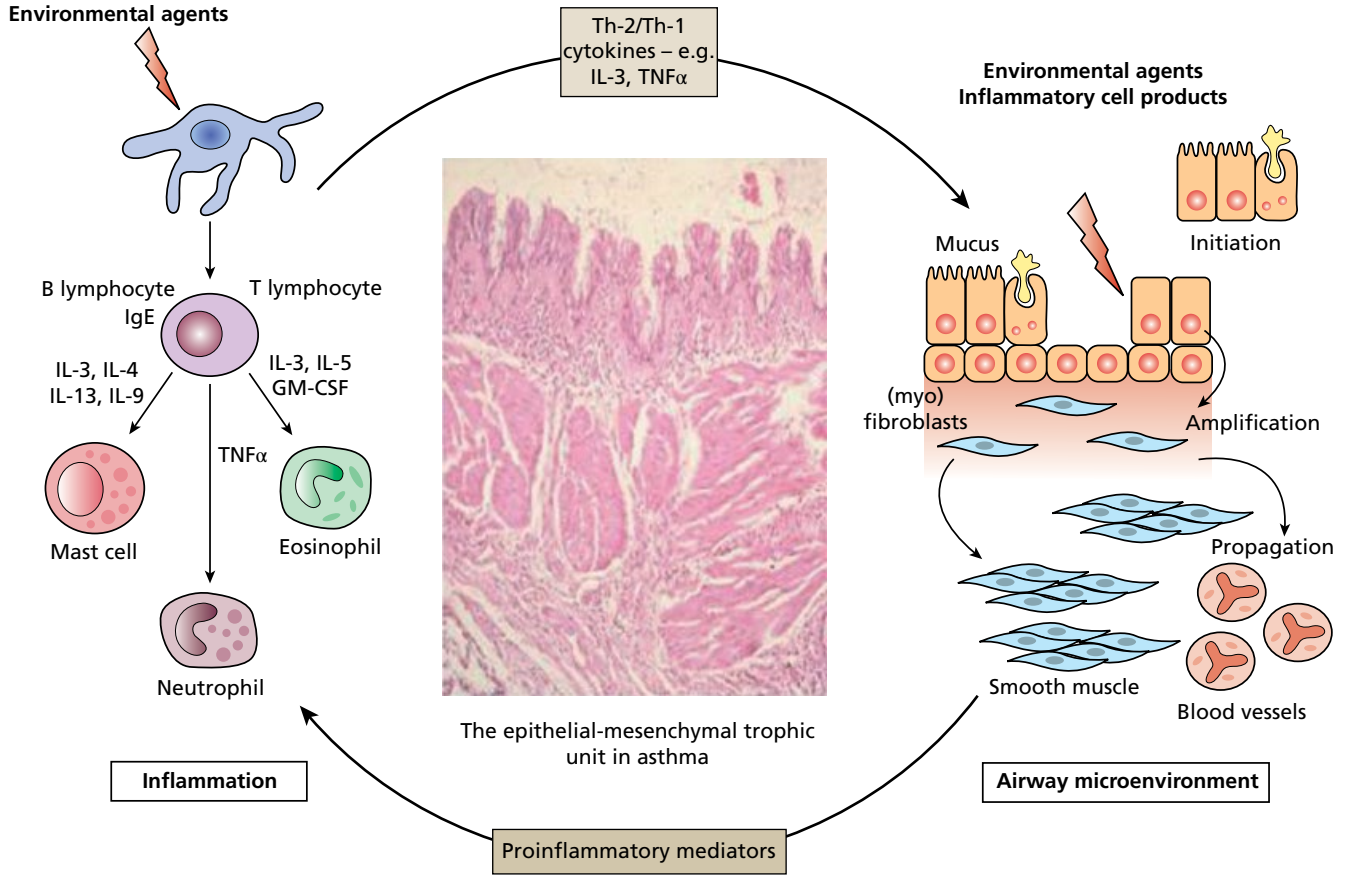

Figure 7.2 Inflammatory and remodeling responses in asthma with activation of the epithelial–mesenchymal trophic unit. Epithelial damage alters the set point for communication between bronchial epithelium and underlying mesenchymal cells, leading to myofibroblast activation and increase in mesenchymal volume, and induction of structural changes throughout the airway wall. GM-CSF, granulocyte–macrophage colony stimulating factor; IL, interleukin; Th, T helper; TNF, tumor necrosis factor. *Source:* Reproduced from Holgate and Polosa [60] with permission of Elsevier.

[59,60] (Fig. 7.2). This means, a chronically abnormal airway characterized by increased smooth muscle, an immune system primed to respond to allergen exposure, and airways chronically narrowed by this inflammation and mucus production will constrict further with acute airway smooth muscle constriction. Particularly in small pediatric patients, the narrow small airways diameter means that a relatively small degree of airway smooth muscle constriction can result in more severe bronchospasm symptoms, given that resistance to airflow is inversely proportional to the fourth power of the airway radius with laminar flow, and the fifth power of the radius with turbulent flow.

Preoperatively, it is important to assess whether the patient has undiagnosed and/or uncontrolled asthma. If possible, surgery should be delayed until asthma symptoms are well controlled. There is no standardization of findings required to confirm an asthma diagnosis. However, most definitions will include some degree of wheeze and bronchial hyperreactivity [50]. Further common symptoms include coughing, difficulty breathing, and chest tightness. Children with frequent or recurrent (nighttime or early morning) wheezing, exercise or allergy induced wheeze, or wheeze in absence of a respiratory tract infection, as well as those with clinical improvement following the administration of a β_2-agonist and/or a (family) history of atopic disease have a high likelihood to have asthma [61].

Therefore, the evaluation of asthma in young children involves a careful history of frequency and severity of episodes and response to treatment, and ascertaining environmental allergens and exposures. Clinical examination is important; active wheezing in the preanesthetic period is cause for concern and should merit cancellation of elective surgery. However, preoperative blood testing or chest X-rays are rarely necessary [62]. While patients with allergy-triggered asthma may present with positive skin prick testing, eosinophilia, and/or specific IgE, these tests do not improve the prediction of perioperative respiratory adverse events [61]. Pulmonary function testing is not well correlated with clinical severity of asthma in children with well-controlled asthma [63]. Due to the reversible nature of the airflow obstruction in asthma, normal lung function values also do not exclude the presence of asthma. Only a metacholine challenge has a high negative predictive value in this setting; however this is not indicated routinely preoperatively [63].

It is of extreme importance to continue all asthma medications throughout the perioperative period. Additional preoperative β_2-agonists may be advantageous in asthmatic children [64] although they maybe of lesser importance in older children without respiratory symptoms undergoing low risk surgery [65]. However, children with active respiratory symptoms benefit slightly from premedication with salbutamol [65]. Treatment of asthma depends on the

age of the patient, and the severity of the asthma. Acute exacerbations of asthma are usually treated with a short-acting β-agonist by inhalation route (nebulized or metered dose inhaler), such as levalbuterol or salbutamol, which will enhance the action of cyclic AMP and thus relax airway smooth muscles. Halogenated inhaled anesthetics are well known to relax airway smooth muscle via inhibition of Ca^{2+} influx. (See Chapter 10 for a complete discussion of the pharmacology of inhaled anesthetics.) In the rare case of acute severe bronchospasm with general anesthesia, where gas exchange is so compromised that any inhaled agent does not reach the airways, intravenous β-agonists (epinephrine, isoproterenol), as well as intravenous magnesium sulfate, can acutely relax airway smooth muscle and allow inhaled agents to reach the airways. The US National Institutes of Health as well as the British Thoracic Society published evidence-based asthma evaluation and treatment guidelines [61]. For intermittent asthma, episodic treatment with short-acting β-agonists as needed is recommended. As the severity and chronicity of asthma increases, additional chronic treatments such as inhaled corticosteroids, cromolyn (mast cell stabilizer), montelukast (leukotriene receptor inhibitor), longer-acting β-agonists, or oral corticosteroids, are added (Fig. 7.3).

Non-steroidal anti-inflammatory drugs (NSAIDs) are often avoided in asthmatic patients, however the basis for this is not very strong and rather more theoretical than a real concern [61,66,67]. However, more recent studies have shown that paracetamol (acetaminophen) may be of more concern [68]. Short-term NSAIDs are associated with a very low risk of adverse effects in asthmatic children and should be preferred as analgesic agents, with the exception of children with asthma and nasal polyps who have a higher likelihood for NSAID-induced bronchospasm.

KEY POINTS: ASTHMA

- The characteristics of bronchial asthma include a variable and often reversible airflow obstruction and bronchial hyperreactivity
- Children with asthma or other diseases associated with airway inflammation (e.g. upper respiratory tract infection) are more prone to the development of respiratory adverse events (bronchospasm and laryngospasm) in the perioperative setting
- Airway inflammation is a fundamental abnormality in asthma pathogenesis
- Evaluation of asthma in young children involves careful history of frequency and severity of episodes, response to treatment, and ascertaining environmental allergens and exposures. Active wheezing in the preanesthetic period is cause for concern and should merit cancellation of elective surgery
- It is of extreme importance to continue all asthma medications throughout the perioperative period
- Children with asthma and nasal polyps have a higher likelihood for NSAID-induced bronchospasm

Bronchopulmonary dysplasia

More than 1 in 10 births worldwide is a premature delivery (<37 weeks of gestational age), accounting for over 15 million premature infants every year with 2.4 million infants born prior to 32 weeks of gestation [69,70]. Bronchopulmonary dysplasia (BPD) was described in 1967 by Northway et al in a series of 32 preterm infants following mechanical ventilation for respiratory distress syndrome (RDS). The disease featured prominent interstitial fibrosis, alveolar overdistention alternating with regions of atelectasis, and airway abnormalities, including squamous metaplasia and excessive muscularization [71]. In those early days of survival of preterm infants, ventilator therapy often included high FiO_2 and high ventilating pressures and volumes – features now known to cause significant lung injury and which contributed to the severe chronic lung disease in many early BPD patients. In recent years, with survival of more and more premature infants, and recognition of pulmonary oxygen toxicity and the adverse effects of excessive pressures and volumes with mechanical ventilation, the BPD phenotype has changed to a histological pattern of arrest of airway and alveolar development: alveolar numbers are reduced and the alveoli are larger than normal in diameter; the more severe changes are absent [72,73] (Fig. 7.4). However, in spite of the improved treatment strategies in preterm infants, BPD is the most common complication of prematurity, with up to two-thirds of children born before 29 weeks being affected [74]. BPD is associated with increased mortality, poor neurodevelopmental outcomes, and chronic respiratory disease [75]. The most common current definition of BPD is a premature infant who had a diagnosis of RDS with a requirement for supplemental oxygen for more than 28 days (independent of the need for mechanical ventilation), with a further classification at 36 weeks of postconceptional age into mild, moderate. or severe BPD [76]. A joint US National Institute of Childhood Health and Development–National Heart Lung and Blood Institute workshop further classified mild BPD as the need for supplemental oxygen at ≥28 days but not at 36 weeks of postconceptional age; moderate BPD was defined as the need for supplemental oxygen at 28 days, in addition to supplemental oxygen at FiO_2 ≤0.30 at 36 weeks of postconceptional age; and criteria for severe BPD included the need for supplemental oxygen at 28 days and at 36 weeks of postconceptional age, the need for mechanical ventilation and/or FiO_2 >0.30 [72].

The incidence of BPD varies by center, but in recent studies of infants born at 24–31 weeks of gestation at 500–1500 g, BPD rates average 25–30% using the definition of oxygen requirement at 36 weeks; however intercenter variability means these rates vary from about 5% to 60% [72]. The overall incidence of BPD is stable or actually increasing slightly, presumably due to increasing survival of more premature infants. Risk factors for BPD include lower gestational age and birthweight, intrauterine growth retardation, male sex, family history of asthma, not receiving antenatal glucocorticoids, and likely a genetic component that is not yet fully elucidated.

Theories about pathogenesis of the new BPD include lung injury in very preterm infants at critical stages of lung development during the late canalicular and saccular phases, resulting in arrested development of lung structures and disrupted repair at critical stages [77]. Proposed risk factors for

Components of severity		Classification of asthma severity (0–4 years of age)			
		Intermittent	Persistent		
			Mild	Moderate	Severe
Impairment	Symptoms	≤2 days/week	>2 days/week but not daily	Daily	Throughout the day
	Nighttime awakenings	0	1–2x/month	3–4x/month	>1x/week
	Short-acting β_2-agonist use for symptom control (not prevention of EIB)	≤2 days/week	>2 days/week but not daily	Daily	Several times per day
	Interference with normal activity	None	Minor limitation	Some limitation	Extremely limited
Risk	Exacerbations requiring oral systemic corticosteroids	0–1/year	≥2 Exacerbations in 6 months requiring oral systemic corticosteroids, or ≥4 wheezing episodes/1 year lasting >1 day AND risk factors for persistent asthma		
		← Consider severity and interval since last exacerbation. Frequency and severity may fluctuate over time. → Exacerbations of any severity may occur in patients in any severity category.			
Recommended step for initiating therapy (See Fig. 6.3C for treatment steps.)		Step 1	Step 2	3 and consider short course of oral systemic corticosteroids	
		In 2–6 weeks, depending on severity, evaluate level of asthma control that is achieved. If no clear benefit is observed in 4–6 weeks, consider adjusting therapy or alternative diagnoses.			

Key: EIB, exercise-induced bronchospasm

Notes

- The stepwise approach is meant to assist, not replace, the clinical decision making required to meet individual patient needs.
- Level of severity is determined by both impairment and risk. Assess impairment domain by patient's/caregiver's recall of previous 2–4 weeks. Symptom assessment for longer periods should reflect a global assessment such as inquiring whether the patient's asthma is better or worse since the last visit. Assign severity to the most severe category in which any feature occurs.
- At present, there are inadequate data to correspond frequencies of exacerbations with different levels of asthma severity. For treatment purposes, patients who had ≥2 exacerbations requiring oral systemic corticosteroids in the past 6 months, or ≥4 wheezing episodes in the past year, and who have risk factors for persistent asthma may be considered the same as patients who have persistent asthma, even in the absence of impairment levels consistent with persistent asthma.

Figure 7.3 (A and B) Classifying asthma severity and initiating treatment in children who are not currently taking long-term control medication: (A) children 0–4 years of age; (B) children 5–11 years of age. (C and D) Stepwise approach for managing asthma in: (C) children 0–4 years of age; (D) children 5–11 years of age. *Source:* Reproduced from [86] with permission of National Heart, Lung, and Blood Institute; National Institutes of Health; US Department of Health and Human Services.

this lung injury include chorioamnionitis and fetal inflammatory response, ventilator-induced lung injury (volutrauma, barotrauma, atelectotrauma), oxygen toxicity (oxygen free radical production and lipid peroxidation), lack of surfactant, and disruption of vasculogenesis (inhibition of vascular endothelial growth factor (VEGF) pathways) [77].

Strategies to reduce the incidence and severity of BPD include non-invasive forms of ventilation, in lieu of endotracheal intubation in premature infants with RDS. Both nCPAP and nasal intermittent positive pressure ventilation (NIPPV), delivered via specially designed nasal prongs, have been used for this purpose. As a primary treatment for respiratory

Components of severity		Classification of asthma severity (5–11 years of age)

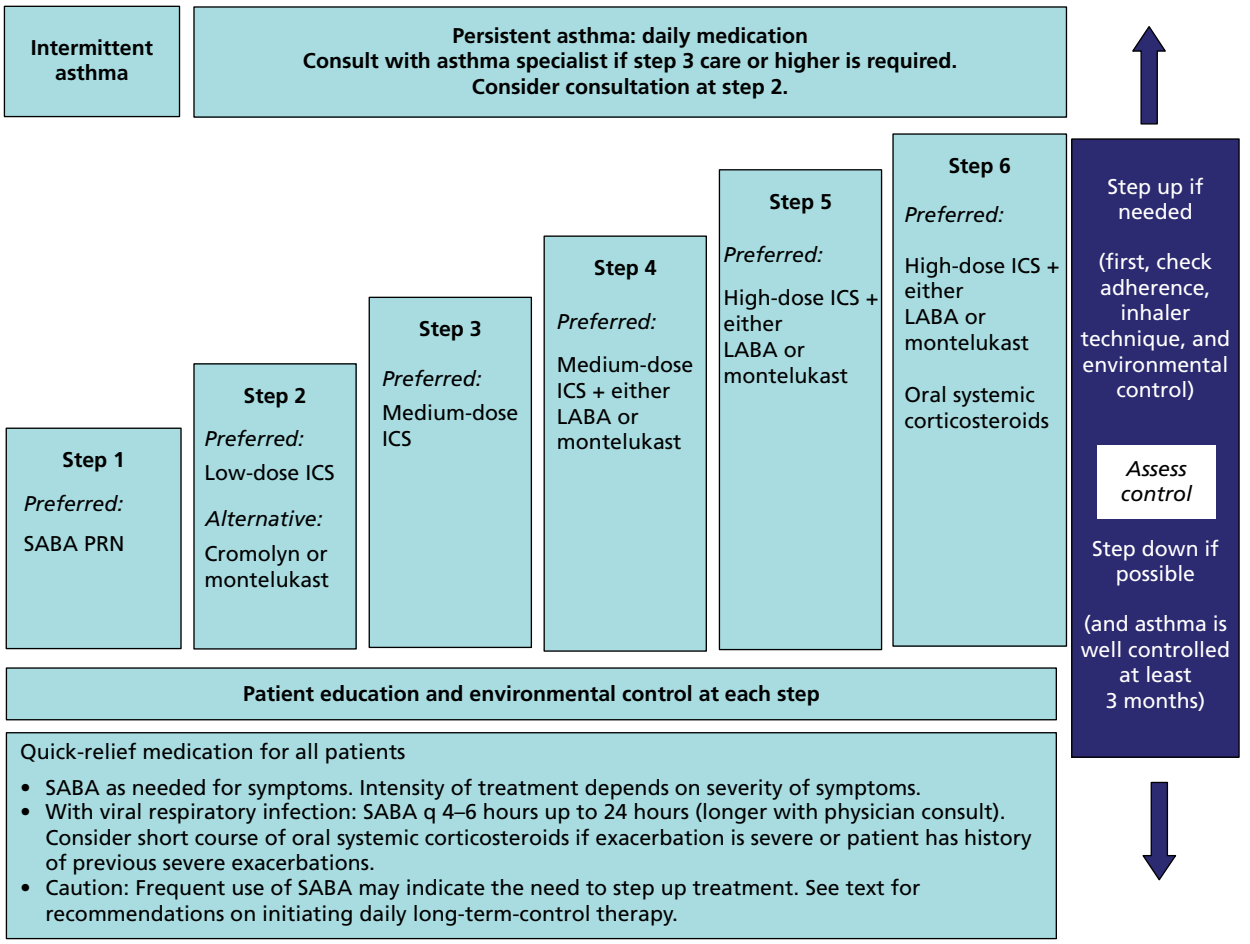
Figure 7.3 (*Continued*)

failure secondary to RDS, non-invasive ventilation may avoid tracheal intubation in some infants, but so far trials have not shown a consistent ability to reduce the incidence of BPD with these modalities. Non-invasive ventilation is well established as a postextubation therapy to reduce the duration of tracheal intubation and mechanical ventilation. However, these modalities used after extubation have not been conclusively demonstrated to reduce the incidence of BPD [73]. Modern conventional mechanical ventilation techniques employ microprocessor technology, allowing patient-triggered synchronized ventilation, volume-targeted ventilation, and flow-cycled ventilation, all of which are proving to have advantages in preventing ventilator-induced lung injury. Volume-targeted ventilation is associated with a lower incidence of BPD as compared with pressure-controlled ventilation modes [16]. Permissive hypercapnea reduces the duration of mechanical ventilation; however, the incidence of BPD with this technique is unchanged. High-frequency oscillatory ventilation is



Key: Alphabetical order is used when more than one treatment option is listed within either preferred or alternative therapy. ICS, inhaled corticosteroid; LABA, inhaled long-acting β_2-agonist; SABA, inhaled short-acting β_2-agonist

Notes:

- The stepwise approach is meant to assist, not replace, the clinical decision making required to meet individual patient needs.
- If alternative treatment is used and response is inadequate, discontinue it and use the preferred treatment before stepping up.
- If clear benefit is not observed within 4–6 weeks and patient/family medication technique and adherence are satisfactory, consider adjusting therapy or alternative diagnosis.
- Studies on children 0–4 years of age are limited. Step 2 preferred therapy is based on Evidence A. All other recommendations are based on expert opinion and extrapolation from studies in older children.

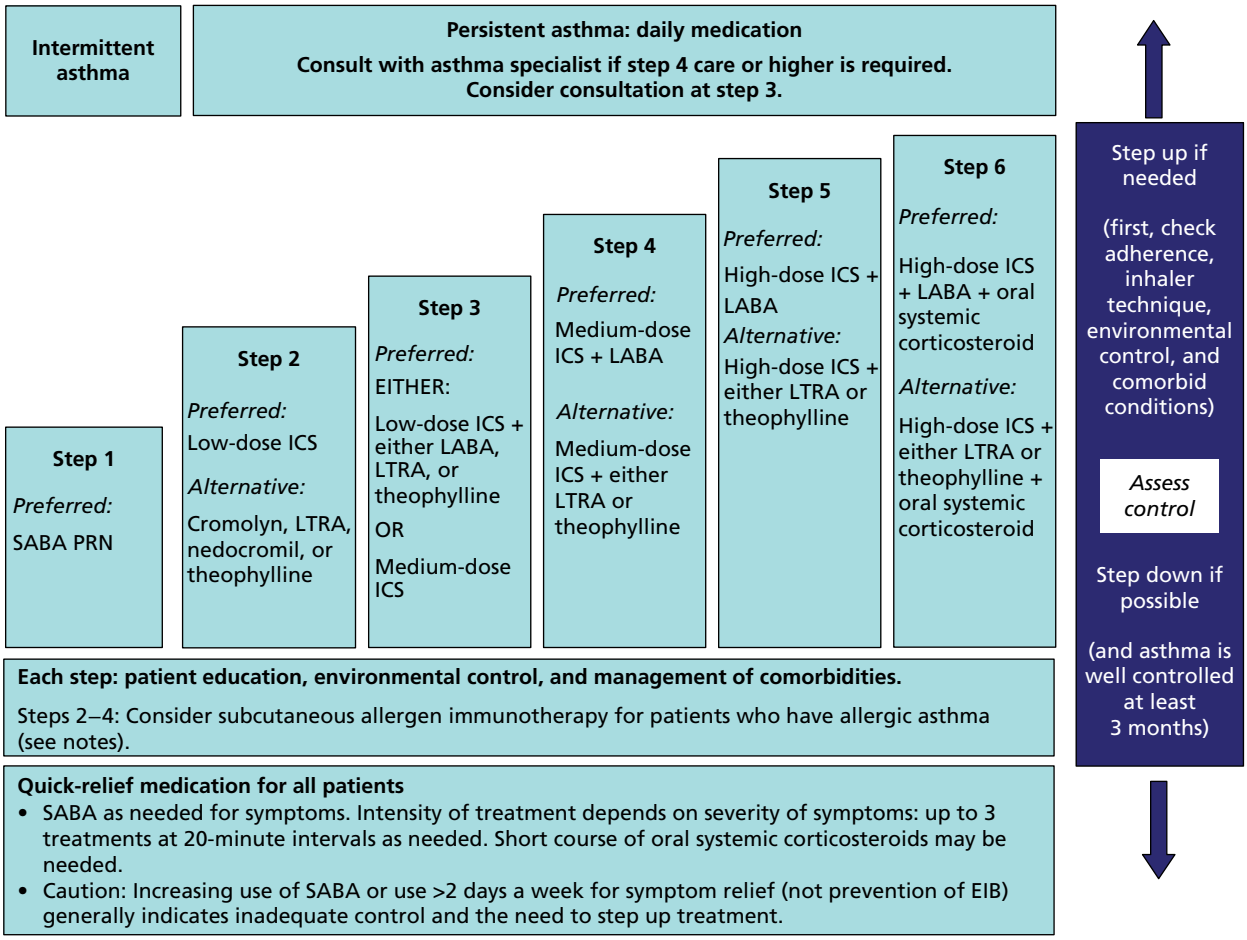
Figure 7.3 (*Continued*)

often used in preterm infants with RDS; this strategy has been found to reduce the incidence of BPD in some studies [73]. Oxygen toxicity has been postulated to have an important role in the pathogenesis of worsening RDS and BPD, and in recent studies, targeting an SpO_{2in} the 85–89% range, rather than the 94–97% range, appears to have some effect in reducing the severity of lung injury and of BPD; meta-analysis of combined trials is underway to further elucidate the magnitude of this effect [78]. Drug therapies used to reduce the severity of RDS include a single course of antenatal glucocorticoids (dexamethasone or betamethasone) to accelerate the maturation of surfactant system in the fetal lung; there is no evidence that this intervention reduces the risk of BPD, probably because of an increase in survival. Surfactant therapy significantly reduces the incidence and severity of RDS, but again does not reduce the incidence of BPD, likely because of the survival benefit. Caffeine therapy, originally used to reduce apnea of prematurity, also reduces the incidence of BPD. Inhaled nitric oxide (iNO), the potent pulmonary vasodilator, has been used in premature infants with hypoxemic respiratory failure, but in randomized controlled trials has demonstrated an inconsistent effect on survival and incidence of BPD and is not recommended as routine therapy in RDS. Other drug therapies that have been used in infants with RDS and evaluated to reduce the incidence of BPD include inhaled corticosteroids, furosemide, β-receptor agonist or



Key: Alphabetical order is used when more than one treatment option is listed within either preferred or alternative therapy. EIB, exercise-induced bronchospasm; ICS, inhaled corticosteroid; LABA, inhaled long-acting β_2-agonist, LTRA, leukotriene receptor antagonist; SABA, inhaled short-acting β_2-agonist

Notes:

- The stepwise approach is meant to assist, not replace, the clinical decision making required to meet individual patient needs.
- If alternative treatment is used and response is inadequate, discontinue it and use the preferred treatment before stepping up.
- Theophylline is a less desirable alternative due to the need to monitor serum concentration levels.
- Step 1 and step 2 medications are based on Evidence A. Step 3 ICS + adjunctive therapy and ICS are based on Evidence B for efficacy of each treatment and extrapolation from comparator trials in older children and adults—comparator trials are not available for this age group; steps 4–6 are based on expert opinion and extrapolation from studies in older children and adults.
- Immunotherapy for steps 2–4 is based on Evidence B for house-dust mites, animal danders, and pollens; evidence is weak or lacking for molds and cockroaches. Evidence is strongest for immunotherapy with single allergens. The role of allergy in asthma is greater in children than in adults. Clinicians who administer immunotherapy should be prepared and equipped to identify and treat anaphylaxis that may occur.

(D)

Figure 7.3 (*Continued*)

anticholinergic inhaled drugs, indomethacin and ibuprofen, vitamin E, and superoxide dismutase; these agents have not reduced the incidence of BPD. Therapies shown to be effective at reducing BPD incidence include, besides caffeine, postnatal corticosteroids, vitamin A, and inositol supplementation in the diet [78].

Most longitudinal studies on BPD after preterm birth find abnormal lung function, which is worsened in extremely premature infants, those with higher severity of BPD, and those with intrauterine growth restriction. Generally, this encompasses varying degrees of airway obstruction, bronchial hyperreactivity, pulmonary hyperinflation, and impaired gas-diffusing capacity [79]. The underlying causes of the bronchial hyperreactivity in children with BPD are still poorly understood, and it is controversial whether it is due to structural changes or neutrophilic airway inflammation.

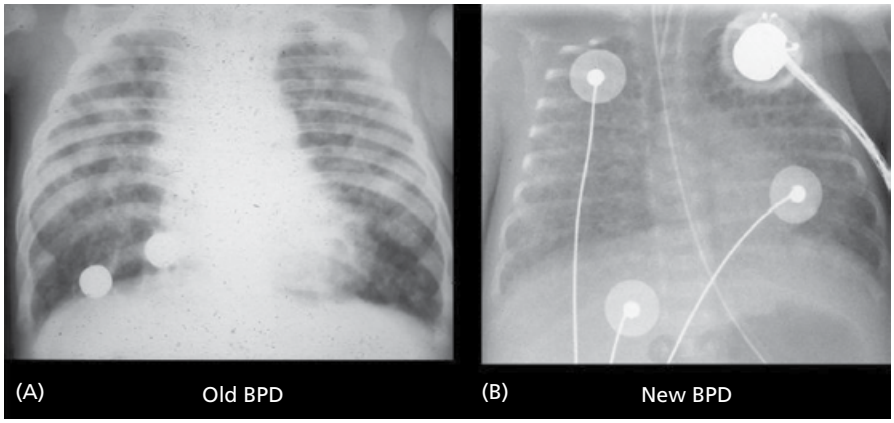


Figure 7.4 Radiographic picture of bronchopulmonary dysplasia (BPD). (A) Old BPD: areas of atelectasis and hyperinflation. (B) New BPD: diffuse opacification of lung fields. *Source:* Reproduced from Gupta et al [73] with permission of Elsevier.

When caring for a patient with a diagnosis of BPD, the anesthesiologist must thoroughly review the history and current chest radiographs if available. The severity of BPD, according to the criteria noted previously, should be assessed. Examination often reveals an infant receiving supplemental oxygen with varying degrees of tachypnea, intercostal and subcostal retractions, and signs of increased lung water or bronchial reactivity, such as fine rales and expiratory wheezing. It is important to understand the patient's baseline oxygen saturation and $PaCO_2$, often available from capillary or venous blood gases. Ventilatory strategies in the operating room should be designed to minimize barotrauma, volutrauma, and oxygen toxicity, and allow permissive hypercapnea to the patient's normal $PaCO_2$. Decreases in lung compliance, increases in resistance, and the increased risk for postoperative mechanical ventilation must all be anticipated and planned for in the infant with BPD. Additional doses of diuretics, or bronchodilators may be needed to optimize perioperative pulmonary outcomes.

Of particular importance for the anesthetist is the presence of bronchial hyperreactivity, particularly in the context of the mechanical stimulation due to airway manipulations. Often the respiratory symptoms in ex-preterm children are classified as asthma, even though the underlying pathophysiological causes seem to be different with no eosinophilic inflammatory pathways observed in children with BPD [79]. This also suggests that routine asthma treatments may not be effective in these children. Additionally, pulmonary hypertension has been recognized as a significant co-morbidity in children with BPD and patients should be screened for pulmonary hypertension preoperatively [75]. Amongst other factors found in the perioperative period, hypothermia, pain, and acidosis can lead to pulmonary vasoconstriction. This can pose a significant risk of hypoxemia due to an increase in ventilation–perfusion inequalities in a child with BPD who already has a limited respiratory reserve [62]. Furthermore, potential right ventricular function impairment may be further increased by anaesthesia.

Although symptoms often decrease with increasing age and the children may seem asymptomatic at preoperative assessments, the rate of bronchial hyperreactivity is still increased, increasing the risk of perioperative respiratory adverse events.

KEY POINTS: BRONCHOPULMONARY DYSPLASIA

- The BPD phenotype has changed to a histological pattern of arrest of airway and alveolar development: alveolar numbers are reduced and the alveoli are larger than normal in diameter; the more severe changes are absent
- The new BPD includes lung injury in very preterm infants during the late canalicular and saccular phases, resulting in arrested development of lung structures and disrupted repair
- Permissive hypercapnea reduces the duration of mechanical ventilation but not the incidence of BPD
- Targeting an SpO_{2in} the 85–89% range, rather than the 94–97% range, appears to somewhat reduce the severity of lung injury and of BPD
- BPD includes varying degrees of airway obstruction, bronchial hyperreactivity, pulmonary hyperinflation, and impaired gas-diffusing capacity
- Pulmonary hypertension is a recognized significant co-morbidity in children with BPD
- Perioperative hypothermia, pain, and acidosis can cause pulmonary vasoconstriction

Cystic fibrosis

Cystic fibrosis (CF) is an autosomal recessive disorder caused by a defect in the cystic fibrosis transmembrane conductance regulator (CFTR) gene with an incidence of 1 in 2000 births in Caucasian populations. It is present in approximately 30,000 children and adults in the United States, and more than 70,000 worldwide [80]. The clinical presentation of children with CF, even those with identical CF mutations, is variable. With improvements in early diagnosis and care, life expectancy has increased markedly over the past several decades, with median life expectancy close to 40 years [81]. CFTR is an adenosine triphosphate (ATP)-binding protein that regulates chloride and bicarbonate transport across epithelial cells via cAMP. CFTR also regulates the airway surface liquid depth through regulation of other proteins, most prominently the epithelial sodium channel. Absent or dysfunctional CFTR results in abnormal electrolyte and fluid content on the

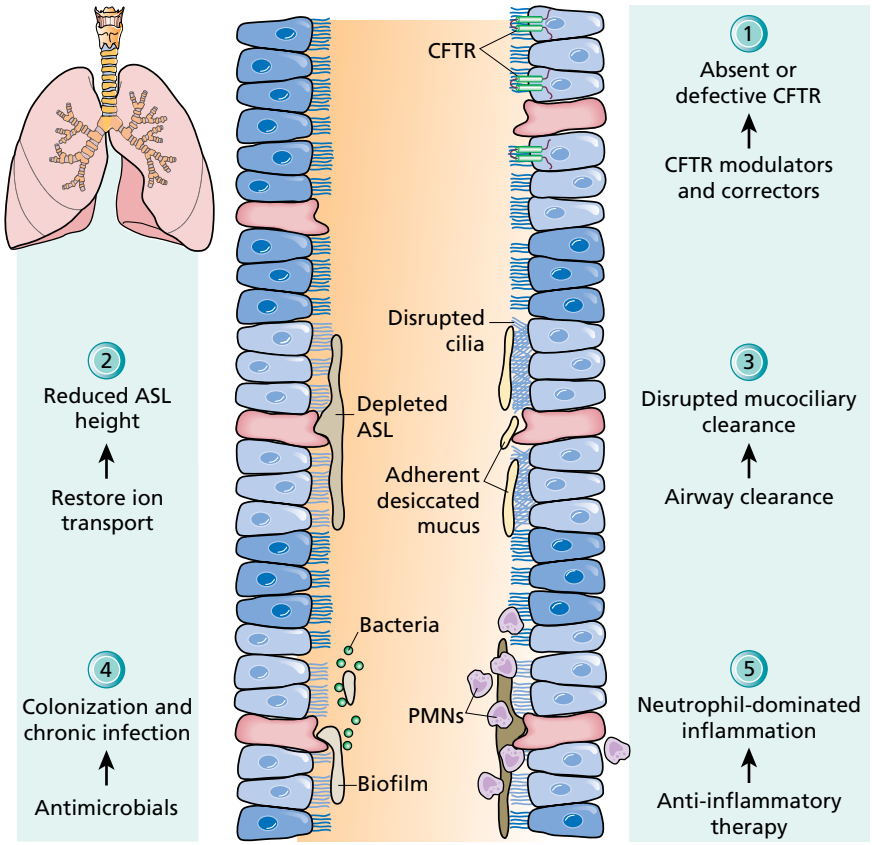

Figure 7.5 The pathogenesis of cystic fibrosis lung disease is characterized by absent or dysfunctional cystic fibrosis transmembrane conductance regulator (CFTR) at the epithelial surface (1), resulting in disordered ion transport and a depleted airway surface liquid layer (2). This contributes to delayed mucociliary clearance (3), setting the stage for colonization and chronic infection with bacterial pathogens (4) and a robust inflammatory response (5). Therapeutic approaches to each feature are indicated. ASL, airway surface liquid; PMN, polymorphonuclear cell. *Source:* Reproduced from Rowe and Clancy [81] with permission of Wolters Kluwer.

epithelia of the lung, pancreas, intestine, hepatobiliary tract, sweat gland, and vas deferens. CF patients have thick, dehydrated, hyperviscous mucus that severely deters effective mucus clearance (Fig. 7.5).

Recent research findings show that the irreversible, progressive lung disease starts to develop early in life even though active symptoms may still be lacking [82]. One of the main underlying factors is the intense inflammation that sets in within the first few weeks of life, even in asymptomatic, culture-negative infants [83]. Similarly, structural changes of the lung also start occurring in infancy and preschool years; mild bronchiectasis, air trapping, and bronchial wall thickening can often be found in asymptomatic infants with the majority of patients having bronchiectasis by age 5. CF patients are susceptible to chronic infection with pathogens such as *Staphylococcus aureus*, *Pseudomonas aeruginosa*, and *Haemophilus influenzae* that may be difficult to eradicate. Inflammation occurs both secondary to chronic infection and independent of microbial disease. Chronic infection and inflammation precipitate a cycle of tissue destruction, bronchiectasis, and airway obstruction, a process that eventually leads to respiratory failure. Slowly progressive lung injury is often accompanied by episodic pulmonary exacerbations, followed by periods of relative disease stability [84] (Fig. 7.6).

Standard therapies for CF include daily airway clearance maneuvers with chest physiotherapy by vibropercussion, hand-administered therapy, or specially designed vests that assist with mucus clearance. Inhaled nebulized recombinant human DNase thins excessive DNA debris in sputum that accumulates due to the bacterial burden and the large influx of neutrophils into the airway lumen. This therapy improves pulmonary function, decreases the frequency of CF exacerbations, and improves quality of life [81]. Nebulized hypertonic saline has also been shown to be effective in some trials. Early and aggressive antimicrobial therapy targeted at the patient's specific organisms and susceptibilities is believed to be responsible for a large component of the improvement in quality of life and reduction in exacerbations in CF patients in recent years. Regular parenteral antibiotic therapy (i.e. every 3 months) is used in some centers, with agents including aminoglycosides, ceftazidime, and meropenem. Antibiotic resistance is a major problem, especially with resistant *Pseudomonas* species and other resistant organisms such as *Burkholderia cepacia*. Inhaled nebulized tobramycin has been shown to be effective at preventing CF exacerbations. Anti-inflammatory therapy with low-dose corticosteroids, or NSAIDs, is also used in some patients [81]. CFTR-modulating drugs are under development and in some clinical trials; gene transfer therapy would be the ideal treatment but faces significant obstacles and clinical use is not imminent. Lung transplantation is reserved for patients with severe CF and a life expectancy of 2 years or less.

CF patients present to the anesthesiologist for a variety of procedures, including diagnostic imaging, vascular access

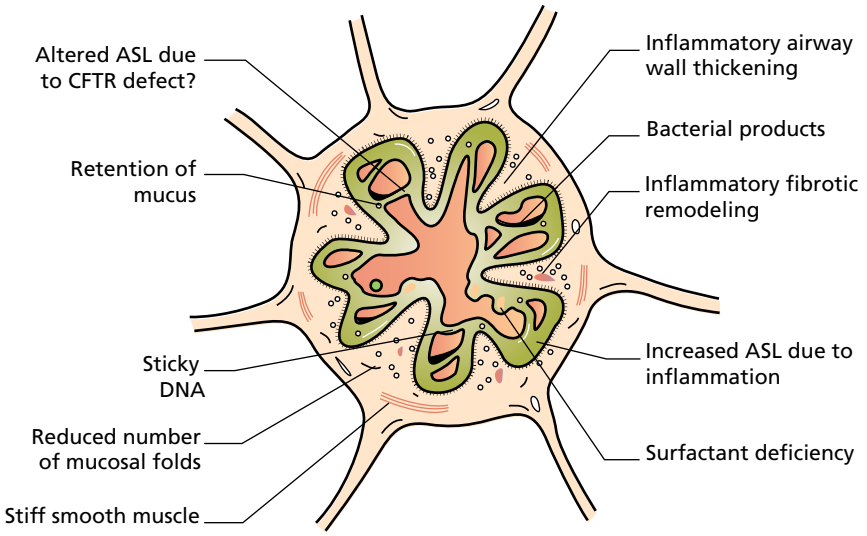

Figure 7.6 Factors that may contribute to small airways obstruction in early CF lung disease. Multiple factors can contribute to filling of the interstices between the folds. procedures, lung biopsies, bronchoscopy, feeding gastrostomy, endoscopic sinus surgery, and lung transplantation. A very thorough review of history, medications, diagnostic testing, and physical examination is important. Since all children with CF are at a particularly high risk for perioperative respiratory adverse events, anesthesiologists optimize the anesthesia management by considering techniques such as intravenous rather than inhalational induction, noninvasive airway devices and deep removal of airway devices if possible [85].

KEY POINTS: CYSTIC FIBROSIS

- Cystic fibrosis (CF) is an autosomal recessive disorder caused by a defect in the cystic fibrosis transmembrane conductance regulator (CFTR) gene
- Median life expectancy is close to 40 years
- Structural changes of the lung also start occurring in infancy and preschool years; mild bronchiectasis, air trapping, and bronchial wall thickening can often present in asymptomatic infants with the majority of patients having bronchiectasis by age 5
- Chronic infection and inflammation precipitate a cycle of tissue destruction, bronchiectasis, and airway obstruction, a process that eventually leads to respiratory failure

Introduction

The child is not merely a small adult. Incompletely developed at birth, the central nervous system (CNS) continues to mature until the end of the second year of life. Because of this delay in maturation, several specific pathophysiological and psychological differences ensue. Neurodevelopment follows a complex interplay between timed genetic events and activity-dependent structural modifications. The unforgiving metabolic vulnerability that occurs with conditions of substrate deprivation challenges the vigorous cellular plasticity of the young brain. A comprehensive understanding of the physics of the intracranial compartment, as well as in-depth knowledge of the vascular physiology of the brain and developmental peculiarities of the nervous system underscores the care of the critically ill child susceptible to neurological injury.

Embryology of the developing brain and spinal cord, changes from fetus to neonate to child

Embryogenesis of the brain

CNS development begins from a relatively simple single layer of cells and progresses to a very complex, multilayered central structure that eventually connects with every part of the body. The processes of CNS embryogenesis follow three steps: (1) neurulation, (2) canalization, and (3) retrogressive differentiation (Table 8.1).

Within 2 weeks of conception, a groove is formed in a plate of embryonic ectoderm, and contains the cells that will become the brain and spinal cord. By 1 month, *neurulation* concludes and the lateral edges of this groove are fused to form the neural tube (Fig. 8.1).

At this time, neural crest cells are excluded from the tube closure and subsequently migrate and differentiate to populate diverse neuronal structures such as the sympathetic chain ganglia, the enteric neuronal plexuses, the dorsal root ganglia, and adrenal medulla, as well as becoming melanocytes in the skin.

Rostrally, the neural tube undergoes differential growth, expansion, and folding to form the three primary brain vesicles: the prosencephalon, mesencephalon, and rhombencephalon. Caudally, the neural tube and surrounding mesoderm retain segmental characteristics and form the portion of spinal cord from the medulla to the midlumbar segments. Secondary brain vesicles are formed as the primary vesicles subdivide. The prosencephalon divides into the telencephalon (cerebral cortex and basal nuclei) and the diencephalon (thalamus, hypothalamus, and retinae). The mesencephalon (midbrain) does not subdivide. The rhombencephalon divides into the metencephalon (pons and cerebellum) and the myelencephalon (medulla) (Fig. 8.2).

Embryogenesis of the spinal cord

The spinal cord from the medulla to the midlumbar segments is derived from the caudal portion of the neural tube. The posterior neuropore closes within a month of gestation,

Table 8.1 Central nervous system embryogenesis

Phase	Gestational age (days)	Outcome
Neurulation	16–28	Brain, spinal cord through L2–L4
Canalization	30–52	Sacrococcygeal segments of the spinal cord
Retrogressive differentiation	46–birth	Filum terminale

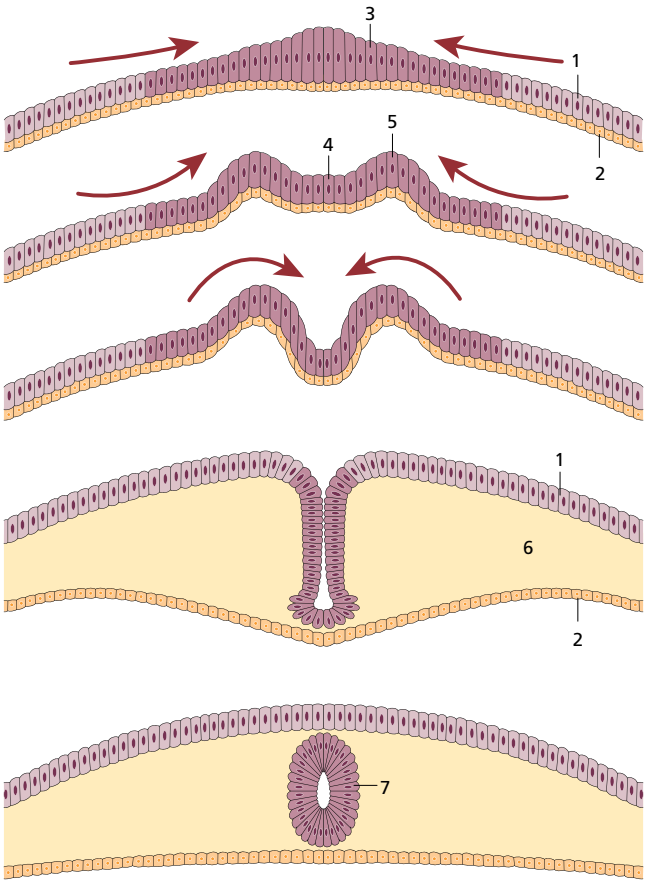

Figure 8.1 Neurulation (see text for details). The arrows indicate the direction of the cell movement. (1) Embryonic ectoderm; (2) embryonic endoderm; (3) neural ectoderm; (4) neural plate with neural groove; (5) neural fold; (6) mesoderm; (7) neural tube. *Source:* Modified from Karfunkel [169] with permission of Elsevier.

and subsequently elongates to form the distal spinal cord and conus medullaris. *Canalization* involves the fusion of the notochord and neural epithelium into a caudal cell mass to form sacral and coccygeal segments between 1 and 2 months of gestation. Microcysts develop and coalesce within this mass. *Retrogressive differentiation* denotes the necrosis of excess cells formed by canalization in the caudal neural tube leaving the filum terminale and cauda equina, a process that continues into the early postnatal period. Vertebral column growth exceeds spinal column growth, resulting in ascension of the conus medullaris from the L3 vertebral segment at birth to the L1 vertebral segment at adulthood (Fig. 8.3).

Neural tube defects

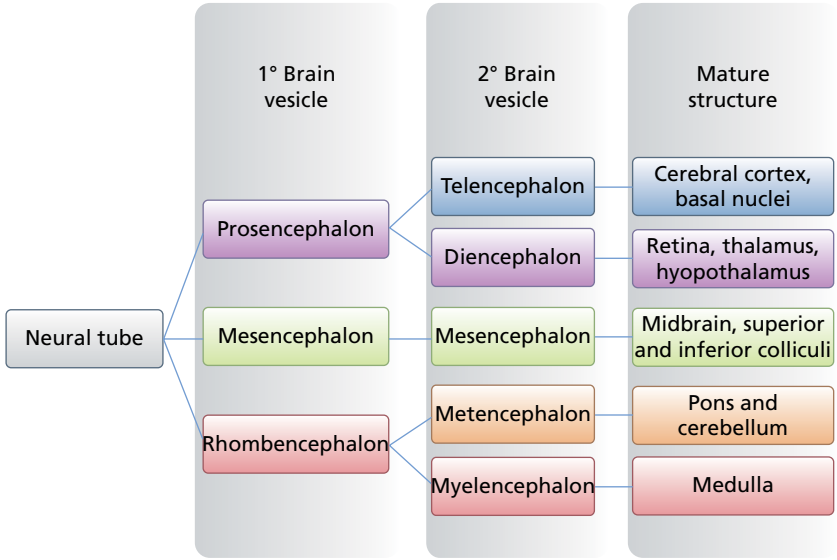
A neural tube defect refers to any defect that occurs during the development of the CNS. We can classify defects occurring during neurulation into: (1) those involving the brain and spinal cord; (2) those involving the brain only; and (3) those involving the spinal cord only. For example, when neurulation fails in early development, a condition of total dysraphism occurs within both the brain and spinal column. If only the brain fails to close, the condition is termed anencephaly. Later in development, many malformations of the brain can occur that have clinical relevance for the pediatric anesthesiologist, including congenital hydrocephalus. Abnormal neuronal migration results in cortical malformations that may be appreciated on gross surface anatomy [1]. Schizencephaly (clefts in the cerebral wall), pachygyri (sparse, broad gyri), and polymicrogyria are examples of anomalies strongly associated with migrational abnormalities. Lissencephaly (smooth brain) is a severe anomaly that may occur after either migrational anomalies or earlier disruptions in neurogenesis. Partial or complete agenesis of the corpus callosum may be associated with any of the above anomalies but it is believed to be a migrational abnormality in and of itself. Failure of canalization results in a myelocele if the lesion is flat, or myelomeningocele if there is an additional dorsal outpouching of the meninges/neural tissue.

Proliferation and migration

Exponential cellular proliferation follows closure of the neural tube, marks the second month of brain development, and continues into the second trimester. Within the second trimester, therefore, the CNS proves particularly susceptible to global insult from teratogen exposure. Radial migration, a well-characterized and robust element of cortical development, denotes a process whereby cells originating from the rapidly dividing periventricular cell layer, and destined to populate the neocortex as both glial and neuronal varieties, migrate along a glial network. They populate the six-layered cortex by migrating past the last-formed layer, such that the youngest cells are found at the outermost layers. At term, cellular proliferation in the cortex is largely completed. However, in premature infants, particularly those at the limits of viability near the beginning of the third trimester, the caudothalamic groove adjacent to the lateral ventricles contains residual germinal matrix. A transient network of fragile vascular overgrowth, which accompanies this ongoing germinal activity, predisposes this site to hemorrhage in the premature neonate [2,3].

Synaptogenesis and myelination

During the third trimester of neuronal development, a period of neuronal growth, synaptic proliferation, axonal growth, and myelination begins. The interplay between genetically determined anatomic directives and environmentally determined plasticity produces a myriad of interneuronal connections that form an incomprehensible network of logical units in the human brain. The basic strategy of network formation calls for the excessive population and interconnection of neuronal networks followed by thinning of these cell populations



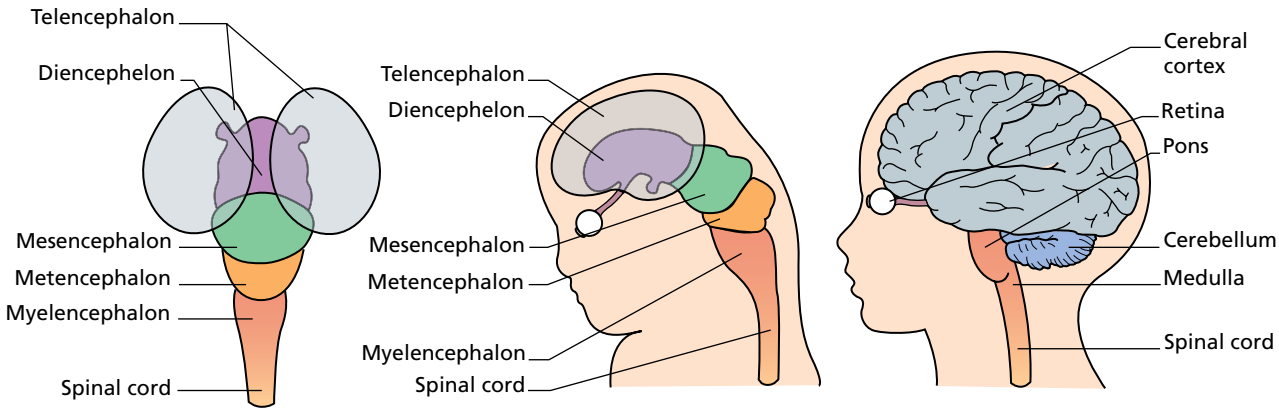


Figure 8.2 Brain development from the neural tube. The neural tube gives rise to three primary brain vesicles, which in turn form five secondary brain vesicles before completing development into the mature brain.

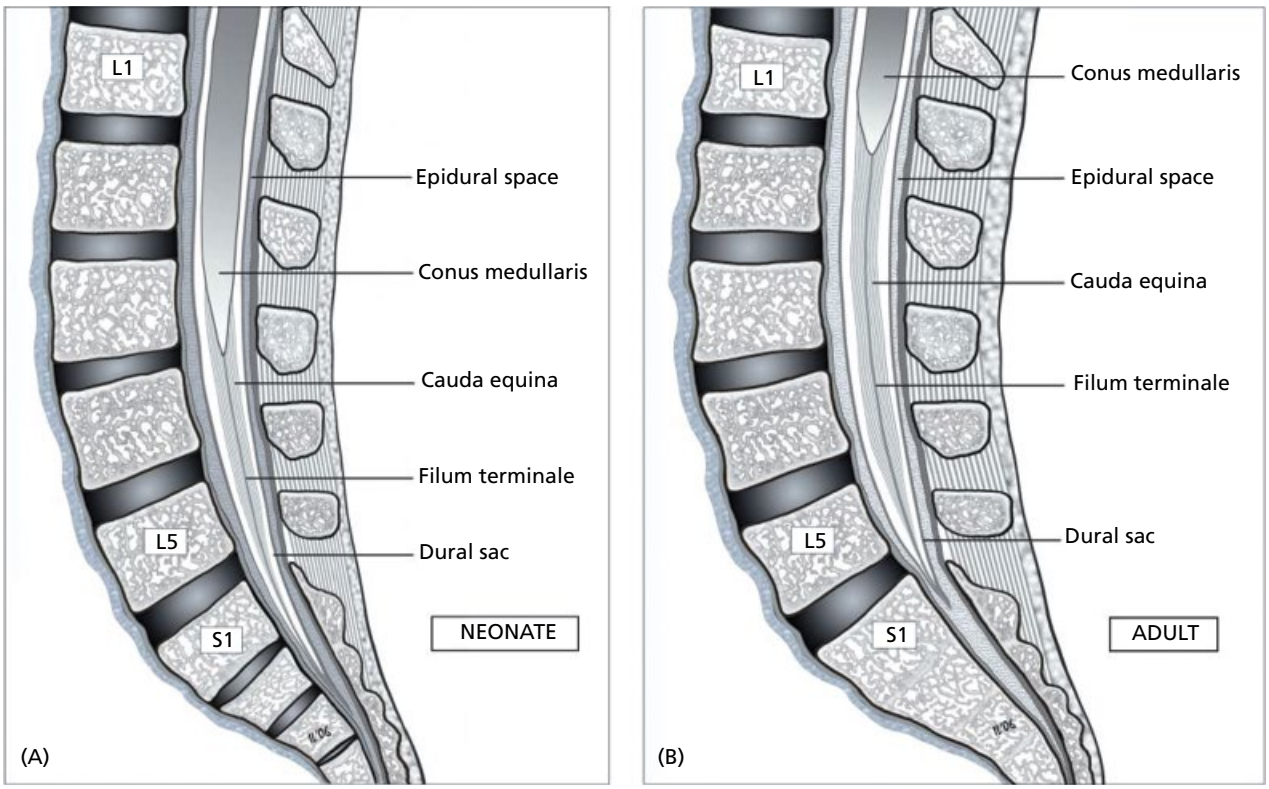

Figure 8.3 Asymmetrical growth of the spine and its vertebral canal causes a change in the position of the conus medullaris with respect to the vertebral column with growth from neonate (A) to adult (B).

by apoptotic mechanisms, pruning of inactive synapse formations, and reinforcement of functional and active connections. Thus, synaptic activity patterns determine the viability of neurons and synaptic connections. The resultant functionality of the network, therefore, depends on sensory and environmental inputs, some of which are known to be time sensitive.

Amblyopia represents the most striking example of synaptogenesis gone awry for lack of appropriate sensory input during a critical stage of development. Normal development of the occipital cortex requires spatially organized and synchronized neuronal activity along the visual pathway. Activity-dependent synapse reinforcement of the occipital cortex begins in darkness, *in utero*, as waves of electrical activity spontaneously pass across the retina, reinforcing spatially-coordinated synaptic connections throughout the visual pathway [4]. After birth, further synaptic reinforcement relies on light-mediated excitation in the retinae. If the retinae receive inadequate or disconjugate light stimulus through the critical development period up to 2 years of age, permanent blindness of the affected eye results from irreversible pruning of synaptic formations in the corresponding cortical network [5–7].

While critical periods for other neurodevelopmental processes are less well defined, we know that the perinatal surge in synapse formation continues through early childhood to the preteen years. The existence of a critical period distinguishes developmental, primary synaptogenesis from other forms of neural plasticity that continue throughout life. The relative permanence of synaptogenic modulation during infancy and childhood is even postulated to create a critical period for development of intellect, behavior, and affect. Environments rich in stimulation, interaction, and socialization promote increased synapse retention, where neglectful, stimulus-poor developmental environments yield synapse-depleted cortical networks, and may lead to permanent cognitive deficits [8–11]. The dendritic arborization of cortical pyramidal neurons has been shown to be environment dependent even in the mature mammalian brain (Fig. 8.4). Further, the introduction of a consistently noxious environment during critical developmental stages may yield undesirable affective changes.

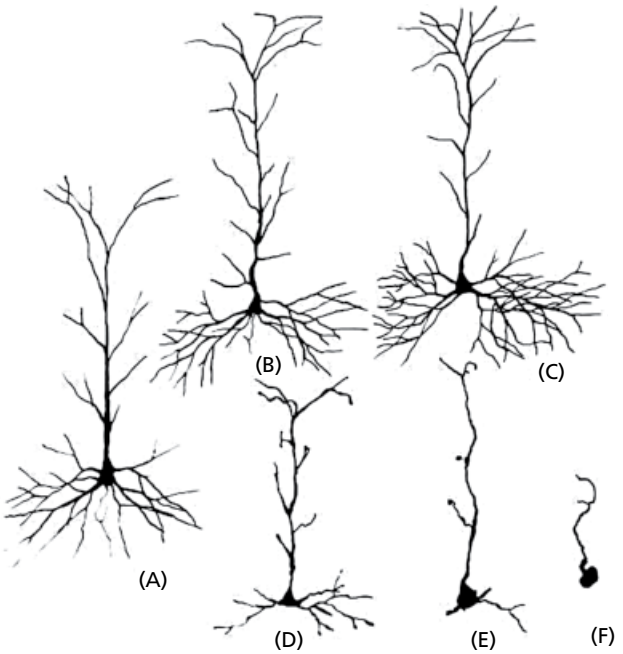

Figure 8.4 Age-related patterns of dendritic arborization of cortical pyramidal neurons. Mature pyramidal neurons (A) can undergo a stimulus-dependent process of stabilization and even increase in synaptic interconnection and dendritic branching (B and C). Alternatively, absent stimulus input, the mature neuron can undergo synaptic pruning and regressive loss of dendritic arborization (D–F). *Source:* Reproduced from Williams and Ramamoorthy [167] with permission of SAGE.

Myelination

Myelination and axonal maturation start in the third trimester, with a peak density of immature oligodendrocytes in the cortical white matter between 23 and 32 weeks of gestation, a time of white matter vulnerability in the premature infant [12]. Myelination continues through childhood and into the teen years, mirroring brain growth. The process of myelination and increased cell size, rather than cellular proliferation, accounts for brain growth from 450 g at birth, to 1000 g at 1 year, and 1400 g at 18 years.

Developmental milestones also follow patterns of myelination. For instance, myelination of the corticospinal tract, which progresses from short to long fibers, and occurs between 36 weeks of gestation and around 2 years of life, correlates anatomically with the head-to-toe disappearance of hyperreflexia and the increased tone seen during the same developmental period. Additionally, axonal maturation of the speech-dominant frontotemporal pathway continues through late childhood and adolescence, correlating with the development of increasingly sophisticated language competency [13]. As with synaptogenic processes, myelination patterns are activity dependent [14].

Magnetic resonance imaging (MRI) of term infants with congenital heart disease demonstrates immature patterns of myelination. Also, pre-cardiopulmonary bypass MRIs reveal lesions in an estimated one-quarter of infants with congenital heart disease, with brain immaturity a risk factor for new MRI lesions after cardiopulmonary bypass. Many of these lesions represent diffuse white matter injury, similar in nature to periventricular leukomalacia seen in preterm infants [15].

Development of pain pathways and responses

The understanding of nociception and the effects of "pain" on the developing infant and child represents, arguably, the greatest contribution of the relatively new pediatric anesthesia specialty. The nociceptive systems develop during the second and third trimesters of gestation, with further maturational changes occurring during the first 2 years of life. Historically, physicians undertreated the pain of neonates and infants due to a belief that the pain system was underdeveloped during these times [16]. However, despite the lack of a "verbal" response to pain, physicians recognized the "physiological" responses to pain that prompted careful exploration of the physiological basis of nociception.

Nociception begins with detection of a stimulus at the level of the peripheral nervous system [17]. Unlike the adult-specific sensations of touch, pressure, heat, or cold, no specific pain sensors exist in the developing fetus. Rather, free

non-specific nerve endings detect the "pain" stimulus. During fetal life, rapidly adapting pressure receptors appear first, followed by the development of slowly adapting pressure receptors, and then rapidly-adapting mechanoreceptors. The depolarization responses of these receptors to mechanical injury, chemical irritants, and inflammatory mediators compare to those of adult receptors [18]. Cutaneous sensory receptors appear in the perioral area at 7 weeks' postconceptual age (PCA), spread to the hands and feet by 11 weeks' PCA, and pervade all cutaneous and mucous surfaces by 20 weeks' PCA [19,20]. Synaptogenesis between afferent fibers and sensory neurons in the dorsal horn of the spinal cord precedes the development of these sensory reflexes.

Free nerve endings of A and C fibers mediate the sensation of pain. These fibers do not demonstrate fatigue; rather, repeated or continuous stimulation *increases* the ease of transmission of the impulse. Histological studies show that the density of nociceptive nerve endings in the newborn skin is similar to that of adult skin [21]. More importantly, the neurophysiological properties of the earliest nociceptors approximate those of adults. Myelinated fibers are the first to grow into the developing spinal cord and form connections with deeper layers of the dorsal horn, as well as generate collaterals to neurons in the substantia gelatinosa. With the ingrowth of unmyelinated C-fibers and their synaptogenesis with superficial dorsal horn neurons, these collaterals undergo developmental degeneration. Myelinated A-fibers transmit nociceptive stimuli in fetal life, and in the extremely premature neonate, until the maturation of C-fiber connections [22].

The first-order neuron, whose cell body lies in the paravertebral ganglion, carries the nociceptive input into the dorsal horn of the spinal cord. The first-order neuron synapses with a second-order neuron in the dorsal horn of the spinal cord. The second-order neuron then crosses the midline and ascends in various pathways including the spinothalamic tract, synapsing in the thalamus with a third-order neuron that projects to the sensory cortex [23]. In the dorsal horn of the spinal cord, nociceptive input is modified (amplified and inhibited) by descending fibers from the CNS and interneurons within the dorsal horn. This modulation is mediated via various chemical compounds (substance P, adrenergic agents, serotonin, and endogenous opioids), which bind to the first- or second-order neuron via specific receptor systems (Fig. 8.5).

In the first trimester of pregnancy, development of the spinal cord and CNS begins with the closure of the neural canal. At this time, the dorsal horn begins to appear. Electron microscopic and immunochemical studies demonstrate that the development of the various neuronal cell types in the dorsal horn with their laminar arrangement, interneuronal connections, and the expression of their specific neurotransmitters and receptors, begins before 13 weeks of gestation and is completed by 30–32 weeks' PCA. Initially, dorsal horn neurons possess a very large receptive field and an extensive overlap with the receptive fields of adjacent neurons. As maturation occurs, the receptive fields of individual dorsal horn cells progressively decrease and can be more precisely defined [24]. On a cellular level, the release of the excitatory neurotransmitters, such as substance P, glutamate, calcitonin gene-related peptide (CGRP), vasoactive intestinal polypeptide (VIP), neuropeptide Y, and somatostatin, mediates and modulates the transmission of nociceptive impulses through the dorsal horn of the spinal cord (Fig. 8.6). Modulation of this nociceptive transmission occurs by the release of met-enkephalin from

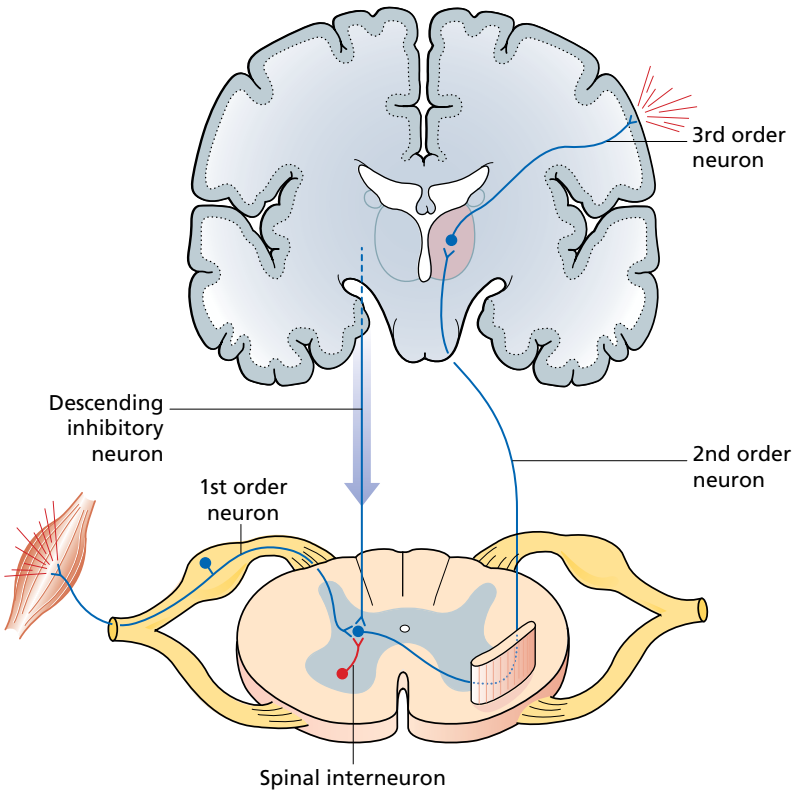

Figure 8.5 Descending inhibitory pathways and spinal interneurons modulate pain transmission at the level of the spinal cord.

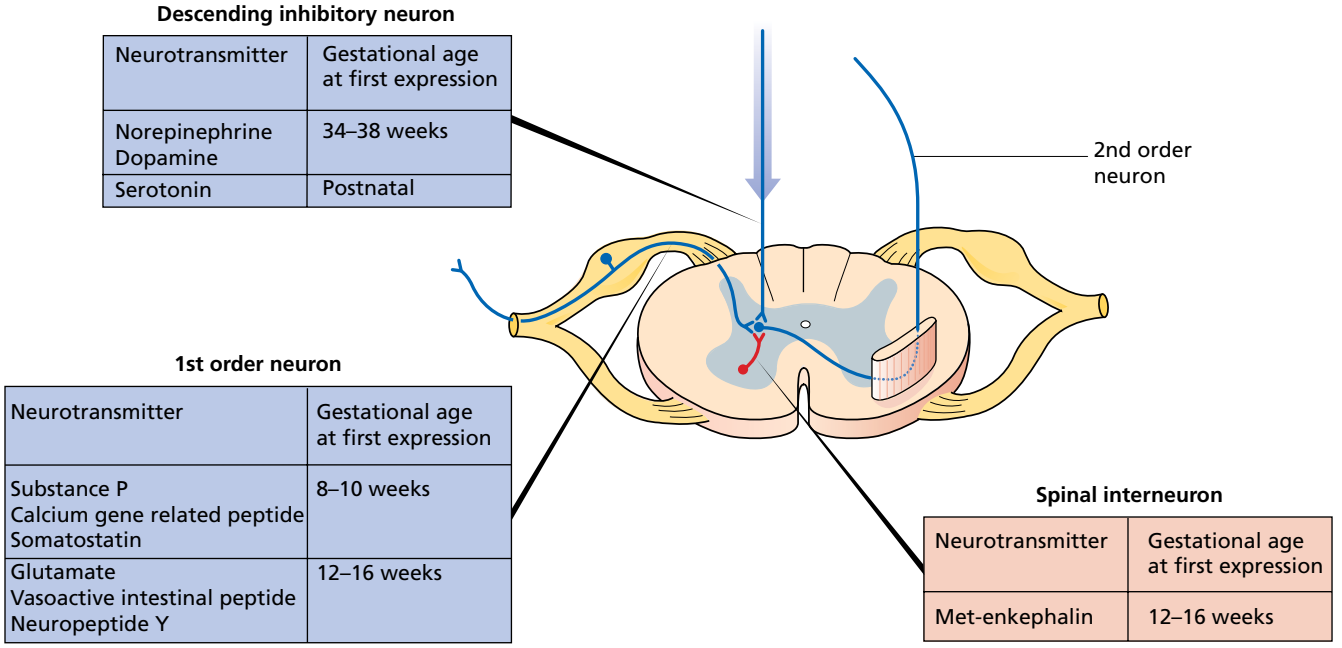

Figure 8.6 Neurotransmitters found in the spinal cord modulating activity of the pain pathway are shown with the gestational age at which they are first expressed.

local interneurons and norepinephrine, dopamine, and serotonin from descending inhibitory axons.

These descending inhibitory axons originate in supraspinal centers and terminate at all levels of the spinal cord and brainstem. During the first and second trimesters up until the latter half of the third trimester, nociceptive mechanisms are unbalanced, favoring amplification, rather than inhibition, of nociceptive input. By 8–10 weeks' PCA, the dorsal horn expresses the nociceptive neurotransmitters substance P, CGRP, and somatostatin. Glutamate, VIP, and neuropeptide Y appear at 12–16 weeks' PCA. Modulation of incoming noxious stimuli in extremely premature infants may occur through the local release of met-enkephalin, which is first expressed at 12–16 weeks' PCA. However, this mechanism likely cannot effectively diminish the transmission of intensive painful stimuli. In the latter half of the third trimester, with the maturation of the descending inhibitory pathways from supraspinal centers, inhibition of incoming sensory stimuli can occur with the release of dopamine and norepinephrine in the dorsal horn of the spinal cord. Inhibitory neurons first express these neurotransmitters at 34–38 weeks' PCA, followed by serotonin during the postneonatal period [25,26].

Conduction of nociceptive impulses to the supraspinal centers occurs via the spinothalamic, spinoreticular, and spinomesencephalic tracts located primarily in the anterolateral and lateral white matter tracts of the spinal cord. Scientists previously proposed the lack of, or decreased, myelination in these tracts as an index of immaturity of the neonatal CNS, and used this to support the argument that neonates cannot feel pain or do not react to it in the same manner as adults. This argument garnered wide support despite the common knowledge that incomplete myelination does not indicate lack of function, but a slower conduction velocity in the central nerve tracts of neonates. Additionally, the shorter interneuronal distances traveled by an impulse in an infant compared to the much larger (and longer) adult completely offset any slowing in the central conduction velocity [27].

Timing of the thalamocortical connection is also of crucial importance for cortical perception of pain since the majority of sensory pathways to the neocortex have synapses in the thalamus. The nociceptive tracts to the brainstem and thalamus are completely myelinated by 30 weeks of human gestation and the thalamocortical pain fibers are fully myelinated by 37 weeks. In the primate fetus, thalamic neurons produce axons that arrive in the cerebrum before midgestation. These fibers remain just below the neocortex until migration and dendritic arborization of cortical neurons are complete and finally establish synaptic connections at 20–24 weeks' PCA [27].

The presence of fetal and neonatal electroencephalographic (EEG) patterns, and the behavioral development of neonates, suggest the functional maturity of the cerebral cortex. Intermittent EEG bursts in both cerebral hemispheres appear at 20 weeks' PCA, become sustained at 22 weeks, and have bilaterally synchrony at 26–27 weeks' PCA. By 30 weeks, we can distinguish between wakefulness and sleep of a fetus using EEG patterns [28,29]. Investigators have recorded cortical components of somatosensory, auditory, and visually evoked potentials in preterm babies before 26 weeks' PCA [30]. Several forms of behavior also imply cortical function during fetal life. For instance, well-defined periods of quiet sleep, active sleep, and wakefulness occur *in utero*, beginning at 28 weeks' PCA. Furthermore, neonates display various cognitive, coordinative, and associative capabilities in response to visual and auditory stimuli in addition to specific behavioral responses to pain, attesting to the presence of cortical function and intact processing of nociceptive input [23].

Development of the response to pain stimulation

The human fetus moves spontaneously and demonstrates complex responses to stimuli early in gestation. Reflex movement in response to direct stimulation, initially localized to

the head and neck region, begins at 7.5 weeks' PCA [31]. Sensitivity develops in a craniocaudal direction with the lower limbs responding by 14 weeks' PCA. Data from the immature rat and other animals reveal inconsistent, non-specific, and poorly localized responses to stimulation initially [32]. However, if triggered, stimuli elicit extremely exaggerated and long-lasting responses [33]. These observations corroborate the neurophysiological animal data and clinical observations in preterm human infants. Single cell studies from the dorsal root ganglion of the rat show that cutaneous receptive fields appear in the hindlimb as soon as innervation to the skin takes place [34]. Initially stimulation of cutaneous afferents fails to produce suprathreshold excitation in dorsal horn cells, but by birth light touch alone initiates depolarization [32]. However, while the synaptic linkage remains weak at birth, suprathreshold stimulation provokes a long-lasting hyperexcitable state in the dorsal horn cells [34].

Polymodal nociceptors, which pass to the dorsal horn via C-fibers, display fully mature responses to pinch, heat, and chemical stimulation by birth [35]. However, despite their observed anatomical connections, these C-fiber afferents fail to evoke activity in the dorsal horn cells until a week after birth. Thus, while the C-fiber connections remain immature at birth and fail to directly transmit their nociceptive input, they may greatly increase the response to other noxious (A-fibers) and non-noxious inputs. Together with the large receptive fields observed in dorsal root ganglion cells, this may increase the likelihood of a central response from the relatively immature nervous system. The lack of functional descending inhibitory pathways from higher centers also contributes to the potentially excitable and poorly damped responses to afferent inputs.

Central integration of afferent inputs

In humans, complex central integration of afferent sensory and nociceptive input is present at 30 weeks' gestation. We can also detect visual and auditory evoked potentials, as well as a complex EEG reactive to external influences, at this time [28,29]. Klimach and Cooke demonstrated the presence of somatosensory evoked potentials (SSEPs) in the preterm neonate [30]. In fact, these authors measured SSEPs in infants as young as 28 weeks' gestation, and demonstrated that the velocity of both peripheral nerve conduction and central conduction increased with gestational age. However, they found considerable variability in peripheral velocity and central processing in the younger infants, suggesting that there are large individual differences in maturation rates. SSEPs continue to mature during infancy [36]. Subarachnoid injections of lidocaine in the ex-premature infant cause rapid loss of the SSEPs corresponding to the onset of motor and sensory blockade. The return of SSEPs and shortening of the latency back to the baseline indicates the offset of the block on monitoring of evoked potentials [37]. Positron emission tomography scans in infants demonstrate that glucose utilization is maximal in the sensory areas of the cerebral cortex, implying a high level of activity [38].

Recent evidence also suggests that cortical activation occurs after painful stimuli in preterm neonates [39]. Bartocci and colleagues, using near-infrared spectroscopy in preterm infants 28–36 weeks' PCA, demonstrated increased blood flow in the somatosensory cortex and not the occipital cortex after venipuncture [40]. In a similar study, Slater and colleagues recorded cortical activation after heel sticks in 18 infants between 25 and 45 weeks' PCA [41]. They noted no cortical response after tactile stimulation even when a reflex limb withdrawal was elicited by the heel stick. Taken together, these studies provide additional evidence that the conscious sensory perception of painful stimuli is present even in preterm newborns. Table 8.2 summarizes the behavioral and physiological nociceptive responses of the neonate.

Table 8.2 Main physiological responses to pain

Assessment	Effect of pain stimulation
Middle cerebral artery pulsatility index	Decrease
Intracranial pressure	Increase
Systemic blood pressure	Increase
Heart rate	Increase (inconstant in neonates)
Transcutaneous oxygen tension	Decrease
Vagal tone (amplitude of sinus arrhythmia)	Decrease
Palmar sweating	Increase
Near-infrared spectroscopy	Decrease

Molecular basis of pain perception

Studies of developmental cytochemistry in animal models focus largely on substance P, opioid peptides and receptors, N-methyl-D-aspartate (NMDA) receptors, and the expression of the C-*fos* gene. While we can detect transmitters early in gestation, they are usually present in very low concentrations and may not always be found at sites that suggest a functional role [42]. By contrast, we can detect receptors early in gestation at higher densities and with a more widespread distribution than in adult life, which may facilitate responses at a time when only low levels of transmitter are available [17]. The transient and puzzling appearance of receptor populations during gestation that cease to be expressed by birth exemplifies the large gap between the *in vitro* cytochemical findings and our current understanding of *in vivo* nociception [43]. Opioid receptors change both in numbers and in type during development. Pasternak et al demonstrated in newborn rats that in conjunction with a large increase in analgesic response to morphine, high-affinity binding sites for a tritiated encephalin ligand increased by up to three-fold in the first 2 weeks of life [44]. In contrast, the effects of morphine on ventilatory drive during this period (2–14 days after birth) remained constant. Other studies subsequently confirmed the increase in opioid receptor quantity and the changes in their binding affinities during *in utero* and postnatal development [45].

The ability to assess gene and protein expression on a cellular and tissue level has led to a more systems-based approach to the adaptation to nociceptive triggers, sparking new insights into the physiological responses to painful stimulus. Assessment of the earliest alterations in gene expression within peripheral nerves, the spinal cord, and brain in both acute and chronic pain response models allows us to evaluate the complex response to painful stimuli and nerve injury in rodent models [46]. Additionally, the development of proteomic and microarray techniques revealed previously unrecognized alterations in actual transcribed and activated

proteins from within a specific cell line and/or tissues [25,47]. The identification of genetic variations and altered expression within the opioid receptor illustrates the vital importance of these techniques. Following the studies of Pasternak and colleagues, these techniques have identified gene-splice variants and single nucleotide polymorphisms within animal and human populations that better explain the variable clinical response to opioid analgesics due to binding kinetics and molecular response [44,48]. Future directions in molecular pain research involve the development of molecular signatures of neuronal and receptor responses that correlate with our phenotypic definitions of acute and chronic nociception and will lead to more personalized pain treatments based on these molecular characterizations (pharmacogenomics) [49].

KEY POINTS: EMBRYOLOGY OF THE BRAIN AND SPINAL CORD

- The processes of CNS embryogenesis follow three steps: neurulation, canalization, and retrogressive differentiation, from the 16th day of gestation through birth
- Cellular proliferation and migration follows closure of the neural tube and continues into the second trimester. Synaptogenesis and myelination begin during the third trimester and continue into the first 2 years of life at a lower rate
- Pain perception pathways and responses start developing during the second and third trimesters, further maturing over the first 2 years of life

The intracranial compartment

The bony encasement of the mature brain both protects and threatens its integrity. The open sutures and fontanelles of the neonate and young infant provide some capability for intracranial contents to expand. The posterior fontanelle ossifies (closes) by about 2–3 months, and the anterior fontanelle by 9–18 months in the normal infant. The brain cannot tolerate acute mass effect because of the elastance of the skull and dura. The risks of herniation and stroke from elevated intracranial pressure have been described for nearly two centuries as the Monro–Kellie doctrine [50,51]. Elastance in the skull is not linear, given that movement of cerebrospinal fluid from the brain to the spinal canal functions as a reserve mechanism. When the increase in intracranial volume exhausts this reserve compliance, further increases cause blood to be pushed out of the skull. Herniation of brain matter occurs with terminal increases in intracranial volume.

Historically, intracranial elastance was estimated by injections of small volumes of artificial cerebrospinal fluid into patients with intracranial pressure (ICP) monitoring. Today, simple ICP monitoring when indicated satisfies most practitioners. More recently, the RAP index, derived from analysis of the pulse amplitude behavior of the intracranial pressure waveform, has been developed to delineate three clinical states of intracranial elastance. Specifically, the correlation coefficient (R) between the pulse frequency amplitude (A) and the mean pressure value (P) of the intracranial pressure wave across periods of slow change in mean intracranial pressure describes the RAP index [52,53]. In the normal state, RAP is near zero because the pulse amplitude of intracranial pressure is low and unchanging within a compliant skull. As compliance reserve is exhausted and the elastic properties of the skull and dura begin to dominate, the pulse frequency amplitude of the ICP becomes passive to slow changes in mean intracranial pressure and RAP trends toward 1. Finally, when ICP is terminal and herniation is imminent, further increases in ICP push blood out of the skull and diminish the pulse amplitude of the ICP, and the RAP becomes negative (Fig. 8.7). In patients with critical ICP, elastance, as represented by the RAP, improves when a surgeon performs a decompressive craniectomy [54].

Eight major bones separated by eight suture lines and six fontanelles form the intracranial compartment. Delayed ossification of these bones permits deforming *compression* of the skull by the birth canal during parturition. This observation leads to the erroneous corollary concept that fontanelles protect the brain against acute mass effect by allowing *expansion* of the cranial vault. In truth, slow growth and expansion of the sutures and fontanelles occurs in the setting of subacute mass effect, but the fibrous interosseous connections lack compliance, and do not accommodate mass added acutely to the intracranial compartment. Although the anterior fontanelle has no protective role in the setting of acute intracranial mass effect, physical examination of it serves as an important monitor of ICP. Tonometry has been applied to the anterior fontanelle to measure ICP non-invasively when ICP monitoring is desirable but not invasively accessible [55]. By 2 years of age, the fontanelles close and bones replace suture lines, but the fibrous sutures permit ongoing bone growth.

The tentorium, a dural separation between the brainstem and cerebellum posteriorly and cortex and diencephalic structures anteriorly, subdivides the intracranial compartment. This impacts the monitoring of ICP in children with posterior compartment neoplasms, given that ICP is monitored in the anterior compartment, and the tentorium divides the intracranial compartment into subdivisions with distinct pressure environments. Posterior compartment mass effect causes deformation of the brainstem, with signs of coma, bradycardia, and hypertension that can exist without bulging fontanelles or elevated anterior compartment pressures.

Cerebrospinal fluid

Derangements of cerebrospinal fluid (CSF) production, flow, and reabsorption account for significant morbidity in the pediatric population. Normal CSF physiology is well described in adults who have an average 150 mL of CSF, 30–40 mL of which is in the ventricles, and produce 20 mL/h of CSF at the choroid plexus. This causes a replacement of the entire CSF volume 3–4 times a day. The constant small pressure gradient between the spinal fluid space and the sagittal sinus drives the flow of CSF through the extracellular spaces of the brain, and its reabsorption through the arachnoid granulations. Age-dependent rates of CSF production have been described in children with external ventricular drains. However, the wide range of CSF production documented across studies likely represents variation that is due to the pathologies associated with the clinical need for drain placement. Nevertheless, Yasuda and colleagues found

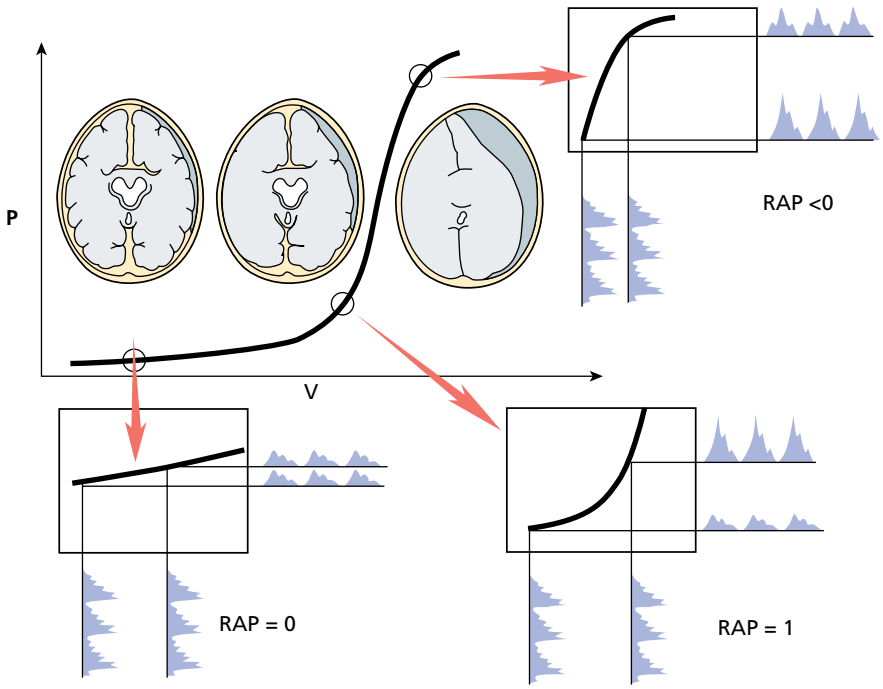

Figure 8.7 Intracranial pressure waves are schematized as a product of fixed cardiac stroke volume pulsations, occurring at different positions on the intracranial pressure–volume curve. Intracranial compliance reserve can be delineated with RAP: correlation (R) between intracranial pressure pulsation amplitude (A) and mean intracranial pressure (P). Three states of intracranial compliance reserve have been defined with this method. (1) RAP = 0: intracranial pressure pulse amplitude does not change with increases in mean intracranial pressure; volume changes are easily absorbed by intracranial compliance reserve. (2) RAP = 1: intracranial pressure pulse amplitude is correlated to changes in mean intracranial pressure; patients on the ascending portion of the intracranial pressure–volume curve have diminished compliance reserve. (3) RAP <0: intracranial pressure pulsations are inversely correlated to changes in mean intracranial pressure. When the RAP is negative, intracranial compliance reserve is exhausted and herniation is imminent.

that CSF production increases logarithmically during the first year of life and reaches 60% of adult production levels at 2 years of age [56].

KEY POINTS: THE INTRACRANIAL COMPARTMENT

- The posterior fontanelle closes by about 2–3 months, and the anterior fontanelle by 9–18 months in the normal infant
- The elastance of the mature skull is not linear; there is some reserve with movement of CSF from brain to spinal canal but when brain swelling or bleeding exhausts this reserve, brainstem herniation occurs
- Infratentorial posterior compartment mass effect causes deformation of the brainstem, with signs of coma, bradycardia, and hypertension that can exist without bulging fontanelles or elevated anterior compartment pressures
- CSF production increases logarithmically during the first year of life and reaches 60% of adult production levels at 2 years of age

Vascular anatomy of the central nervous system

Brain vascular anatomy

A healthy 3 kg infant with a normal 500 g brain has a cardiac output of 250 mL/kg/min, and a cerebral blood flow of 25 mL/100 g/min (= 42 mL/kg/min). The infant brain, therefore, consumes 17% of cardiac output, and also accounts for 17% of the body mass. For comparison, a healthy 50 kg teenager with a 1400 g brain and a cardiac output of 100 mL/kg/min has a normal cerebral blood flow of 22 mL/kg/min. The mature brain therefore comprises just over 2% of total body mass, but utilizes 25% of the cardiac output.

An extensive network of arteries originating from paired internal carotid and vertebrobasilar arteries supplies blood flow to the brain. These arteries branch into the anterior cerebral arteries and the posterior cerebral arteries, respectively, anastomose with each other on the ventral surface of the brainstem to comprise the anterior and posterior segments of the circulus arteriosus cerebri (circle of Willis), and complete the circuit by joining the anterior communicating artery and posterior communicating arteries. The circle of Willis provides collateral blood flow to the brain parenchyma; therefore, damage to any one vessel typically does not result in clinically significant ischemia. However, damage, obstruction, or incomplete formation of any one of the major cerebral vessels may result in a cerebrovascular accident (CVA). The vessels comprising the circle of Willis are prone to the formation of berry aneurysms, congenital birth defects related to defective arterial wall formation. Despite being congenital defects, these aneurysms rarely rupture until early to middle adulthood. Arteriovenous malformations (AVM), the most frequently occurring congenital cerebrovascular malformations, result in the shunting of blood from the arterial to the venous side secondary to anomalous dilated capillaries. Fifty percent of patients present with seizures or neurological deficits as a result of compression or a steal phenomenon, while the other 50% present with hemorrhage. The vast majority of AVMs

occur in the supratentorial compartment (typically in a lobar region), while only 10% occur in the infratentorial region.

The cerebral veins run in the pial layer, while the large collecting veins run in the subarachnoid layer. They eventually transverse the subdural space and open into the cranial venous sinuses. Venous sinuses located between the dura mater and the cranial periosteum primarily make up the venous drainage system of the brain. The walls of the venous sinuses lack both valves and muscle.

Other sinuses within the venous drainage system are of importance to the anesthesiologist, particularly the superior sagittal sinus. Its relatively superficial and midline location predisposes it to damage during surgical correction of craniosynostosis or during a morcellation craniectomy. The superior sagittal sinus ends by becoming continuous with the right transverse sinus 60% of the time, becoming continuous with the left transverse sinus in the remaining 40%. The transverse sinus courses laterally to the sigmoid sinus superior to the tentorium cerebelli. The S-shaped sigmoid sinus (hence its name) lies within the posterior cranial fossa and eventually enters the venous enlargements known as the internal jugular venous bulbs. Most of the venous drainage system empties into the sigmoid sinuses and subsequently into the internal jugular vein excluding the inferior petrosal sinuses, which enter the internal jugular veins directly. A thin plate of bone separates the sigmoid sinus anteriorly from the mastoid antrum and mastoid air cells. The occipital sinus, which lies along the foramen magnum, ends in the confluence of sinuses. The cavernous sinus, which surrounds the sella turcica, joins the superior petrosal sinuses draining into the transverse sinus.

Spinal cord vascular anatomy

The arterial supply of the spinal cord primarily arises from a single anterior spinal artery and two posterior spinal arteries, both originating from the vertebral artery. Radicular arteries originating from spinal branches of the ascending cervical, deep cervical, intercostal, lumbar, and sacral arteries also provide supplemental blood flow to the spinal cord. The anterior spinal artery supplies the ventromedial aspect of the spinal cord that includes the corticospinal tracts and motor neurons. The two posterior spinal arteries, forming a plexus-like network on the cord surface, supply the dorsal and lateral aspects of the spinal cord, which includes the sensory tracts responsible for such sensations as proprioception and light touch [57].

The anterior spinal artery courses ventrally on the spinal cord to supply the white matter tracts and penetrates the cord parenchyma, where it divides within the gray matter. Given the discontinuity of the anterior spinal artery one of the anterior radicular branches from the aorta, the arteria radicularis magna (great radicular artery of Adamkiewicz), supplies blood to as much as the lower two-thirds of the spinal cord from its usual, but variable, origin between T9 and L5 on the left. The ventral spinal cord largely depends on collateral flow through radicular arteries given the lack of collateral blood flow between the anterior and posterior circulations (Fig. 8.8). Only six to eight of the 62 radicular vessels present during intrauterine development persist into adulthood, with less than five present in up to 45% of the general population. Generally, most individuals possess one or two cervical, two to three thoracic, and one or two lumbar radicular arteries.

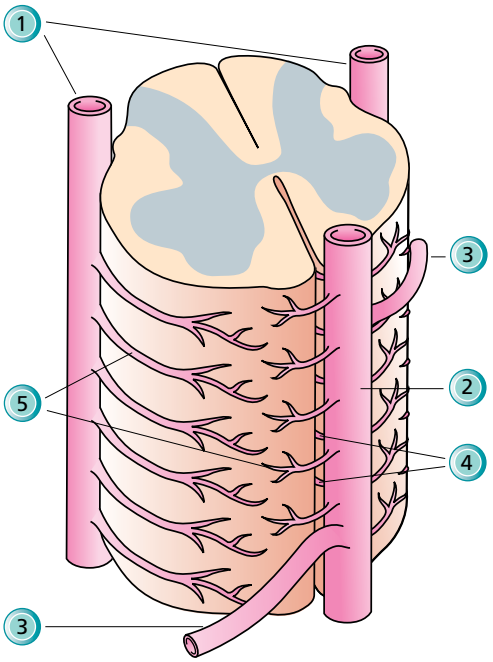

Figure 8.8 The spinal cord blood supply: (1) posterior spinal arteries; (2) anterior spinal artery; (3) anterior radicular artery; (4) sulcal branch arteries; (5) pial arterial plexus.

This leaves the spinal cord susceptible to ischemia at the upper thoracic and lumbar areas, especially during aortic or spinal surgery, or following trauma.

The venous return of the spinal cord consists of two median longitudinal veins, two anterolateral longitudinal veins, and two posterolateral longitudinal veins that drain into the vertebral venous plexus [58]. The venous drainage consists of an internal and external plexus that communicate with each other, as well as with the segmental systemic veins and the portal system. The internal plexus, consisting of thin-walled and valveless veins, connects to a vein from the spinal cord and basivertebral vein at each spinal segment, and communicates through the foramen magnum with the occipital and basilar sinuses. The internal plexus empties into the intervertebral veins that pass through the intervertebral and sacral foramina to the vertebral, intercostal, lumbar, and lateral sacral veins. Joined veins that exit from each vertebral body to form the anterior vertebral plexus form the external plexus. Veins that pass through the ligamentum flavum form the posterior vertebral plexus.

KEY POINTS: VASCULAR ANATOMY OF THE CENTRAL NERVOUS SYSTEM

- The circle of Willis provides collateral blood flow to the brain parenchyma; therefore, damage to any one vessel typically does not result in clinically significant ischemia
- The superior sagittal sinus is midline and relatively superficial, predisposing it to damage during craniosynostosis repair or craniectomy
- The arterial supply of the spinal cord arises from a single anterior spinal artery and two posterior spinal arteries, both originating from the vertebral artery

Cerebral vascular physiology

The data collected in the decades following the groundbreaking work by Kety and Schmidt led to the establishment of the normal adult cerebral blood flow values of 50–75 mL/100 g/min [59–62]. These values represent, in fact, an average of data with significant variability. The wide between-subject variability in these reports comes from the fact that cerebral blood flow itself varies and that substrate delivery is tightly matched to the cerebral metabolic rate of oxygen consumption, not from imprecise measurements. The adaptation of the technique for children age 3–10 years showed that preteen children have a cerebral blood flow nearly twice that of adults [63]. Subsequent measurements in healthy and preterm infants without respiratory distress syndrome revealed cerebral blood flow roughly one-third of adult values at birth, which also appeared to hover near the ischemic threshold of 20 mL/100 g/min in many infants [64–67]. Figure 8.9 depicts the normal developmental changes in cerebral blood flow across age.

The cerebral blood flow developmental pattern mirrors the trend of cellular growth, synaptogenesis, and myelination that occur in the first years of life. Global cerebral metabolism in infants begins at 30% below that of adults, only to increase between birth and 4 years of age to exceed adult rates by twofold [68,69] (Fig. 8.10).

Fully functional vascularity exists in the term brain, but infants born at the current limits of viability possess underdeveloped and anatomically incomplete cerebral vasculature. Neurovascular regulation as a generic principle requires complete vascularization and development of muscular arterioles capable of reactivity. As mentioned previously, a fragile periventricular vascular overgrowth accompanies the persistence of the germinal matrix in the premature infant that is prone to hemorrhage. Premature infants lack a complete system of penetrating arterial growth from the pial surface into deep white matter structures. Adult brains include a redundant arterial network in the white matter circulation whereas the premature infant brain contains a poorly anastomosed white matter circulation vulnerable to ischemic injury [70,71]. According to studies in fetal sheep, vasoreactivity to arterial pressure changes occurs at two-thirds gestation, which would correspond to the current limits of viability. However, the limits of reactivity are much closer to resting blood pressure than in the term animal [72]. Development of the muscularis layer

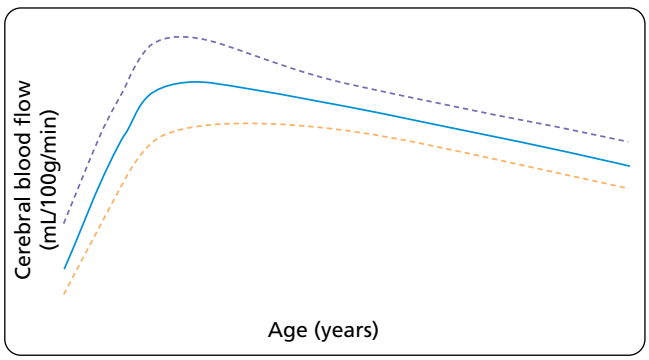

Figure 8.9 Developmental changes in cerebral blood flow. At birth, blood flow to the brain is low compared with adult levels of cerebral blood flow. During the first years of life, blood flow rates increase sharply to a peak at 4 years of age and then taper off during adolescence to adult values.

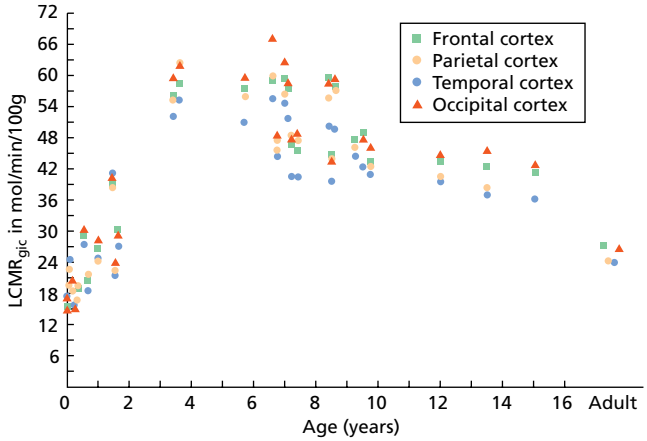

Figure 8.10 Cerebral metabolism, quantified by the local cerebral metabolic rate of glucose ($LCMR_{glc}$) utilization, is low at birth, increases in the first years of life and tapers during adolescence. This pattern recapitulates and explains the developmental pattern of cerebral blood flow changes.

involved in vasoreactivity of arteries and arterioles occurs during the third trimester, first in the larger pial vessels, and then in progressively smaller arterioles. This would predict coarse vasoreactivity in the extremely preterm infant and more fine-tuned vasoreactivity with increasing gestational age. Consistent with this, normal preterm infants appear to spend significant portions of time with pressure-passive circulation, a state seen in adults with shock or intracranial pathology [73]. The peculiarities of preterm circulation and pressure autoregulation pose a conundrum for the anesthesiologist making decisions about blood pressure management for critically ill preterm neonates. The special case of the preterm neonate is further discussed in the sections that follow.

Several layers of servomechanisms contribute to the critical homeostasis of cerebral metabolic demand and substrate delivery. These mechanisms operate at different frequencies, with distinct precision, and with varying regional specificity in the brain. This chapter presents four separate mechanisms of cerebral blood flow control. The first three are presented sequentially as increasingly precise mechanisms working in concert to fine-tune cerebral blood flow in a dynamic pressure-flow system: the systemic vasoconstrictive response, pressure autoregulation, and neurovascular coupling. Next, the cerebral vascular responses to homeostatic perturbations of arterial carbon dioxide, oxygen, and glucose concentration are discussed. The developmental considerations of these mechanisms are evaluated separately.

Systemic vasoconstrictive response

The systemic vasoconstrictive response, which renders cerebral blood flow independent of cardiac output, provides the crudest method for preserving cerebral blood flow. Decline in cardiac output results in increased sympathetic tone, activation of the renin–angiotensin–aldosterone axis, and increased vasopressin activity. All three of these axes exert a vasoconstrictive response on the systemic vasculature that is greater than on the cerebral vasculature. The net effect of the systemic vasoconstrictive response is to preserve cerebral perfusion at the expense of systemic perfusion [74–77]. For this reason,

renal failure and necrotizing enterocolitis may occur without neurological injury in normotensive shock. Thus, when systemic vasoconstrictive responses are functional, the brain takes a variable percentage of total cardiac output to maintain cerebral blood flow [78–80]. In severe low-output shock, as can occur with diarrhea, hemorrhage, or myocardial failure, this antagonistic relationship between cerebral and systemic perfusion can threaten systemic perfusion. Clinically, inadequate systemic perfusion manifests as progressive peripheral (digit loss), gut, or kidney ischemia, which can worsen after institution of pressor therapy titrated to maintain cerebral perfusion. Even during cardiopulmonary bypass, this mechanism preserves cerebral blood flow so long as perfusion pressure is adequate, and regardless of the flow rates [81].

This balance between systemic and cerebral perfusion presents a management dilemma in children with congenital heart disease. Afterload reduction is an essential therapy known to increase survival in the setting of congestive heart failure and shunted circulation post bypass. In this setting, clinicians must balance reduction of systemic vascular resistance against the need for adequate cerebral perfusion pressure (CPP). Even adult patients with heart failure, for whom more defined limits of CPP exist, suffer symptoms (syncope, presyncope) of cerebral hypoperfusion when aggressively treated with vasodilators. Pediatric patients, although less likely or able to report presyncopal symptoms, bear the same risk. Additionally, the strategy of maintaining infants undergoing cardiopulmonary bypass at a critically low CPP using vasodilator therapy improves renal and splanchnic perfusion, as well as overall survival, but decreases cerebral perfusion [82–84]. It should be noted that the impact of this strategy on the high incidence of neurological injury in children undergoing heart surgery has yet to be defined (Fig. 8.11).

The sympathetic nervous system develops early in gestation, and the parasympathetic nervous system develops and increases in tone near term [85]. This higher baseline sympathetic tone confers on the preterm vasculature a lower reserve for mounting a systemic vasoconstrictive response, compromising its ability to maintain perfusion pressure to the brain. The near maximal contractility and elevated heart rates also present at baseline limit the ability of the preterm heart to modulate cardiac output. Hence, preterm infants lack the first homeostatic cerebral blood flow mechanism, maintenance of perfusion pressure, which bestows vulnerability on the brain. The inability to maintain perfusion pressure manifests as hypotension, especially in the first hours and days of life when elimination of the low-resistance placental circulation (clamping of the umbilical arteries) increases the afterload against which the underdeveloped myocardium pumps [86].

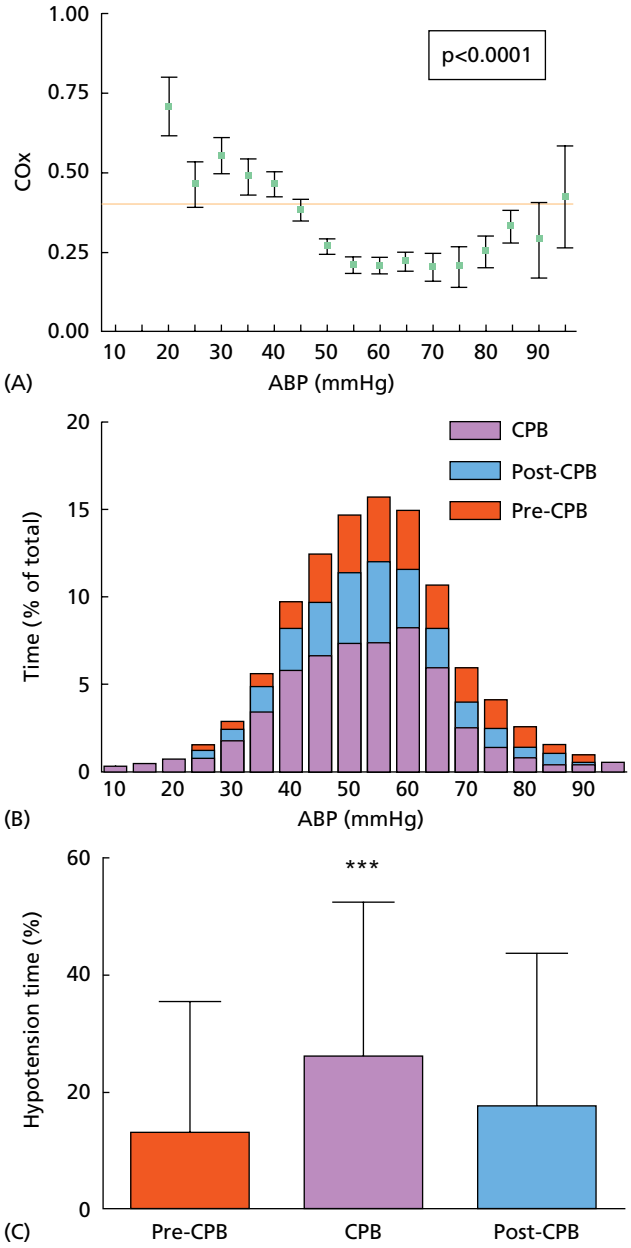

Figure 8.11 Cerebrovascular pressure autoregulation was quantified in children during cardiac surgery by correlation between arterial blood pressure (ABP) and cerebral oximetry (COx), which indicates pathological pressure passivity with increasingly positive values. (A) When normotensive, subjects showed intact pressure autoregulation that was increasingly disturbed with progressive hypotension. (B) The majority of time during the recordings was from normotensive periods with intact autoregulation. (C) Hypotensive recordings with impaired autoregulation occurred most frequently during cardiopulmonary bypass (CPB).

Pressure autoregulation

The next layer of cerebrovascular control, commonly referred to as pressure autoregulation, maintains a constant cerebral blood flow across a range of cerebral perfusion pressures. Impairment of pressure autoregulation is associated with death and poor neurological outcomes after traumatic brain injury in both adults and children [87–91]. However, newer methods for continuous monitoring of autoregulation suggest that the pressure autoregulation mechanism is robust and difficult to ablate entirely; rather, the loss of autoregulation is often due to hemodynamic management that exhausts vasodilatory mechanisms (blood pressure too low) or, less commonly, vasoconstrictive mechanisms (blood pressure too high). Deviation from "optimal blood pressure," specifically blood pressure that results in maximal pressure autoregulation, is associated with increased death and neurological disability after traumatic brain injury [92,93]. Morbidity and operative mortality in adults undergoing cardiopulmonary bypass are associated with greater magnitude and duration of time spent below the lower limit of autoregulation [94,95].

Pressure autoregulation, like the systemic vasoconstrictive response, allows the brain to steal and shunt blood flow to and from the systemic vasculature. In contrast to the systemic vasoconstrictive response, which reacts to changes both in arterial pressure and cardiac output, pressure reactivity is a response solely to changes in arterial blood pressure. Pressure autoregulation responds much faster than does the systemic vasculature, occurring within 4–10 s of a change in arterial blood pressure in one adult study, and within 2 s of a change in blood pressure in a study of neonates [96,97]. In animal models, direct measurement of the timing of the pressure autoregulation response showed that sustained blood pressure changes lasting 30–60 s fully engage the pressure autoregulation mechanism [98]. Pressure autoregulation allows for changes in cerebral blood flow at the pulse and respiratory frequencies, but acts as a high-pass filter that prevents fluctuations in cerebral blood flow that persist for longer than 30 s.

Physiological recordings of ICP, blood volume, blood flow, blood flow velocity, and oxygenation can reveal autoregulatory activity during slow changes of arterial blood pressure lasting between 20 and 300 s. In the normal autoregulating brain, blood volume and intracranial pressure are inversely related to blood pressure at these low frequencies. Dilatation and constriction of the resistance arterioles that mediate autoregulation cause this inverse relationship. The inverse relationship results in constant cerebral blood flow, flow velocity, and oxygenation during slow blood pressure changes. At blood pressures below the lower limit of autoregulation, the unresponsive cerebral vasculature dilates and constricts passively to changes in arterial blood pressure. In this setting, cerebral blood volume, ICP, cerebral blood flow, flow velocity, and oxygenation all positively correlate with slow changes in arterial blood pressure. These distinctions between intact and perturbed autoregulation form the basis of physiological monitoring of the state of autoregulation [99–102] (Fig. 8.12).

Additionally, the limits of pressure autoregulation, and its response times, vary and respond to changes in CO_2 tension. It is now understood that the lower limit of autoregulation, originally described at 50 mmHg in adults by Lassen, has a wide interpatient and contextual variability [62,103] (Fig. 8.13).

The lower limit of autoregulation in pediatric populations has yet to be defined, but infants on cardiopulmonary bypass have shown a lower limit between a mean arterial blood pressure of 30 and 40 mmHg [82,84]. Full-flow bypass is not protective against hypotension, as cerebral blood flow is reduced when arterial blood pressure is less than the lower limit of autoregulation regardless of the total systemic output (Fig. 8.14).

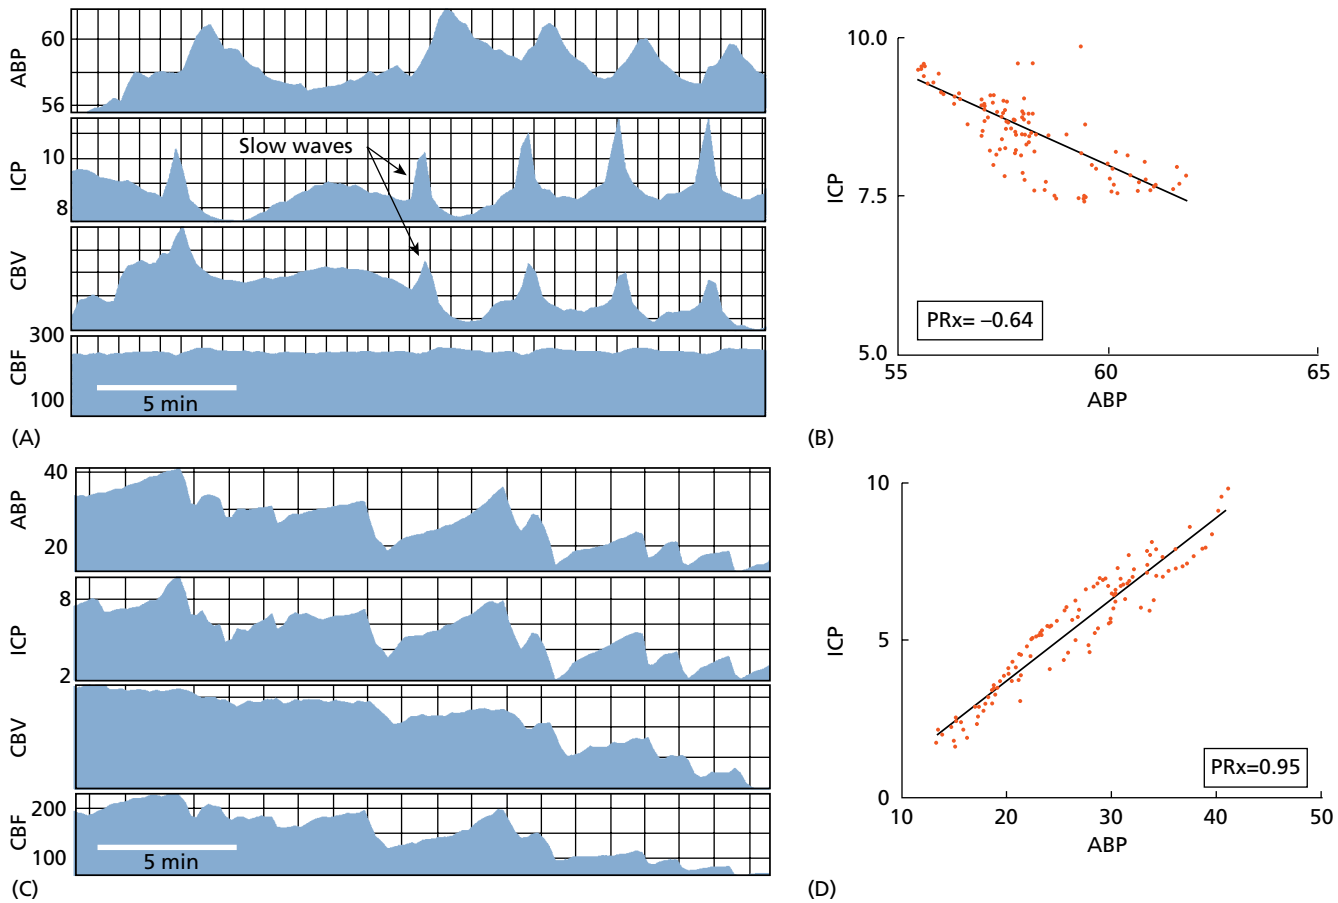

Figure 8.12 Pressure autoregulation and vascular reactivity can be quantified and monitored. Recordings from a normotensive piglet (A and B) of arterial blood pressure (ABP), intracranial pressure (ICP) cerebral blood volume (CBV) and cerebral blood flow (CBF) show intact autoregulation. Slow waves of ABP cause reactive dilatation and constriction of resistance arterioles, which is reflected in both CBV and ICP as slow waves that are inverted when compared with the ABP tracing. CBF is constant in this state of intact autoregulation. The pressure reactivity index (PRx) quantifies the inverted ICP–ABP relationship with a negative Pearson's coefficient of correlation, indicating healthy vascular reactivity. In a hypotensive piglet (C and D), ABP, ICP, and CBV are all in phase at the slow wave frequency, indicating pathological pressure passivity. CBF is fluctuant in this state of impaired autoregulation, and the PRx is positive.

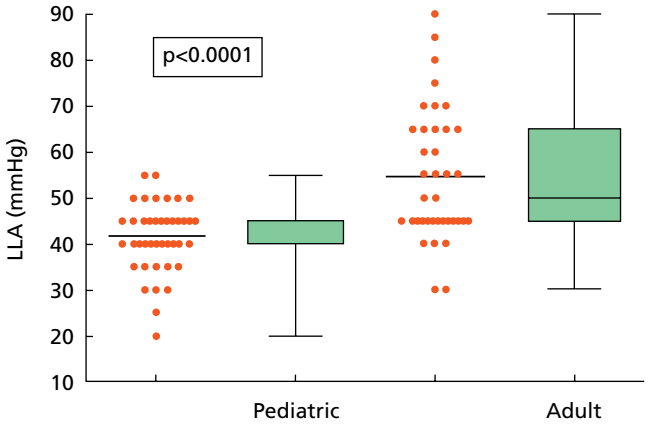

Figure 8.13 The lower limit of autoregulation (LLA) is not necessarily 50 mmHg. Individual determinations of the LLA were made for pediatric and adult populations during cardiac surgery. The blood pressure threshold associated with pressure-passive cerebral oximetry was determined for each subject in the study. Pediatric patients, in general, tolerated lower blood pressures than adult patients, and intersubject variability was high, suggesting that a single blood pressure threshold is not adequate for hemodynamic management guidelines. *Source:* Reproduced from Brady et al [84] with permission of Wolters Kluwer.

Pressure autoregulation and critical closing pressure in prematurity

Evidence of some pressure reactivity has been observed at surprisingly low pressures in preterm infants, but there is no consensus for a safe threshold of low blood pressure in the setting of prematurity [104,105]. Blood pressures in preterm infants are low during transition from fetal circulation. Causes for preterm transitional hypotension are variable but include a strained, immature myocardium adjusting to a sudden increase in afterload. The low blood pressure values seen after preterm deliveries are close to the critical closing pressure (the blood pressure at which flow to the brain is zero). Small variations in the critical closing pressure in these patients can therefore mean the difference between the presence and absence of cerebral blood flow. This precarious scenario is not seen in term infants without elevated ICP.

Rhee and colleagues studied middle cerebral artery blood flow velocity patterns, pressure autoregulation, and the critical closing pressure in a cohort of preterm neonates [106,107]. It was observed in many subjects in that study that cerebral blood flow was limited to the systolic phase of the cardiac cycle. When the diastolic blood pressure is less than

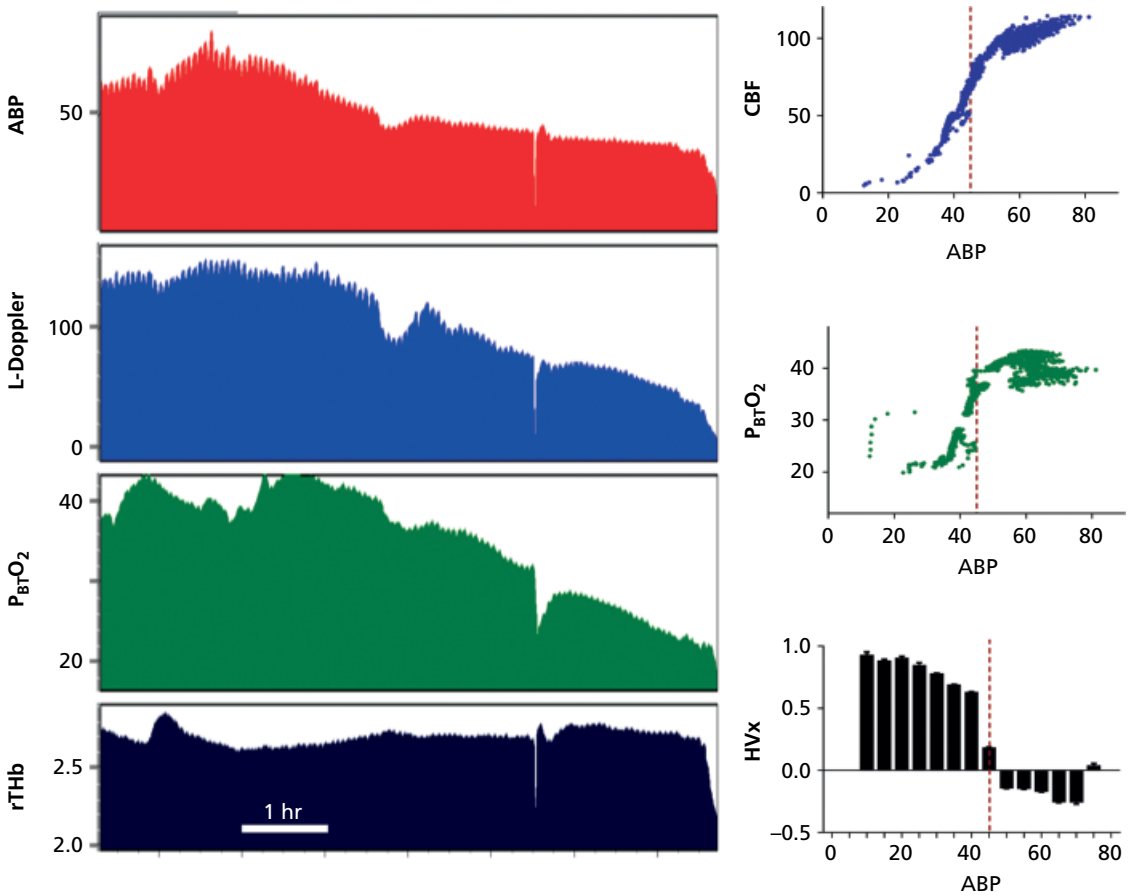

Figure 8.14 Full-flow bypass does not protect the brain from ischemia due to hypotension. A piglet on cardiopulmonary bypass at full flow (120 mL/kg/min) is made progressively hypotensive by the administration of enalaprilat. ABP, arterial blood pressure; L-Doppler, cerebral blood flow measured by invasive cortical laser Doppler flowmetry; $P_{BT}O_2$, oxygen tension in the white matter measured by Licox monitoring; rTHb, cerebral blood volume trended with near-infrared spectroscopy. Plots of cerebral blood flow (CBF), white matter oxygenation, and autoregulation (HVx, hemoglobin volume index derived from rTHb) all indicate a lower limit of autoregulation at an ABP of 45 mmHg. Despite full bypass flow rates, when ABP was below 45 mmHg in this animal, cerebral blood flow was decreased, white matter oxygen tension was reduced, and autoregulation was disturbed (positive HVx indicates a pressure-passive state).

the critical closing pressure, flow is absent during diastole, and cerebral blood flow becomes heart rate-dependent, a state which renders pressure autoregulation less relevant (Fig. 8.15).

To deal with the issue of the closing pressure in their cohort, Rhee and colleagues measured and analyzed systolic and diastolic values of cerebral blood flow and arterial blood pressure separately. They found that diastolic cerebral blood flow was either zero or passive to arterial blood pressure in nearly all subjects. However, in some subjects, systolic cerebral blood flow was constrained across arterial blood pressure changes even when diastolic blood flow was passive (Fig. 8.16). Thus, when they used systolic flow velocities to quantify pressure autoregulation in the preterm neonate, they found minimal evidence for pressure reactivity at 23–26 weeks of gestation, but progressively increasing reactivity across the second half of the third trimester [106–108].

Critical closing pressure is the sum of intracranial pressure (external vascular compression force) and vascular wall tension (intrinsic vascular compression force). As, by definition, the critical closing pressure is the pressure at which cerebral blood flow is zero, it follows that the closing pressure can be used to normalize arterial blood pressure to quantify cerebral perfusion pressure (cerebral perfusion pressure = arterial blood pressure – critical closing pressure) [109–111]. In the Rhee cohort of preterm infants, cerebral perfusion pressure was estimated in this way as the diastolic closing margin (diastolic ABP – critical closing pressure). Increases in diastolic closing margins were associated with intraventricular hemorrhages, when the uncorrected arterial blood pressure was not. This finding underscores the need for a normalization factor that accounts for variance in the critical closing pressure of preterm infants [112].

Until a clinically viable method is available to monitor the critical closing pressure and the state of autoregulation, absolute safe arterial blood pressure recommendations cannot be made. Furthermore, such recommendations might prove inapplicable to critically ill populations, as factors related to critical illness may impair autoregulatory function and shift the limits of intact pressure autoregulation. For instance, newborn piglets without intracranial pathology possess an average lower limit of autoregulation at a cerebral perfusion pressure of 30 mmHg, and piglets with hydrocephalus demonstrate an average lower limit of autoregulation at 50 mmHg [113]. Even monitoring ICP would fail to account for the shift in autoregulation function seen in that study. In the absence of information about the state of autoregulation, practitioners should still apply the crude concepts of blood pressure and cerebral perfusion pressure to the protection of the pediatric brain.

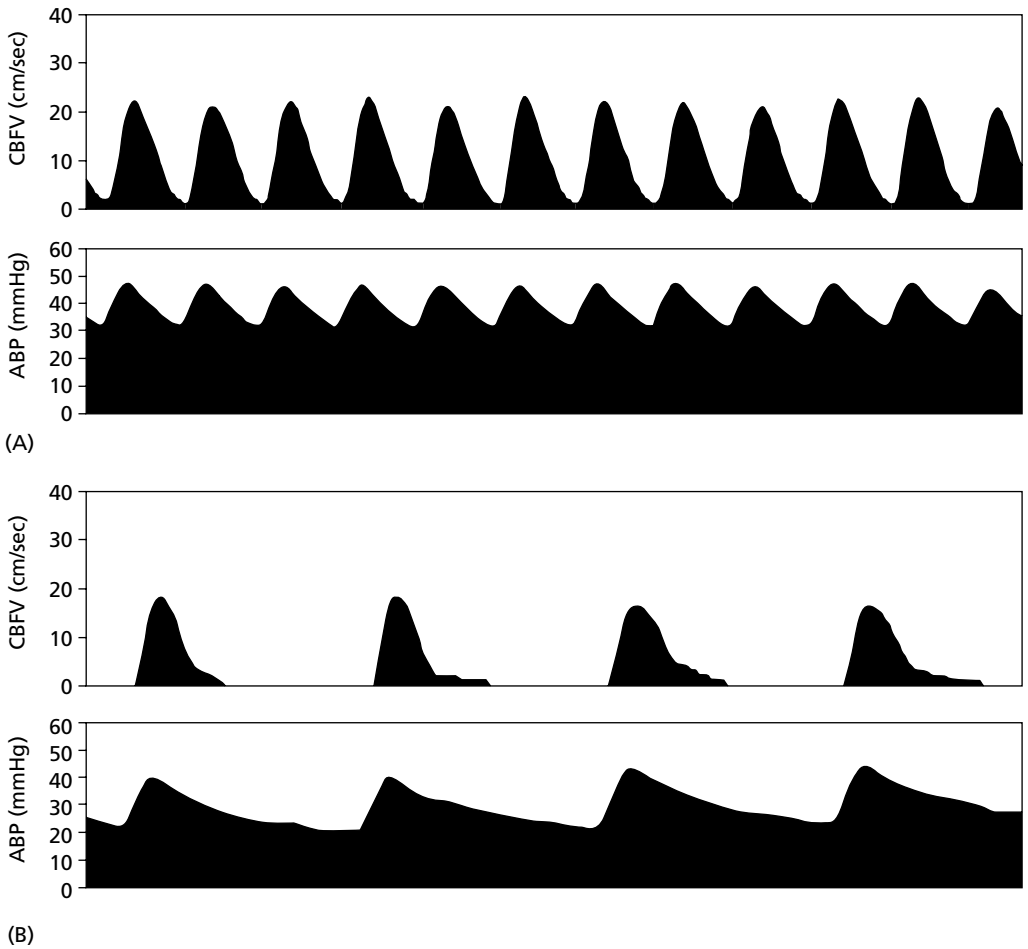

Figure 8.15 Middle cerebral artery flow velocity (CBFV) and arterial blood pressure (ABP) monitored in a preterm infant at baseline (A) and during bradycardia (B). Diastolic ABP in this infant is at or near the critical closing pressure, as evidenced by cerebral blood flow that is restricted to systolic events. Bradycardia dramatically reduces the overall cerebral blood flow in this state.

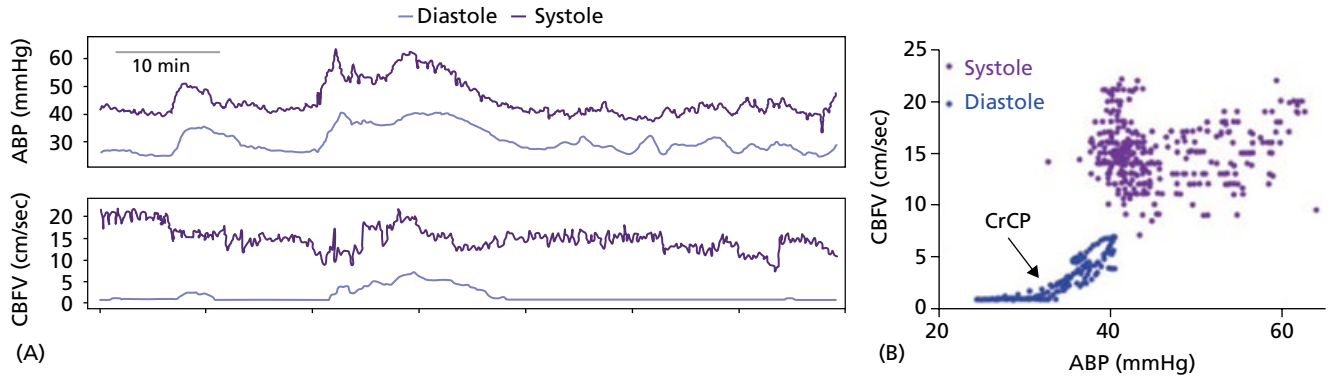

Figure 8.16 Arterial blood pressure (ABP) and middle cerebral artery flow velocity (CBFV) monitored in a preterm infant on the first day of life. (A) Time trends of systole and diastole are shown in purple and blue respectively for both ABP and CBFV. (B) When CBFV is plotted as a function of ABP, paired systolic values (purple) demonstrate autoregulation: a non-correlated relationship between CBFV and ABP. However, paired diastolic values (blue) from the same time interval show that diastolic cerebral blood flow is either zero or pressure-passive in this newborn. The diastolic ABP at which cerebral blood flow first occurs is demarcated with an arrow, and is the critical closing pressure (CrCP) for this infant.

Neurovascular coupling

In 1890, 54 years before the Kety–Schmidt technique was first applied to measure cerebral blood flow, Roy and Sherrington observed a relationship between neuronal activity and cerebral blood flow.

> We conclude then, that the chemical products of cerebral metabolism contained in the lymph which bathes the walls of the arterioles of the brain can cause variations of the caliber of the cerebral vessels: that in this re-action the brain possesses an intrinsic mechanism by which its vascular supply can be varied locally in correspondence with local variations of functional activity. Roy and Sherrington, 1890 [114].

Roy and Sherrington directly measured regional brain volume change in response to electrical stimulation of exposed sensory nerves in dogs to show activity–flow coupling in the brain. Since then, the advent of sensitive regional blood flow measurement techniques has renewed focus on investigating neurovascular interactions. Recently, Koehler et al explained activity-dependent flow using the emergent model of a neurovascular unit composed of an astrocyte that bridges a collection of synapses and penetrating arterioles [115]. From these studies it was learnt that neurovascular coupling affects flow only in the immediate region of neuronal activation (spatial specific), and initiates quickly, effecting vascular diameter change within 1 s of neuronal activation. Neurovascular coupling also produces a finer control of cerebral blood flow when compared to the relatively slow and global pressure autoregulation mechanism. Metabolic regulation of cerebral blood flow can cause large changes in cerebral blood volume, as seen with the induction of barbiturate coma for treatment of elevated ICP. With increasing doses of barbiturate, cerebral oxygen consumption and cerebral blood flow fall concomitantly. At doses sufficient to produce EEG silence, barbiturates reduce cerebral blood flow and volume to half-awake values, and higher doses fail to reduce cerebral blood flow further (Fig. 8.17) [116].

Propofol administration produces similar effects to burst suppression [117]. This technique aids in reducing the brain volume to improve the surgical field and to decrease ICP in patients with acute intracranial mass effect. When temperature is reduced to suppress brain metabolism, the plateau at EEG silence is not observed. Reductions in temperature

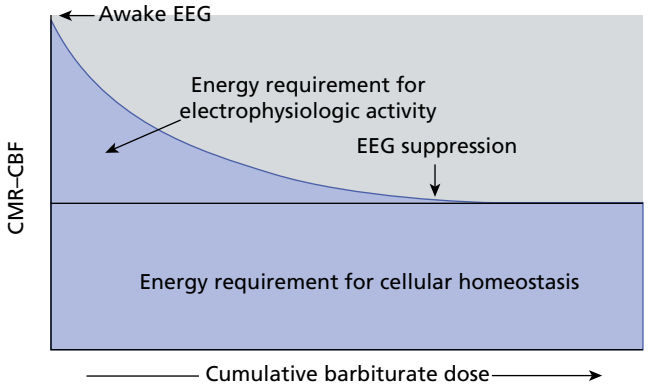

Figure 8.17 More than half of cerebral metabolism (CMR) is utilized for the maintenance of voltage gradients discharged during neuronal activity. EEG silence, induced with barbiturate administration, ablates this metabolic activity and results in a concomitant reduction of cerebral blood flow (CBF) as flow–metabolism coupling is maintained.

continue to reduce both cerebral blood flow and volume because of slowing of cellular metabolism not related to the discharge and maintenance of membrane voltage potentials. The moderately hypothermic brain maintains a cerebral blood flow that is half that of the normothermic brain, and deep hypothermia yields a cerebral blood flow that would be below the critical threshold for ischemia in a normothermic brain [118–120].

Both hypothermia and electrical suppression therapies maintain and utilize the coupling of metabolism and cerebral blood flow. Hypocarbia-induced cerebral blood flow decrements, however, reduce cerebral blood flow to below metabolic demand. This uncoupling of metabolism and cerebral blood flow creates an ischemic vulnerability, which may explain why patients with head trauma have worse outcomes when prophylactic hypocarbia is applied [121].

Flow response to homeostatic derangements

Non-physiological chemical derangements override the three flow and pressure control mechanisms of cerebral blood flow outlined previously. Well-characterized examples include

disturbances of arterial carbon dioxide, oxygen, and glucose. Logically, the brain would be expected to have fail-safe vascular compensations during states of inadequate substrate delivery, even in the context of otherwise adequate perfusion pressure.

Cerebrovascular response to carbon dioxide

Acute decreases in arterial carbon dioxide tension cause vasoconstriction of the cerebral vasculature, and acute increases in arterial carbon dioxide tension cause cerebral vasodilation. The carbon dioxide response of the cerebral vasculature largely occurs across the physiological range of carbon dioxide and correlates with changes in CSF pH. Low pH in the CSF adversely affects neuronal function. Although the blood–brain barrier is impermeable to hydrogen ions, carbon dioxide diffuses freely into the CSF to modulate its pH.

Two mechanisms working in concert control CSF pH. First, robust metabolic buffering occurs through rapid CSF turnover by ependymal cells of the choroid plexus that have a high carbonic anhydrase activity. Second, the coupling of cerebral blood flow to arterial carbon dioxide tension modulates the removal of carbon dioxide from the CSF. CSF buffering partially explains the time course of cerebral blood flow responses to changes in carbon dioxide. The vasoreactive response to a change in arterial carbon dioxide begins within seconds and reaches steady state within 10 min. A gradual return toward baseline cerebrovascular resistance follows over the next 3–6 h, consistent with the time course of pH regulation [122,123]. Persistent hypercapnia results in late hyperemia that is not explained by this model and that does not return to normal after normalization of serum carbon dioxide.

Pediatric anesthesiologists commonly use carbon dioxide as a drug to effect changes in cerebral blood flow. Decreasing cerebral blood volume using hyperventilation facilitates craniotomy in the presence of elevated ICP. But, as previously mentioned, using hyperventilation to manage intracranial volume also reduces cerebral blood flow and disrupts normal metabolic coupling to cerebral blood flow. Ischemic injury occurs in pediatric patients with traumatic brain injury when prophylactic hyperventilation is used to manage ICP. This led the Brain Trauma Foundation to declare prophylactic hyperventilation contraindicated except when used transiently during surgery or to prevent impending herniation.

Conversely, hypercarbia mitigates pulmonary overcirculation and enhances cerebral oxygen delivery in single-ventricle patients with a large left-to-right shunt. In this setting, serum hypercarbia and acidosis increase pulmonary vascular resistance, while hypercarbia and acidosis in the CSF cause decreased cerebral vascular resistance. When arterial carbon dioxide modulation is used as a therapy to change cerebral blood flow, the effect is mediated by changes in CSF pH. Because of rapid CSF turnover and a high range of responsiveness of carbonic anhydrase during CSF production, the magnitude of a pH change in the CSF is blunted after 3–6 h. Because the blood–brain barrier separates serum and CSF buffers, the brain pH returns to normal even if the serum pH remains abnormal. Thus, buffering of the CSF limits the duration of effectiveness of carbon dioxide-modulating therapies. Further, normalizing the serum pH of a patient after prolonged respiratory acidosis or alkalosis may cause injury. For instance, the presence of a low serum pH and a high serum carbon dioxide tension at the initiation of rescue cardiopulmonary bypass is associated with stroke and hemorrhage [124–126].

Cerebrovascular response to oxygen delivery

Arterial oxygen tensions between 60 and 300 mmHg do not appreciably change cerebrovascular tone. When arterial hypoxia or anemia impairs oxygen delivery, however, cerebral vascular resistance decreases and cerebral blood flow increases [127–129]. The response of the cerebral vasculature to extremes of arterial oxygen tension contrasts with the carbon dioxide response, which largely occurs within the normal physiological range of arterial carbon dioxide tension. Essentially, only when oxygen delivery hits a critical threshold does global hypoxic vasodilatation disrupt autoregulatory mechanisms.

Cerebrovascular response to glucose delivery

Despite having a metabolism 7.5 times that of the average tissue, the adult brain maintains only about 2 min worth of glycogen stores within neurons. The lack of a local glucose buffer means that the brain depends on a constant capillary supply. While most cells require insulin for glucose transport from the serum to the intracellular space, glucose diffuses readily into neurons, even in the absence of insulin. Glucose deprivation in the adult brain leads to vasodilation only after unconsciousness and EEG changes have occurred. In contrast, in the newborn brain the vasodilatory response possesses a higher threshold, with vasodilatory changes occurring at serum glucose levels of 30 mg/dL, without loss of consciousness or EEG changes [130–132].

Critical closing pressure

Traditionally, oxygen delivery to the brain is described as a function of cerebral perfusion pressure (CPP): the difference between arterial blood pressure (ABP) and intracranial pressure (ICP) (or jugular venous pressure (JVP) if JVP is higher than ICP). The CPP concept has oversimplifications that are evidenced by clinical scenarios such as vasospasm, in which the ABP, ICP, and JVP are apparently normal but cerebral blood flow (CBF) is reduced to the point of neurological deficit. An alternative view of perfusion pressure incorporates measurement of the critical closing pressure (CrCP) to understand impedance to CBF at the frequency of the cardiac cycle [111]. CrCP is the instantaneous sum of a theoretical collective vascular wall tension and ICP. When ABP is equal to CrCP, vascular patency fails and CBF ceases. Thus, only ABP greater than CrCP contributes to cerebral perfusion pressure (also referred to as the "closing margin"). In a progressively hypotensive child, the cessation of flow initially occurs only during diastole when diastolic blood pressure decreases below CrCP, represented as the diastolic closing margin [109]. Subsequently, further decrements of systolic blood pressure to below CrCP halt flow of blood to the brain altogether.

Measurement of CrCP has been proposed to better define optimal blood pressure goals for preterm infants. The lack of consensus on proper blood pressure goals for premature infants is due to conflicting pressure-associated outcome data in this population. Recently, Rhee and colleagues demonstrated that the ABP of preterm and low-birthweight infants is

close to CrCP, and sometimes below CrCP. They showed that intersubject variability in CrCP was as great as the variability in ABP, explaining why raw ABP is not a meaningful surrogate of CPP for preterm infants, even when ICP is low [106]. CrCP increases along with gestational age in premature infants through the third trimester, and increases with age after birth, tracking trends in ABP [106]. The same group subsequently found that a higher perfusion pressure (ABP normalized to the CrCP) was associated with intraventricular hemorrhage in preterm infants [112]. Currently, the only method available to monitor CrCP is estimation of the time constant between invasive ABP changes and middle cerebral artery flow velocity changes at the frequency of the cardiac cycle [111]. Although clinically impractical, this development may lead to a more effective management strategy for the preterm population as the technology advances.

KEY POINTS: CEREBRAL VASCULAR PHYSIOLOGY

- Cerebral blood flow in the infant is low compared with adult levels, increases dramatically until 4 years, then tapers during adolescence to adult values
- Pressure autoregulation develops during the third trimester, but from 23–26 weeks' gestation blood flow is pressure passive, and in many patients is limited to the systolic phase of the cardiac cycle
- Cerebral blood flow is acutely responsive to arterial CO_2 levels across the physiological range; excessive hyperventilation can lead to cerebral ischemia
- Cerebral vasodilation occurs only at critical levels of hypoxemia below 50–69 mmHg, and glucose below 30 mg/dL in the neonate

Electroencephalogram

When appropriately applied, electroencephalogram (EEG) monitoring provides a continuous recording of electrical activity between reference electrodes placed at specific positions on the scalp. Perioperatively, EEG may identify abnormalities and potential periods of cerebral injury or malfunction. The electrical activity is believed to originate from the postsynaptic potentials of the dendrites of cortical neurons, and EEG waveforms are classified according to frequency: delta (1–3/s), theta (4–7/s), alpha (8–12/s), and beta (13–20/s) (Fig. 8.18). Many factors such as age, state of awareness/alertness, tasks (e.g. eye opening), medications, and various disease states alter these waveforms. Sleep, in particular, can manifest unique alterations such as sharp waves (K complexes) and sleep spindles (regular 12–14/s) confined to the central electrodes. Various combinations and locations of spike and slow wave activity characterize seizure or epileptiform activity and may interfere with processed EEG validity. Therefore, adequate interpretation of continuous EEG tests requires good lead contact and continuous analysis by a trained technician/clinician. Brain maturation and environmental factors such as anesthetic agents, pain, cerebral metabolism, and temperature also affect EEG signals.

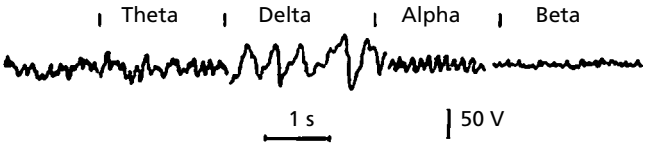

Figure 8.18 The electroencephalographic (EEG) waveforms are classically divided according to frequency as delta (1–3/s), theta (4–7/s), alpha (8–12/s), and beta (13–20/s). Notice that delta waves are also characterized by a higher amplitude (>75 μV), while beta waves have a very low amplitude (<10 μV). These waves are interpreted based on the clinical state of the patient (i.e. level of arousal or seizure activity). The propensity and distribution of these various waveforms change throughout life and during different mental activities. For example, adult subjects monitored with EEG who are sleeping have increased delta wave activity whereas those who are awake and thinking have more alpha and beta wave activity.

When used appropriately, EEG may confer diagnostic and management benefit. For instance, trained clinicians have used EEG during cardiopulmonary bypass to titrate cooling strategies, detect intraoperative events, and monitor for postoperative seizures. Both comprehensive (raw EEG waveforms from multiple leads) and processed (computer algorithm-driven simplified EEG display) EEG have been used in these studies [133]. Most patients demonstrate isoelectricity on the EEG during cardiopulmonary bypass [134]. With deep hypothermic circulatory arrest, waiting to achieve an isoelectric EEG during cooling before initiating circulatory arrest may confer neuroprotection [135]. Significant interpatient variability exists with regard to the degree of hypothermia required to induce electrocerebral silence. Temperatures at which electrocerebral silence on EEG occurs are lower than those when evoked potentials disappear, making EEG a more reliable method of neuromonitoring during cooling [136].

EEG activity resumes upon cerebral reperfusion and rewarming. The temperature at which continuous EEG activity returns predicts postoperative neurological dysfunction, as this appears to be related to intraoperative brain injury. In adult studies, the risk of postoperative confusion or stroke significantly increases with every degree higher at which continuous EEG activity resumes [137].

In addition, perioperative EEG monitoring detects seizures that clinically would be missed due to pharmacological neuromuscular blockade and sedation, including subclinical seizure activity [138]. Seizures may occur secondary to cerebral injury and worsen pre-existing or ongoing neuronal damage. Clancy et al performed EEG monitoring on 183 infants after cardiac surgery and identified that 11% of the patients had EEG-detected seizure activity postoperatively, though there were no clinically apparent seizures. Most recently, postoperative, diffuse EEG slowing has been reported in children during the first 48 h following cardiac surgery. However, EEG slowing was not associated with neurological deficits or MRI changes [139] (Fig. 8.19). Preoperative EEG monitoring has also been used in premature infants to detect seizure and ischemic events.

Despite the demonstrated potential for clinical benefit, the logistical and technical limitations, as well as the need for expert interpreters, limit the use of comprehensive and continuous EEG monitoring in the intensive care unit and operating room.

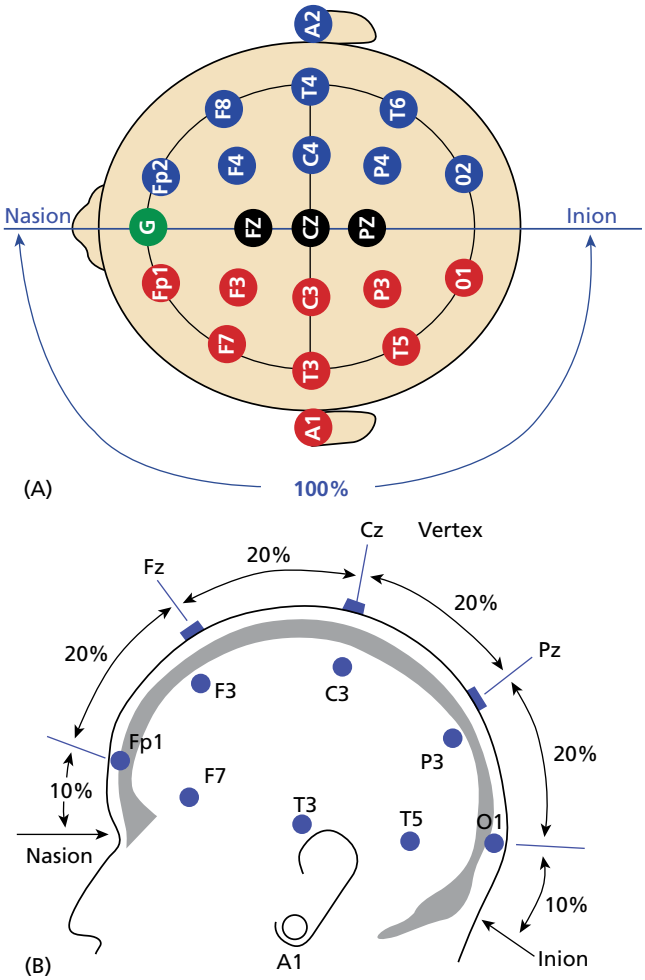

Figure 8.19 The standardized placement of scalp electrodes for a classical EEG recording has become common since the adoption of the 10/20 international system. (A) In the sagittal view, the "10/20" orientation of the electrodes can be related to the relative percentages of distance between the nasion-inion and other fixed points. These points are marked as the frontal pole (Fp), central (C), parietal (P), occipital (O), and temporal (T). The midline electrodes are marked with a z, which stands for zero. (B) In the coronal view, odd numbers are used to indicate positions over the left hemisphere, and even numbers over the right.

Processed EEG monitoring

Maynard and Prior pioneered the use of processed EEG monitoring in clinical anesthesia practice. Multiple studies described the use of comprehensive and processed EEG signals to help in the identification and management of patients at risk for adverse perioperative events. Prior and Maynard divided the clinical applications of such neurophysiological monitoring into three categories: (1) where it had been shown conclusively to reduce the risk of iatrogenic harm to an at-risk patient during elective procedures; (2) where it had provided additional useful information not obtainable by other means; and (3) where it could have been of potential value but its advantages in terms of reduced morbidity or mortality remained unproven [140,141]. Eliminating the need for a technologist/neurologist by using a processed EEG monitor is appealing to many perioperative clinicians. A review by Davidson provided an excellent review of this monitoring principle in children [142]. For the purposes of this text, we will focus on the available techniques/technologies in current clinical practice.

Amplitude-integrated EEG (aEEG) uses the P3–P4 positions and ground Fz to monitor the vulnerable watershed region in neonates. An amplified signal passes through an asymmetrical band-pass filter that strongly attenuates activity below 2 Hz and above 15 Hz in order to minimize artifacts from sources such as sweating, muscle activity, and electrical interference. Additional processing includes semi-logarithmic amplitude compression, rectification, and time compression. aEEG recordings with a cerebral function monitor, such as the "BraiNZ" monitor, obtained continuously from two biparietal electrodes, have also been shown to be useful in the early prediction of the severity of brain injury. Of 35 infants with a moderately abnormal or suppressed tracing and/or seizures, 27 died or survived with neurological abnormalities on follow-up at 18–24 months. Of 21 babies with normal amplitude, 19 were normal on follow-up [143]. Training bedside clinicians to recognize and interpret the background amplitudes of aEEG and to correlate the pattern with the clinical status of the patient poses a challenge [140]. With regard to anesthesia in particular, McKeever et al demonstrated poor prediction probability with aEEG in children younger than 2 years old [144].

Continuous comprehensive EEG can be technically difficult to use and interpret in the operating room. However, limited-channel EEG-based technologies with automated interpretation are easy to use and demonstrate correlation between electrical brainwave activity and depth of anesthesia or awareness in adults. The commercially available Bispectral Index (BIS) (ASPECT technologies, USA) and SEDline monitors (Masimo, USA) use algorithm-based analysis of multiple EEG characteristics and integrate these into a single dimensionless number. Unlike routine EEG, these monitors require placement of a single sensor containing multiple electrodes on the forehead and temple in an easily identified and reproducible location. The BIS utilizes a unilateral sensor array, while the SEDline uses a bilateral sensor. Glass et al demonstrated that BIS recorded using several different electrode arrangements (or montages) provided similar results across arrangements [145]. They used a frontal (Fp1 and Fp2) to CZ electrode montage, as well as an alternative placement (FPz–At) that approximates the BIS sensor electrode positions.

The SEDline uses a bilateral four-channel frontal array (FP1, FP2, F7, F8) to generate the Patient Safety Index or PSI. Although the US Food and Drug Administration (FDA) approved these monitors for assessment of anesthetic depth, authors have reported additional applications (i.e. burst suppression, sedation monitoring) [142,146,147]. The PSI and BIS indices both range from 0 (isoelectric EEG or electrocerebral silence) to 100 (awake), though studies have demonstrated differences in the actual interpretation of these scales in relation to depth of anesthesia. For instance, multiple studies correlate increased BIS values (>80) with awareness and decreased BIS values with increased depth of anesthesia, as well as hypothermia during bypass [148]. Similar studies demonstrate that PSI values from 25 to 50 provide protection from awareness and avoid issues of delayed emergence (seen with PSI <25) [149,150]. Limited studies evaluate the SEDline in children. However, several studies demonstrated good correlation of BIS values, when used to predict depth of anesthesia between the children younger than 2 years of age in these studies and previous adult studies, despite the BIS

algorithm being based on adult subjects [151]. Recent evidence suggests that BIS does have a better prediction probability in older children when compared to infants [152].

Other processed EEG monitors with similar functionality but differing lead array placement and signal analysis are available. The wireless and handheld Cerebral State Monitor (Danmeter A/S, Odense, Denmark) uses a proprietary algorithm and a 0–100 scale, with 40–60 indicating an adequate depth of hypnosis. The Cerebral State Index (CSI) derives from the time and frequency domain analysis that inputs into a fuzzy logic inference system to produce the index. A comparative study of the BIS and the CSI found a predictive probability statistic for depth of anesthesia of 0.87 for both monitors, which demonstrates good performance. The CSI performed better for deeper levels of anesthesia than the BIS, which performed better at lighter levels [152].

The Narcotrend monitor (MonitorTechnik, Bad Bramstedt, Germany) also processes raw EEG signals and uses either one-channel or two-channel recordings from different electrode positions. Early models graded the depth of hypnosis into six stages from A (awake) to F (very deep level of anesthesia). The latest Narcotrend software (version 4.0) calculates the Narcotrend Index, another dimensionless 0–100 scale similar to those calculated by the monitors described previously. The Narcotrend Index performed slightly better for depth of sedation when compared to the BIS (predictive probability statistic 0.88 versus 0.85) [153].

Additional approaches to brain monitoring in the intensive care unit and operating room include response entropy and state entropy [154]. The irregularity of the EEG signal can be quantified, using a publicly available algorithm, to reflect depth of sedation. This Entropy Monitor (GE Healthcare, Fairfield, CT, USA) utilizes the electromyographic (EMG) signal, which may provide information useful for assessing whether a patient is responding to an external stimulus, such as a painful stimulus. The combination of EEG and EMG is presented as the response entropy; the lower-frequency EEG signals alone are presented as the state entropy. The prediction probability values of the entropy indices for differentiating between consciousness and unconsciousness compare well with those for BIS [155]. Noxious stimulation does increase the difference between response entropy and state entropy, but an increase in the difference does not always indicate inadequate analgesia [156]. Additionally, Sciusco and colleagues recently demonstrated that for both response and state entropy, prediction probabilities increase with age, with indicators performing worse in infants and better in older children [152].

Evoked potential monitoring

A variety of evoked potential (EP) monitoring methods assess the integrity of both ascending and descending neural pathways. The stimulation of the CNS using a specific stimulus of the visual, auditory, sensory, or motor system produces an electrical response termed the EP. Perioperative evoked potential assessment tools and their application are summarized in Table 8.3.

Germaine to this chapter, the complex and sometimes dynamic interaction between patient-related factors and clinical management necessitates an understanding of the basic neurophysiology of these tests. As with the EEG, state of arousal, presence of various anesthetic agents, metabolic derangements, and temperature can dramatically impact these monitoring modalities. For ascending (dorsal/posterior) pathway monitoring, supracortical monitors detect changes in cortical electrical activity initiated by a peripherally applied stimulus. This allows for assessment of amplitude, latency, and decay. The experience of the team and the availability of resources necessary to perform continuous evoked potential monitoring limit its consistent utilization. Certainly, in spinal surgery, somatosensory evoked potentials (SSEPs) have become a widely accepted practice standard.

Table 8.3 Perioperative electrophysiological monitoring [157–167]

Monitor	Procedures	Current practice
EEG	AVM repair/clipping	Used in most centers
	Cardiopulmonary bypass	Used in some centers
	Level of consciousness	Used in some centers
BAEP	Acoustic neuroma	Monitoring recommended
	CN V decompression	Used in some centers
	CN VII decompression	Used in some centers
	Level of consciousness	Used in some centers
SSEP	Spine surgery	Monitoring recommended
	Aortic surgery	Used in some centers
MEP	Spine surgery	Used in most centers
	Aortic surgery	Used in some centers
VEP	ICU care of TBI	Used in some centers
	Optic surgery	Research

AVM, arteriovenous malformation; BAEP, *brainstem auditory evoked potential*; CN, cranial nerve; EEG, electroencephalography; ICU, intensive care unit; MEP, motor evoked potential; SSEP, somatosensory evoked potential; TBI, traumatic brain injury; VEP, visual evoked potential.

The assessment of the descending (anterior) pathways with motor evoked potentials (MEPs) involves the quantification of the peripheral motor response to stimulation of the cerebral cortex. The monitoring of intraoperative MEPs is an important practice in pediatric anesthesiology; however, as with other EP monitoring modalities, operative or anesthetic factors, as well as the neurodevelopmental status of the patient, can alter signals. A retrospective study of children age 2–12 undergoing surgery for idiopathic scoliosis revealed a strong correlation between MEP thresholds and age [161]. Although the exact mechanisms responsible for this finding remain debatable, these findings agree with the earlier observations of Parano and colleagues [168]. They hypothesized that delayed neuronal maturational changes with age led to significantly diminished delayed conduction and decreased EP amplitudes in the youngest children. Specifically, multifactorial issues of ongoing synaptogenesis, incomplete nerve integration, and decreased myelination represent this delayed neuronal maturation. This dynamic difference makes empirical numbers less useful, and often forces clinicians to use each patient as their own baseline. In addition, the impact of various anesthetic agents on these monitoring modalities varies greatly, and changes with both the age of the patient and agents used. Because of these issues, many centers favor intravenous anesthetic techniques to minimize or eliminate the use of inhalational agents [161,162]. MEPs can be monitored in conjunction with SSEPs to provide dual assessment of anterior and posterior spinal cord integrity. See Chapter 29 for further discussion of spinal cord monitoring.

KEY POINTS: ELECTROENCEPHALOGRAM AND EVOKED POTENTIAL MONITORING

- Perioperative EEG monitoring can detect an isoelectric state that may confer neuroprotection during deep hypothermic circulatory arrest, and clinically silent seizures that may be amenable to treatment
- Processed EEG monitoring algorithms are based on mature adult EEG patterns and have limited utility in infants and young children
- Somatosensory and motor evoked potentials have gained increasing use for spinal and aortic surgery and can prevent ischemic insults and permanent neurological damage

Conclusion

For the safe and effective perioperative care of infants and children at risk for neurological injury, pediatric anesthesiologists must command a working knowledge of the unique neurodevelopmental events and neurophysiological principles relevant to the pediatric patient. Our specialty continues to add to the growing body of knowledge that will reduce the toxicity of critical illness to the developing human brain. We can expect further refinement of anesthetic practices designed to protect normal neurodevelopmental processes. Neuromonitoring modalities will continue to adapt and provide an increasingly complex, real-time data set to the anesthesiologist caring for critically ill children. When combining this information with neurodevelopmental principles, the physics of the intracranial compartment, and neurovascular physiology, we improve the clinical decision making to yield improved outcomes for our patients.

The liver

The embryological development of the liver, its subsequent transition at birth, and maturation in infancy constitute a hugely complicated subject. Hypoglycemia, jaundice, and impaired drug metabolism are common in the first weeks of life. Knowledge of the principles of hepatic development allows the anesthesiologist to understand the susceptibility of the liver to disease in infancy.

Embryology of the liver

The liver and gastrointestinal tracts arise from modifications of the primitive gut (see section "Basic gastrointestinal tract embryology") [1,2]. The liver develops from a thickening of the endoderm on the ventral surface of the foregut. These endodermal cells proliferate to form the hepatic diverticulum, which gives rise to cords of hepatoblasts within the mesenchyme of the transverse septum. The hepatoblasts are undifferentiated cells which can become hepatocytes, bile canaliculi, or hepatic ducts under the influence of Notch signaling; abnormalities of this process are associated with Alagille syndrome, described towards the end of this section. The hepatocytes divide rapidly and arrange themselves around vitelline veins to form hepatic sinusoids.

The transverse septum is an important area and develops at a junctional site in the embryo – internally between foregut and midgut, and externally where the endoderm of the yolk sac meets the ectoderm of the amnion. The mesenchyme of the transverse septum also gives rise to the stromal cells which provide the serous and fibrous tissues of the liver, such as the liver capsule and the falciform ligament. The various connective tissues and smooth muscle of the biliary tracts also form from this mesenchymal tissue.

The gallbladder and cystic duct originate from a thickened portion of the ventral duodenum just below the hepatic diverticulum at around 4 weeks; this is known as the cystic diverticulum. As the connection between the hepatic diverticulum and foregut (duodenum) narrows, the hepatic ducts form. The cystic duct and hepatic ducts form the common bile duct which enters the duodenum, initially anteriorly, later from the left (see section "Basic gastrointestinal tract embryology"). The growth of the liver and biliary tracts is rapid and by the 9th week the liver accounts for about 10% of the weight of the fetus (Fig. 9.1).

Fetal hematopoiesis

Hematopoietic stem cells capable of producing erythrocytes, megakaryocytes, and macrophages migrate from the yolk sac to the liver, where hematopoiesis begins [3]. There is a second influx of hematopoietic stem cells originating from mesoderm surrounding the dorsal aorta. These cells are later programmed to migrate to the bone marrow and other lymphatic tissue. The immature fetal erythrocytes are bigger than mature red cells and, like white cells and platelets, they increase in number throughout gestation.

Gregory's Pediatric Anesthesia, Sixth Edition. Edited by Dean B. Andropoulos and George A. Gregory.

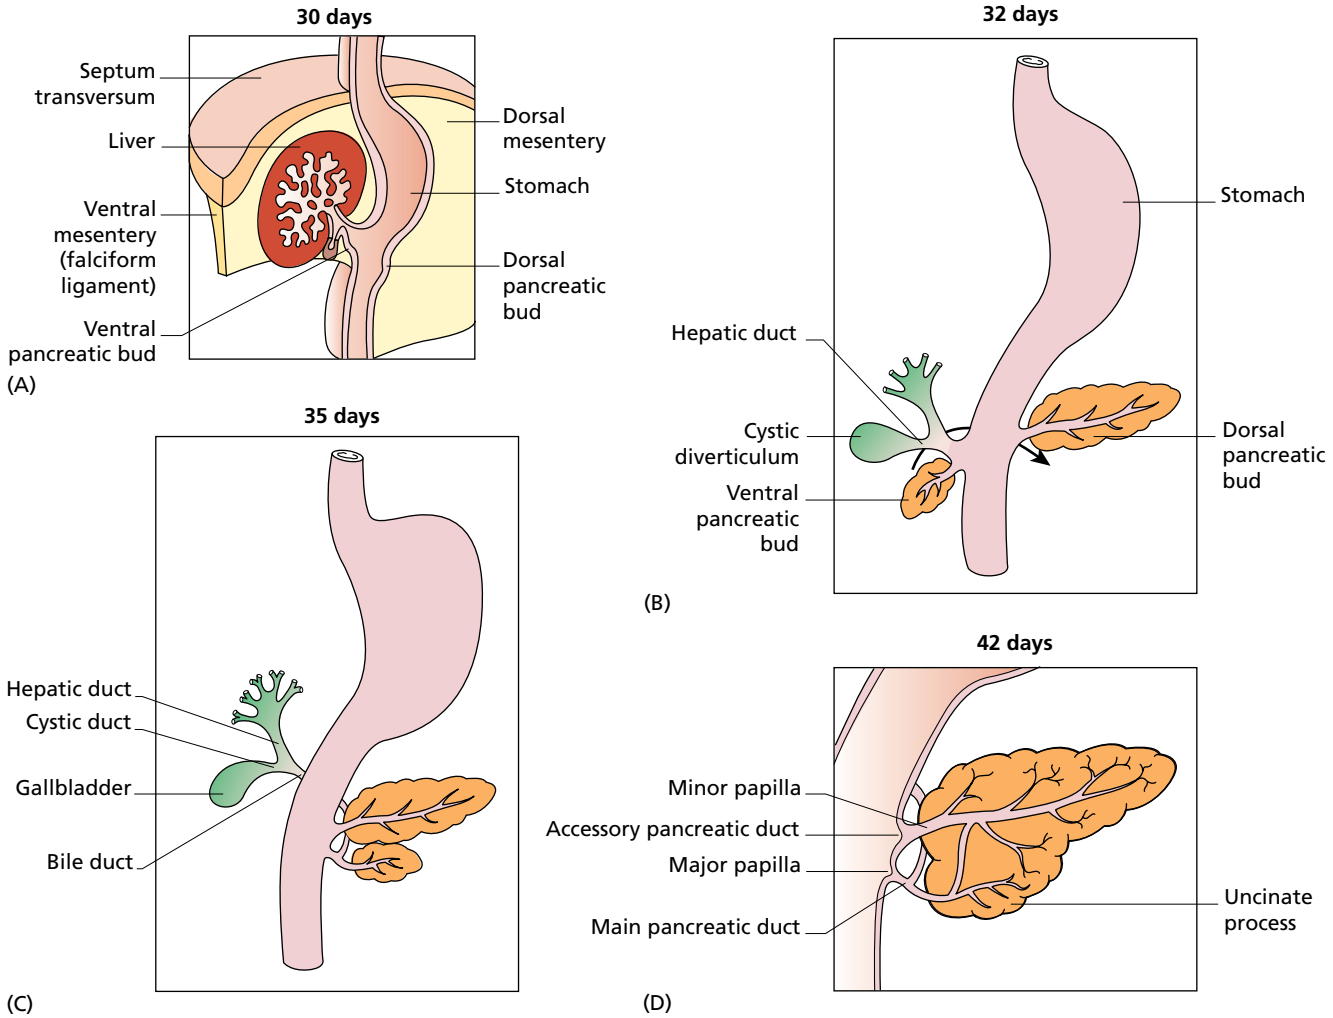

Figure 9.1 Development of the liver, gallbladder, and pancreas and their duct systems from endodermal diverticula of the duodenum. (A) The liver bud sprouts during the 4th week and expands in the ventral (anterior) mesentery. (B) The cystic diverticulum and ventral pancreatic bud also grow into the ventral mesentery, whereas the dorsal pancreatic bud grows into the dorsal mesentery. (C) During the 5th week, the ventral pancreatic bud migrates around the posterior side (former right side) of the duodenum to fuse with the dorsal bud. (D) The main duct of the ventral bud ultimately becomes the major pancreatic duct, which drains the entire pancreas. *Source:* Reproduced from Schoenwolf et al [1] with permission of Elsevier.

Development of the circulation in the fetal liver

The circulation in the fetal liver is complex, and the reader is advised to refer to Chapter 5.

The arterial supply to the liver, like the rest of the foregut, originates from the vitelline arteries arising from the yolk sac [4]. A plexus of arteries between the vitelline vessels and the dorsal aorta coalesces to form three distinct arteries, supplying the whole of the gut from the aorta as the yolk sac shrinks. The celiac artery supplies the foregut, the superior mesenteric artery supplies the midgut, and the inferior mesenteric artery supplies the hindgut. The arterial supply to the liver and gallbladder is the common hepatic artery, which originates from the celiac artery.

Venous blood is received into the two horns of the sinus venosus from three bilaterally symmetrical venous systems: the vitelline veins return blood from the developing gut, the umbilical veins return oxygenated blood from the placenta, and the cardinal veins return blood from the embryo.

The vitelline veins originate as a network of vessels in the yolk sac, which in time form the venous drainage of the primitive gut. A plexus of vessels arises between the paired vitelline veins in the septum transversum, and as the hepatic diverticulum expands in the transverse septum, hepatic cords arrange themselves around this venous plexus to form primitive hepatic sinusoids. Caudal to the liver, the vitelline veins form numerous anastomoses; the left vitelline vein receives blood from the splenic and superior mesenteric veins, and the distal right vitelline vein regresses. The anastomosis between the left and right vitelline veins becomes the distal part of the portal vein. The proximal part of the portal vein is formed from the proximal right vitelline vein. The proximal left vitelline vein disappears at the time when the left sinus horn regresses to form the coronary sinus, and a series of transverse anastomoses carry blood to the right vitelline vein. Cephalad to the liver, an enlarged right vitelline vein returns all of the blood to the heart, and in time will become the inferior vena cava.

The two umbilical veins receive blood from the chorionic villi of the placenta and thus deliver oxygenated blood, rich in nutrients, to the developing fetus. In the second month of development the right umbilical vein regresses; possibly

abnormalities in this process can cause abdominal wall defects (see Chapter 31 for clinical management of abdominal wall defects). The remaining left umbilical vein carries oxygenated blood to the fetus, entering the ductus venosus and then, via the inferior vena cava, the right atrium. Early in the neonatal period, the umbilical vein atrophies because blood is no longer flowing through it, forming the ligamentum teres. The atrophic ductus venosus forms the ligamentum venosum. In the presence of portal hypertension these ligamentous remnants can recanalize.

KEY POINTS: EMBRYOLOGY OF THE LIVER

- Major development of the liver and adjacent structures occurs at 30–42 days' gestation
- The fetal liver is incompletely developed
- The liver is a major source of hemoglobin production *in utero*
- Abnormalities of development are causes of later hepatic malfunction

Functional development

The liver constitutes 10% of the weight of the fetus at 9 weeks' gestation, decreasing to 4% of the neonate and around 2% of adult bodyweight. The fetal hepatocytes are smaller than the mature cells, lack many enzyme systems, and are deficient in glycogen.

Carbohydrate metabolism

Neonatal hypoglycemia is a common problem and highlights the crucial role that the liver plays in glucose metabolism. The fetus receives all its glucose from the mother, via the placenta; following birth, the newborn rapidly acquires the ability to maintain independent glucose homeostasis [5]. By the 9th week of gestation the fetal hepatocytes are able to synthesize glycogen. At term, stores of glycogen are high (40–60 mg/g of liver), providing some reserve for the neonate until milk production and digestion start. A healthy term baby can withstand a fast of 12 h by the liver generating and releasing glucose by glycogenolysis [6]. Glycogenolysis is catalyzed by glycogen phosphorylase, the activity of which is promoted by glucagon and epinephrine. Following delivery, there is a rise in glucagon and a fall in insulin levels. Premature neonates lack the ability to effectively store and break down glycogen and so are at greater risk of hypoglycemia.

Following birth and before the establishment of effective feeding, glucose is in short supply and ketogenesis has yet to commence. The neonate depends on gluconeogenesis from lactate and pyruvate, which is thought to be stimulated by the high circulating levels of glucagon and catecholamines following delivery.

Gluconeogenesis is insignificant in the fetal liver [7], probably due to high insulin levels and low levels of the rate-limiting enzyme phosphoenolpyruvate carboxykinase, the activity of which rises rapidly following birth. Similarly, levels of hepatic galactokinase, the enzyme responsible for phosphorylation of galactose, increase near term. This allows the newborn to metabolize galactose in its diet. Interestingly, the utilization of glucose by the fetal liver is low, using amino acids and lactate for energy instead. Following birth, there is little glucose utilization by the liver of the neonate; instead, galactose is preferred for carbohydrate synthesis, and glucose is utilized preferentially by peripheral tissues. Glucose-6-phosphatase activity, needed to convert glucose-6-phosphate into glucose, is low in the fetal liver. Thus glucose production is low, promoting the storage of glycogen to the required high level. Levels of this enzyme also increase near term.

The transition of glucose metabolism from the fetus to the newborn is highly complex and the controls of the enzyme systems responsible for glucose metabolism are still a matter of research. Delivery and suckling also have a role in the initiation of glucocorticoid pathways and the decrease in insulin levels.

Amino acid metabolism

The majority of protein catabolism occurs in the liver, producing amino acids which may be used for protein synthesis. Amino acids may also be deaminated by aminotransferases and used to produce glucose, ketones, or fatty acids. Ammonia is produced as a product of deamination and is converted into urea.

Animal studies suggest that amino acids provide about 40% of the energy requirements of the fetus, with even essential amino acids utilized as fuel. *In utero*, the fetal liver has a high uptake of amino acids, which declines following delivery. The urea cycle enzymes are well established in the second trimester, and the fetal liver accounts for the majority of ammonia clearance. Accumulation of ammonia is toxic and contributes to the raised intracranial pressure and encephalopathy seen in acute liver failure.

Nearly all amino acids cross the placenta from mother to fetus by active transport, the exceptions being glutamate, serine, and aspartate, which are produced by the fetal liver. The enzyme systems necessary for the regulation of amino acids are expressed at birth, but the appearance of p-hydroxyphenyl pyruvate oxidase may be delayed. This enzyme is responsible for the breakdown of tyrosine, and may account for a transient tyrosinemia following delivery.

Lipid metabolism

The oxidation of fatty acids provides a major source of energy for the developing fetus [8]. Fatty acids may be synthesized by the fetus; non-esterified fatty acids may diffuse from the placenta or, in the case of some long chain fatty acids, undergo active transport across the placenta to the fetus. Free fatty acids are stored in the liver and adipose tissue, but are not used by peripheral tissues.

Animal models suggest relatively low levels of acetyl coenzyme A carboxylase (responsible for fatty acid synthesis) in the fetal liver, as compared to adults. Ketones and glucose from the mother may act as precursors for fatty acid synthesis in the fetus.

Following birth, the accumulated fat in the fetal liver is mobilized for oxidation to produce energy as adenosine triphosphate (ATP), and for ketone body formation, which may be used peripherally in tissues. This ability to oxidize fatty acids matures rapidly in the first few days of life, in response to falling insulin and rising glucagon levels. The liver is the most

important source of ketone bodies (acetoacetate, 3-hydroxybutyrate, and acetone). Fat stores are particularly important for preterm infants, due to immature glucose metabolism.

Following birth, the newborn suckles and takes milk, which is relatively high in fat but low in carbohydrate compared to solid foods (see section "Breast milk, the suckling period, and bacterial colonization"). Long and medium chain fatty acids in the diet stimulate gluconeogenesis by increasing the supply of gluconeogenic substrate for the liver. Weaning increases the amount of carbohydrate in the infant's diet, and the ability of the liver to produce fat is again increased.

Drug metabolism

The liver's central role in the metabolism of substances absorbed by the gut means that it has many of the enzyme systems necessary to alter alien substances (xenobiotics), such as drugs. Liver immaturity may alter the ability to clear drugs, as well as rendering it susceptible to damage from them and their breakdown products. Infant drug metabolism is complex as it depends on liver mass (usually relatively greater than in adults), protein binding, and blood flow, as well as enzymatic metabolism and clearance processes.

The metabolism of most drugs involves chemical processes to modify their structure, followed by conjugation to make them more polar (water soluble), so allowing excretion. These are termed phase 1 and phase 2 reactions. Phase 1 reactions are the result of electron transfers carried out by the cytochrome P450 enzymes – nicotinamide adenine dinucleotide phosphate (NADPH) and NADPH-cytochrome c reductase. They cause oxidation by electron removal or sometimes reduction by electron addition. Phase 1 reactions also include hydrolysis of esters and amides, sulfation, dehalogenation, N-dealkylation, and O-demethylation.

Cytochrome P450 (CYP) is a group of iron-containing membrane-bound enzymes found in endoplasmic reticulum and mitochondria. There are at least 57 human CYP genes producing enzymes which are classified according to the degree of amino acid homogeneity shown [9]. There are at least 18 families of CYP enzymes; they are named "CYP" plus the family number, followed by a letter, then a final number.

Phase 2 reactions involve conjugation with a substrate to form a more polar and water-soluble conjugate, for example a glucuronide, sulfate, or acetylated derivative. Glucuronidation involves the addition of an activated form of glucose (uridine diphosphate glucuronic acid, UDPGA) by the enzyme glucuronyl transferase. The glucuronide compounds so formed are readily excreted in urine or, in the case of larger compounds, in bile. Bilirubin is excreted in this way; however, glucuronyl transferase activity is low in the newborn, so a significant amount of hemolysis will overload the conjugating capacity of the enzyme and result in an unconjugated hyperbilirubinemia. Phenobarbital may be used to induce the enzyme.

The expression of CYP enzymes is an important factor in the development of drug metabolism in the fetus and newborn. CYP enzymes are active in the human liver early in intrauterine development; indeed, many systems are available for xenobiotic metabolism before 8 weeks' development. There is a gradual increase in activity throughout fetal development, and a major increase following birth.

To analyze the development of all the CYP enzymes is beyond the scope of this chapter, so we will attempt to highlight some examples of the CYP enzyme groups. The CYP 3A family serves as a good example of development; it is the most abundant of the CYP enzymes and is involved in the metabolism of many common drugs [10]. CYP 3A7 is the most abundant CYP enzyme in the fetus, is present during organogenesis, and plays a role in steroid metabolism. Expression of this enzyme ceases at delivery. Conversely, CYP 3A4 is the most abundant member of the CYP 3A family following birth and is involved in 50% of CYP-dependent drug metabolism; its expression is low in the fetus but increases to 50% of adult levels by 1 year of life; there are more than 20 human CYP 3A4 alleles and hence a lot of variability in drug handling [11]. CYP 2E1 is involved in the metabolism of alcohol and is responsible for the conversion of acetaminophen to the hepatotoxic metabolite N-acetyl-P-benzoquinone-imine. CYP 2E1 expression is low in the fetus, increasing to around 40% of adult levels at 1 year of age, and is not fully expressed until 10 years.

The development of the phase 2 enzymes is less well understood; however, there are significant differences in gene expression between infancy and adulthood, as well as genetic polymorphism. The uridine glucuronyl transferase enzymes catalyze the glucuronidation of bilirubin, as well as agents such as morphine and acetaminophen. In the midterm fetus the glucuronidation of morphine is only 10–20% of adult levels. Following birth, morphine glucuronidation reaches mature levels at around 2–6 months, but this may be delayed until 2 years of age. Similar polymorphism has been identified for other glucuronyl transferase enzymes. Abnormalities of uridine glucuronyl transferase 1A (UGT1A) are responsible for Crigler–Najjar syndrome and Gilbert syndrome, which are described later in this chapter.

KEY POINTS: FUNCTIONAL DEVELOPMENT

- The liver is necessary for optimal nutrition during development
- Metabolism of carbohydrates, lipids, and proteins is often different than in older children
- Enzymes for drug metabolism are reduced *in utero* and tend to reach adult levels during the first year of neonatal life

Development of bile formation and secretion

The liver is responsible for the excretion of bilirubin, bile acids, and xenobiotics with bile into the small intestine, for ultimate elimination in the feces. It plays an important role in nutrition, as excretion of bile acids into the intestinal lumen is involved in the absorption of long chain fatty acids and fat-soluble vitamins as well as a number of drugs and hormones. This is of particular importance in the nutrition and thus growth of infants with cholestasis.

The immaturity of bile synthesis and secretion is clinically apparent in the susceptibility of the sick neonate to develop cholestasis in response to sepsis or administration of parenteral

nutrition (PN), as well as the phenomena of physiological jaundice and breast-milk jaundice in the healthy baby.

Bile secretion starts at 4 months' gestation and thereafter the biliary system always contains bile, which is secreted into the gut and gives meconium its distinctive color [12]. During fetal life, the placenta carries out bile acid metabolism and detoxification. Throughout the third trimester, the predominant bile acids present in the gallbladder change from taurine-conjugated dihydroxy bile acids (mainly tauro-chenodoxycholic acid) to taurocholic acid and glycocholic acid. The transition to glycine conjugate bile acids, as seen in adults, occurs approximately 2–7 months postnatally. Secondary bile acids are formed via cleavage by colonic bacteria, and hence are not formed in the fetus. Placental transporters of bile acids facilitate bile acid transfer between the maternal and fetal circulations. The fetal enterohepatic circulation is poorly developed due to poor bile acid reabsorption in the small intestine. This, combined with the clearance of bile acids into the maternal circulation, means that the fetus and neonate have a small bile pool. Due to the reliance on the placenta and maternal liver function, bile salt elimination from the fetus can be disturbed in the event of maternal hepatic dysfunction [13].

Bile secretion increases throughout infancy. The ability of the gallbladder to empty in response to a test feed occurs soon after birth, but is reduced in preterm neonates of 27–32 weeks' gestation.

Bile flow is driven by the secretion and enterohepatic circulation of bile acids. Bile acids absorbed from the small intestine are taken up from portal blood by bile acid importer proteins. Over 75% of conjugated bile salts are transported into the hepatocyte by Na-dependent secondary active transport, via the Na-taurocholate co-transporting polypeptide (NTCP). In contrast, unconjugated bile acids are transported by a non-Na-dependent mechanism, the organic anion transporting polypeptide family (OATP). The unconjugated bile acids then undergo N-acyl amidation within the hepatocyte. Following this, the bile acids are rapidly transported across the hepatocyte cytoplasm and secreted into the bile canaliculi. The ATP-dependent bile salt export pump (BSEP) is the transporter responsible for the secretion of the major bile acids. It performs this function against a steep concentration gradient [14].

Mutation of the gene responsible for BSEP is responsible for progressive familial intrahepatic cholestasis 2 (PFIC2); this and related conditions are described in the section concerned with metabolic causes of conjugated hyperbilirubinemia.

Conjugated bilirubin is secreted into bile by means of a separate transporter protein, MRP2, mutation of which leads to Dubin–Johnson syndrome. This autosomal recessive condition results in a mild conjugated hyperbilirubinemia with normal liver function tests. Dubin–Johnson syndrome is asymptomatic, and affected individuals have a normal lifespan (Fig. 9.2).

Cholestasis

Cholestasis is classically regarded as due to an anatomical blockage or obstruction of part of the biliary tree. However, the various constituents of bile are secreted by different transporter proteins and thus deficiencies, or abnormalities, of these may cause cholestasis. The hepatocyte is the main cell responsible for the manufacture and secretion of bile acids and bile; thus the liver is the organ most likely to be damaged by bile acid retention when bile flow is reduced. The intracellular accumulation of bile acids appears to be the most significant pathological consequence of cholestasis.

Obstruction of the biliary tree, as in biliary atresia, or impaired secretion by the hepatocyte (e.g. PFIC2) can lead to a high concentration of bile acids in the hepatocyte cytoplasm. Bile acids exert their deleterious effects by a number of mechanisms; they may act as detergents which alter membrane

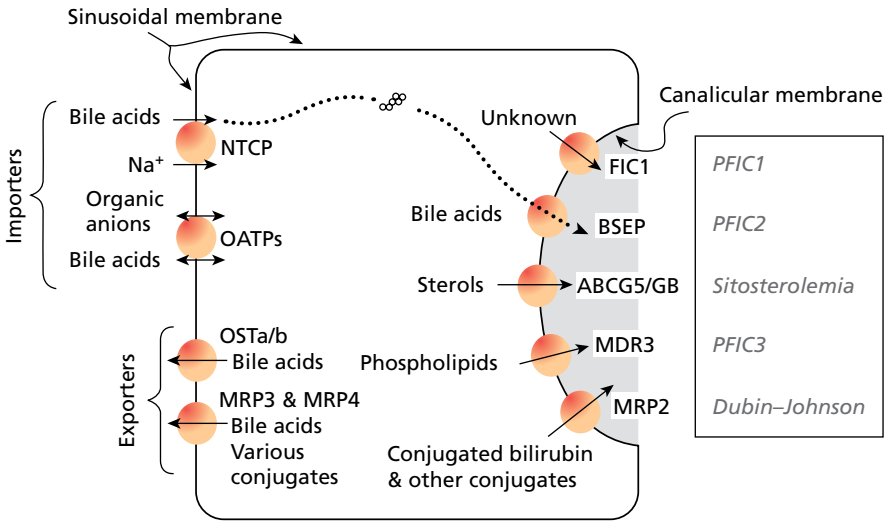

Figure 9.2 Roles for critical hepatic transporters in the formation of bile and adaptation to cholestasis. On the left is a representation of the sinusoidal surface, and on the right a canalicular surface. Diseases associated with defects in specific canalicular transporter genes are noted in italics. Note that bile acids have several means of transport across the sinusoidal membrane, both import and export, whereas there is one canalicular bile acid transporter, BSEP. These transporters allow for fine-tuning of intracellular bile acid concentrations as a way of adapting to a variety of cholestatic conditions. The principal means for bile acid flux across the hepatocyte is shown by the dotted line. NTCP, Na^+/taurocholate co-transporting polypeptide; OATP, organic acid transporting polypeptide; OST, organic solute transporter; MRP, multidrug resistance-related protein; FIC1, familial intrahepatic cholestasis 1; BSEP, bile salt export pump; MDR, multidrug resistance protein; PFIC, progressive familial intrahepatic cholestasis. Official gene designations: *FIC1 (ATP8B1)*, *BSEP (ABCB11)*, *MDR3 (ABCB4)*, *and MRP2 (ABCC2)*. *Source:* Reproduced from Karpen [15] with permission of Cambridge University Press.

structure and function, or may alter cellular signaling pathways and gene expression. CYP 450 pathways are activated to detoxify the liver; Kupffer cells, stellate cells, and myofibroblasts are also activated, potentially leading to fibrosis [15].

Neonatal jaundice

The following section deals with jaundice in infancy; it is not intended to be an exhaustive list of differential diagnoses but rather an illustration of the pathophysiological mechanisms described previously. Some of the conditions are rare, and a few only become manifest later in childhood; however, the jaundiced baby is a problem commonly encountered by the pediatric anesthesiologist. Neonatal jaundice has a variety of causes which may require investigation, and of crucial importance is the diagnosis of treatable conditions, such as biliary atresia. The causes of neonatal jaundice described here are divided into unconjugated and conjugated hyperbilirubinemia.

Unconjugated hyperbilirubinemia

The excretion of bilirubin, a breakdown product of heme, is one of the principal roles of the liver. Bilirubin is a toxic molecule, and diffusion of its free form into neural tissue, particularly the basal ganglia, can cause kernicterus in the premature neonate. As bilirubin is bound tightly to albumin, the usually low free levels may be increased by hypoalbuminemia or by drugs that displace bilirubin from its binding sites, e.g. sulfonamides and furosemide.

Physiological jaundice

Transient neonatal jaundice occurs in around 50% of babies in the first week of life [16,17]. It is due to immaturity of glucuronyltransferase, leading to an unconjugated hyperbilirubinemia. Occasionally the jaundice may be significant, with a serum bilirubin over 12 mg/dL, which may be associated with prematurity, bruising, and breast feeding. Physiological jaundice peaks at day 3 of life and declines thereafter, but the hyperbilirubinemia may persist for as long as 14 days. Treatment is usually unnecessary as the jaundice is self-limiting; however, if it is slow to clear, phototherapy can be used and is an effective treatment.

Breast milk jaundice

Unconjugated hyperbilirubinemia associated with breast feeding is common. Jaundice tends to occur after day 4 of life, may overlap with physiological jaundice, and can sometimes be protracted. The etiology is still to be elucidated but hypotheses include enhanced enterohepatic recirculation of bilirubin due to free fatty acids in breast milk, and the action of β-glucuronidase causing deconjugation of bilirubin. The diagnosis is clinical and no treatment is usually required other than reassurance and exclusion of more sinister causes of liver disease.

Crigler–Najjar syndrome

Crigler–Najjar syndrome is an autosomal recessive condition resulting from deficiency of the enzyme bilirubin uridine diphosphate glucuronyltransferase (UDPGT). The syndrome is divided into two types: type 1 has no UDPGT present, and in type 2 levels of the enzyme are reduced. Consequently, type 1 is the more severe condition and presents in the newborn with rising unconjugated bilirubin levels, with the risk of kernicterus.

Management of type 1 Crigler–Najjar syndrome often involves phototherapy. Acute exacerbations may be precipitated by sepsis and require plasmapheresis or exchange transfusion. Liver transplantation is a long-term option to avoid neurological deterioration. Type 2 Crigler–Najjar syndrome follows a more benign course.

Gilbert syndrome

Gilbert syndrome is a condition leading to mild unconjugated hyperbilirubinemia and results from a defect of the UDPGT gene. The affected individual, usually male, has mild jaundice worsened by intercurrent illness. Presentation is typically in teenage years, but heterozygotes for the genetic defect may present in the neonatal period. Treatment is unnecessary.

Conjugated hyperbilirubinemia

The identification of conjugated hyperbilirubinemia essentially allows the clinician to distinguish jaundice that is due to liver disease from the more common but generally more benign causes, which present with unconjugated hyperbilirubinemia.

The liver synthesizes all of the clotting factors except for the von Willebrand fraction of factor VIII, which is derived from vascular endothelium. Factors II, VII, IX, and X require vitamin K for their synthesis, so their levels are liable to fall if there is any biliary obstruction, because the fat-soluble vitamin K is poorly absorbed from the gut unless dietary fat is emulsified by bile salts. Vitamin K deficiency bleeding occurs in 1:10,000 babies. It classically occurs on the first day or in the first week of life, but in around half of cases it may occur after the first week, and is usually associated with breast feeding or liver disease. The risk of intracranial hemorrhage is high in this group. Vitamin K supplementation at birth is routine in Europe and North America.

Acquired cholestasis

Cholestasis associated with sepsis

Sepsis originating outside the liver is the most common cause of cholestasis in infants. It appears to be primarily an impairment of hepatocyte function causing reduced bile flow and intrahepatic cholestasis. This may explain the particular susceptibility of the immature liver to various insults. In animal models the administration of endotoxin lipopolysaccharide invariably leads to a sustained reduction in bile flow at the canalicular level. The mechanism responsible is a combination of inhibition of bile transporter activity and downregulation of bile salt transporter gene expression. Within an hour of endotoxin exposure, both BSEP and MRP2 proteins are reduced significantly. Cytokines also contribute via inhibiting cyclic adenosine monophosphate (cAMP)-dependent functions of transporters. There are also endotoxin receptors on the membranes of hepatocytes, and there is alteration in hepatocellular cytoskeletal structure, implying a direct action of endotoxin.

Hemolysis during sepsis can also contribute to jaundice. Excess bilirubin from red cell breakdown can exceed the capacity of the sepsis-challenged liver [18,19].

The liver also plays a central role in the acute-phase response to infection and injury. This is mediated by endotoxin, and results in expression of genes coding for a host of proteins and enzymes necessary to fight infection and repair tissue.

Cholestasis secondary to parenteral nutrition

Cholestasis associated with PN administration is particularly common in the neonatal population. The clinical scenario is familiar to the pediatric anesthesiologist – a premature neonate, who has undergone extensive bowel resection, is in trouble with sepsis and requires PN administration.

The mechanisms of PN cholestasis are multifactorial and complex; prematurity, infection, short gut, and toxic or missing components in the PN regimen all probably play a role. The inherently immature ability of the neonatal liver to produce bile and handle drugs suggests that neonatal livers are particularly susceptible to cholestatic insults. It is interesting that PN-associated cholestasis is rare in older children and adults. Recurrent central venous catheter infections will often provoke acute rises in serum conjugated bilirubin. A lack of oral intake interrupts the enterohepatic circulation of bile acids and may contribute to cholestasis, possibly secondary to abnormal gut hormone secretion. Bacterial overgrowth in the small intestine may lead to bacterial translocation and endotoxin production; metronidazole may sometimes be helpful. The absence or presence of certain constituents within PN remains an attractive explanation; excessive amounts of lipid (>1 g/kg/day) may overwhelm the liver's ability to handle it, and high levels of glucose infusion may cause increased insulin secretion which enhances the rate of fatty acid synthesis and impairs breakdown, and hence the accumulation of fatty acid within hepatocytes. It is therefore important not to overfeed with PN; introducing fasting breaks by avoiding continuous infusion is probably beneficial, if it can be tolerated.

The striking feature of PN-associated cholestasis is the association with prematurity, intestinal failure, and sepsis [20]. This provides the clinician with a therapeutic rationale to support the infant nutritionally, allowing growth and development while avoiding the progression of cholestasis to liver cirrhosis. Attention to strict aseptic technique is crucial to avoid central venous catheter infections. Innovative intestinal surgical techniques may lessen the chance of bacterial translocation and reduce the risk of sepsis. If possible, an increase in enteral feeding is encouraged, to reduce the volume of PN administered, stimulate gut hormone secretion, and support the enterohepatic circulation. The duration of PN administration should be limited as far as possible. The PN formulation should contain sufficient trace elements, amino acids, and essential fatty acids, although copper and manganese have been implicated as potential causative agents of cholestasis.

Structural abnormalities

Biliary atresia

Biliary atresia accounts for about a third of cases of neonatal cholestasis. It is an important condition, as delay in diagnosis and treatment can result in irreversible liver damage. It remains the most common indication for liver transplantation in children [21].

Biliary atresia is characterized by a progressive inflammation and destruction of the extrahepatic bile ducts, as well as damage to intrahepatic bile ducts; if left untreated, hepatic fibrosis and biliary cirrhosis develop. The most accepted classification system is based on the anatomical location of the damage (Fig. 9.3).

The condition has an incidence of around 1:10,000–15,000 in the United Kingdom and the United States. The etiology of biliary atresia remains obscure but the association with other anomalies makes an embryological hypothesis attractive (syndromic biliary atresia). Approximately 10% of infants with biliary atresia have associated anomalies including polysplenia, abnormal portal vein, interrupted inferior vena cava, and cardiac defects.

Infants with biliary atresia are typically healthy term babies who initially appear normal but soon develop persistent jaundice and pale stools. Lethargy, pruritus, and poor weight gain soon become apparent. Hepatomegaly is often noted and, as the condition progresses, signs of portal hypertension such as splenomegaly and ascites appear.

On confirmation of the diagnosis, the surgical treatment is the Kasai portoenterostomy, which involves excision of the atretic portion of the biliary tree, formation of a Roux-en-Y loop of jejunum and its anastomosis to the transected tissue at the porta hepatis, to allow bile drainage. As biliary atresia is a progressive inflammatory condition, many children proceed to liver cirrhosis despite achieving apparently adequate bile drainage. The success rate is much lower in those older than 8 weeks or with advanced hepatic fibrosis or established cirrhosis at the time of the operation. The Kasai procedure achieves some biliary drainage in 70% of infants, which may be adequate to ensure survival to 5 years in around 60% of cases; however, in around 30% of infants, hepatic dysfunction occurs later despite successful surgery [22,23], and by the age of 20 years nearly half of untransplanted cases have cirrhosis [24].

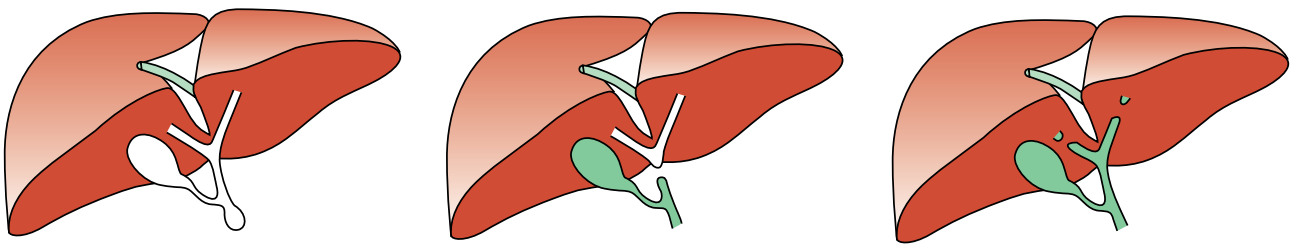

Figure 9.3 Classification of biliary atresia. Type 1: atresia affecting the common bile duct, often associated with proximal biliary cyst. Type 2: atresia affecting the common hepatic duct. Type 3: obliteration and atresia affecting the whole of the extrahepatic biliary tree. *Source:* Reproduced from Millar [21] with permission of John Wiley and Sons.

See Chapter 31 for additional discussion of the Kasai procedure. Liver transplantation offers excellent results for those who do not do well after Kasai portoenterostomy. See Chapter 30 for a discussion of the anesthetic management of liver transplantation.

Choledochal cyst

Choledochal cysts are congenital localized swellings of the bile ducts with an incidence of 1:100,000; they are more common in girls (female:male ratio 5:1). Interestingly, the condition is more prevalent in Japan. The position of the cysts is variable, leading to a number of classification systems; the cysts are most frequently found on the common bile duct, but may occur anywhere along the biliary tree (Fig. 9.4). The etiology of the cysts remains obscure.

Presentation may occur at any age and antenatal diagnosis on antenatal scanning sometimes occurs. Symptoms are classically pain and jaundice with a palpable abdominal mass. Diagnosis is confirmed by ultrasound scanning or magnetic resonance cholangiopancreatography. Secondary stone formation, cholangitis, pancreatitis, and spontaneous rupture may occur; the cysts also have a potential for malignant change in the long term. Portal hypertension may occur due to portal vein compression or as a result of cirrhosis. Treatment is by surgical excision of the cyst with biliary drainage via a Roux-en-Y anastomosis. The prognosis is generally very good and reversal of portal hypertension has been reported.

Alagille syndrome

Alagille syndrome is a rare autosomal dominant disorder affecting 1:100,000 deliveries and is characterized by the paucity of interlobular bile ducts. It is caused by a mutation of the *Jagged1* gene [25], which encodes for proteins involved in the Notch signaling pathway. The syndrome is characterized by triangular facies, butterfly hemivertebrae, and peripheral pulmonary stenosis often leading to pulmonary hypertension. The cardiac abnormalities are variable and may include hypoplastic pulmonary arteries, pulmonary valve stenosis, and ventricular septal defect. The affected infants are often developmentally delayed and short in stature. The severity of the liver disease is variable, with many children having mild disease, but pruritus is often severe.

Treatment is supportive with management of pruritus, nutritional support, and in some cases corrective cardiac

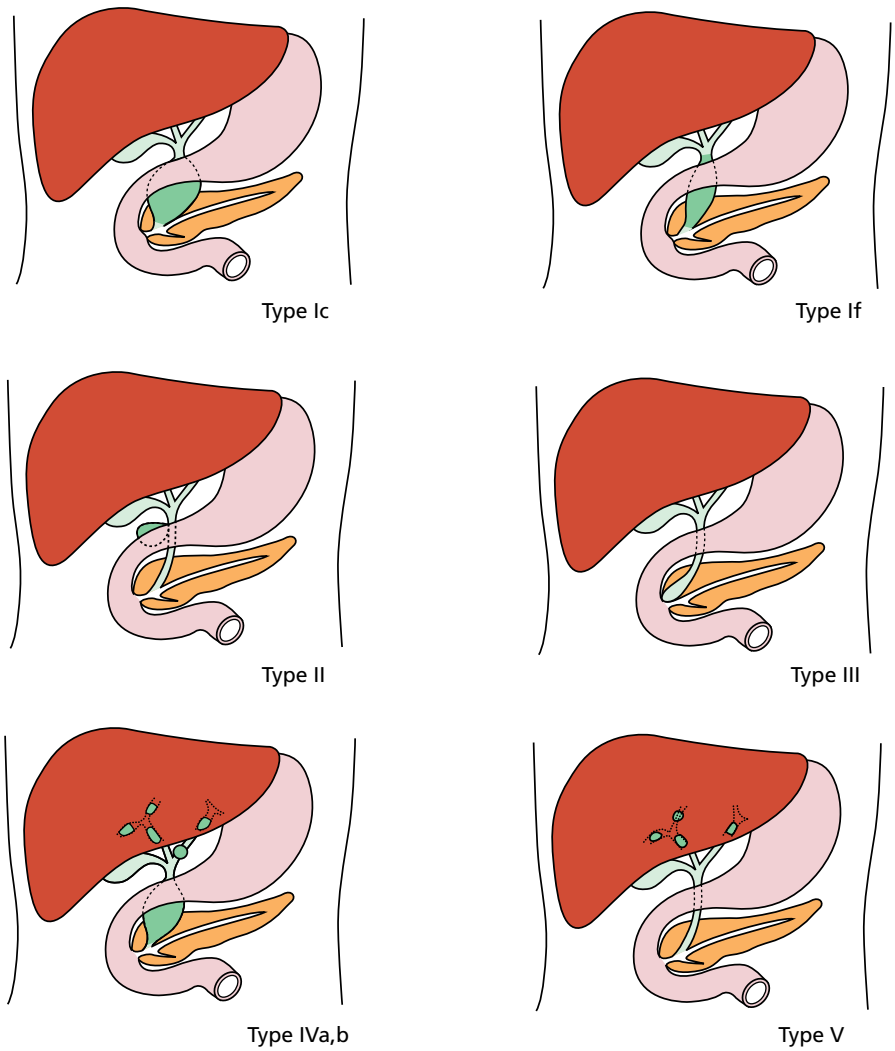

Figure 9.4 Classification of choledochal cysts. Type I dilations may be cystic (Ic) or fusiform (If) and typically associated with pancreaticobiliary malunion. Other types are II (diverticulum), III (choledochocele), IVa (multiple cystic dilations of the extrahepatic and intrahepatic ducts), IVb (multiple extrahepatic cysts), and V (single or multiple intrahepatic duct cysts). *Source:* Reproduced from Millar [21] with permission of John Wiley and Sons.

procedures. Liver transplantation is an option for those with decompensated liver disease or in whom pruritus is intolerable; however, the outcome following transplantation may be affected by the associated cardiac disease, and careful planning and assessment are necessary.

Metabolic conditions

α1-Antitrypsin deficiency

α1-Antitrypsin deficiency (α1-ATD) is the most common inherited disorder causing neonatal jaundice, with an incidence of 1 in 1600 livebirths. Only a few patients with the deficiency develop liver disease, but it is a common cause of emphysematous lung disease in adults [26]. α1-Antitrypsin is a protease inhibitor produced by the liver; it is an acute-phase reactant and responsible for inactivation of leukocyte elastase. Deficiency is due to mutation of its gene, which is found on chromosome 14. Over 70 phenotypes are described but the PiZZ phenotype (Pi stands for protease inhibitor, ZZ is the isoelectric focusing banding pattern of the abnormal α1-antitrypsin protein) is the most significant, with homozygous PiZZ individuals at risk of progressive liver disease. The pathogenesis of the condition remains obscure and is associated with a build-up of an abnormal α1-antitrypsin molecule in the hepatocyte. However, as not all individuals with the genetic defect develop liver disease, other pathophysiological processes are likely to be important.

The clinical presentation is similar to biliary atresia: a jaundiced baby with pale stools and hepatomegaly. Infants who are homozygotes have a low serum α1-antitrypsin level. Liver biopsy reveals histological findings of neonatal hepatitis and periodic acid–Schiff (PAS)-positive granules within the hepatocytes. Management consists of nutritional support, fat-soluble vitamin supplementation, and treatment of pruritus. The prognosis is variable; many individuals do well, but a proportion progress to cirrhosis and may deteriorate precipitately, requiring liver transplantation. The outcome following liver transplantation in α1-antitrypsin deficiency is good.

Progressive familial intrahepatic cholestasis

Progressive familial intrahepatic cholestasis (PFIC) is a group of autosomal recessive disorders associated with abnormalities of bile canalicular transport proteins [27]. PFIC-1 is caused by mutation of the *FIC* gene, which is expressed in the bile canaliculi; it is characterized by cholestasis, diarrhea, and pancreatitis presenting in the first months of life. Bile duct paucity is seen on liver biopsy. Treatment is generally supportive but external biliary diversion has been used in some cases. Liver cirrhosis occurs in early childhood and may progress to require liver transplantation. PFIC-2 is due to deficiency of the bile salt export pump and is similar to PFIC-1 except that pancreatitis is not seen. It has a worse prognosis and children often require liver transplantation in the first decade of life. PFIC-3 is due to a defect in the canalicular phospholipids transporter MDR3 and presents with intrahepatic cholestasis but with an elevated γ-glutamyltransferase, unlike PFIC-1 and PFIC-2. The condition is similar to PFIC-1, but presentation is often delayed into adult life and the prognosis is variable.

Cystic fibrosis

Cystic fibrosis affects around 1:3000 livebirths and is the most common life-threatening autosomal recessive condition. It affects the lungs, pancreas, sweat glands, and liver. There is great variation in the severity of liver disease; it affects one-third of individuals with cystic fibrosis but is the most important non-pulmonary cause of death. Liver disease usually presents in the teenage years but may rarely present in infancy with neonatal cholestasis, inspissated bile ducts, or meconium ileus [28]. Presentation with the last of these is particularly important, as it may be associated with sepsis and PN administration. The neonatal cholestasis usually resolves spontaneously, and appears not to predict future liver disease.

The reader should understand that although the causes of liver disease are varied, the pattern of progression to advanced liver disease may be similar. Therapeutic advances in hepatology and transplantation offer much hope to children with liver disease, but present an array of challenges to the pediatric anesthesiologist.

KEY POINTS: BILE FORMATION AND CHOLESTATIC CONDITIONS

- Cholestasis is a common finding in neonates due to physiological and anatomical lesions
- Common problems such as cystic fibrosis and α1-antitrypsin deficiency can affect multiple organs making anesthesia more challenging
- Biliary atresia with liver failure is a common reason for liver transplant

Developmental physiology of the gastrointestinal tract

Overview

Anesthesiologists tend not to take much notice of the gastrointestinal tract, except perhaps to wonder if the preoperative nil per os (NPO) period has been long enough. It probably merits more attention than this. The proper functioning of the gastrointestinal tract is fundamental to the well-being of the organism, in some ways as much as the cardiovascular, respiratory, and renal tracts, on which we concentrate so much, quite rightly. It is true that problems in the gastrointestinal tract may take longer to show their full impact, but we all know from experience of our own physiology how little we notice our gastrointestinal tract when it functions well and how ill we feel when it does not. Some of the sickest patients the anesthesiologist will ever encounter are in this desperate condition as a result of problems which have arisen in the gastrointestinal tract.

The great majority of animals, and all of those regarded as the more complex, conform to the same basic body plan: they are modified tubes and the inner surface is, or originates from, the gastrointestinal tract. The importance of this collection of structures and organs is indicated by the degree to which the developmental plan is conserved across classes of organisms which otherwise vary enormously. The genetic scientist can learn a great deal about the gastrointestinal tract of the human by studying that of the fruit fly or the nematode.

We are not so much interested in the details of the genetics of development, although the understanding of this topic has grown amazingly in the recent past, and our realization of its complexity similarly. This section will describe the embryology of the gastrointestinal tract in outline, and show how the anomalies which the anesthesiologist will encounter may have arisen. Relatively more attention will be given to those points which have a relevance to the diseases and conditions which may be seen by the practical pediatric anesthesiologist, but the management of these conditions will be covered in other chapters.

The development of the gastrointestinal tract is dictated by an unavoidable deadline. By the time a baby is born, the gastrointestinal tract must be ready to supply fully the baby's needs for fluid and electrolyte intake, to digest its food, initially completely milk, to provide sufficient energy and biochemical raw materials for extremely rapid growth and development, and to do so efficiently enough not to upset the immature homeostatic control mechanisms. At the same time, a sudden onslaught of pathogenic organisms and potential poisons has to be resisted. Within a few months of birth, the gastrointestinal tract has to be ready for weaning from its comforting milk diet to whatever the environment can be made to provide – one of the first crucial steps to independent existence. Thereafter, the demands made on the gastrointestinal tract do not alter so radically, and although there is a lot of growing to be done and full functional maturity will not be attained for some years, the processes remain more or less unchanged for the rest of the individual's life. This timescale means that the pace of development *in utero* is hectic, and after birth many of the remaining functional changes normally happen soon.

It will be obvious that physiological experiments on the developing gut are difficult to carry out, even in animal models, so there are gaps in scientific knowledge, sometimes glaring enough to be obvious to the non-specialist. Some (maybe even much) of what is known is extrapolated from data from other species, and although the homogeneity of gastrointestinal tract design means that this may often be accurate, some of it may not.

Basic gastrointestinal tract physiology

An abbreviated account of the physiology of the gastrointestinal tract follows. It is merely intended as an *aide-mémoire*. The interested reader is referred to standard physiology texts for a more complete account.

The gastrointestinal tract epithelium comprises four basic types of cell: enterocytes, goblet cells (secreting mucus), endocrine cells, and Paneth cells. The 'basic' gastrointestinal tract cell is the enterocyte, which has a brush border of microvilli facing into the gut lumen and tight junctions with its neighboring enterocytes. It sits on a basement membrane, beneath which capillaries and lacteals provide access to the circulation and lymphatic systems. Above the basement membrane, between adjacent cells, the basolateral surfaces border the fluid-filled paracellular space, which is crucial to the handling and transport of fluid and electrolytes. The enterocytes are arranged on villi, tiny finger-like mucosal projections into the gut lumen (Fig. 9.5).

The mass of crowded villi give the healthy gut luminal surface a velvety macroscopic appearance. Between villi, pits project down into the gut submucosa – these are known as crypts (of Lieberkühn). Enterocytes originate from stem cells in the crypts and there is a continuous procession of maturing cells from the crypts out and up on to the villi, gradually working their way to the tips of the villi, from where they are shed into the lumen.

The enterocyte has numerous digestive and absorptive functions. Substances can be taken into the cell by pinocytosis, passive diffusion, facilitated diffusion, and active transport. Enormously complex neural networks coordinate activity. This is explored in more detail in the section on the development of motility.

Basic gastrointestinal tract embryology

An understanding of basic embryology is necessary to make sense of the common structural anomalies.

By day 5 after fertilization, the late blastocyst consists of a hollow ball of cells. The outer cells will go on to form the trophoblast, and later the structures that will make the fetal component of the placenta. An inner cell mass forms a small mass lying against the side of the blastocyst. The inner cell mass soon develops into a bilayered structure: on one side, ectodermal cells border the amniotic cavity and on the other, the endoderm borders the yolk sac. The plate-like embryo starts to curl round and over, side to side and head to tail, so that the endoderm becomes more and more the lining of the inner side, and cells migrating inwards from the primitive streak on the ectodermal side become mesodermal cells, which surround the endoderm. The endoderm still communicates with the yolk sac, which lies outside the middle part of the embryo. By day 25, the caudal and cephalic ends of the endoderm have invaginated at the anterior and posterior intestinal portals to form the blind-ending tubes of the primitive gut. The gut has buds which grow out to form, in order from head to tail, the thyroid, the tracheobronchial bud, the liver, the pancreas, and the allantois, a hollow endodermal projection which still lies outside the embryo.

It is customary to describe the gut in four parts: the pharynx, which extends as far as the tracheobronchial bud; the foregut, from there as far as the liver bud; then the midgut, as far as the posterior intestinal portal, which is where the caudal blind-ending tube starts in the early embryo – in the adult, this point will be two-thirds of the way along the transverse colon. From here onwards is the hindgut.

The gut becomes an open tube at both ends; cephalad, a pit develops, which is closed by the buccopharyngeal membrane. This meets the pharynx and perforates to form the proximal opening. At the end of the hindgut a similar pit grows inwards to meet the hindgut and form the common opening of the gut and urogenital system, the cloaca. In the foregut, the tracheobronchial bud develops ventrally; normally the only communication between the two is where the larynx opens into the oropharynx. The esophagus elongates as the tracheobronchial bud grows downwards and the heart descends [29].

The most common congenital defect in this area is esophageal atresia with tracheo-esophageal fistula, which occurs about 1:4000 births [30]. The cause is unclear. In the most common form (over 80% of cases), the upper esophagus ends as a blind tube and the distal esophagus opens into the

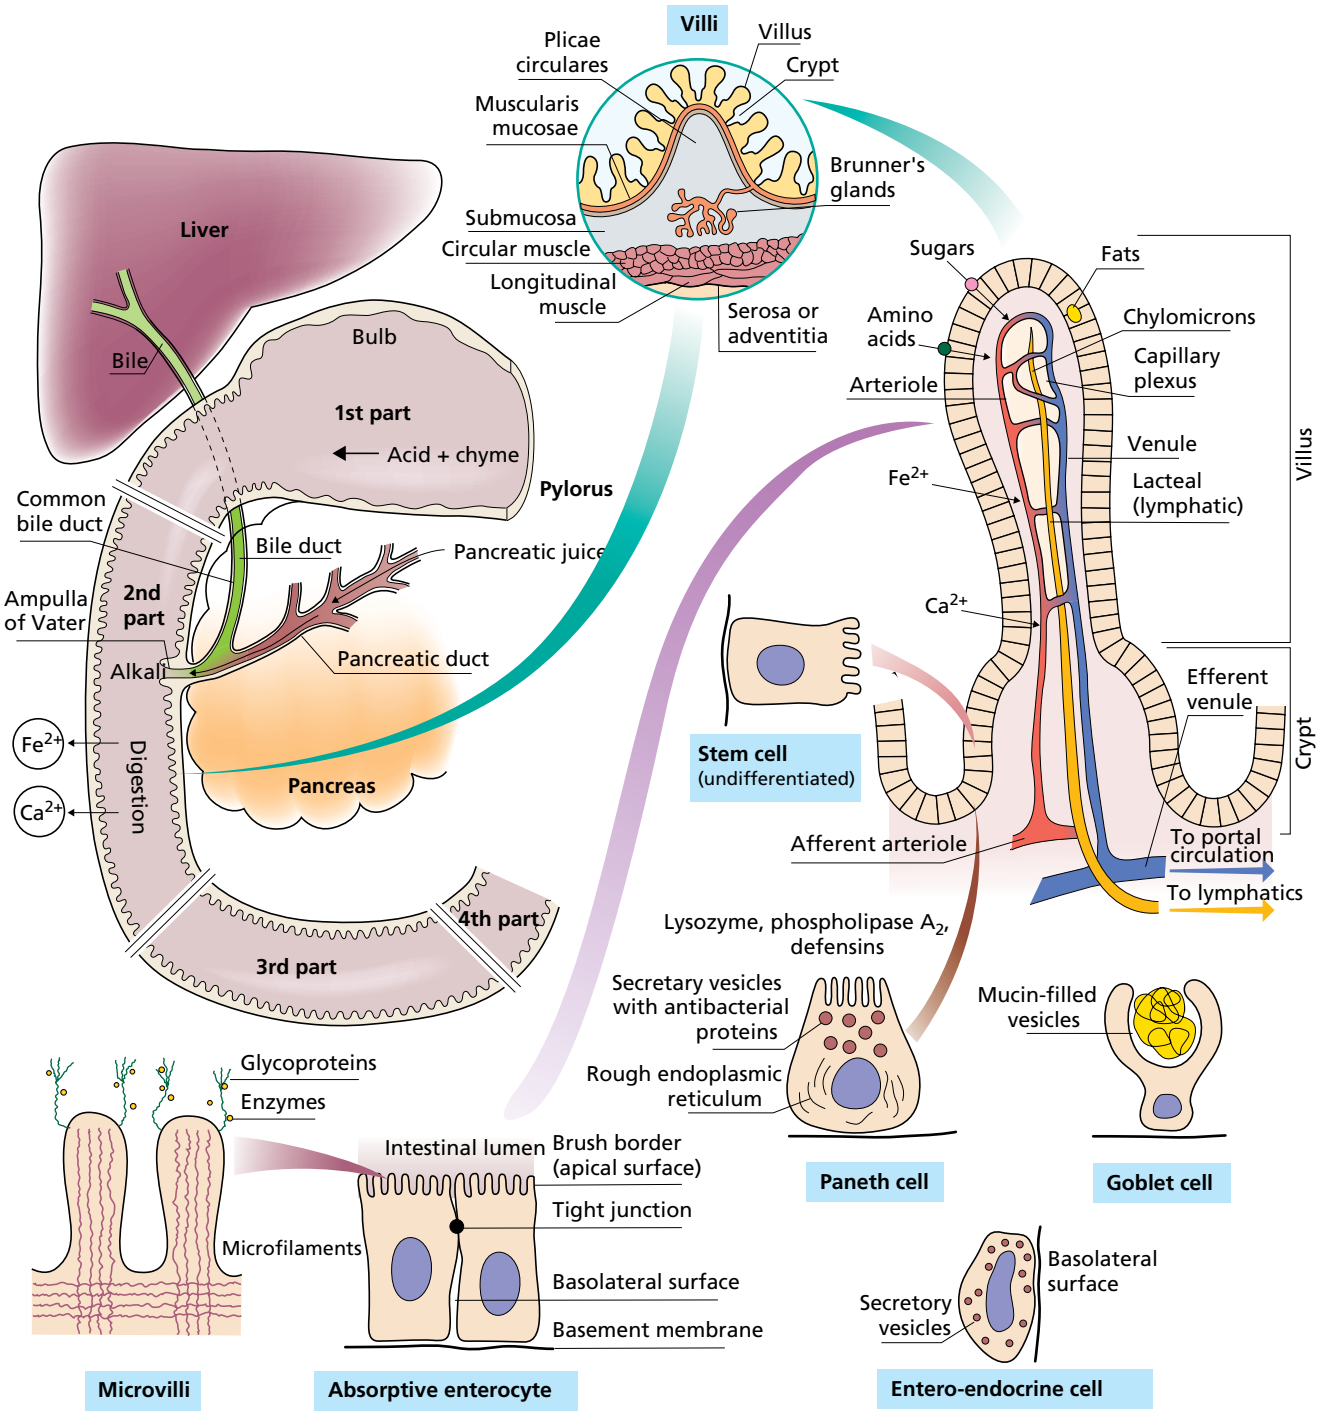

Figure 9.5 Basic structure and function of the gastrointestinal tract (duodenum). See text for further details. *Source:* Reproduced from Keshav and Bailey [161] with permission of Blackwell Publishing.

trachea posteriorly near the level of the carina. Other combinations are seen but esophageal atresia or stenosis without any fistula into the respiratory tract is unusual (Fig 9.6). Chromosomal abnormality (e.g. trisomy 21) is sometimes associated, and in more than half of cases there are associated anomalies, especially cardiac, renal agenesis, microcephaly, other gut atresias, limb reduction defects, and polycystic kidneys [31].

The stomach starts as a dilation in the foregut. It rotates round clockwise so that the left side becomes anterior and the right side becomes posterior; as this process occurs, its mesentery is dragged behind and forms a pocket of peritoneum behind the stomach – the lesser sac. The stomach is therefore surrounded by peritoneum, preventing its fixation and allowing for the necessary movement and expansion. The posterior wall (now left side) grows faster than the right, causing the distal part to be pushed out to the right. The liver bud develops from the ventral part of the duodenum; it grows up and forwards, so its upper surface lies in contact with the septum transversum and this structure, part of which gives rise to the diaphragm, is all that separates it from the base of the right lung and the heart. The duodenum also participates in

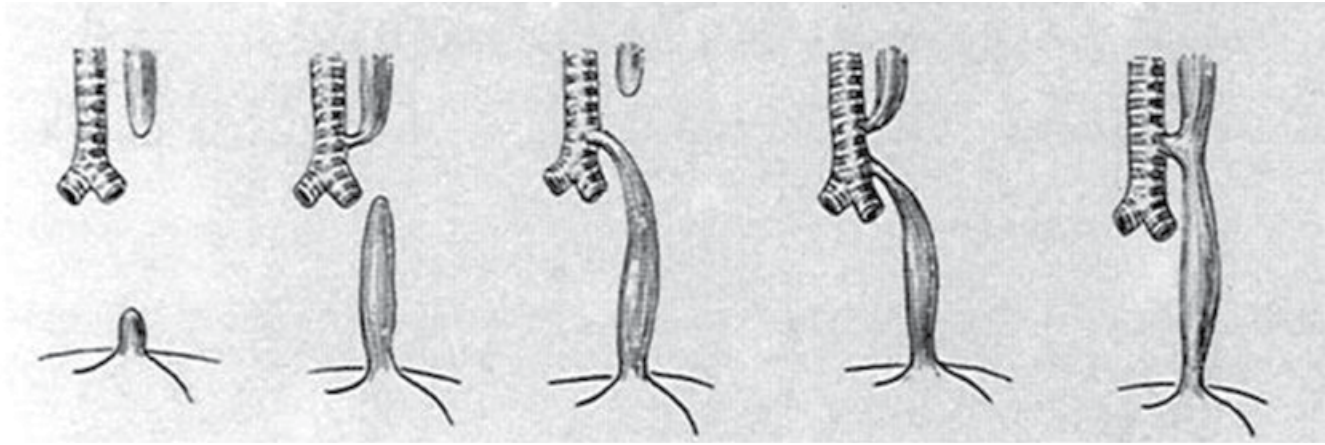

Figure 9.6 Anatomical classification of anomalies of the esophagus and trachea, with approximate incidences. Type A: esophageal atresia without tracheoesophageal fistula (TEF); Type B: esophageal atresia with proximal TEF; Type C: esophageal atresia with distal TEF; Type D: esophageal atresia with proximal and distal TEF; Type E: H-type TEF without esophageal atresia. *Source:* Reproduced from Gross [157] with permission of Elsevier.

this left-to-anterior rotation, so that the connection with the liver, which is drawn out into the thin common bile duct, is pulled behind the duodenum and ends up opening into the duodenum on the left side, at the papilla (see Fig. 9.1).

There are two pancreatic buds, ventral and dorsal. The ventral bud is also pulled round behind the duodenum and ends up touching and partially fusing with its dorsal counterpart. It is still recognizable in the adult as the uncinate process of the pancreas, which normally lies a little below the main body. The pancreatic ducts generally fuse to form a common pancreatic duct, which opens, with the common bile duct, into the duodenum at the papilla.

From here on, the midgut grows enormously, forming a long loop. Its blood supply, the superior mesenteric artery, is pulled out in the mesentery. The midgut undergoes rotation so the distal part is pulled upwards and to the right counterclockwise, so that the dilation that will form the cecum ends up in the right upper quadrant in front of the rest of the gut and the liver. As this part later elongates to form the ascending colon, it drops down towards the right lower quadrant, so the final rotation ends up approximating 270° (Fig. 9.7).

The small bowel loops repeatedly as it lengthens, whereas the colon does not. The growth of the midgut is so rapid that it cannot be accommodated in the abdominal cavity, so it herniates out. As the abdominal cavity becomes more spacious because of the growth of the whole fetus and the lifting up of the heart and liver, the midgut is gradually retracted back into the abdominal cavity by 11 weeks' gestation, the yolk sac obliterates, and the abdominal wall closes over it, leaving only the umbilical cord and its vessels passing out of the body cavity. At the point where the involuted yolk sac meets the midgut, a remnant may persist (Meckel's diverticulum) which may contain ectopic stomach epithelium, or there may be a fibrous cord, sometimes containing a vitelline cyst, tethering it to the anterior abdominal wall.

The hindgut is separated from the urogenital opening by the downward growth of the urogenital septum, which meets the cloacal membrane, dividing it into two: the anterior part, derived from the allantois, which will form the urinary bladder and genital tract, and the posterior part which forms the

rectum. By 9 weeks' gestation, the ectodermal anal pit perforates into the rectum, opening the distal end of the gut.

Imperforate anus occurs in around 1:5000 births and ranges from a thin membrane across the anus to complete failure of the formation of the anal canal and associated sphincters. There may be other defects in urogenital structures, and the anomaly may be associated with spinal defects, omphalocele, and aganglionosis [32].

Congenital abdominal wall defects: gastroschisis and omphalocele (exomphalos)

In gastroschisis, there is a defect in the abdominal wall, generally to the right of the umbilicus, and usually less than 5 cm across. The etiology is uncertain; there may be more than one causative factor [33], and explanations have been proposed for the rising incidence, including the effects of environmental pollutants [34]. It could be that a failure of mesenchymal cell migration means that the abdominal wall never completely closes over the defect left by the physiological herniation of the gut, which is normally retracted into the abdominal cavity around the 10th week of gestation, and so, as growth of the gut progresses, the gut reherniates. Possibly in some cases a weakness or ischemia of the abdominal wall causes it to rupture, having initially closed. The position to the right of the umbilicus may indicate defective involution of the right umbilical vein. Sometimes the liver is also herniated. The herniated gut is not covered and is exposed to amniotic fluid, and is necessarily exposed after birth. The blood supply to the herniated part can be compromised, and the ischemic gut can be reduced to fibrous bands or may contain segments of atresia. Even if this is not the case, the gut may not develop normally and its function may be impaired. Sometimes the gut is covered with a fibrinous "peel" which may form as a response to gut contents which have leaked into the amniotic fluid bathing the exposed gut; the presence of a peel predicts a worse outcome [35].

In omphalocele (also known as exomphalos), the gut herniates through the umbilical ring itself, which is wide open. The gut is covered by amnion, the membrane that surrounds the umbilical cord, which forms a sac, although this may rupture, especially if it is large. The size is variable; there may be anything from only a small amount of bowel in the sac to most of the small bowel, liver, and spleen.

The incidence of the two abdominal wall defects together is around 1:2000 births but the proportion of each varies by region and in many places is changing over time, the general trend in the developed world being that gastroschisis is becoming more common while omphalocele remains the same or is declining slightly, so that in many areas gastroschisis is seen slightly more frequently than omphalocele. Gastroschisis is related to young maternal age but is often the only abnormality, just 17% or so having other congenital abnormalities, whereas in omphalocele over 60% have anomalies elsewhere [36].

Congenital umbilical hernia resembles omphalocele, but in this case the abdominal wall originally closed normally, so when the hernia occurs it is covered by peritoneum as well as amnion.

Prune belly syndrome is an uncommon condition, occurring in less than 1:30,000 births, almost always in boys [37]. The muscles of the anterior abdominal wall are replaced by thickened collagenous bands, perhaps due to defective migration of mesenchymal elements which normally give rise to striated muscle. The abdomen therefore looks lax, the shapes of loops of bowel can be made out beneath the wrinkled skin, which gives the condition its name, and there may be visible peristalsis. The musculature of the bladder and renal tract is also affected and there may be a large thick-walled bladder, hydroureter, and renal dysplasia. The very rare megacystis–microcolon intestinal hypoperistalsis syndrome presents a similar appearance.

Malrotation

When the embryo's midgut is outside the abdominal cavity before the 10th week of gestation, the gut rotates through 270° so that the cecal bud, which would lie at 6 o'clock if there were no rotation, comes first to lie at 12 o'clock with the first 180° of rotation, and then finally round at 9 o'clock with a further 90°, which brings the cecal bud to lie in the right upper quadrant, next to the liver, and means that the colon lies over (anterior to) the duodenum. The gut loops on the left return first, so that as the cecal bud descends with the growth of the ascending colon, these structures lie on the right. Where the gut mesentery comes to lie on the peritoneum, it may fuse and so fix the gut at that point; normally the C-loop of the duodenum, ascending and descending colon, become fixed, and the small bowel loops and transverse colon retain a mesentery.

In malrotation, the gut rotation sometimes amounts to just 90°; if the left-sided structures return to the abdomen first, this will mean the distal parts will return first and the colon (all of it) will lie on the left and the small bowel loops will lie on the right.

If the malrotation is 90° clockwise instead of counterclockwise, then the duodenum will overlie the colon rather than the other way around.

The problems with malrotations are that the gut can be obstructed by the abnormal positioning or, lacking the normal fixation of parts of the gut to the retroperitoneum, the mesenteries can twist (volvulus), causing ischemic damage, or the abnormal peritoneal bands can themselves cause obstruction. This can commonly occur when the cecum lies to the left of the duodenum, so that the fibrous bands to the cecum lie over the duodenum (Ladd's bands) [38]. Sometimes the malrotated gut can function perfectly normally, and volvulus or obstruction occurs later in life, or it may cause no trouble and never be discovered, or only incidentally as a result of imaging or surgical exploration carried out for unrelated reasons. However, over 70% of cases present before the age of 1 year, and a similar proportion will have congenital abnormalities elsewhere. Malrotations are quite common, occurring in 1:500 births.

Intestinal atresias, stenoses, and webs

The duodenum is thought to pass through a solid phase in development, the lumen being re-established by the coalescing of vacuoles in week 8–10 of gestation (there is some doubt about this account [39]). If recanalization is incomplete then a stenosis, web, or atresia occurs, or if there is no connection to the lumen at all, a duplication cyst may result. Duodenal atresia is frequently (50%) associated with intrauterine growth retardation, polyhydramnios, prematurity, and congenital anomalies elsewhere which may be part of the VACTERL association (vertebral, anal, cardiac, tracheo-esophageal, renal, and limb anomalies [40]). Sometimes a duodenal stenosis can be surrounded by a ring of pancreatic tissue (annular pancreas), but it is not clear whether this is the cause of the stenosis or a result of it [41].

Jejunoileal atresias may be due to *in utero* interruptions in blood supply to a portion of the gut at a much later stage of development than duodenal atresias. They vary from stenosis, through cases where a small length of bowel is replaced by

a fibrous band, to multiple atresias with long sections of missing gut and defects in the mesentery. Sometimes the interrupted gut may be supplied by a marginal blood vessel, and therefore a length of progressively tapering hypoplastic gut winds around it in a spiral shape, giving rise to the "apple peel" or "Christmas tree" malformation (type IIIb) [42] (Fig. 9.8). They are not particularly associated with other abnormalities. Often the gut may be dilated proximal to the obstruction and collapsed or hypoplastic distal to it, although some stenoses may show distal dilation (wind-sock deformity).

Colonic atresias may occur by similar mechanisms but are more unusual – less than 15% of all intestinal atresias.

KEY POINTS: DEVELOPMENTAL ANOMALIES

- An understanding of the embryology of the gut is necessary for understanding many gut anomalies, e.g. tracheoesophageal fistula, malrotation of the gut, etc. (VACTERL syndrome)
- Omphalocele and gastroschisis occur commonly. The former is often associated with other congenital anomalies; the latter is not
- Malrotation of the gut leaves the child prone to midgut volvulus, a true neonatal emergency

Functional development of the gastrointestinal tract – vesicles, carbohydratase enzymes, transmembrane transporters

The epithelium of the gut changes from stratified to simple columnar between the 9th and 10th weeks of gestation [43]. Some absorptive processes are possible at the stratified stage, but significant functional capability does not become evident until the columnar stage. Maturation is not uniform, either between types of cell or between regions of the gut. In general, absorptive cells mature first, then goblet and endocrine cells, and Paneth cells last. Development also proceeds from proximal to distal. Villi appear first, proliferating to such a degree that the lumen may be obliterated. Crypts develop later. Epithelial cells differentiate from stem cells in the proliferative zone, which comes to lie in the crypts; Paneth cells migrate down into the crypts, all the others up towards the tips of the villi. There are therefore two axes of development: vertically on the crypt–villus axis and along the gut on the proximo-distal axis. The interaction between the endoderm-derived epithelium and the mesodermal elements that migrate into position beneath is crucial to the organized development of the gut [44]. The villi tend to be tallest in the jejunum and get shorter more distally. The mature colon does not have villi, only crypts, but there are villi in the immature colon.

A fundamental property of absorptive cells is that they can take up substances from the lumen in vesicles. Specialized

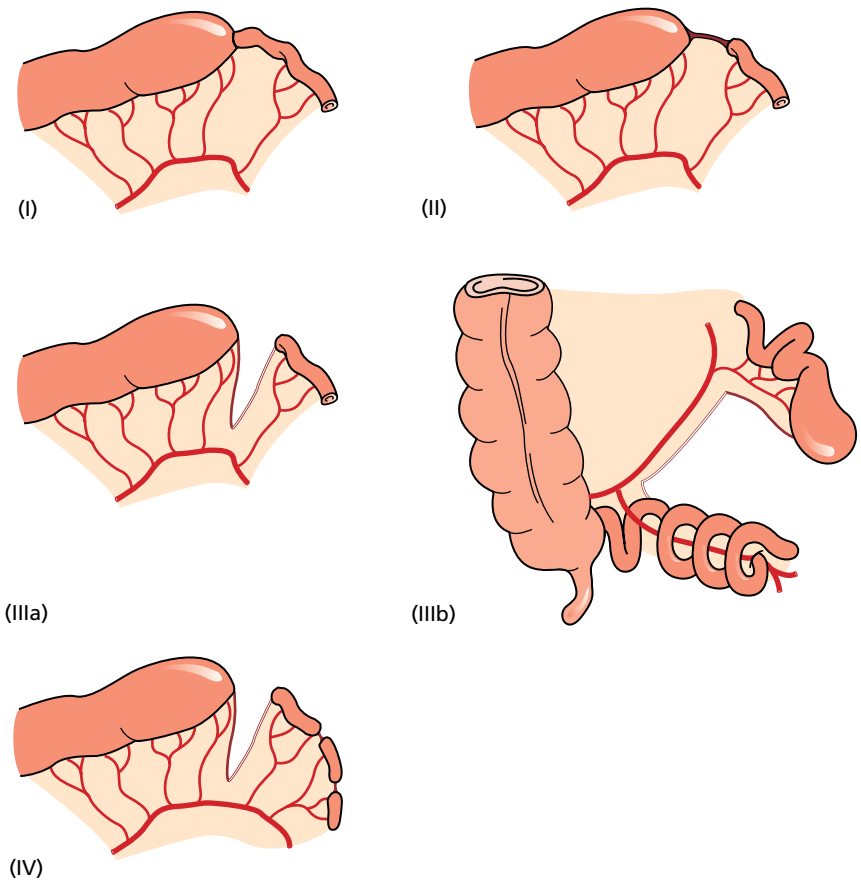

Figure 9.8 Classification of jejunoileal atresia describes the pathology as type I (mucosal web), type II (fibrous cord), type IIIa (mesenteric gap defect), type IIIb ("apple peel") or type IV (multiple atresias). *Source:* Reproduced from Welch et al [159] with permission of Elsevier.

proteins associated with vesicles (e.g. clathrins and caveolin) allow for selective absorption and onward intracellular distribution of substances from the gut lumen [45,46].

Developing enterocytes are structurally different from mature ones – at around 17 weeks' gestation, giant lysosomes can be seen in the ileum. There are more lysosomes in the adult gut than in the neonate, but no giant ones [47]. The developing gut needs to absorb more macromolecules undigested (growth factors, hormones, immunoglobulins) from amniotic fluid and milk, and is therefore more permeable to these, which may account for a greater susceptibility to pathogens and allergies at this stage.

Apical carbohydratase enzyme development has been studied in some depth, particularly lactase and the double complex sucrase/isomaltase [48]. Neither enzyme appears until the epithelium becomes columnar. Thereafter levels gradually increase. From 32 weeks' gestation there is a sudden large increase in lactase and sucrase activity. In most mammals (including humans), lactase activity declines sharply after weaning (later childhood in humans), typically to 10% or so of its peak, leaving most adult humans lactose intolerant [49]. Lactase is the only enzyme capable of cleaving the disaccharide lactose into its component glucose and galactose moieties. Lactose intolerance is by far the most common disaccharide intolerance. Other disaccharide intolerances are much rarer and are the result of transporter defects, not enzyme deficiency. In those of northern European ancestry, lactase activity usually persists into adulthood. These populations often have a tradition of consuming domesticated animal milk and milk products, and may at one time have been dependent on it or, at least, its availability conferred a survival advantage. Mutations reducing or eliminating the decline in lactase activity with age may have originated separately in several different human populations. The distribution of the enzymes also varies along both crypt–villus and proximo-distal axes; lactase is concentrated in more proximal regions of the small bowel, and towards the tips of the villi, where it is vulnerable to being sloughed off if there is any inflammatory process. Sucrase is evenly distributed up the villus and further along the small bowel, but neither enzyme is found in the adult colon [50].

Development of transporters

The principal carbohydrate transporters are: SGLT-1, which is a brush border (apical) sodium co-transporter for glucose and galactose; GLUT-5, which is a brush border facilitative transporter for fructose; and GLUT-2, which is a basolateral facilitator for all hexoses. Carbohydrate transporters start to be expressed during gestation, the number and density increasing and accelerating as term approaches. At birth, SGLT-1 is found along the whole length of the villus, whereas in adults it is found only on the third nearest the tip. Therefore the absorptive capacity per unit area of intestine tends to decrease with age but the total intestinal area of course increases, approximately proportional to the bodyweight after the neonatal period or slightly less [51]. The transporters are much more numerous proximally, where high carbohydrate concentrations would be expected. At the time of weaning, the transport capacity for sugars declines further and is at least in part genetically programmed, as it occurs even if a totally milk diet persists.

Amino acid transporters are more complicated; there are more types, absorbing different groups of amino acids, although their affinities may overlap with each other somewhat. Small peptides (mostly 2 and 3 amino acids) also have their own transporters.

There are specific transporters for bile salts which, unlike the other transporters, are much more numerous in the ileum. Curiously, they do not appear until weaning; presumably before that bile salts are absorbed passively all along the small bowel, as an enterohepatic circulation certainly exists during the suckling stage [52]. It may be that it is important for the development of colonic bacterial flora that bile salts enter the colon during suckling.

Carbohydrate malabsorption can be a dangerous problem. The consequences are that sugars reach the colon, where they cause an osmotic diarrhea. The sugars are fermented by colonic bacteria and hydrogen, methane, and carbon dioxide are produced. By far the most common cause is a loss of the brush border carbohydratase enzymes, the most common being lactase deficiency. Congenital lactase deficiency in infants was usually fatal before the advent of lactose-free milk substitutes. Genetic defects in the other carbohydratase enzymes are very rare, but acquired deficiency can be caused by a range of factors that may cause mucosal damage, including inflammatory, ischemic, or allergic processes.

Defects in nutrient transporters are rare. Glucose–galactose malabsorption is due to defective synthesis of SGLT-1.

The enteric nervous system

The enteric nervous system (ENS) is essential for the functioning of the gastrointestinal tract. All the nerves of the ENS are derived from neural crest cells and are broadly arranged into two plexuses: the inner submucosal plexus, situated as its name suggests; and the myenteric plexus, which lies between the inner circular smooth muscle layer and the outer longitudinal one. The ENS is much more than an extension of the parasympathetic branch of the autonomic nervous system. It contains a vast number of neurons (as many as the spinal cord) and many different cell types, and it is capable of functioning without any input at all from outside. Its neurons, which may be sensory, motor (both muscular and secretory), or interneurons, include types that resemble those found in the central nervous system (CNS): glial cells, astrocytes, and so on. One could go as far as to say that the complexity of the ENS, and its independence, allow it to be considered a "second brain." The largest share of the relatively tiny number of nerve connections to other systems comes from the vagus nerve, and 90% of those fibers are sensory – so perhaps in some respects the ENS controls the CNS more than the other way around.

Among the properties of the neural crest cells that find their way into the ENS are that they are highly migratory and highly pluripotent, and they originate from restricted areas – the vagal neural crest of the hindbrain supplies cells that populate the whole of the gut, starting proximally and eventually reaching the whole hindgut. Some neurons that derive from other parts (neural tube and sacral somites) also contribute to the ENS, and functioning ganglia cannot be generated anywhere without all the normal components in a favorable matrix. The factors that control this migration and differentiation are extremely complex.

Hirschsprung disease is a congenital defect in the development of the ENS in which ganglia are absent from a variable length of the gastrointestinal tract starting from the distal end (although occasionally, and disastrously, it may be complete). The presentation is of obstruction usually associated with megacolon. The fundamental defect is a failure of neuronal migration, and several different factors may be involved. The gene coding for a tyrosine kinase (c-RET) is clearly implicated, as are glial-derived growth factor and an endothelin receptor, ENDRB. Other genes that have a role in regulating development in neurons, *SOX-10* and *MASH-1*, can have mutations that mimic Hirschsprung disease in animals [53]. Many other genes are now known to be involved but still many cases of Hirschsprung disease (less than 50% in 2017) do not show mutations in any of these genes [54]. Clearly, the process of getting the right neuron in the right place is extraordinarily complex, and far from completely understood.

Motor function in the developing gut

The functionality of the immature gut is perhaps more limited by deficiencies in the motor function of the gut than by the lack of structural elements, cell types, or digestive enzymes and secretions. The development of motor function rather lags behind these other factors. It is at least 2 years before the system can be considered mature. The main movements that are required are swallowing, sucking, mixing and propulsion of gut contents, and evacuation. The esophagus, and those parts proximal to it, are striated muscle and under voluntary control. The muscle of the rest of the gastrointestinal tract, until the external anal sphincter, is smooth muscle; although neural projections and humoral influences from higher centers can modify its function, it is essentially autonomous and regulated by its own ENS and humoral factors.

Swallowing

Swallowing movements are evident in the fetus at 16 or 17 weeks' gestation, and there is a steady increase in the volume of amniotic fluid swallowed, from less than 20 mL daily at 20 weeks to around 450 mL daily at term [55]. There is much more to this than just "practice"; amniotic fluid contains nutrition and growth factors, and the development of the gut is promoted by it. An interruption of fetal swallowing can lead to polyhydramnios. In the premature infant, propulsive pressures in the esophagus are lower than at term; the movement may not be completely or properly coordinated, and complications due to reflux and aspiration are more likely. The function of the lower esophageal sphincter (LES) is particularly important in this. Although the lower LES pressure found in premature neonates would seem to make reflux more likely, reflux episodes appear to be more related to transient relaxations in the LES [56], the causes of which are not fully clear, than to inadequate resting LES pressure.

Sucking movements can be seen from 28 to 30 weeks' gestation but effective coordination with swallowing and breathing is generally not achieved until 37 weeks or so. Babies more premature than this may still be able to suckle by stopping breathing for short periods and then resting.

In both stomach and small bowel, the smooth muscle shows a typical pattern of slow-wave electrical activity, the periodicity of which is controlled by the pacemaker activity of the interstitial cells of Cajal. A muscle contraction is caused by a spike potential causing an additional depolarization on top of the slow wave and over the threshold for muscle contraction.

In the mature stomach and small bowel, in the fasting state the characteristic feature is the migrating motor complex (MMC), which is a wave of contraction passing from the stomach to the rectum. In the adult, these are seen every 90 min or so. Feeding abolishes them and for 3 or 4 h only segmentations and short peristaltic waves are seen, before the MMC re-establishes. A fully developed MMC is not seen until nearly full term [57,58] but this mature electromyographic pattern is not essential for successful enteral feeding. Gastric emptying can be seen up to 6 weeks before the appearance of the MMC, and contractile activity long before that, but in more premature infants nasojejunal feeding may be needed to overcome inadequate gastric emptying. It is clear that enteral feeding promotes the development of effective motor activity and so in conditions where full enteral feeding is impossible, at least some enteral feed is beneficial. Certainly, in some animals, bacterial colonization is also required for normal gut development.

The rate of gastric emptying is of course of great interest to the anesthesiologist wishing to provide safe anesthesia for his or her patient. Unfortunately, it is highly variable. Very dogmatic adherence to a protocol NPO period before anesthesia rather implies a lack of understanding of gastrointestinal physiology. The half-time for gastric emptying in premature infants is usually 20–40 min, rather slower than it is for term babies, and it will be slower for formula feed than for breast milk.

The colon also shows propagated waves of contraction when mature, and the passage of fecal material into the rectum may lead to reflex relaxation of the internal anal sphincter and defecation. The frequency of these contraction waves decreases with age from several times per hour in the term infant, especially just following a feed, to once or twice per day in the adult. Most babies pass their first stool within 2 days of birth, but it may be longer than that in the case of prematurity. There is normally no passage of meconium into the amniotic fluid *in utero*, and evidence of it is often considered a sign of fetal distress.

Many factors can interrupt the normal process of gastrointestinal tract motor maturation, including some that appear to be outside the gut; babies with hypoxic brain injury are much more likely to have problems with reflux and experience delays in establishing enteral feeding.

Meconium ileus is most commonly seen in infants with cystic fibrosis. Cystic fibrosis (CF) is caused by a defect in the gene coding for a protein that forms a cAMP-dependent chloride channel (cystic fibrosis transmembrane conductance regulator, CFTR). The disease is characterized by abnormally thick, viscid mucus, which typically causes blockage and infection in the respiratory tract or causes pancreatic insufficiency. There are other changes in CF goblet cell secretions and intestinal mucus apart from lack of chloride – for example, it contains more protein, specifically more albumin. The result is that the sticky meconium causes an intestinal obstruction. Rare cases that occur without CF may be due to motility disorders, for instance defective interstitial cells of Cajal.

KEY POINTS: FUNCTIONAL DEVELOPMENT

- Development of enzymes for uptake of material from the gut varies and usually increases with time
- Lactase is present in significant amounts in the infant but decreases in adults, possibly leading to lactose intolerance
- Hirschsprung disease is due to a lack of migration of the enteric nervous system of the gut, leading to macrocolon and occasionally bowel obstruction. The only effective treatment is excision of that portion of the gut

Immunity in the gastrointestinal tract

The very purpose of the gastrointestinal tract is to take substances in from the environment and transport them into the organism; it follows that this process is a major liability when that environment teems with potential pathogens. To protect the organism effectively from these myriad threats requires an extremely sophisticated multimodal defense system.

Innate immunity

The goblet cells secrete a mucus that forms a physical barrier, which also contains antimicrobial compounds, protecting the mucosa from pathogens. The number of goblet cells increases in inflammatory conditions and in response to some parasites. The enterocytes may contribute to immunity by an unusual mechanism [59]. The lifespan of enterocytes after birth is short, around 3–5 days. As these cells die and are shed into the lumen, they release histones, which are components of the cell nucleosome but which also seem to have significant antimicrobial activity (similar compounds are present in macrophages). So many enterocytes are shed into the lumen that this could be an effective protection, and it is not otherwise apparent why their lifespan needs to be so short; Paneth cells (originating from the same precursors) live much longer, as do fetal enterocytes in their sterile environment. Enterocytes therefore seem to have an immune function which is secondary to their main function. However, the primary function of Paneth cells is immunological. Paneth cells secrete a range of bactericidal compounds. They contain numerous granules (like neutrophils), and the granules seem remarkably similar, containing lysozyme, phospholipase A_2, and peptides known as α-defensins. All these components show antimicrobial activity. Most, and possibly all, of the Paneth cell granules are released into the lumen and so their antimicrobial activity occurs outside the cell, unlike neutrophils and macrophages; also unlike those cells of myeloid lineage, Paneth cells are fixed, in the epithelium of the crypts. Paneth cells can be detected in humans at about 13–14 weeks of gestation and produce low levels of defensins straight away. The levels increase markedly around the time of birth but defensin levels are still several times lower in neonates than in adults.

Acquired immunity

A detailed account of the mechanism of cellular and humoral immunity is outside the scope of this chapter, so we will assume some knowledge of these systems. The fundamental problem that the gastrointestinal tract poses to the immune system is that while the organism must be capable of defending itself against a vast array of pathogens that may attack by this route, it is unavoidable that the ingestion of food will also present an enormous range of foreign antigens and to respond to every one would be unfeasible, wasteful, detrimental, and potentially disastrous. Therefore there must be an accurate and subtle method for inducing tolerance to antigens that are harmless (and may be required), whilst maintaining immune vigilance against genuine threats. Perhaps needless to say, the precise and complete details of how this is achieved are not known and, anyway, the complexities of what is known need not trouble us too much for the purposes of this account.

Lymphocytes appear in the gastrointestinal tract in three broad areas: as intraepithelial lymphocytes, in Peyer's patches, and in the lamina propria.

Intraepithelial lymphocytes appear at around 11 weeks' gestation and increase continuously, so by 27 weeks about 70% of the infant level is reached [60]. In the lamina propria, B- and T-cells are present from 12 to 14 weeks' gestation, and similarly increase their number towards birth. The cell subsets present are distinctly different in these two areas and cell proliferation is seen throughout, whereas in the adult proliferation is confined to the Peyer's patches: these can be seen from around 18 weeks' gestation, mostly in the ileum, as in adults. There are typically around 100 at birth, increasing to 250 or so in teenagers, thereafter gradually declining. As soon as they appear, the epithelium overlying the patches changes from columnar to cuboidal, and the enterocyte-derived M-cells appear – their function is to transport antigens from the lumen and present them to lymphocytes [61]. Mature M-cells are surrounded by clusters of lymphocytes.

In utero, the sterile conditions do not test the immune system, but at birth there is a sudden influx of antigens. Premature infants are capable of mounting both humoral and delayed hypersensitivity-type reactions, but the response is less reliable than in term babies. After birth, the immune system continues to develop quickly, at least in part stimulated by luminal antigen (the process is less effective in parenterally fed infants), and normally after 1 year of age there are three times as many intraepithelial lymphocytes as in the neonate.

B-cells and the immunoglobulins they produce are crucial to the protection of the huge mucosal surface of the gastrointestinal tract. Peyer's patches are fundamental to the production of activated plasma cells. The clonal expansion of specific cell lines is carried out there, and the maturing cells disperse out into the circulation and so are distributed to the whole of the lamina propria. Immunoglobulin-secreting plasma cells produce predominantly IgA which is packaged with a secretory component and exported into the lumen by the enterocytes. In the neonate, significant amounts of IgA are supplied by the mother's breast milk, compensating to some extent for the immature humoral immune system.

Breast milk, the suckling period, and bacterial colonization

Breast milk is considered to provide many advantages over artificial alternatives [62]. The composition of human breast milk alters as the baby ages, is not uniform during a single

feed, and varies quite a bit between individuals. For the first few days postpartum, colostrum is produced; the volume is rather lower and its composition different from more mature milk.

Milk proteins

There are a very large number of milk proteins, which are classified into two groups according to whether they clot, forming a curd on exposure to acid (caseins), or not (whey). Caseins form micelles in the watery milk environment, containing ions, especially calcium and phosphorus. The principal caseins in human milk are β- and κ-casein. Of the whey proteins, those with the highest concentrations are α-lactalbumin, lactoferrin, secretory IgA (sIgA), and serum albumin.

Secretory IgA (90% of milk immunoglobulin) has an obvious immunological utility; the clonal varieties will be directed against antigens that the mother has encountered and are therefore tailored to the probable local environment. Immunosglobulins are resistant to degradation in the infant gut.

In addition, there are small amounts of important enzymes in milk, such as bile salt-activated lipase, which assists in the digestion of milk fat content. This enzyme, and the plasma membrane that encloses milk lipid droplets as they are secreted in the mammary gland, ensure that milk fat is particularly easily digestible.

Some growth factors, for example insulin-like growth factor, transforming growth factor, and epidermal growth factor, promote gastrointestinal tract cell proliferation, which can be extremely rapid after the first feed, intestinal mass as much as doubling within 3 days in piglets [63].

Hormones present in milk include insulin, thyroxine, and glucocorticoids, and these and other factors such as nucleotides may have important roles in gut maturation.

Cytoprotective substances such as prostaglandins and phospholipids are also present.

Non-protein components of milk

Mature human milk (produced at least 3 weeks postpartum) contains typically [64] 4% fat, almost all triglycerides of medium- or long-chain fatty acids, 7% carbohydrate, almost all lactose, and 1–1.5% protein (about 40% caseins, 60% whey).

Colostrum contains less fat and carbohydrate (about 75% of that in mature milk) and much more whey protein (about double) which includes up to 5–12 times as much sIgA, as well as high concentrations of trophic factors, especially in the first day or two [65,66]. By comparison, cow's milk is very different – it contains about half as much lactose, a little less fat, about three times as much caseins, and has a higher electrolyte concentration.

The infant stomach does not produce much acid (the pH in the neonate's stomach is 4–5), so pepsin activity and hence protein digestion are very limited. The stomach is much more important in the digestion of milk fat. Gastric lipase activity is very high in the neonate (even if premature) and it seems that this enzyme is required to start the breakdown of the membrane-coated milk fat globule, which otherwise resists the activity of bile salt-activated lipase (a milk constituent).

Initially there is significant transport of macromolecules unaltered across the gut mucosa. This certainly occurs *in utero*, and factors present in amniotic fluid appear in the fetal circulation. Later, the gut becomes much less permeable, a process known as closure. The precise timing of closure is difficult to determine; it happens rather earlier in humans than in some other mammals – in the rat, closure occurs long after birth. Certainly the human gut is more permeable in the neonatal period, and factors in breast milk may promote closure; this may be protective against infection.

Gut colonization and the development of the microbiome

It is now recognized that the human is in fact not a single organism but rather a colony of many different creatures living in association; if the DNA from every cell in or on a human were sequenced, up to 99% of the genes found would be discovered to be not human but from a variety of bacteria, fungi, viruses, Archaea, and others. Most of them are tiny, so of course by weight we are mostly human. The great majority of these organisms that make up the microbiome are beneficial or at least benign, but the characterization of these relationships is still at an early stage. The gastrointestinal tract harbors the largest population of these symbionts. Before birth, the gastrointestinal tract is sterile, so the appearance of the various species that later populate it is a matter of great interest. It is postulated that the species that inhabit the gut are significant for healthy development, and evidence is accumulating that this is true. Furthermore, the microbiome does not relate only to the health of the gastrointestinal tract itself but also to that of many other organ systems. A faulty or pathological microbiome has been implicated in the development of necrotizing enterocolitis, inflammatory bowel diseases of various sorts, atopy, allergy (especially pathological sensitization to food allergens), autoimmune diseases, neuropsychiatric disorders such as autism and attention deficit hyperactivity disorder, diabetes, obesity, and many others.

The origins of many early colonizers of the gastrointestinal tract are the mother's genital tract, and breast milk. It is clear that these colonizing organisms are different in infants who have been delivered vaginally and breast fed compared to those who have effectively bypassed the usual sources of colonizing organisms by being delivered by caesarean section and fed on formula milk. The breast-fed infant's gut is primarily colonized by bifidobacteria and lactobacilli, whereas those on formula feed have a smaller population of organisms in total but more *Bacteroides*, enterococci, *Atopobium*, clostridia, and anaerobic streptococci. As the infant ages and grows, the balance of species alters as the gut itself matures and the variety and type of foods taken changes; an 'adult'-type microbiome is generally established by the age of around 3 years. Some exposure to a range of microbes appears protective against the development of pathological allergies; these are less common in children living in close proximity to domesticated animals and exposed to water-borne microbes [67].

Antibiotic therapy and indeed just being in hospital can change the gut microbiome in a possibly harmful way. The study of these features has largely not reached the stage where cause and effect can be attributed to the presence or deficiency of particular communities of microorganisms and the appearance of a disease state in the human host. Still less can any attributions be made that a therapeutic effect can be achieved by the manipulation of the microbiome by the administration of probiotic substances, direct introduction of desirable species, or reduction of undesirable ones by antibiotic or phage

agents. There is a growing volume of research addressing these questions and undoubtedly this new knowledge will be translated into novel medical interventions. For now, most research is geared towards finding possible associations between diseases and the composition of the microbiome. Infants are much more susceptible to infection by *Salmonella*, *Campylobacter* and pathogenic *E. coli* strains than are adults.

KEY POINTS: DEVELOPMENT OF THE MICROBIOME

- *In utero*, the bowel is sterile. The microbiome develops rapidly after birth
- The microbiome differs between breast-fed and bottle-fed infants
- Alteration of the normal microbiome may affect development of postnatal complications, e.g. necrotizing enterocolitis

Necrotizing enterocolitis

Necrotizing enterocolitis (NEC) is the most common gastrointestinal disorder in the neonate. Despite its frequency, and a large volume of research, the causes remain obscure [68]. It is much more prevalent in premature babies, affecting about 10% of babies born weighing less than 1500 g, and the more prematurely the baby is born, the more likely it is to develop NEC. The condition is unusual in babies born later than 35 weeks' gestation. When it does occur in a term neonate, the onset is typically within a few days, but may be several weeks after birth in very premature babies.

It is attractive to ascribe an infective cause and it is true that in advanced severe cases, the clinical picture is of sepsis. Cases also sometimes cluster, suggesting an epidemic etiology. However, it is clear that no one particular organism is responsible. Many cases of NEC show heavy gut colonization with clostridia, but these bacteria are commonly found in healthy babies and this finding is not universal. In a breast-fed infant, bifidobacteria tend to predominate, and counts of these species are lower in NEC cases; possibly giving probiotics to enhance their growth may be protective [69]. Breast milk has a protective effect against NEC and contains anti-inflammatory substances, sometimes in higher concentrations in the milk of mothers of premature babies [70]. The gut of the preterm infant has an increased expression of Toll-like receptor 4 (TLR-4) which clearly plays a role in normal gut development. It may be that endotoxin from gram-negative bacteria binds to TLR-4 and produces an exaggerated inflammatory response via a number of different cytokine intermediaries, which culminates in gut ischemia, bacterial translocation, and systemic sepsis [71].

The clinical picture is often of a premature baby who may initially progress well on enteral feeds but then becomes feed intolerant and may have abdominal distension and vomiting. Apneas are common, and the baby may seem lethargic or appear to be uncomfortable. Radiographs may show dilated bowel loops and gas in the gut wall or, if the condition progresses to full-thickness ischemia and intestinal perforation, free gas in the peritoneum. Systemic signs may be hypothermia, acidosis, and other electrolyte disturbances, and eventually cardiovascular collapse and multiorgan failure.

Treatment consists of resting the gut (PN may be required), general supportive measures and antibiotic therapy, and celiotomy if the condition worsens. Sections of ischemic gut may have to be resected, and stoma formation may be necessary. Mortality remains high, up to 50% in babies weighing less than 1500 g at birth. Survivors may suffer later complications from short gut or malabsorption disorders.

KEY POINTS: NECROTIZING ENTEROCOLITIS

- NEC is a common cause of gastrointestinal illness in neonates, especially in those who are preterm
- Mortality increases with decreasing gestational age and may be as high as 50%
- Breast-fed infants may have some protection against NEC

Developmental physiology of the renal system

Developmental abnormalities of the kidney and urinary tract are the most common cause of childhood renal failure in the United States [72]. Defects occur in as many as 1:100 livebirths and range from benign, asymptomatic duplications to lethal conditions such as bilateral renal agenesis [73].

Embryology and development

Kidney and urinary tract

The definitive kidney has two embryonic precursors: the pronephroi and the mesonephroi. Although ultimately both degenerate, they are essential for normal renal development. The pronephroi arise from intermediate mesoderm early in the 4th week and are rudimentary, non-functional kidneys composed of simple tubules in the neck region [72]. The pronephroi drain into bilateral ducts, precursors of the Wolffian (nephrogenic) ducts, which elongate caudally to fuse with the cloaca. The mesonephroi develop caudally to the pronephroi at the end of the 4th week. They comprise well-developed nephrons and vascular glomeruli that drain into the Wolffian duct and function as interim kidneys for about 4 weeks. They regress at the end of the first trimester although they have several adult derivatives in the male [74].

Development of the permanent kidneys begins early in the 5th week. A diverticulum known as the ureteric bud arises from the caudal end of the mesonephric duct and is the precursor of the ureter and renal collecting system (Fig. 9.9). It penetrates a specialized area of intermediate mesoderm at the level of the hindlimb termed the metanephric mass, which is the precursor of the renal parenchyma. The ureteric bud elongates to form the ureter and branches to form calices and collecting tubules. The end of each collecting tubule induces cells of the metanephric mass to form vesicles that elongate to become definitive tubules (Fig. 9.10).

Nephron development commences around the 8th week. It occurs in a centrifugal pattern with cortical nephrons

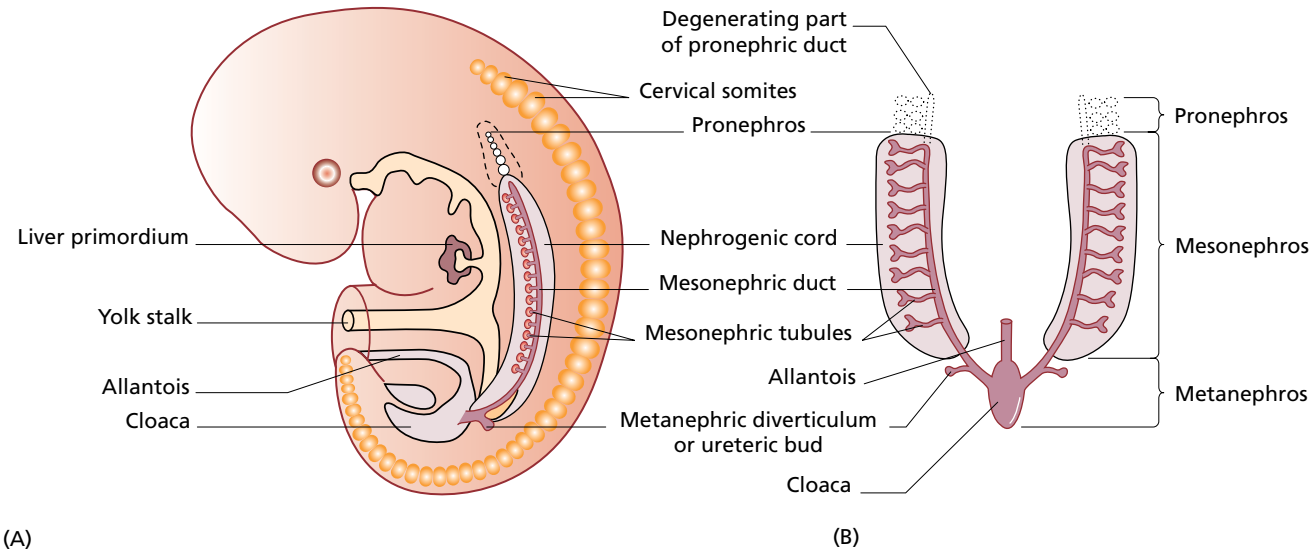

Figure 9.9 The three sets of excretory systems in an embryo during the 5th week. (A) Lateral view. (B) Ventral view. The mesonephric tubules have been pulled laterally; their normal position is shown in (A). *Source:* Reproduced from Moore and Persaud [74] with permission of Elsevier.

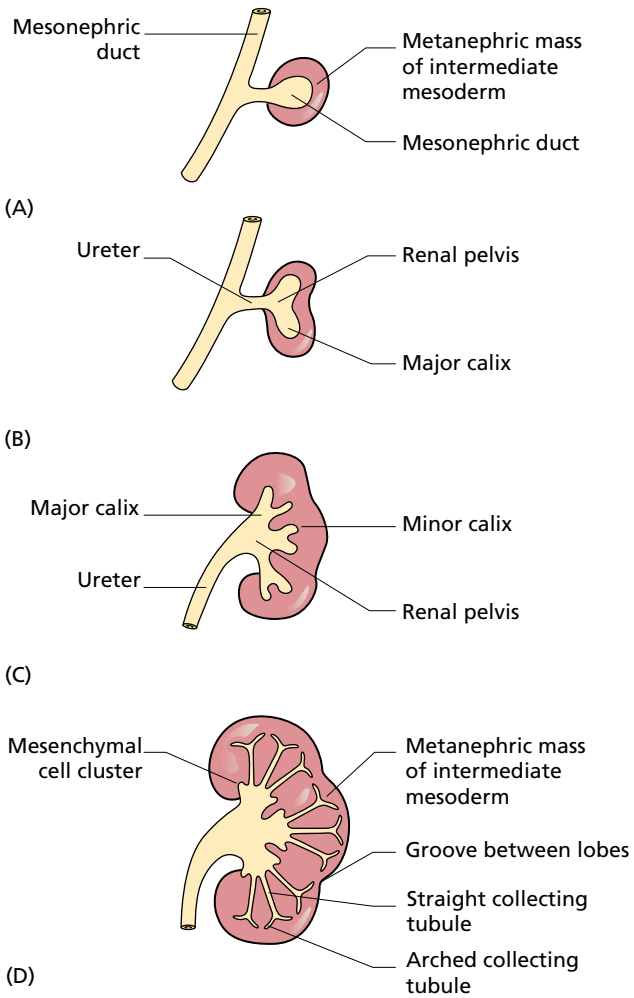

Figure 9.10 Development of the permanent kidney. (A–D) Successive stages in the development of the metanephric diverticulum or ureteric bud (weeks 5–8). formed after juxtamedullary ones. The rate of development increases rapidly after 18 weeks' gestation and is complete by 34–36 weeks, with each kidney possessing between 800,000 and 1,000,000 nephrons [75]. Renal growth after this is mainly due to elongation of the proximal convoluted tubule and an increase in interstitial tissue. Abnormalities in ureteric bud induction of nephrogenesis underlie many congenital defects; details of common ones are given in Table 9.1. Premature and low-birthweight infants have fewer nephrons, leading to high nephron filtration rates and glomerular hypertrophy [78]. Low nephron numbers are clearly associated with the development of hypertension, cardiovascular disease, and increased susceptibility to renal disease in later life [79,80].

Urinary bladder

The cloaca is partitioned by the urorectal septum into a ventral urogenital sinus and dorsal rectum. The bladder arises mainly from the vesical part of the urogenital sinus, with the trigone derived from the caudal ends of the mesonephric ducts. As the ducts are incorporated, so the ureters come to open into the bladder, their orifices moving superolaterally as a result of "traction" from the ascent of the kidneys. The bladder is initially contiguous superiorly with the allantois (a vestigial structure) which constricts to become the urachus, represented in adults by the median umbilical ligament. If fetal bladder emptying is obstructed, the urachus may remain patent, allowing urine to leak out around the umbilicus.

Renal migration and blood supply

The kidneys initially lie close to each other in the pelvis and attain their abdominal, retroperitoneal adult position by the 9th week. This apparent migration is due to embryonic growth caudal to the kidneys rather than movement of the kidneys themselves, and abnormalities in this process are common (see Table 9.1).

Table 9.1 Common abnormalities of the urinary tract and their embryological origins

Condition	Embryological etiology	Clinical effects
Renal agenesis	Failure of ureteric bud to contact metanephric mesoderm	Unilateral – 1:1000 livebirths. Usually detected incidentally, may be associated with higher risk of chronic kidney disease in later life
	Complete involution of a severely dysplastic kidney	Bilateral – 1:10–30,000 livebirths. Absence of fetal urine leads to oligohydramnios sequence (see text). Usually fatal
Urinary tract duplication	Ureteric bud division	Bifid ureter with either a divided kidney or a supernumerary kidney
	Duplication of ureteric bud	Two ureters each with their own kidney on the affected side
Renal ectopia	Arrested or aberrant migration ± fusion while kidneys lie in fetal pelvis	Pelvic kidney – unilateral failure to ascend. No symptoms but may be confused with tumors or damaged during surgery
		Crossed renal ectopia – one kidney migrates to contralateral side. May occur with fused kidneys
		Discoid or "pancake" kidney – complete fusion in pelvis. Kidney mass lies above bladder with short ureters
		Horseshoe kidney – 1:500 livebirths (7% of those with Turner syndrome). Fusion of kidney poles (usually inferior). U-shaped kidney lies in hypogastrium as normal ascent is prevented by root of inferior mesenteric artery. Usually no symptoms
Dysplastic or hypoplastic kidneys	Failure of induction of nephrogenesis by the ureteric bud	From small kidneys with low numbers of normal nephrons to normal-sized kidneys with a wide variety of tubular defects. Dysplastic kidneys may also be multicystic – these often involute spontaneously *in utero* or the first few years of life. Together, the most common cause of established renal failure worldwide. Molecular mechanisms are being elucidated [76]
Wilms tumor	Nephrogenic rests: abnormal structures arising from failure of mesenchyme differentiation	Kidney malignancy affecting 1:10,000 children. Nephrogenic rests are found much more frequently in children with Wilms tumors [77]

Renal arteries and veins start as branches of the common iliac vessels; as the kidneys ascend, they receive new branches from successively more superior points of the aorta and inferior vena cava. Inferior vessels usually degenerate but their persistence explains much of the variation seen in the renal vasculature. A single renal artery to each kidney is present in only 75% of adults, and 25% of kidneys have two to four accessory arteries [81]. These usually drain into the hilum but accessory arteries may be end-arteries, rendering portions of a kidney vulnerable to ischemia, and those to the lower pole may obstruct the ureter and cause hydronephrosis [82].

Fetal urine production and the oligohydramnios sequence

Urine production by the fetal kidney begins by week 10 and is responsible for 90% of amniotic fluid volume by week 20. Production increases from 0.1 mL/min at 20 weeks to 1 mL/min at 40 weeks' gestation, which is far in excess of urine production rates in the term neonate [83]. Fetal urine production may be measured by ultrasound and in cases of uteroplacental insufficiency low values predict adverse perinatal outcomes [84]. The absence of adequate amniotic fluid gives rise to the oligohydramnios sequence. Characteristic facial features, known as Potter's facies, include micrognathia, wide-set eyes, flattened nasal bridge, and large, low-set ears which lack cartilage [85]. Skeletal anomalies associated with oligohydramnios include club feet, hip dysplasia, scoliosis, torticollis, and contractures. Amniotic fluid is also essential for normal lung development; pulmonary hypoplasia is the main reason for the high mortality associated with significant oligohydramnios [86]. The fetus swallows significant volumes of amniotic fluid daily which is absorbed by the intestine. However, fetal waste products are transferred across the placenta for excretion by maternal kidneys. The kidneys do not assume their excretory role until after birth (see Table 9.1).

Developmental physiology

Glomerular filtration

Glomerular filtration is the process whereby water and solutes cross the glomerular membrane. Ultrafiltrate is virtually identical to plasma apart from containing very little protein. The rate of ultrafiltration is governed by four factors: the balance of Starling forces across the capillary wall; plasma flow rate; glomerular capillary wall permeability; and total surface area of the capillaries.

Quantifying glomerular filtration rate (GFR) is important for the rational prescribing of drugs and in monitoring chronic kidney disease. Comparing direct measurements from small infants to adults requires scaling to a standard of reference. Although kidney weight cannot be directly measured, both kidney weight and absolute GFR correlate well with body surface area (BSA). Adjusting GFR for BSA removes the variability caused by the variation in pediatric body size [87]. BSA in children and adolescents may be calculated from the formula [88]:

$$\mathrm{BSA}\left(\mathrm{m}^2\right) = 0.024265 \times \mathrm{Weight}^{0.5378} \times \mathrm{Height}^{0.3964}$$

The most common method of measuring GFR is based on the concept of clearance. The renal clearance of a substance x (C_x) is expressed by the formula:

$$C_x = U_x V / P_x$$

where U_x is the urine concentration, P_x the plasma concentration, and V the urine flow rate. If a substance is freely filtered and not metabolized, synthesized, or transported by the kidney then its clearance is equal to GFR.

Despite the importance of GFR, accurate measurement remains problematic. Renal clearance of inulin is still the gold standard in all age groups. However, its utility is compromised by availability, difficult assays, and the practical problems of collecting urine samples in children. Urine volumes

are inaccurate in the presence of vesicoureteric reflux and conditions that preclude complete voiding [89]. Creatinine is freely filtered and secreted by tubular cells but measurements are affected by diet and muscle mass. Furthermore, extrarenal clearance of creatinine is markedly increased in the presence of renal dysfunction so GFR tends to be overestimated [90]. Radiolabeled isotopes are accurate but not ideal agents in children, particularly for repeated assessments.

More recent approaches have used alternative markers. Iohexol is a non-ionic contrast agent already used at higher doses for radiological procedures even in the presence of renal dysfunction. Cystatin C is an endogenous cysteine protease inhibitor that is produced constantly and freely filtered, independent of inflammatory conditions, sex, muscle mass, and age above 1 year. Equations utilizing iohexol plasma clearance and serum cystatin C appear very accurate, but these assays are not widely available [91]. Iohexol may be accurately quantified from blood spots on filter paper, which may facilitate late sampling by patients at home and the use of iohexol as an epidemiological tool [92].

The Schwartz formula is commonly used to calculate GFR in children and has undergone several iterations to incorporate both newer biomarkers and more accurate laboratory assays [93]. The full Schwartz equation uses iohexol plasma clearance as its gold standard and now incorporates serum creatinine, blood urea nitrogen, cystatin C, height, and gender. A simpler bedside version, utilizing only height and creatinine, shows reasonable accuracy but the association with measured GFR is poorer and the rate of disease progression overestimated. For accurate GFR estimation utilizing endogenous markers, the complete Schwartz equation is to be recommended [94,95].

Glomerular filtration begins in the fetus during the 9th week. GFR reaches 12 mL/min/1.73 m^2 in the premature infant at 30 weeks and 20 mL/min/1.73 m^2 by term. Maturation continues rapidly in the postnatal period with a doubling of GFR by 2 weeks, a proportional rise that is seen in both premature and low-birthweight babies [96,97]. Adult values of GFR (corrected for BSA) are reached by 18–24 months of age [98]. Low GFR is primarily mediated by vasoconstriction through the renin–angiotensin system (see section "Control systems") and may represent a necessary adaptation to prevent excessive fluid and electrolyte loss secondary to tubular immaturity [99].

Tubular function

Sodium

Fractional excretion of sodium (FE_{Na}) falls from 12.8% at 30 weeks to 3.4% at 38 weeks and 1% in the normal adult [100]. Prematurity is associated with significant salt wasting and a risk of hyponatremia. Term neonates have a limited capacity both to conserve sodium necessary for growth and to excrete a sodium load. Excessive administration of sodium to term neonates may cause extracellular volume expansion, edema, and significant hypernatremia with serious short- and long-term consequences [101,102]. Sodium excretion usually exceeds oral intake (breast or formula milk) in the first few days of life, leading to negative sodium balance with associated weight loss. As FE_{Na} falls further and oral intake increases, birthweight is regained in 5–7 days. The ability to excrete a sodium load matures by around 1 year [103].

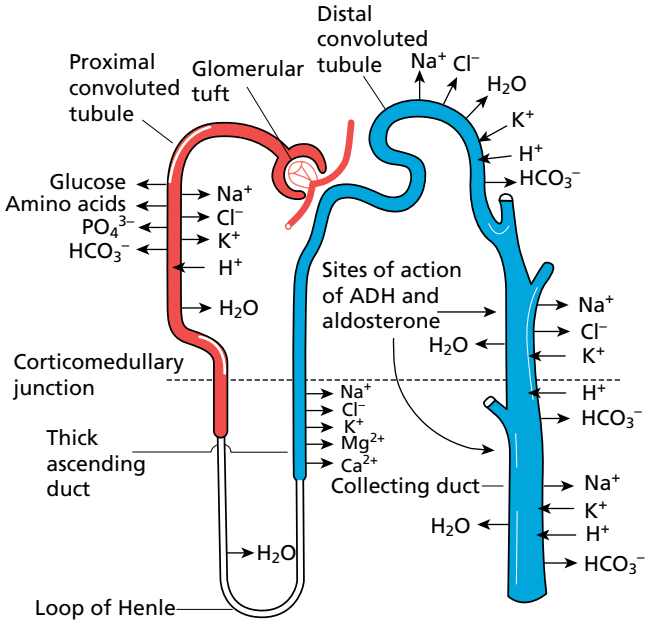

Figure 9.11 Excretion and reabsorption of water and electrolytes. Water is reabsorbed in the proximal tubule together with glucose, amino acids, phosphate, sodium, and bicarbonate, and from the distal nephron under the influence of antidiuretic hormone and the hypertonic medulla. In the distal tubule sodium is reabsorbed under the influence of aldosterone with associated excretion of potassium and hydrogen ions. *Source:* Reproduced from Cumming and Swainson [160] with permission of Elsevier.

Sodium is reabsorbed along the entire nephron length via different mechanisms. A key component is the Na-K-ATPase enzyme, located on the basolateral membrane of tubular cells, which actively transports sodium out of the cell into interstitial fluid and the peritubular capillaries, creating an electrochemical gradient for the movement of sodium out of the tubular lumen (Fig. 9.11). This movement often occurs via specific transporter proteins to which the transfer of many other electrolytes and compounds is coupled. In the neonate, reabsorptive mechanisms in both the proximal and distal convoluted tubule are immature and, despite reduced sensitivity to mineralocorticoids, aldosterone is essential for adequate sodium retention [104].

Water

Infant nutrition is entirely liquid, so a high urine flow rate is necessary to maintain fluid balance. This is achieved with a high fractional excretion of water (FE_{H2O}). Water reabsorption in the proximal convoluted tubule is isotonic. Neonates have reduced plasma protein, so the hydrostatic and osmotic forces acting from lumen to capillary are reduced, resulting in decreased proximal water reabsorption. Distally, water reabsorption is under the influence of antidiuretic hormone (ADH), to which even preterm babies are sensitive. Neonates are able to adjust water excretion appropriately from day 2 of life and can achieve FE_{H2O} of up to 13% (a similar value in adults would produce 20 L of urine per day) [105].

While minimum urine concentration equals adult levels of 50 mmol/kg at birth, maximum urine concentration is only 600–800 mmol/kg, which is about half that of older children. This reflects both shorter loops of Henle and reduced tonicity of the medullary interstitium (urea levels are low, reflecting

the anabolic state of the growing infant). Assuming a solute load of 10–15 mOsm/kg, the minimum urine flow rate required to prevent solute retention is 25 mL/kg/day [106]. This approximates to 1 mL/kg/h and is the basis for the use of this figure as an indication of renal failure.

Potassium

The immature kidney has a reduced capacity to excrete potassium; neonates excrete 9% of the filtered potassium load whereas children and adults excrete around 15%. The main site of potassium excretion is the distal convoluted tubule and cortical collecting ducts. Aldosterone acts on the principal cells of these regions to enhance the activity of the Na-K-ATPase pump on the basolateral membrane, which elevates intracellular potassium. It also increases the permeability of the luminal membrane to potassium, thus promoting its excretion. Aldosterone levels are high in infants but the cellular response is attenuated. In addition, lower tubular flow rates lead to higher potassium concentrations, reducing the gradient for diffusion. Normal values are achieved by around 3 months of age. The reduced ability of infants to excrete potassium is only likely to be of significance in cases of excess administration or pathological cellular release, where hyperkalemia may ensue more rapidly [107].

Glucose

Glucose is completely reabsorbed in the early portion of the proximal convoluted tubule by a stereo-specific transporter protein. The process involves secondary active transport and is saturable (see Fig. 9.11). Term infants have a threshold for glucose that is equal to older children and adults when corrected for GFR. However, premature infants demonstrate significant glucose wasting, which may be due to reduced nephron numbers, reduced basolateral Na-K-ATPase pump activity, or changes in the expression and density of the transporter proteins [108].

Phosphate

Rapid growth requires the normal infant to be in positive phosphate balance; plasma phosphate is high *in utero* and in infancy and decreases with age. Neonates demonstrate a reduced fractional excretion of phosphate that is not attributable to reduced load from a lower GFR. Rather, the immature kidney has an increased ability to reabsorb phosphate in both the proximal and distal convoluted tubules that is independent of parathyroid hormone activity and dietary phosphate. Growth hormone may have a regulatory effect, suggesting that this represents an appropriate physiological response to the need for phosphate, rather than an immature system [109].

Acid–base balance

Neonates have a reduced capacity to maintain acid–base status for several reasons including a reduced ability to reabsorb bicarbonate, secrete organic acid, and produce ammonia and a low level of titratable acid, specifically phosphate. However, the ability to acidify urine is acquired by 1 month, even in premature infants, suggesting that distal tubular hydrogen ion secretion is inducible independent of the gestational age of the kidney [110].

Bicarbonate is usually 85–90% reabsorbed in the proximal convoluted tubule, an energy-dependent process requiring the secretion of hydrogen ions in exchange for sodium. The renal threshold for bicarbonate (the level at which it appears in the urine) is 18 mEq/L in the premature infant, and approximately 21 mEq/L in the term neonate, rising to adult levels of 24–26 mEq/L by around 1 year [111]. Decreased bicarbonate reabsorption may be due to immature luminal Na-H antiporters or a reduced activity of the Na-K-ATPase pump which lowers the driving force for sodium. The main site of hydrogen ion secretion is the distal convoluted tubule, which in maturity can excrete hydrogen against a gradient of as much as 1000:1 (compared to gradients of 4–10:1 by secondary active transport in the proximal convoluted tubule) [112].

Amino acids

Infants demonstrate a transient physiological aminoaciduria in the first few weeks of life. This is unlikely to represent a generalized disorder as not all are wasted to a similar degree [113]. Amino acids are freely filtered at the glomerulus; adults reabsorb 98–99% in the proximal convoluted tubule, against a concentration gradient, using secondary active transport across the luminal membrane and facilitated diffusion across the basolateral membrane (see Fig. 9.11). These specific transport systems exist from birth but do not function at full capacity for reasons that remain unclear [114]. Neonates and infants are more susceptible to dietary protein inadequacies. For example, taurine is important for retinal development and has been shown to be low in plasma of low-birthweight infants receiving PN without supplementation [115].

Control systems

Plasma renin is high in the fetus and is approximately twice adult levels at term. Levels increase for the first few weeks of life and then start a gradual decline until adult levels are reached at around 6–9 years of age. As renin is the rate-limiting step in angiotensin II (AII) production, levels of the latter follow a similar pattern. AII has important trophic effects on the developing renal system. Maternal administration of angiotensin-converting enzyme inhibitors (ACEi) during the second and third trimesters results in renal dysplasia, renal failure, oligohydramnios, and pulmonary hypoplasia [116]. AII is a potent systemic vasoconstrictor in adults; it reduces renal blood flow but preserves GFR by constriction of efferent arterioles. This pressor response is present but reduced in neonates, possibly due to high occupancy of AII receptors by existing high levels of AII. Prostaglandins are the most important counterbalance to AII and mediate afferent arteriole dilatation.

Renal blood flow

The proportion of cardiac output distributed to the kidneys is 2.5–4% in the fetus, 6% by 24 h of life, 8–10% by 1 week, and 15–18% by 6 weeks. Effective renal plasma flow reaches adult levels (corrected for BSA) by 12–24 months [117]. The neonatal kidney can autoregulate its blood flow at appropriately lower systemic perfusion pressures although the response appears to be less efficient. Intrarenal blood flow is distributed differently, with a higher proportion of neonatal blood flow going to juxtamedullary nephrons, leaving cortical nephrons at higher risk of ischemia. The rise in renal blood flow with

maturation is probably due to alterations in cardiac output, perfusion pressure, and renovascular resistance. While AII seems important in maintaining a basal tone, other neurohumoral agents also play a role, including ADH, atrial natriuretic peptide, adenosine, and endothelin [118].

Pediatric renal disease

Acute kidney injury

The Kidney Disease: Improving Global Outcomes (KDIGO) guidelines define acute kidney injury (AKI) as an abrupt decrease in kidney function that occurs over a period of 7 days or fewer [119]. It is characterized by the inability of the kidney to fulfill its excretory functions and manage fluid and electrolyte balance appropriately. Causes of AKI may be divided into prerenal injury, intrinsic renal disease, and obstructive uropathies (Table 9.2). Etiology is age dependent: cortical necrosis and renal vein thrombosis are more common in neonates, whereas hemolytic uremic syndrome (HUS) is more common in young children, and rapidly progressive glomerulonephritis (RPGN) is generally found in older children and adolescents.

AKI in hospitalized children is likely to be multifactorial, with prerenal as well as hypoxic/ischemic and nephrotoxic insults being important; those at risk include children with sepsis, those receiving stem cell transplants, those undergoing cardiopulmonary bypass or extracorporeal membrane oxygenation (ECMO), and low birthweight/premature neonates [120].

Epidemiological study has mainly considered acutely ill children in single-center studies and has been limited by the lack of a standardized definition of AKI. Nonetheless, over the last two to three decades there appears to have been a shift in etiology from primary renal disease to systemic illness as the leading cause of AKI. The overall incidence is also increasing, reflecting increased use of invasive management and a higher illness severity of critically ill children [121]. The first attempt at a standard definition came from the Acute Dialysis Quality Initiative group with the RIFLE criteria [122]. These criteria have subsequently been modified three times: the paediatric version of the RIFLE criteria (pRIFLE), the Acute Kidney Injury Network (AKIN) classification, and lastly the KDIGO guidelines [119,123,124]. All use serum creatinine as their biomarker and the clinical measure of urine output. When applied to a paediatric ICU population all three performed well but produced differences in both incidence (between 37% and 51%) and staging [125]. Whilst all have their relative merits the need to adopt a single definition remains.

The use of creatinine as a biomarker is pragmatic but inadequate. Creatinine is a measure of kidney function, not damage, and serum levels do not rise until 48–72 h following injury when significant damage has already occurred. More sensitive biomarkers are required to allow earlier diagnosis and timely implementation of protective and preventive measures. Most promising are panels of investigations including plasma cystatin-C, neutrophil gelatinase-associated lipocalin, urinary interleukin-18, and kidney injury molecule-1 [126].

Prerenal injury

Prerenal injury occurs when blood flow to the kidneys is reduced. If prolonged, this may result in a hypoxic/ischemic acute tubular necrosis. However, this process is not sudden and the insult is reversible provided the kidney is intrinsically normal [127]. Compensatory mechanisms include the relaxation of afferent arterioles under the influence of intrarenal prostaglandins, a response that may be impaired by administration of cyclo-oxygenase inhibitors. The use of these agents to promote ductus arteriosus closure in premature newborns carries a risk of renal insufficiency, although this appears less with ibuprofen than indomethacin [128].

Urinary parameters may assist in distinguishing prerenal from intrinsic renal injury. In response to decreased perfusion, functioning tubules will appropriately conserve sodium and water, producing concentrated urine with osmolality 400–500 mOsm/L, urinary sodium 10–20 mEq/L, and fractional sodium excretion of less than 1%. The renal tubules of neonates are relatively immature so corresponding values for renal hypoperfusion are osmolality >350 mOsm/L, sodium <20–30 mEq/L, and fractional excretion <2.5%.

Tubules that have sustained injury are unable to conserve sodium in this manner, producing dilute urine with osmolality <350 mOsm/L, sodium 30–40 mEq/L, and fractional

Table 9.2 Etiology of acute kidney injury in neonates and children

Type	Etiology
Prerenal	Decreased intravascular volume – dehydration – salt-wasting renal or adrenal disease – hemorrhage – third space losses – sepsis, trauma Renal hypoperfusion (with normal intravascular volume) – cardiac failure/tamponade – hepatorenal syndrome
Intrinsic renal disease	Acute tubular necrosis – ischemic/hypoxic injury – drug induced, e.g. aminoglycosides, contrast agents – toxins – endogenous, e.g. hemoglobin, myoglobin – exogenous, e.g. methanol, ethylene glycol Interstitial nephritis – drug induced, e.g. penicillins, NSAIDs, sulfonamides – idiopathic Rapidly progressive glomerulonephritis Vascular lesions – renal artery or vein thrombosis – cortical necrosis – hemolytic uremic syndrome Uric acid nephropathy and tumor lysis syndrome Congenital abnormalities – hypoplasia/dysplasia with or without obstruction – idiopathic – maternal drugs, e.g. ACEi, NSAIDs – polycystic kidney disease
Obstructive uropathy	Congenital malformations – posterior urethral valves – ureteroceles – vesicoureteric reflux – prune belly syndrome Acquired obstruction – kidney stones – tumors, e.g. sacrococcygeal

ACEi, angiotensin converting enzyme inhibitor; NSAIDs, non-steroidal anti-inflammatory drugs.

sodium excretion of >2%. However, these values require that initial tubular function was normal, and urinary indices are difficult to interpret in those with pre-existing renal disease or those who have received diuretics [129].

Intrinsic renal disease

Hypoxic/ischemic AKI is characterized by early vasoconstriction followed by patchy tubular necrosis, although the mechanism of cellular injury is not yet clear. ATP depletion occurs early and leads to disruption of the cytoskeleton and loss of cellular polarity, with Na-K-ATPase found on the luminal as well as the basolateral membrane. The same mechanism has been shown to contribute to kidney dysfunction in transplanted kidneys [130]. Alteration of vascular tone regulation by nitric oxide and endothelin, as well as the generation of reactive oxygen and nitrogen molecules, may also play a role [131].

Nephrotoxic injury may be caused by a wide variety of agents. Aminoglycoside toxicity is common and thought to be related to lysosomal dysfunction of proximal tubules. The incidence is dose and duration dependent, but is reversible once therapy is discontinued. Hemoglobin or myoglobin in urine produces tubular injury via several mechanisms, including vasoconstriction, precipitation in the tubular lumen, and/or heme protein-induced oxidant stress [132].

Uric acid nephropathy and tumor lysis syndrome are most commonly seen in children with acute lymphocytic leukemia and B-cell lymphoma. The pathogenesis is complex, but an important mechanism relates to the precipitation of uric acid crystals in either tubules or the renal vasculature. The rapid breakdown of tumor cells can also cause severe hyperphosphatemia with subsequent precipitation of calcium phosphate crystals also contributing to AKI. There is growing interest in the role uric acid may play in AKI associated with both heat injury and other etiologies [133].

Prognosis

AKI is far from a benign diagnosis: its presence has been associated with marked mortality increases in paediatric ICU patients with a wide variety of diagnoses. It is also associated with increased length of stay both within and outside an ICU setting [120,125]. In survivors, although clinical recovery of renal function occurs in most cases, one study revealed that 34% of 176 children had reduced renal function or were dialysis dependent on discharge from a tertiary center after an episode of AKI [134]. It appears that histological repair is often incomplete and a progressive focal tubulointerstitial fibrosis can be demonstrated [121]. Children who have apparently recovered from an episode of AKI remain at risk of subsequent renal impairment and this is true for all ages and all conditions [135,136]. The term acute kidney disease has been proposed to define the clinical course following AKI in patients in whom the pathophysiological processes are still active [137].

Chronic kidney disease

Chronic kidney disease (CKD) is defined as abnormalities in kidney structure or function that persist for more than 90 days. The main cut-off value for GFR is less than 60 mL/min/1.73 m^2 although there is some suggestion that a value of <75 mL/min/1.73 m^2 would be more appropriate for children older than 2 years, adolescents, and young adults [138]. CKD is characterized by progressive decline in renal function associated with significant morbidity and mortality. It may present at any age from the antenatal period onwards; because of the renal role played by the placenta, even lethal malformations may not result in biochemical disturbance for several days. Causes of established renal failure (ERF) are given in Table 9.3 [139].

Table 9.3 Etiology and prevalence of established renal failure in children in the UK

Etiology	Percentage
Renal dysplasia with or without reflux	35
Obstructive uropathy	19
Glomerular disease	11
Congenital nephrosis	10
Tubulointerstitial disease	7
Renovascular disease	5
Polycystic kidney disease	4
Metabolic	4
Uncertain diagnosis	3
Malignancy and associated disease	2
Missing from registry	1

Cardiovascular disease is much more common in children with ERF than age-matched controls, and accounts for up to 30% of deaths in children undergoing dialysis [140]. Growth retardation is proportional to the decrement in GFR, and is more common in children undergoing dialysis than those being treated conservatively or with a transplant. Factors contributing to poor growth include metabolic acidosis, renal osteodystrophy, malnutrition, glucocorticoid therapy, and reduced responsiveness to growth hormone. Catch-up growth after transplant is poor with 60% of children with CKD having short stature in adulthood. Daily dialysis regimes and use of recombinant growth hormone (rGH) may ameliorate matters although clinical response to rGH is not always maintained and there are concerns about its post-transplant use precipitating rejection [141]. A variety of neurocognitive deficits have been identified, from severe developmental delay to more subtle verbal and attention deficits; improvements in dialysis, correction of malnutrition, and decreased aluminum exposure have improved outcomes [142].

Treatment of CKD in children is not easy; dialysis and the access it requires pose particular problems (see Chapter 30). Only one clinical trial that looked at strict blood pressure control has demonstrated any means of modifying disease progression [143]. Novel urinary and serum biomarkers to quantify and monitor CKD are being investigated and these may assist in developing new treatments [144].

Polycystic kidney disease

In children, polycystic kidney disease mainly consists of two hereditary diseases: autosomal dominant polycystic kidney disease (ADPKD), and autosomal recessive polycystic kidney disease (ARPKD). Worldwide, ADPKD is the most common hereditary renal disease, affecting 1:400–1000 livebirths, but only around 2% of cases present in childhood. By contrast, ARPKD affects 1:10,000–40,000 livebirths but is a disease of children, so the prevalence of each in pediatric practice is

approximately equal [145]. In ADPKD epithelial-lined cysts arise from about 5% of tubules and detach from the parent tubule (usually at about 2 cm). There is massive enlargement of the kidneys secondary to cyst growth and progressive renal impairment. Associated features include hepatic cysts and intracerebral aneurysms. In ARPKD renal cysts arise from the distal collecting duct and cause progressive renal impairment without renal enlargement. Congenital hepatic fibrosis is a universal feature, although renal symptoms are more common in early life and hepatic complications later. In older children, features of hepatic fibrosis and portal hypertension tend to dominate the clinical picture; combined renal and hepatic transplantation is used successfully [146].

ADPKD is caused mainly by two genes: *PKD1* on chromosome 16 encoding the transmembrane protein polycystin 1 (85% of cases), and *PKD2* on chromosome 4 encoding polycystin 2. ARPKD is caused by mutations of the *PKHD1* gene on chromosome 6 which encodes a protein polyductin. All three proteins have been found in primary cilia where they appear to interact and share intracellular signaling pathways that alter intracellular calcium and cAMP levels. Elucidation of these pathways has given rise to new therapeutic strategies. Tolvaptan is a vasopressin V2 receptor antagonist that lowers cAMP in cystic tissues. It is effective at reducing the progression of cystic kidney disease in adults and a trial is ongoing in children [147]. Manipulation of the renin–angiotensin system and the use of pravastatin are also being investigated in this population [148].

Renal cysts also occur in other disease states. Nephronophthisis (NPH) is a chronic tubulointerstitial nephritis. The infantile form is characterized by cortical microcysts and progression to ERF by 5 years of age, whereas cysts occur much later in the juvenile form [149]. Up to 20% of patients with tuberous sclerosis complex (TSC) will have multiple, bilateral renal cysts. The gene *TSC2*, which accounts for around 75% of sporadic cases of TSC, is found within 48 base pairs of *PKD1* on chromosome 16.

Prune belly syndrome

Prune belly syndrome (PBS) occurs in 1:29,000 to 1:40,000 livebirths [150]. It is 20 times more common in males, four times more common in twins, and infants of younger mothers appear to be at greater risk [151]. The syndrome comprises a triad of abnormal abdominal muscles, bilateral cryptorchidism, and dilated ureters. It takes its name from the characteristic wrinkled and prune-like appearance of the abdominal wall in which normal musculature fails to develop [152]. Urinary tract abnormalities include a dilated, thick-walled bladder, tortuous, dilated and thick-walled ureters, and kidneys that may be hydronephrotic or dysplastic.

The mechanism by which PBS occurs remains unclear. Some theories emphasize early urethral obstruction which leads to bladder distension, degeneration of the abdominal wall musculature, and prevention of testicular descent. However, a more convincing theory proposes abnormal mesenchymal development, termed mesodermal arrest, between weeks 6 and 10 as the underlying abnormality. This is supported by findings of abundant collagen, smooth muscle, fibrous and connective tissue throughout the renal tract; these features are difficult to explain with a purely obstructive lesion [153].

Attempts can be made to alleviate lower urinary tract obstruction *in utero* with vesicoamniotic shunting or fetal cystoscopy, and scoring systems have been developed to target treatment appropriately [154]. Renal failure occurs in around 30% of children due to renal dysplasia and scarring secondary to infections. Dialysis is required earlier than in children with other causes of renal failure, and mortality is higher than in those with other obstructive uropathies [155]. The abdominal wall abnormalities do not appear to increase the complication rate associated with peritoneal dialysis if it is required [156].

KEY POINTS: THE RENAL SYSTEM

- Differences in renal function may result in abnormal electrolyte function and make neonates more subject to excessive fluid and electrolyte administration
- Neonates have reduced ability to correct acid–base abnormalities due to immature ability to resorb bicarbonate and secrete acids
- Glucose wasting is increased in preterm neonates due to reduced numbers of nephrons and glucose transporters. This may result in an osmotic diuresis and hypovolemia

CHAPTER 10
Pharmacology

Jean X. Mazoit
Département d'Anesthésie-Réanimation, Hôpitaux Universitaires Paris-Sud AP-HP, Paris, France

Introduction

Children are not small adults. Their body hydric content, and the partition between central and peripheral blood, their metabolic rates, their pulmonary volumes, and cardiac and hemodynamic variables markedly differ from those of adults. However, *children are also small adults* in that they have the potential of their future in their genes. Some phenotypic expression may be absent in the early life, but most genetic traits are fully expressed at birth.

Development of uptake, distribution, protein binding, metabolism, and excretion systems for drugs in the fetus, newborn, infant, and child [1]

Uptake, disposition, and elimination

Volumes, flows, and rates

Body composition differs markedly among neonates, infants, and adults (see Chapter 11). This is particularly important for total body water, which decreases from 80–85% of bodyweight in 26 and 31 weeks' gestation infants to 75% at full term and to 60% in adolescents. The extracellular compartment, which is mainly regulated by the sodium intake after birth, decreases from 65% of bodyweight at 26 weeks' gestation to 40% at full term and 20% by 10 years [2,3]. Therefore, the volume of distribution of hydrophilic drugs, e.g. succinylcholine, is higher in newborns and infants than in older children. Membranes are also immature at birth. For example, drug efflux systems are not fully mature at birth, making cerebral bioavailability of numerous hydrophobic (the term hydrophobic will be used instead of lipophilic throughout the text) drugs higher in newborns than in children or adults [4,5]. Cardiac output is also different and is closely related to body surface area. The volume of the central compartment of volatile anesthetics is higher in neonates than in adults on a weight basis.

Scaling

Until recently, the only way of correcting for these differences was to use the rule of three, i.e. to divide by 70 kg or 1.73 m^2 and multiply by the weight or surface area of the subject. Different approaches are used today [6–8]. Allometric scaling considers that extensive parameters, such as metabolic rates or clearances, are related to the corresponding adult parameters raised to an empirical power:

$$CL_{Ped} = CL_{Adult}\left(\frac{BW_{Ped}}{BW_{Adult}}\right)^{x}$$

where CL_{Ped} and CL_{Adult} are the pediatric and adult parameters respectively (clearance in this example) and BW_{Ped} and BW_{Adult} are the pediatric and adult bodyweights respectively; x is the empirical scaling factor. This approach has excellent predictive powers when incorporated in pharmacokinetic (PK) or pharmacodynamic (PD) models (Fig. 10.1) [9]. Allometric scaling cannot account for all the changes observed during development. Therefore, other approaches, such as physiological models, may provide more accurate results [7,10].

Uptake and absorption

The gastric pH rapidly increases from 1–3 to 5–7 immediately after birth and remains basic during the first month of life [11]. Gastric emptying and intestinal transit are also slower in

Gregory's Pediatric Anesthesia, Sixth Edition. Edited by Dean B. Andropoulos and George A. Gregory.

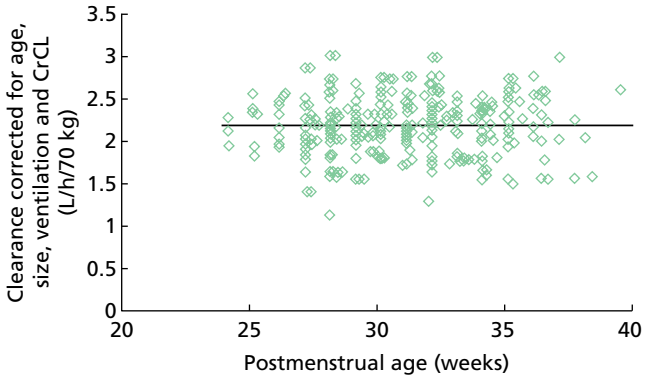

Figure 10.1 Predicted vancomycin clearances in individual premature babies. The data are standardized to a 70 kg person, using allometric scaling, and corrected for age and creatinine clearance (CrCL) (NONMEM). Simple covariates included in the model markedly decreased interindividual variability. *Source:* Reproduced from Anderson et al [9] with permission of John Wiley and Sons.

newborns than in infants and adults. The rate and extent of gastric and intestinal absorption are variable, due to immature membrane transport, pancreatic enzyme activity, and bile salt secretion. Oral medications may have erratic bioavailability and absorption rates in this age group. Also, the first-pass effect is often reduced in neonates due to immature liver metabolism. Consequently, drug potency may increase in some cases.

Absorption by other routes is often rapid in infants and children. For example, after topical anesthesia of the pharynx and larynx, peak concentrations of lidocaine may appear 2–4 min later [12]. Lidocaine toxicity has occurred following infiltration of the drug for laceration repair in young patients. Because the rate and extent of absorption depend on the drug and site of injection, this topic will be discussed in the PK section for each drug.

Transport of molecules across membranes: the effect of transporters

Drugs are small molecules that are susceptible to passive or active transport through biological membranes. Uptake and elimination transporters are found in all cell membranes [13,14]. Two superfamilies of transporters, the solute carrier (SLC) and ATP-binding cassette (ABC), control molecular traffic across membranes [4,15]. While SLC transporters are usually for uptake, some are involved in bidirectional transport. ABC transporters are efflux pumps that remove chemicals from the cell.

The organic anion transporting polypeptides (OATPs), the organic cation transporters (OCTs), and the organic anion transporters (OATs) are the principal solute carrier transporters. These membrane proteins are localized to the sinusoidal boundary in heart, liver, brain, kidney, and placenta. One SLC family, the multidrug and toxin extrusion transporters (MATEs), excretes oxaliplatin, cimetidine, metformin, and procainamide from cells.

ATP-binding cassette transporters comprise P-glycoprotein (P-gp), which is encoded by a variety of multidrug resistance (MDR) genes and the MDR-associated proteins. These are excretion pumps that transport endo- and xenobiotics such as unconjugated bilirubin and anticonvulsants. Like SLC transporters, these transporters are ubiquitous in the blood–brain barrier (BBB), blood–CSF barrier, gut and intestinal wall, hepatocytes, and renal tubular cells [16]. P-gp is located at the luminal membrane of endothelial and epithelial cells. P-gp appears in human brain as early as 22 weeks' gestational age (GA) and is almost totally mature at birth [17]. All these transporters are highly polymorphic. In conjunction with polymorphism of the 3A4 and 2C9/19 isoforms of the cytochrome P450 or of UDP-glucuronosyltransferase (UGT) 1A and 2B, polymorphism of P-gp increases resistance to most antiepileptic drugs (phenytoin, carbamazepine, phenobarbital, gabapentin, felbamate, topiramate, lamotrigine, valproic acid, diazepam, and lorazepam).

To date, little is known about the ontogeny of these transporters. The human fetal liver has only a small number of transporters. mRNA expression of SLC and ABC transporters increases from birth to 4 years of age and full expression is attained by 7 years [15,18]. Similar findings have been reported in the kidneys and gut.

P-gp has been detected as early as 22–26 weeks' human GA in some parts of the brainstem. By term, P-gp seems to be fully functional. Multiple drug resistance-associated protein 1 (MRP1) is detected in the fetus at 22–26 weeks' GA and has almost the same intensity as in adults. This is consistent with observations that the choroid plexus and tight junctions are mature before birth, which makes the blood–CSF barrier functional [5,16]. Lipids and possibly small hydrophobic molecules can cross the barrier with less selectivity until 6 months of age.

Disposition of drugs: transport in the blood and distribution

After either intravenous injection or administration by another route, drugs distribute within the body. Because cardiac output and the central compartment volume are larger than those of adults, distribution of drugs to target organs occurs more rapidly in young patients. Sophisticated models that tentatively explain the relationship between age, volumes, clearance, and the dose required to produce anesthesia have been described. However, population PK-PD models using age as a covariate and parameters such as the exit rate constant from the effect compartment (ke0) and the pseudo-steady-state concentration leading to half maximum effect (Cpss50 or Ce50) are now used to characterize the disposition of drugs from the central to the effect compartment and the resulting effect [19,20]. The ke0 is equivalent to the rate constant for transfer from the central compartment to the effect compartment at steady state. This parameter (or T½ke0, the corresponding half-life) is the best indicator of a drug's access rate to its target. It is directly related to time to peak action. Ce50 is the concentration of the drug in the (virtual) effect compartment and is approximated by Cpss50, the drug concentration in the effect compartment at steady state. Drugs also distribute in deeper compartments, depending on plasma and tissue protein binding, hydrophobicity, pKa, steric bulk, and clearance when steady state is not attained. This distribution process is important because it is the main factor that causes differences in delay of awakening after short or prolonged administration of drugs (volatile anesthetics, propofol). This has led to the concept of context-sensitive half-time [21]. In addition, distribution into deep compartments

(including gastric and bowel contents) may cause recirculation of drugs such as fentanyl when cardiac output and body temperature increase after surgery.

Protein binding

Many drugs are bound to serum proteins, mostly albumin (human serum albumin – HSA) and α1-acid glycoprotein (AGP). Acidic drugs such as thiopental (thiopentone) and propofol bind preferentially to HSA and basic drugs to AGP. Protein-bound molecules may or may not cross barriers depending on factors such as the nature of binding (rate of association–dissociation to the receptor) and the organ transit time [22,23]. In the liver, the presence of the space of Disse slows transit times. Clearance of drugs metabolized by the liver is frequently independent of protein binding [24]. In organs with rapid transit times, such as the brain and heart, protein binding often controls the amount of drug absorbed by the organ.

Serum albumin is the most abundant protein in plasma (approximately 0.6 mM). It contains three homologous helical domains (I–III) with binding pockets. HSA has two major high-affinity binding sites with association constants in the range 10^4 to 10^6 M^{-1} [24,25]. Site 1 binds warfarin, thiopental, propofol, and many other drugs. Site 2 binds endogenous carboxylic acids (eicosanoids, fatty acids), propofol, volatile anesthetics, and most non-steroidal anti-inflammatory drugs (NSAIDs), often in a stereospecific and allosteric manner (Fig. 10.2). Some metabolites of NSAIDs bind covalently, leading to permanent occupation of the site. Bilirubin also binds to multiple sites on HSA [26]. Drugs such as propofol can displace bilirubin, increase the amount of free bilirubin, and possibly produce kernicterus in newborns [27].

AGP, also called orosomucoid (ORM) is an acute-phase protein. At birth, AGP concentrations are about one-third to one-fourth adult concentrations and increase slightly over the next 9–12 months [28,29]. The first consequence of reduced AGP is increased free drug that can cross barriers (BBB, blood–heart), causing increased drug effects. The second consequence of the increased amount of free drug is a greater apparent total hepatic clearance than is expected for drugs with low hepatic clearance, e.g. bupivacaine. AGP has two to three high-affinity sites that mostly bind basic drugs [30,31]. However, some acidic drugs (e.g. phenylbutazone) and neutral drugs also bind to AGP. Three genetic variants (A, F1, and S) cause two main forms (F1S and A) that differently bind xenobiotics. During inflammatory processes, the AGP concentration and its affinity for drugs markedly increase. During the postoperative period, the AGP concentration almost doubles (Fig. 10.3). For drugs with low to moderate hepatic extraction ratios, such as bupivacaine, this may produce time-dependent changes in total clearance (but not in the intrinsic clearance of the free drug) after surgery (Fig. 10.4) [28]. Like most basic drugs, local anesthetics and phenylpiperidine opioids (fentanyl, sufentanil, alfentanil) are primarily bound to AGP.

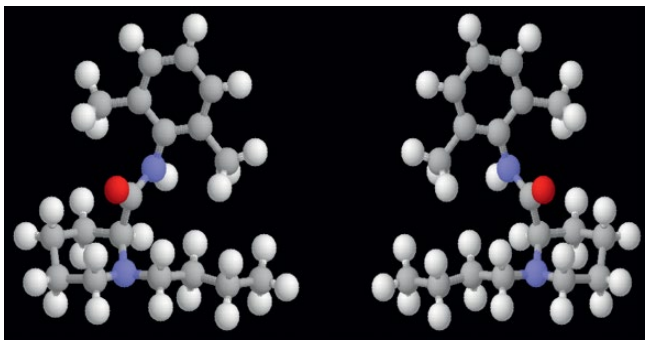

Figure 10.2 The two enantiomers of bupivacaine. The chiral carbon is at the center of the molecule. Numerous drugs such as volatile anesthetics, non-steroidal anti-inflammatory drugs, ketamine, etomidate, and local anesthetics have different stereoisomers, either true enantiomers with a chiral center or other isomers.

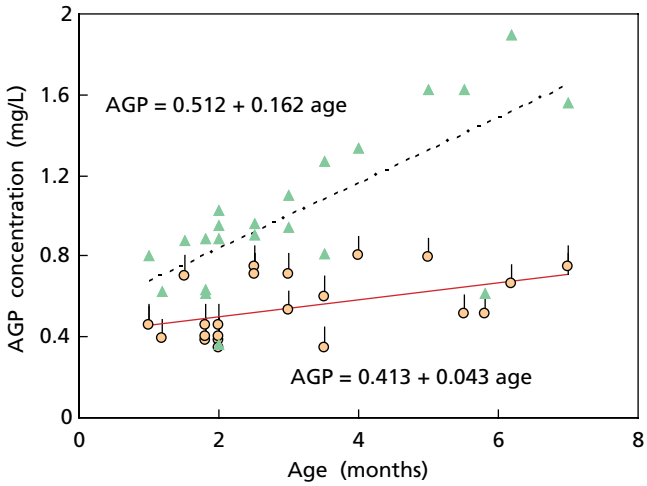

Figure 10.3 α1-Acid glycoprotein (AGP) concentrations in infants according to their age. AGP concentrations are very low at birth and progressively increase with age. The concentration of AGP increases rapidly after an inflammatory insult. Circles are individual values measured before surgery and triangles are the values measured 2 days later. AGP concentrations increased in all patients after surgery. *Source:* Reproduced from Meunier et al [28] with permission of Wolters Kluwer.

Protein–drug adducts

Binding of drugs to proteins may be entropy driven (passive phenomenon as with xenon) or enthalpy driven (usually exothermic) [32]. This causes strong binding of the drug (covalent, van der Waals forces). Covalent binding of drugs or their metabolites to tissue or plasma proteins produces mostly toxic protein–drug adducts [33]. These adducts often induce immunological reactions that cause hypersensitivity. The toxicity of halothane, paracetamol (acetaminophen), diclofenac, sulfonamides, and valproic acid is the result of adducts.

During cardiopulmonary bypass the concentration of unbound propofol increases significantly due to decreased protein binding [34]. This is probably true for most drugs with strong protein binding.

Metabolism and clearances including genetic polymorphism

Renal function

Renal function (glomerular filtration rate and tubular function) is immature at birth. Therefore, elimination of most renally excreted drugs and their active metabolites is impaired until 2–3 years of age. For example, theophylline and caffeine have very low clearances at birth. In the same way, morphine-6-glucuronide, which is an active metabolite of

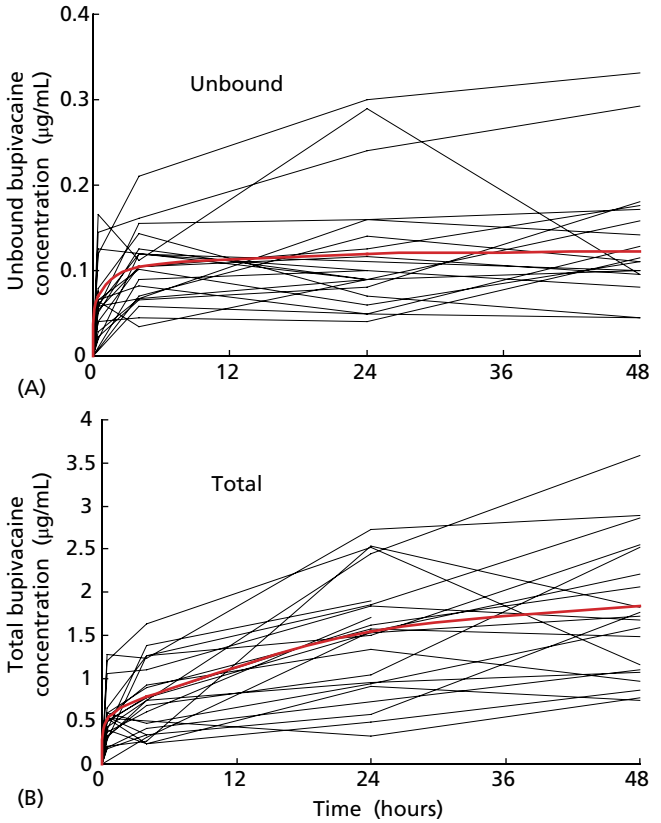

Figure 10.4 Unbound (A) and total (B) bupivacaine concentration in plasma after epidural administration (bolus at T0 followed by a continuous infusion of 0.375 mg/kg/h for 2 days). Black lines are individual data and red lines are population value fitted using NONMEM. The unbound concentration reaches steady state in less than 12 h, whereas the total concentration has not reached steady state 48 h after initiating the infusion. The continuous increase in α1-acid glycoprotein concentration caused by the inflammatory process increases protein binding. However, the unbound concentration, which is the toxic moiety, is at steady state because intrinsic hepatic clearance remains constant. *Source:* Reproduced from Meunier et al [28] with permission of Wolters Kluwer.

morphine, accumulates in premature and full-term infants, increasing the risk of respiratory depression [35,36]. Drugs such as aminoglycoside antibiotics may also be toxic. Prostaglandin concentrations are elevated in newborns to maintain an effective glomerular filtration rate. By blocking the effects of prostaglandins, NSAIDs may induce renal hypoperfusion and renal failure [3].

Hepatic metabolism [37–40]

Most drugs used for anesthesia, preoperative care, and pain control are metabolized by the liver. Hepatic metabolism of xenobiotics is by phase I and phase II reactions. Phase I reactions are characterized by microsomal oxidative metabolism that inactivates or sometimes activates the drug (Table 10.1). Phase II reactions involve conjugation and take advantage of the electrophilic properties of either the original drug or the product of phase I metabolism (Table 10.2) [39,40]. Phase II reactions occur mainly in the liver but can occur in the gut wall, the kidney parenchyma, and the lung. Enzymes involved in phase I reactions are located primarily in endoplasmic reticulum, while phase II conjugation enzyme systems are primarily cytosolic.

Cytochrome P450 is a family of enzymes located primarily at the centrilobular portion of hepatic lobules. CYP3A4 is the most abundant isoform (Fig. 10.5) [41–44]. Two factors characterize the importance of an isoform for metabolizing a given molecule: the capacity, i.e. the abundance of the enzyme; and the affinity and rate of metabolism (Km and vm in the Michaelis–Menten equation). Xenobiotics may be substrates for, inhibitors of, or inducers of the reaction and cause drug–drug interactions that have clinical consequences. Maturation of these enzymes is variable and occurs from early in intrauterine life to several years of age. For example, morphine elimination via UGT is impaired until 9 months of age [35,36,45] whereas fentanyl, which is metabolized by the CYP3A4/3A7 isoform of cytochrome P450, is adequately metabolized by very young preterm infants [46]. Ropivacaine metabolism by CYP1A2 is not fully mature before the age of 4–6 years [47].

Children are small adults

Individuals have the potential of their future in their genes. Some phenotypic expression may be absent early in life, but most genetic traits are fully expressed at birth. The most common factors influencing drug dosing are related to genetic polymorphism of metabolizing enzymes [48–54].

Polymorphism of CYP2D6 may increase rates of biotransformation of tramadol to the opioid receptor agonist O-desmethyl tramadol (M1) [55]. Codeine is also metabolized to morphine by CYP2D6 [56,57]. One death is suggested to have occurred when a breast-feeding mother extensively metabolized codeine to morphine postoperatively [58]. The increased amounts of morphine in breast milk caused severe apnea and death of the infant. Toxic events have been reported in infants and young children treated with codeine for more than one day, in children with renal failure [59], and also in children receiving tramadol after tonsillectomy [60]. On the other hand, about 5–8% of Caucasians and 20–25% of Japanese metabolize codeine poorly and do not obtain analgesic effects from the drug [61].

KEY POINTS: DEVELOPMENTAL DETERMINANTS OF PHARMACOLOGY

- Children are not small adults:
  - Their volumes, rates are different from those of adults
  - Transport of small molecules across membranes (e.g. the blood–brain barrier) is immature
- Children are small adults:
  - Genetic polymorphism is an important determinant of drug action and side effects, e.g. CYP2D6 duplication

Pharmacokinetics and pharmacodynamics of inhaled anesthetics

Gases and vapors were the first agents used for general anesthesia (ether in 1842, nitrous oxide in 1844, and chloroform in 1847). Their mechanism of action is far from fully elucidated,

Diazepam strongly inhibits the metabolism of morphine and codeine; ketamine inhibits the metabolism of morphine; ranitidine inhibits the metabolism of morphine and acetaminophen. Rifampin is an inducer of metabolism of codeine, morphine, acetaminophen, lamotrigine, propafenone. Phenobarbital (and possibly thiopental) and phenytoin are inducers of acetaminophen metabolism, which may enhance its toxicity.
(1) The lack of the 1A1 isoform induces the autosomal recessive Crigler–Najjar and Gilbert syndromes.

even today [62,63]. A thermodynamic effect on biological membranes has long been thought to be their mode of action. Now specific effects of these drugs on ion channels and receptors are favored. However, a body of facts leads one to think that there is a complex combination of these actions. The Meyer–Overton theory (and other related theories) is based on the observation that anesthetics non-specifically disturb the physical organization of membranes by solubilizing into lipids. There is still debate on the validity of the Meyer–Overton rule [64,65]. Interestingly, xenon, which is a rare gas, binds non-specifically to proteins, mainly by weak van der Waals forces [66,67]. A unified theory combining non-specific thermodynamic effects on the lipid bilayer and direct inhibition of excitatory neuronal channels is emerging, tentatively explaining the specific effect of anesthetics on the spinal cord [68,69]. Indeed, all anesthetic agents provoke immobility, even when noxious stimuli induce sympathetic responses. In addition, isobolographic analysis and response-surface curves of a combination of agents (both intravenous (IV) and volatile) show only additivity, which is a strong argument for a common mechanism of action [70–72].

In the usual conditions of pressure and temperature, nitrous oxide and xenon are gases, whereas halogenated anesthetic agents are in liquid form (desflurane boils at 22.8°C, thus necessitating special vaporizers) (Table 10.3). N_2O is now the single most important ozone-depleting substance emitted [73]. In addition, halogenated volatile anesthetics (and N_2O) are greenhouse gases. Twenty-year global warming potential ((GWP (20)) values and the carbon dioxide equivalent calculated at 1 minimum alveolar concentration (MAC) show a ratio of 2.2, 1, and 26.8 for isoflurane, sevoflurane, and desflurane respectively [74].

Nitrous oxide

Nitrous oxide (N_2O) is a gas with a molecular weight of 44 Da and a blood/gas distribution ratio of 0.47. At an inhaled concentration of 70%, rapid equilibrium takes place between the inspired and expired fractions of N_2O [75–77]. The kinetics of N_2O are rapid; the deep peripheral compartment is no greater than 8–10 L. Severinghaus first recognized this when he demonstrated that N_2O does not follow the Kety principle, thus leading to the first description of context-sensitive times. When administration is discontinued, elimination is rapid. Even after several hours of administration, elimination is only slightly delayed. In addition, because N_2O is rapidly diffusible, the phenomenon of diffusion hypoxia or "Fink effect" may occur when room air is administered in patients previously breathing a mixture of N_2O and O_2 [78,79]. Because of its ability to diffuse into cavities, N_2O should be used with caution when middle ear or bowel pressures are critical. N_2O has a MAC of at least 104% [80], and N_2O has an additive effect with volatile and IV anesthetics. In addition, N_2O has euphoric, neuroprotective, analgesic, and antihyperalgesic properties, probably because of its effect on the N-methyl-D-aspartate (NMDA) receptor [81,82]. It is why a 50% mixture of N_2O and O_2 is often used outside the operating room for sedation and analgesia. N_2O increases postoperative nausea and vomiting. N_2O moderately increases cerebral blood flow (CBF) and decreases vascular resistances. The net results on intracranial pressure (ICP) vary, but it usually increases [83].

Xenon

Xenon (Xe) is the heaviest non-radioactive natural noble gas (molecular weight (MW) 131.3). It is a dense monoatomic gas with a density of 5.89 and a high viscosity of 2.3 Pa/s (both under normal conditions). The high viscosity may theoretically render its use difficult in patients with increased airway resistances and in premature infants [84]. Its MAC is 70%. Xenon reaches 90% equilibrium between inspired and alveolar gas concentration after 5 min of administration. Because of its large atomic polarizability, xenon binds within cavities in all proteins [66,67,85]. This is why xenon has been considered to act by physical properties, such as the Meyer–Overton rule or the London dispersion forces (or weak van der Waals forces). Like N_2O, xenon acts as a low-affinity use-dependent NMDA receptor antagonist, but while xenon inhibits ketamine-induced c-fos expression in the rat cortex, N_2O enhances it [86,87]. In addition, xenon is a potent antinociceptive agent. This effect is thought to be independent of the opioid or adrenergic pathways. The mechanisms involved seem different from those implicated in neuroapoptosis caused by ketamine or halogenated agents.

In preliminary studies, xenon successfully protected the brains following neonatal asphyxia [88]. Another interesting property of xenon is cardiovascular stability and cardioprotection. Xenon does not alter myocardial contractility nor

Table 10.3 Gases and volatile anesthetics: physicochemical properties and pharmacokinetics

does it markedly changes vascular tone. Xenon preconditioning before an ischemic insult has then been observed both at the neuronal and myocardial level. Like local anesthetics, xenon modulates the inflammatory response of the immune system by decreasing the production of tumor necrosis factor (TNF)-α and interleukin (IL)-6 by monocytes in response to stimulation by lipopolysaccharide (LPS) [86]. The problem of industrial production and cost will certainly limit the use of xenon in the near future.

Halogenated agents

Halogenated agents are small molecules with MW from 168 to 200 Da (see Table 10.3) [89–91]. They are mildly hydrophobic and dissolve rapidly in blood and tissue. Halothane is an alkane substituted with bromide, chloride, and fluoride. Isoflurane, sevoflurane, and desflurane are ethers, substituted with chloride and fluoride (isoflurane) or fluoride alone (desflurane and sevoflurane). Halothane, enflurane, and isoflurane are chiral drugs, i.e. they have an asymmetric carbon, and they are marketed as racemic mixtures. Sevoflurane is non-chiral. Degradation of sevoflurane with CO_2 absorbents induces the formation of compound A, which is toxic for the kidney of rats [92]. However, the risk in humans seems almost non-existent [93].

Mode of action

The principal effect of anesthetic agents is to provoke immobility through effects that occur at the spinal cord level. Apart from the Meyer–Overton theory (see section "Pharmacokinetics and pharmacodynamics of inhaled anesthetics"), the mechanism of action of halogenated agents is thought to be related to interactions with ion channels and receptors in spinal cord and brain [62,63,94]. They simultaneously enhance the activity of the γaminobutyric acid receptor, A subunit (GABAA) and glycine receptors and inhibit glutamate receptors (α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA), kainite, and NMDA receptors). They also inhibit the neuronal nicotinic receptors, a mechanism that is common with N_2O and xenon. NMDA inhibitors are known to protect against ischemia-reperfusion and to suppress the hyperalgesia induced by surgery. However, they also promote apoptosis through the mitochondrial pathway, particularly in the developing brain [95,96].

Pharmacokinetics

All halogenated agents bind to HSA in the following order: desflurane>isoflurane>halothane>sevoflurane [94,97–99]. HSA binds approximately 3 moles of anesthetic/mole of HSA.

Halogenated agents are absorbed and eliminated by the blood–alveolar interface. These agents, which are hydrophobic, distribute in deep compartments, and trace amounts can be measured in expired gases several weeks after anesthesia. Their hydrophobicity allows rapid transfer to the effect compartment and absorption by the fat. The agents with low solubility (see Table 10.3) rapidly reach saturation, i.e. pseudo-steady state [90,100]. The consequence is a more rapid induction of anesthesia and less context-sensitive increase in decrement time. Because an important amount of data are available on the solubility of these molecules in organs, as well as regional blood flows and volumes, physiological kinetic models have often been used to describe the time-course of halogenated agents in the body. Classical compartmental models are now preferred, mainly because they allow simple interpretation of basic parameters such as volumes, clearance, and half-times, and easy application to clinical situations [101–106]. The pharmacokinetics of halogenated agents is best described by first-order kinetics, using linear mammillary models. After inhalation of a gas containing the vapor, transfer from alveolar gas to blood is rapid, and distribution to peripheral compartments, including brain (effect compartment), occurs. Elimination occurs via the same route, except for the variable amount of drug that is metabolized by the liver. The alveolar fraction of vapor (F_A) is considered to reflect the arterial concentration, and the inspired fraction (F_I) the concentration in the invasion compartment. During induction of anesthesia, the F_A/F_I ratio (alveolar to inspired fraction) versus time reflects the rate of invasion (washin). After drug administration is discontinued, the ratio of alveolar fraction to alveolar fraction at the time of discontinuation (F_A/F_{A0}) reflects elimination (washout). The end tidal fraction (FET) (%) or end tidal partial pressure (mmHg) usually approximates F_A.

The uptake and elimination of volatile anesthetics depend on cardiac output and the extent of ventilation. As always in pharmacokinetics, there is no direct correspondence between physiological and kinetic compartments. The volume of the central compartment depends on cardiac output and clearance; clearance depends on both minute ventilation and cardiac output. In an analogy with hepatic clearance of drugs eliminated by liver metabolism, ventilation is equivalent to intrinsic (metabolic) clearance and cardiac output (CO) to hepatic blood flow. Because CO is a major scaling factor it would be interesting to have data relating CO and uptake and elimination in pediatrics [107]. It is also important to remember that 40% of halothane entering the body is eliminated by hepatic metabolism [101,102,108,109].

Context-sensitive decrement times

Because the kinetics is multicompartmental (steady state is not attained before several days of administration, mainly because intercompartmental clearances are very slow), the observed decline is highly context sensitive [70,104]. After a short period of administration (less than 30 min) the decline of F_A/F_{A0} of sevoflurane or desflurane is faster than that for N_2O. This is due to the fact that N_2O reaches near steady state by 20–30 min, whereas sevoflurane or desflurane are at about 60–80% of steady state by this time. After 90 min, the difference between agents becomes clinically significant (Fig. 10.6). As with the effects of minute ventilation and cardiac output on kinetics, pediatric data describing decrement times as a function of age are lacking. Moreover, most articles are now based on data files generated with the aid of software (e.g. GasMan®, Med Man Simulations, Boston, MA, USA) and do not verify their adequacy with data from patients.

Pharmacodynamics

The measure of anesthetic action has been the subject of research for more than 40 years. The initial criterion was the MAC leading to a specific effect in 50% of the patients studied [110]. The MAC is the equivalent of Ce50 for IV agents. The concept of the MAC is based on the strong assumption that alveolar concentration is almost immediately in equilibrium with the cerebral concentration and adequately reflects the concentration at the neuronal effect site. MAC is defined as the alveolar concentration of volatile anesthetic agent (in oxygen or in a mixture of oxygen and N_2O) that abolishes the movement response to skin incision in 50% of subjects tested. One may also consider other effects, such as the cardiovascular depression induced by these agents, depression which is particularly important in neonates and in infants. The MAC has a great number of variations that have appeared over time: MACINT, which is the MAC for tracheal intubation, MACBAR, which is the MAC for abolition of sympathetic response to incision (tachycardia and increase in blood pressure), MACEXT, which is the MAC for deep tracheal extubation, and others [111–115]. The MAC of isoflurane was

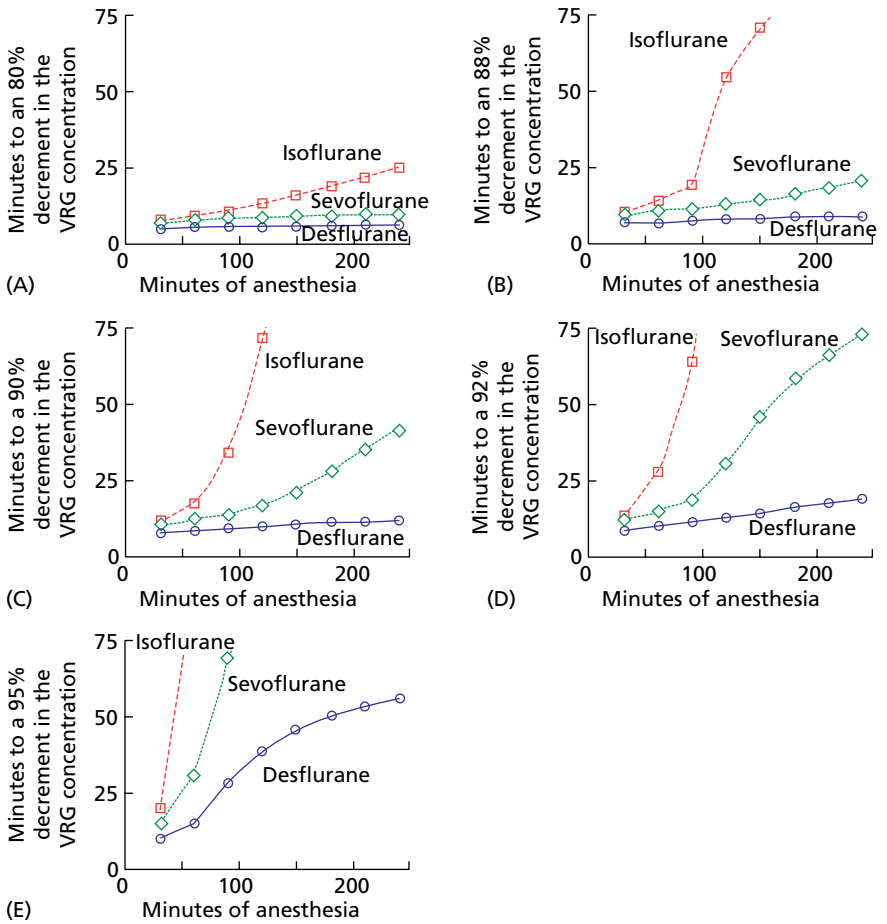

Figure 10.6 Context-sensitive decrement times in the rich vascularized compartment (VRG), i.e. brain, heart, kidney, liver, according to the duration of volatile anesthetic administration. *Source:* Reproduced from Eger and Shafer [70] with permission of Wolters Kluwer.

found to be lower in preterm babies than in term neonates. This relatively low MAC in immature babies is thought to be a general phenomenon of all volatile anesthetics, although we lack data in this age group. At birth and during the first months of life, MAC is at its peak value for all drugs (except for halothane, which attains its peak value several months after birth). After the first year of life, there is a reversal in the relationship between age and MAC; MAC decreases with age (Fig. 10.7). In summary, infants aged 6 months have a MAC 1.5–1.8 times that observed for a mean adult aged 40 years [116–119]. Also, preterm infants are supposed to be more sensitive to cardiac depression than neonates, who are also more susceptible than older children and young adults [120].

The MAC gives the probability of inappropriate anesthesia in an average patient. The possibility of modulation of anesthesia depth in line with the patient's status now exists using several indexes obtained by electroencephalogram (EEG) monitoring, such as the Bispectral Index (BIS™, Medtronic-Covidien, Minneapolis, MN, USA) and the spectral entropy or Narcotrend® Index (MonitorTechnik, Bad Bramstedt, Germany) [121–124]. In adults, numerous studies have shown that the population values of T½ke0 given by these indexes were similar and close to the values expected from clinical experience (see Table 10.3) [125–129]. However, great interindividual variability has been observed. This variability is similar to that observed with propofol, for example. In addition, the correlation between different MAC methods is difficult because, as with IV agents, all these EEG-derived algorithms are perturbed because hypnosis and analgesia are simultaneously measured. In children older than 2 years, it appears that the correlation between BIS IC50 and the different MAC measures is similar to that of adults [126,130]. To date, none of these monitors can correctly predict hypnosis in infants, perhaps with the exception of using regional and general anesthesia together (Fig. 10.8) [131–134].

Effects of volatile anesthetics on different functions

Isoflurane and desflurane are pungent and can cause airway irritation during induction of anesthesia [135]. Only halothane, which is less and less used because of its lower margin of safety compared to other agents, and sevoflurane are used for anesthesia induction. This pungency does not increase the risk of laryngospasm after induction.

Specific action on the central nervous system

Volatile anesthetics depress neuronal activity in a concentration-dependent manner. High concentrations depress EEG, and burst suppression occurs at concentrations greater than 2 MAC [136]. Sevoflurane induces epileptic activity with epileptiform discharges at concentrations usually greater than 1.5 MAC, but this also occurs at lower concentrations in some patients [137]. Convulsion-like movements may accompany these EEG signs. The morbidity of these manifestations is unknown, and no sequelae have yet been reported. However, it is recommended not to use sevoflurane concentrations in excess of 6% for induction of anesthesia and to maintain anesthesia with concentrations not higher than 1.5 MAC. Volatile anesthetics are often associated with agitation during emergence from anesthesia and for many minutes afterwards [138,139]. Emergence agitation is more frequent with newer agents such as sevoflurane. Concomitant administration of

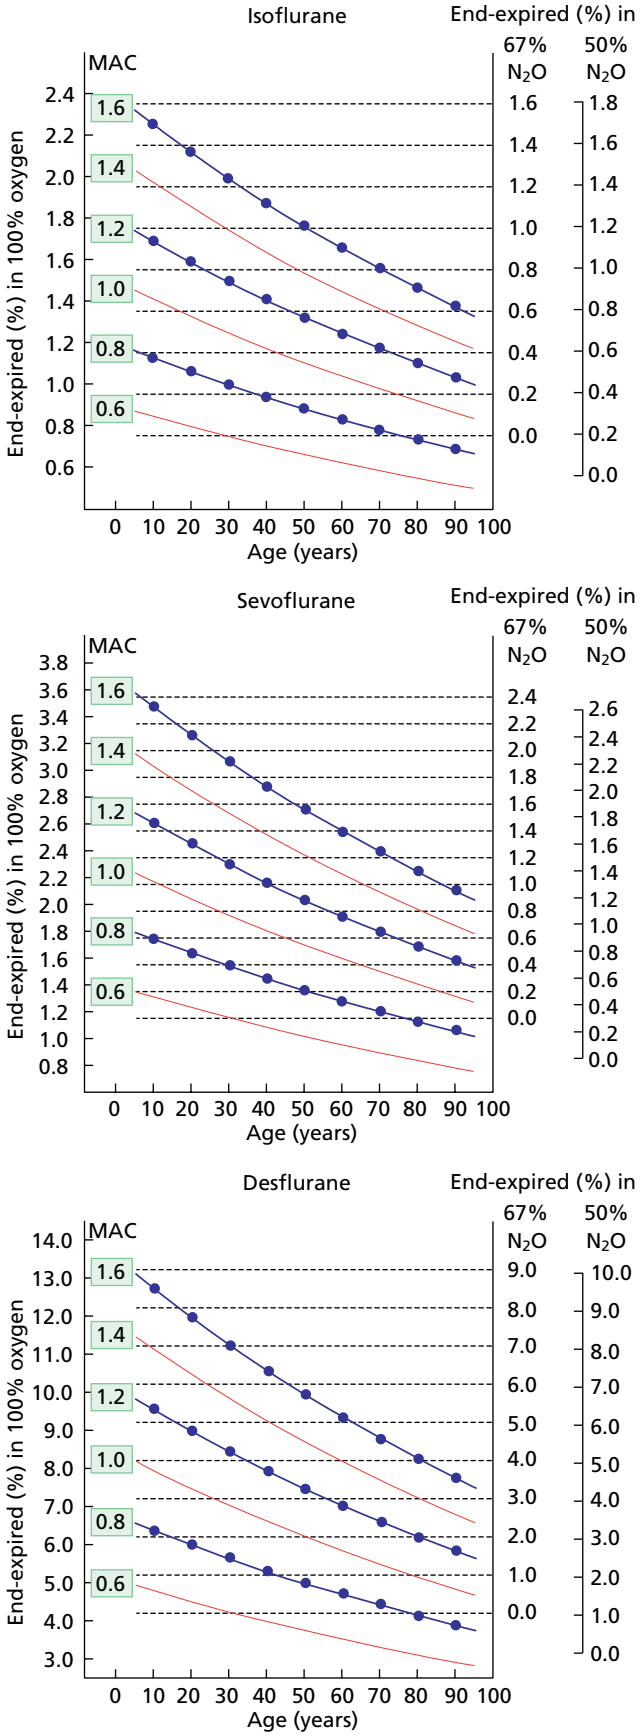

Figure 10.7 Minimum alveolar concentration (MAC) of isoflurane, sevoflurane, and desflurane according to age. Premature infants have a lower MAC than neonates. *Source:* Reproduced from Nickalls and Mapleson [119] with permission of Elsevier.

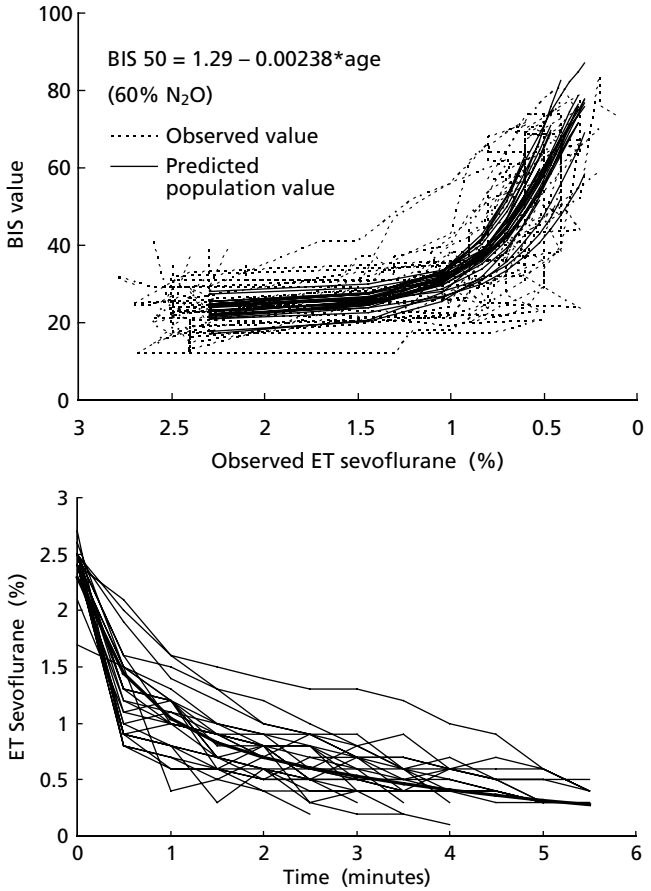

Figure 10.8 BIS values in 6 (mean) ± 3 (SD)-year-old children as a function of end-tidal (ET) sevoflurane. All patients had a regional block. Dotted lines are individual values and solid lines are Bayesian values calculated using NONMEM. Interestingly, in the absence of a nociceptive signal, the relationship between BIS value and ET sevoflurane is excellent and exhibits a negative correlation with age. *Source:* Reproduced from Lopez et al [142] with permission of Elsevier.

opioids, propofol, regional anesthesia, or ketamine may prevent emergence agitation. Dexmedetomidine should be favored as the treatment when agitation may lead to self injury [140]. Awareness is more frequent in children than in adults, but implicit memory seems to be less of a concern in pediatric patients [141,142]. Both midazolam and propofol inhibit conscious memory, but midazolam does not prevent implicit memory if present [143].

Apart from the possible neuroapoptosis induced by volatile anesthetics in infants and young children, volatile anesthetics exert a protective effect on the nervous system that is similar to that observed for the heart [144–147]. This effect seems to be independent of the inhibition of the NMDA receptor. In addition to a direct neuroprotective effect, preconditioning with isoflurane, sevoflurane, and desflurane appears efficacious in protecting against focal ischemia and apoptosis induced by ischemia or hypoxia-reperfusion. This effect seems related to the activation of various two-pore potassium channels and to the activation of inducible NO synthesis. Preconditioning seems to be particularly promising for neonatal cardiac surgery.

All volatile anesthetics increase CBF [148,149]. This increased blood flow is accompanied by a marked increase in intracerebral blood volume, which explains why increases in ICP are greater in children receiving volatile anesthesia than with IV anesthesia. Desflurane increases ICP more than isoflurane or sevoflurane. However, autoregulation is depressed in a dose-dependent manner, and the administration of less than 1–1.5 MAC seems to preserve enough autoregulation for clinical purposes, inasmuch as the main factor causing a decrease in cerebral perfusion pressure is the arterial pressure, which should be preserved [150,151].

Effect on the respiratory system [152–154]

All volatile anesthetics depress ventilation by reducing tidal volume, which is not compensated for by a parallel increase in respiratory rate. Interestingly, halothane depresses the ventilatory response to CO_2 less than the other agents. However, the important clinical issue is the response to acute hypoxia, which is depressed more by halothane than by isoflurane. Sevoflurane and desflurane are the least depressive agents. In case of a sudden decrease in PaO_2, desflurane and sevoflurane are safer agents. During one-lung anesthesia, no difference between isoflurane, desflurane, and sevoflurane has been reported. Also, no difference is reported between propofol and volatile anesthetics. At 0.5 MAC, all agents are bronchodilators. At higher concentrations, bronchoconstriction appears with desflurane at concentrations >0.5 MAC and with sevoflurane at concentrations higher than 1–1.5 MAC. Only isoflurane maintains its bronchodilating properties at 2 MAC. However, in children with airway susceptibility, for instance those with recent upper respiratory tract infection, desflurane markedly increases bronchial resistances, whereas sevoflurane exerts a bronchodilating effect [155].

Effect on the cardiovascular system [156–162]

All anesthetics depress contractility and inhibit sympathetic tone. Halothane significantly does so at 1 MAC, whereas isoflurane, desflurane, and sevoflurane only do so at concentrations above 1.5 MAC. In addition, halothane causes marked bradycardia, whereas sevoflurane has almost no effect on cardiac rhythm below 1.5 MAC. Isoflurane and desflurane have been shown to increase heart rate in adults, but an increase in heart rate is not as critical in pediatric patients. Interestingly, depression caused by halothane is poorly corrected by atropine, whereas it increases contractility in infants and children who are anesthetized with the other three agents. This difference between halothane and other agents (mainly sevoflurane has been studied) has been observed in patients without myocardial dysfunction, or with various congenital heart diseases. This is true also in patients breathing spontaneously. In addition, only halothane significantly potentiates epinephrine-induced cardiac arrhythmias. Halothane, isoflurane, and sevoflurane depress the autonomic control of arterial pressure in a similar manner. However, the bradycardia caused by halothane should be considered. Premature infants, who have an immature baroreflex, are particularly sensitive to the depression induced by anesthetics. In conclusion, halothane should be avoided when possible in infants and children, as halothane overdose has been associated with deaths in this age group. Halothane is no longer used in most countries, but is still available in some developing countries.

Isoflurane, desflurane, and sevoflurane possess cardioprotective effects, and both desflurane and sevoflurane have been

shown to decrease postoperative mortality in adults suffering from coronary artery diseases. Indeed, the cardiac depressive effect reduces oxygen demand and may protect during ischemia. However, there is evidence of a specific effect related to pre- and post-conditioning. This may be beneficial for cardiac procedures in infants and children [157,163,164].

Effect on muscle relaxation

Volatile anesthetics have an intrinsic effect on muscle relaxation [165–167]. Their prejunctional effect decreases the firing rate of motor fibers. In addition, they may also affect the sensitivity of the motor endplate. Volatile anesthetics interact with muscle relaxants. They do not interact with the kinetics of nondepolarizing muscle relaxants, but decrease Ce50 [168]. The dose of rocuronium or atracurium needed to achieve similar effect is decreased by about 25–30% in patients anesthetized with sevoflurane compared to those anesthetized with propofol [169]. At similar MACs, all volatile anesthetics enhance the action of pancuronium, vecuronium, rocuronium, atracurium, and cisatracurium to a similar degree [170].

Malignant hyperthermia (see Chapter 45)

All volatile anesthetics may induce malignant hyperthermia (MH) [171–174]. Succinylcholine increases its severity. MH is a genetic disorder of the ryanodine receptor of the skeletal muscle and has a prevalence estimated between 1:3000 and 1:8500. Indeed, the prevalence largely varies between populations. The incidence of MH associated with general anesthesia is estimated at between 1:30,000 and 1:100,000. Patients with various myopathies may be susceptible to MH. Central core disease and hypokalemic periodic paralysis are particular risks [175,176]. The usual clinical presentation is an uneventful induction of anesthesia, progressive development of tachycardia and hyperthermia, and a rise in end-tidal CO_2 tension. The associated muscle rigidity is a direct sign of impaired intracellular calcium regulation. In patients spontaneously breathing, a progressive rise in minute ventilation is also observed. Acidosis, hyperkalemia, and a serum creatinine kinase >10,000 IU/L are the main biological manifestations. If untreated, MH may be rapidly lethal. These manifestations are not always typical, and there is a risk that the diagnosis will be missed because MH may progressively develop after discharge of the patient from the operating room or because a lethal episode may occur during a future anesthetic. Dantrolene is the specific treatment (2–3 mg/kg up to 10 mg/kg as a bolus). Clinical signs determine the dose of dantrolene needed. Following treatment, the signs and symptoms of MH may recur, making it necessary to reinject dantrolene. This is why dantrolene must always be readily available. Dantrolene must be dissolved in sterile water (possibly warmed to 40°C), because dissolution is very difficult with the standard preparation. A new preparation of dantrolene, Ryanodex® (Eagle Pharmaceuticals Inc., Woodcliff Lake, NJ), is available that requires only 5 mL of sterile water to dissolve 250 mg of the drug. It is important to change the anesthesia machine and the entire circuit, to cool the patient if necessary, and to correct acidosis if necessary. The diagnosis is ascertained by a muscle biopsy, which should always be performed. Prevention of MH in susceptible subjects consists of preparing the anesthesia machine by removing the vaporizers and changing the circuit. Total IV anesthesia is used and succinylcholine is avoided.

KEY POINTS: PHARMACOKINETICS AND PHARMACODYNAMICS OF INHALED ANESTHETICS

- The mechanism of halogenated anesthetic is primarily through binding to the $GABA_A$ receptor, depressing neuronal function
- Increased minute ventilation and cardiac output will increase uptake and distribution
- MAC profile differs by agent: MAC is the highest at the age of 1–12 months for desflurane, isoflurane, and sevoflurane; MAC is lower in neonates with isoflurane and desflurane, but higher in neonates with sevoflurane

Pharmacokinetics and pharmacodynamics of intravenous anesthetics

Benzodiazepines

Benzodiazepines interact with a specific site of the GABAA receptor, increasing the affinity of the receptor for GABA [177,178]. GABAA is the principal inhibitory neurotransmitter and increases the frequency of opening of the chloride channel. Under normal conditions, chloride concentration is lower inside the cell than outside. Opening of the channel increases the concentration of chloride inside the cell and hyperpolarizes the membrane. Benzodiazepines have hypnotic and sedative properties. They are potent anticonvulsants. They are also anxiolytic and provoke antegrade amnesia. Although they are weak muscle relaxants (a central effect), they do not notably interact with peripherally acting muscle relaxants.

Pharmacokinetics

Benzodiazepines are weak bases bound to serum proteins, mainly AGP (Table 10.4) [179,180]. Only midazolam is water soluble [180]. Benzodiazepines rapidly cross the BBB and quickly access the receptor: their T½ke0 is lower than 3 min, except for lorazepam [181–184]. Conversely, the duration of action mainly depends on the affinity for the receptor. Midazolam, clonazepam, and lorazepam have an affinity constant to the receptor 20 times higher than that of diazepam, and the duration of action is as follows: diazepam 2 h, midazolam 2–4 h, clonazepam 24 h, lorazepam 24–72 h.

Benzodiazepine metabolism takes place in the liver via the CYP3A4 isoform of cytochrome P450, with the exception of lorazepam, which is metabolized by UGT [185–187]. There is no phase I metabolism. Diazepam has active metabolites, mainly N-desmethyldiazepam, which may accumulate in intensive care unit (ICU) patients with kidney failure. Midazolam has an active metabolite, α1-OH-midazolam, but the ratio between metabolite and parent drug remains constant, even in ICU patients. Because all these molecules have low hepatic extraction ratios, their elimination mainly depends on hepatic function; in the setting of liver failure, the clearance of benzodiazepines is markedly decreased. After oral administration, absorption of midazolam is rapid; its bioavailability is 50% and its T_{max}, the time-to-peak

Ce50 is for loss of consciousness (LOC) or for a 50% decrease in the BIS value (BIS50). BIS, entropy, and various measures based on EEG give similar results.
CL, clearance; T½, terminal elimination half-life; T½ke0, rapid equilibration half-life; Vc, volume of the central compartment; Vss, steady-state volume of distribution.

concentration, occurs 40–50 min after administration. Absorption is very rapid after rectal administration. In children, T_{max} is 10 and 15 min for diazepam and midazolam respectively. After rectal administration, bioavailability is 50–80% for diazepam and 20–50% for midazolam. The intramuscular route has been abandoned because of unpredictable absorption. The volume of distribution is large (1–2 L/kg) and the terminal half-life long (see Table 10.4) [188–191]. Apart from some inhibitors of retroviral replication, such as ritonavir, few interactions between benzodiazepines and other drugs metabolized by the CYP3A4 have been described. Because of immaturity of CYP3A4, midazolam clearance is very low in preterm infants and during the first 2–3 months of life [192,193].

Pharmacodynamics

Action on the central nervous system

Benzodiazepines cause sedation through their effect on GABAA receptors. Their indications include premedication and sedation in ICUs [194]. When a benzodiazepine is used as a premedicant, a paradoxical agitation reaction sometimes occurs. However, their sedative, anxiolytic and amnesic effects make midazolam one of the preferred drugs for premedication, particularly for uncooperative children or patients who have undergone multiple procedures. However, the effect on anterograde amnesia and implicit memory remains controversial [143]. Benzodiazepines have almost no effect on CBF, ICP, or the cardiovascular system, which makes these drugs suitable for sedation in ICUs, particularly in neonates and in patients with head trauma, when long-term propofol administration is a risk [195].

Action on the respiratory and cardiovascular systems

Midazolam depresses ventilation by decreasing sensitivity to CO_2 [196]. Opioids potentiate this effect. Diazepam and midazolam produce only mild cardiovascular depression and a minimal reduction in blood pressure, due to a decrease in vascular resistance [197]. This effect is increased when the drug is administered concomitantly with narcotics or other sedatives. When given to ICU patients for several days, midazolam has no significant effect on liver or adrenal function. Tolerance and tachyphylaxis may occur, particularly with longer-term infusions (≥3 days). Benzodiazepine withdrawal syndrome occurs with high-dose/long-term midazolam infusions [198].

Dosing

For premedication in infants and children after the age of 3–6 months: midazolam 0.3–0.5 mg/kg orally (or rectally if the oral route is not possible) 30–40 min before induction of anesthesia; diazepam (if midazolam is not available) 0.1 mg/kg 60 min before surgery. As an adjunct for the induction of anesthesia, 0.15 mg/kg is given. As the sole agent for anesthesia induction, 0.3–0.6 mg/kg IV is used. The infusion dose of midazolam in critically ill patients is 0.03–0.3 mg/kg/h (30–300 µg/kg/h). The dose of midazolam is adjusted in ICU patients according to the patient's clinical condition (use of a sedation score by the attending nurse is highly recommended).

Flumazenil, a specific benzodiazepine antagonist, reverses all the effects of benzodiazepines. However, its rapid elimination kinetics makes continuous infusion of the drug necessary to maintain therapeutic efficacy [199]. The dose by IV bolus is 5–10 µg/kg every min up to 40–50 µg/kg. It may be necessary to follow this titrated dose with a continuous infusion of the drug at a rate corresponding to the titrated dose given over an hour.

Thiopental

Thiopental (thiopentone) is no longer an important drug for induction of anesthesia in younger patients, as in adults, and is not available in many parts of the world. Like propofol, thiopental modulates the GABAA and glycine receptors, but it mainly acts at the spinal cord level and preferentially on the glycine receptor [178,200–202].

Pharmacokinetics

Thiopental is a weak acid (pKa 7.6) and an octanol/buffer distribution ratio of 490 (LogP = 2.69) (see Table 10.4) [91]. It is a racemic mixture of two stereoisomers [S-(+) and R-(–)], the S-(+) isomer being twice as potent as the R-(–) isomer. Thiopental binds to HAS with an average free fraction of 15% in adults and 28% in neonates [203]. Thiopental is metabolized by the cytochrome P450 system, but the precise pathway(s) remain(s) to be characterized. Its terminal half-life is very prolonged [204–206]. After a bolus injection, the drug distributes rapidly, making its effect transient. Following a single injection, thiopental's pharmacokinetics is best described by a two-compartment linear model, with a terminal half-life of ≈12 h in adult patients. The rate of administration markedly influences the total dose needed to achieve a predetermined effect: because of rapid redistribution of the drug, the higher rate of administration leads to high, but transient peak concentration, which is unable to correctly cross the BBB; a minimum duration of plateau concentration is needed to achieve clinical efficacy. This is consistent with an equilibration half-time (T½ke0) of 2.4 min between central and effect compartment (see Table 10.4). In pediatric patients older than 6 months of age, clearance is higher than in adults, and the average T½ is 6.1 h (see Table 10.4). With prolonged administration (for example in patients with critically increased ICP), thiopental exhibits nonlinear (Michaelis–Menten) kinetics, with an apparent terminal half-life of 15 h. In neonates and young infants, kinetics are not profoundly altered but the pharmacodynamics are likely different, with an ED50 (the dose leading to loss of lid reflex in 50% of children) of 3.4, 6–7, 5.5, and 4.2 mg/kg in patients aged 0–14 days, 1–6 months, 6–12 months, and older than 1 year respectively [207,208]. Interestingly, the curve representing ED50 versus age is very similar to those of MAC versus age for halogenated agents. Studies considering allometric scaling are lacking.

Pharmacodynamics

Effect on the central nervous system

Thiopental does not increase CBF and may decrease ICP (although the cerebral perfusion pressure may not significantly change). The very prolonged elimination that is the result of Michaelis–Menten kinetics must be taken into account.

Effect on the respiratory and cardiovascular system

Thiopental depresses ventilation, likely because of decreased sensitivity to CO_2. In adults, more critical respiratory events occur in the immediate postoperative period with thiopental use than with propofol, although both cause similar changes in functional residual capacity (FRC) [209]. This increase in the number of events is likely related to the higher residual sedation associated with thiopental.

Thiopental decreases arterial blood pressure. Contrary to propofol, this decrease is not only related to decreased vascular tone but also to decreased myocardial contractile force [210]. Consequently, thiopental must be used with care in patients with cardiac failure.

Other effects

Thiopental, like other barbiturates, may induce porphyria. Its use is absolutely contraindicated in patients susceptible to such pathology. The acidity of thiopental solutions may cause necrosis at the injection site if extravascular diffusion occurs. Inadvertent arterial injection has caused severe necrosis.

Dosing

Because the risk of necrosis is high following inadvertent extravascular injection, the use of dilute solutions is recommended (2.5% in children and adults, 1% in infants). When adjuncts (opioids) are used for induction of anesthesia, the usual dose of thiopental is 2.5–3 mg/kg in neonates <10 days of age, 6–7 mg/kg in infants, and 5 mg/kg in children.

When ICU patients have thiopental infused for prolonged periods of time, thiopental kinetics become non-linear, in both adults and children. It may then be important to monitor thiopental plasma concentrations if the rate of administration exceeds 4–5 mg/kg/h.

Propofol

Propofol has largely replaced thiopental for induction and maintenance of anesthesia. The latter indication is likely related to the emergence of computer-driven systems for drug administration, since propofol kinetics and dynamics have been extensively studied [211]. Propofol enhances gating of the GABAA receptor by GABA and slows desensitization of the receptor [200,201]. In addition, propofol depresses presynaptic excitatory synaptic transmission and decreases glutamate release. Propofol also enhances the activation of the glycine receptor by glycine.

Pharmacokinetics

Propofol is a weak acid with a pKa of 11.5 and an octanol/buffer distribution ratio around 6500 [91]. Because of high hydrophobicity, propofol is "solubilized" in lipid emulsions. Propofol binds to red blood cells and serum albumin, and the free fraction is <1% [212–214]. Binding is markedly decreased in patients on cardiopulmonary bypass [215] and those in ICUs who have decreased serum concentrations of HSA. The pharmacokinetics largely varies with age,

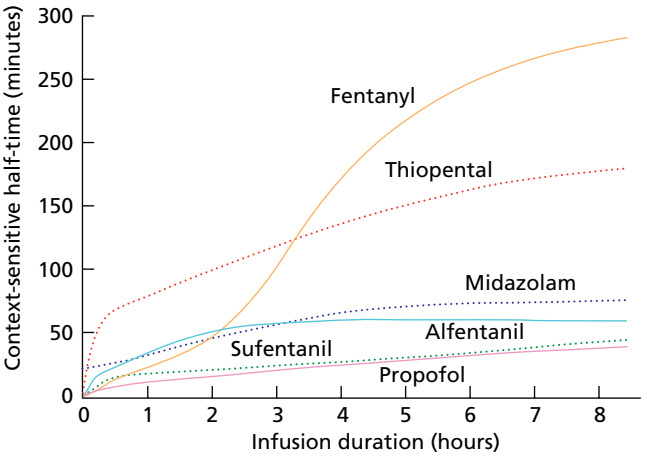

Figure 10.9 Context-sensitive decrement times of the principal agents used intravenously. Remifentanil is not depicted on this figure since its decrement times are constant. *Source:* Reproduced from Hughes et al [21] with permission of Wolters Kluwer.

explaining the differences in dosing between infants, children, and adults (see Table 10.4) [216–219]. When one compares a typical 20 kg, 5-year-old child and a typical 70 kg, 30-year-old adult, the main findings are: (1) an elimination clearance moderately higher in children than in adults; and (2) more importantly, volumes (both Vc and Vss) are between 2 and 2.5 times greater in children than in adults, and the associated intercompartmental clearances are 1.5 times greater in children than adults. When allometric scaling is performed, clearance is constant across species and age in humans: CL = 71 * (BW/70)^0.78 L/min, where BW is bodyweight and 70 the standard bodyweight for adult humans [220]. Propofol exhibits marked multicompartmental kinetics and context-sensitive decrement times (Fig. 10.9). Altered kinetics (decrease in elimination clearance) has been reported in ICU patients and in neonates [221]. In premature infants less than 38 weeks' postmenstrual age, clearance is very low since maturation of metabolism occurs at birth. Interestingly, there are almost no differences in pharmacodynamic parameters across age [222–227]. The differences are mainly kinetic, i.e. Ce50, the concentration in the effect compartment needed to achieve a desired effect, is nearly similar among infants, children, and adults. Conversely, T½ke0 and the time to peak effect are shorter in younger patients than in adults, and the difference is identical to the difference measured for volumes and intercompartmental clearances (see Table 10.4). Interestingly, the effects on ventilation and arterial blood pressure do not have the same kinetics [228,229]. In adult patients, T½ke0 for respiratory depression is 2.6 min, similar to the T½ke0 for hypnosis, whereas T½ke0 for a half decrease in systolic blood pressure from baseline to 80 mmHg is 6 and 11 min in 20- and 75-year-old patients respectively.

Pharmacodynamics

Specific action on the central nervous system

Propofol has little effect on CBF or ICP when normocarbia is present [229,230]. This is why propofol is so popular in ICUs for sedation of patients with increased ICP [231]. Propofol is also used to treat seizures, mainly in cases of status epilepticus [232].

Effect on the respiratory and cardiovascular systems

Like all hypnotic agents, propofol depresses ventilation by decreasing sensitivity to CO_2. This effect is central since the T½ke0 of respiratory depression is similar to the T½ke0 of hypnosis [232].

Propofol has a direct negative inotropic effect at very high (supratherapeutic) concentrations [210]. At therapeutic concentrations, its effect on contractility is insignificant [233]. The main cardiovascular effect of propofol is on vascular tone, probably because it inhibits the sympathetic nervous system. The prolonged T½ke0 on vascular tone strongly suggests that the effect is at least partly peripheral [227]. Propofol protects the myocardium against ischemia-reperfusion injury through its ability to inhibit the mitochondrial permeability transition pore and its antioxidant and free-radical scavenging properties [234,235].

Propofol infusion syndrome

After more than two days of infusion of propofol in ICU patients, severe toxic effects have occurred [236,237]. This "propofol infusion syndrome" is likely caused by the uncoupling effect of propofol on the respiratory chain in the mitochondria. The clinical presentation includes lactic acidosis, rhabdomyolysis, and cardiovascular collapse (bradycardia, sometimes Brugada-like ECG, asystole). Green or red urine has been described in some patients [238]. This syndrome was initially described in children and adults who had head trauma and received high-dose propofol for sedation. If sedation with propofol seems to benefit the patient, it is recommended to give <4 mg/kg/h for less than 48 h. Close monitoring of acid–base status, serum lactate, and creatine kinase concentrations should be performed. The use of propofol for total intravenous anesthesia (TIVA) for several hours has not been reported to cause adverse effects in children.

Presentation and dosing

Propofol is available as a 1% or 2% emulsion. The carrier emulsion was originally Intralipid®, but other lipid emulsions are used in generic preparations. Propofol contains EDTA, sodium metabisulfite, or benzyl alcohol as an antimicrobial agent. Pain at the site of injection is common and may be attenuated by lidocaine (0.5–1 mg/kg), either injected before the propofol or in the same syringe with the drug. Propofol should not be prepared in advance, since bacteria grow rapidly in the emulsion. Postoperative nausea and vomiting occur less frequently with propofol than with other agents (e.g. volatile anesthetics). To achieve similar plasma concentrations in children and in adults, the initial dose must be 2–3 times greater in children [239]. Because the volume at steady state is also markedly different, the initial 15–60 min of an infusion must be higher in children than in adults [240]. However, the significant hemodynamic effect of propofol must be taken into account, and balanced anesthesia with adjuncts seems preferable for induction of anesthesia. The usual doses for anesthesia induction are <1 month 2 mg/kg, 1 month to 3 years 2–3 mg/kg, 3–8 years 3 mg/kg, >8 years 2–3 mg/kg. Loss of consciousness lasts for 5–10 min after a single injection. It has also been proposed to use low doses of propofol for elective intubation in neonates [241]. The dosing scheme for continuous infusion of the drug is provided in Table 10.5.

Table 10.5 Propofol and ketamine infusion scheme

Propofol infusion dosing in infants and children. After induction of anesthesia with propofol (3–5 mg/kg), anesthesia is maintained with the following scheme. Anesthesia needs to be complemented with fentanyl/alfentanil/sufentanil or regional anesthesia (adapted from Steur et al. [240])

Age	Time (min)					
	First 10	10–20	20–30	30–40	40–100	>100

Etomidate

Etomidate is a carboxylated imidazole that is highly hydrophobic, has hypnotic properties, and has little effect on the cardiovascular system. It is often used for induction of anesthesia in patients with critical hemodynamic conditions, despite its suppressive effect on adrenal steroid synthesis [242,243]. Etomidate has a high degree of enantioselectivity. The R-(+) enantiomer is 10 times more potent than the S-(–) enantiomer [244,245]. The commercial preparation is the pure R-(+) enantiomer. Like propofol, etomidate interacts with the GABAA receptor, but the actions of these two drugs on the different subunits of the receptor differ [244–246]. Etomidate causes marked *in vitro* endothelium-dependent vasodilatation. However, this effect is less than that observed with propofol and is reversed by adrenergic stimulation [247].

Pharmacokinetics

Etomidate is a weak base, hydrophobic (the active molecule is "solubilized" in propylene glycol or in a lipid emulsion), and is bound to AGP. Protein binding is decreased in patients with kidney and liver failure, which may increase the sensitivity of these patients to the drug [248,249].

Etomidate is metabolized in the liver by the cytochrome P450 system, but the specific isoform(s) involved remain(s) to be characterized. CYP3A2 may be involved because etomidate decreases antipyrine clearance [250]. Clearance of etomidate is decreased in cirrhotic patients [251–253]. Metabolites are inactive. In children, the volume of the central compartment is more than twice that of adults (0.66 versus 0.27 L/kg) [254]. Clearance is also higher. However, the volume of the central compartment depends on the cardiac output.

If, indeed, children with normal cardiovascular function need a greater dose of drug for induction of anesthesia, those with impaired hemodynamics may require less [255,256].

Pharmacodynamics

Specific action on the central nervous system

Etomidate has no intrinsic action on CBF. It decreases ICP. Cerebral perfusion pressure is likely unchanged because of the etomidate-induced slight decrease in arterial blood pressure, which may explain the decrease in CBF and subsequent decrease in ICP.

Effect on the respiratory and cardiovascular systems

Etomidate induces moderate respiratory depression by reducing sensitivity to CO_2.

Etomidate is mainly used for induction of anesthesia (particularly in emergency cases) because of the hemodynamic stability observed [210,255,257–259]. Etomidate has no effect on heart rate, and contractility is only moderately impaired. *In vitro* and *in vivo* studies in animals and in humans have shown that etomidate has an intrinsic negative inotropic effect that is similar to the effects observed with ketamine and midazolam. This effect is totally reversed by β-adrenergic stimulation. More importantly, etomidate only moderately impairs vascular tone. Baroreflex control is preserved, in contrast to propofol and thiopental.

Effect on adrenal function

Etomidate blocks 11-β-hydroxylase, thus inhibiting conversion of cholesterol to cortisol [260]. After an induction dose of etomidate, adrenal suppression last for about 24 h. This effect may be clinically relevant, particularly in patients with septic shock who have compromised adrenal function.

Formulation and dosing

Two formulations are distributed, depending on the solvent used. The initial formulation uses propylene glycol (35% vol/vol), and the second uses a lipid emulsion (propofol) as the carrier. Both preparations are painful on injection, but the propylene glycol preparation is particularly irritating because of its osmolality (4640 mOsm/L).

For induction of anesthesia in the emergency department, 0.2–0.3 mg/kg is used in children with compromised cardiovascular function and 0.3–0.6 mg/kg in patients in a stable condition. Myoclonus may occur with injection of the drug. In pediatric patients, rectal induction of anesthesia is possible with a dose of 6–8 mg/kg. Continuous administration of the drug is not recommended because it suppresses cortisol synthesis.

Ketamine

Ketamine has hypnotic, analgesic, and antihyperalgesic properties and produces "dissociative anesthesia," profound analgesia, and marked sympathomimetic reactions [261]. However, ketamine has unwanted side-effects, such as hallucinations, confusion, delirium, hypersalivation, and bronchial hypersecretion. Ketamine anesthesia is characterized by rapid immobility and cataleptic appearance, mydriasis, nystagmus, and increased muscular tone. Emergence from anesthesia is characterized by a state of confusion, often with hallucinations. This state, which is amplified by light and noise, is less frequent in younger children than in adults and may be prevented by administering adjunct drugs such as benzodiazepines. Ketamine has moderate effects on the cardiovascular system. It has an asymmetric carbon, with two enantiomers R-(–)- and S-(+)-ketamine. The S-(+) enantiomer is about four times more potent than the R-(–) enantiomer [262].

Ketamine acts mainly as a non-competitive NMDA receptor antagonist. It inhibits presynaptic release of glutamate and potentiates GABAA. Ketamine also has opioid and muscarinic properties. The effects on the NMDA receptor include both the neuroprotective and proapoptotic effects of ketamine [263–267].

Pharmacokinetics

Ketamine is 50% ionized and 50% non-ionized at pH 7.4. Both the parent drug and its metabolite norketamine are bound to serum proteins, with a free fraction of 40% and 50% respectively [268]. Ketamine is metabolized by CYP2B6 and 3A4 [269–272]. N-demethylation produces norketamine, which has about 30% of the activity of ketamine. Norketamine undergoes almost the same metabolism as ketamine (hydroxylation by the CYP2B6 and glucuroconjugation) and has a terminal half-life of similar duration (≈4–6 h) [273–275]. Norketamine is then considered to be responsible for some of the effects of ketamine. Access to the receptor is very rapid, with a T½ke0 of <1 min (see Table 10.4). Drug redistribution rapidly occurs (the initial distribution half-life is <15 min), and after a single 1 mg/kg IV injection, anesthesia lasts 6–10 min. Because of the multicompartmental nature of ketamine's pharmacokinetics, decrement times are markedly context sensitive.

Pharmacodynamics [276–279]

Specific action on the central nervous system

Ketamine has specific effects on the CNS [280,281]. It enhances EEG activity and increases CBF and cerebral metabolic rate of O_2 ($CMRO_2$). Because the arterial pressure increases, there is an increase in ICP that is proportional to the increase in CBF. However, when adjuncts are used with ketamine and, more importantly, when normocarbia is maintained, ICP does not increase. Thus ketamine is often used in neurologically impaired patients. Ketamine has neuroprotective effects through its effects on the mitochondria. However, the effects of ketamine on the ATP-sensitive mitochondrial K+ channel remain a subject of debate. On the other hand, ketamine also induces apoptosis via the mitochondrial pathway. This is considered a major issue in neonates and infants. The neurotoxicity of ketamine on the brains of developing animals seems clear. Consequently, this agent should probably be used with care in younger patients.

Effect on the respiratory and cardiovascular systems

Ketamine does not depress ventilation, and the CO_2 response remains intact [282]. Tidal volume and respiratory rate are unchanged. Ketamine does not alter FRC, even at high doses, but it does induce moderate bronchodilation.

The pharyngo-laryngo-tracheal reflexes are partly conserved, leading to a relative airway protection.

Ketamine has minimal effects on myocardial contractility [283,284]. It preserves sympathetic activity and baroreflex activity [285,286]. In healthy subjects, ketamine raises arterial blood pressure slightly, increases the myocardial contractile force, and increases cardiac output. However, in patients with decreased cardiac reserve, negative inotropic effects of the drug can be unmasked when myocardial contractility fails to increase with β-adrenergic stimulation. In addition, the increase in MVO_2 may be deleterious in patients who have insufficient coronary reserve. It has been reported that ketamine inhibits ischemic preconditioning via its inhibition of ATP-sensitive K+ channels, but this is still subject to debate. The S-(+) enantiomer is undoubtedly less deleterious on both contractility and loss of ischemic preconditioning of the myocardium than the R-(–) enantiomer.

Antihyperalgesic effect of ketamine

By its anti-NMDA action, subanesthetic doses of ketamine are potently antihyperalgesic [287]. Ketamine limits opioid-induced hyperalgesia and has potent morphine-sparing effects. These effects are observed when ketamine is used early in the time-course of nociceptive stimulation, i.e. in the perioperative period. When ketamine is used only in the postoperative period, even when used with patient-controlled analgesia (PCA), the results are not so clear. In pediatric patients, these effects need to be confirmed. The use of ketamine before the age of 2–4 years is still controversial because of possible neurotoxicity.

Effects on immune function and inflammation

Like local anesthetics, ketamine has potent immunomodulatory and anti-inflammatory properties. Ketamine decreases nuclear factor κ B (NFκB) activation and TLR4 expression and is more frequently used in septic and trauma patients [288]. These anti-inflammatory properties have not been shown in pediatric patients. Further studies are needed to assess the beneficial effect of ketamine in septic or cancer patients.

Formulations and dosing

Ketamine has various formulations. The initial preparation of the racemic mixture contains benzethonium chloride as a preservative. Both the R-(–) enantiomer and the preservative are neurotoxic. In numerous countries, the S-(+) enantiomer without preservative is available because it is less toxic. However, even the pure S enantiomer may be neurotoxic at high concentrations, and its use is not recommended as an adjuvant for epidural injection.

Numerous routes for ketamine delivery are used. For IV induction of anesthesia, 1–2 mg/kg is used. For maintenance anesthesia, 2–4 mg/kg/h of ketamine is infused. However, because of the context-sensitive half-time of the drug, it may be better to use an adapted regimen (see Table 10.5). Ketamine may also be injected intramuscularly at a dose of 5–8 mg/kg. The onset of anesthesia is slower (5–10 min) and its duration is prolonged (20–30 min). Ketamine may also be given rectally at the same dose. Ketamine is also increasingly used for procedural sedation, particularly in the emergency department, using 1–1.5 mg/kg IV or 4–5 mg/kg intramuscularly (IM) [289,290]. The low-dose regimen used to prevent postoperative hyperalgesia consists of an IV loading dose of 0.15–0.30 mg/kg before surgery and a continuous infusion of 0.1–0.3 mg/kg/h for 24 h. As an adjunct to PCA, the dose is 1 mg ketamine per mg of morphine. However, most pediatric studies do not show a benefit to low-dose ketamine.

Dexmedetomidine

Dexmedetomidine is an imidazole derivative sedative/hypnotic agent that acts at CNS α_2-adrenergic receptor binding sites as a highly selective agonist, with a 1600:1 α_2:α_1 selectivity (by comparison, clonidine is 200:1 α_2:α_1 binding). Dexmedetomidine produces hypnosis and anxiolysis by binding presynaptic α_2 receptors in the locus coeruleus, and analgesia by binding to α_2 receptors in the spinal cord [291]. It was approved by the US Food and Drug Administration (FDA) in 1999 for use as an ICU sedative in ventilated adults, and a second indication was approved in 2007 for procedural sedation in spontaneously ventilating adults. Dexmedetomidine is now available in European and most other countries; however it is not labeled for use in children in any country despite its widespread use in children. Dexmedetomidine use has increased greatly in the past decade as a sedative in the ICU setting, an adjunct to general anesthetic techniques including volatile anesthetics and TIVA, a procedural sedative alone or in combination with other drugs, a premedication, a prevention or treatment for postanesthetic delirium, and an adjunct for caudal or epidural analgesia [292].

Pharmacokinetics

In children, IV dexmedetomidine is 93% protein bound, the rapid redistribution phase after an IV loading dose is about 7 min, clearance is approximately 15 mL/kg/min, and the terminal elimination half-life is about 2 h [293]. Eighty-five percent of the drug undergoes glucuronidation in the liver by UDP-glucuronidyl transferase, and 15% by cytochrome P450 2A6, into inactive metabolites, with a very small fraction excreted unchanged in the urine and stool. Using allometric size modeling, clearance is about 300 mL/min/70 kg in term neonates, and increases to about 600 mL/min/70 kg by about 1 year of age to over 700 mL/min/70 kg in older children [294]. Dexmedetomidine can be delivered by non-IV routes, and its bioavailability is intranasal 65%, orogastric 16%, buccal 84%, and IM 100%.

Specific action on the central nervous system

Presynaptic α_2 receptor binding in the locus coeruleus results in decreased norepinephrine release, producing sedative effects that mimic natural sleep, as evidenced by EEG studies in children that document a state similar to non-rapid eye movement sleep [293]. Plasma levels of about 600 pg/mL or higher produce significant sedation in children. Dexmedetomidine reduces CBF proportionally to cerebral metabolic rate, and does not appear to affect ICP. The drug preserves both somatosensory and motor-evoked potentials. When administered via the epidural space, dexmedetomidine has analgesic and antinociceptive properties in children.

In preclinical animal models, dexmedetomidine does not cause neuroapoptosis, and either completely or partially

blocks neuroapoptosis by volatile anesthetic agents, ketamine, and propofol [295]. This property has made dexmedetomidine a leading candidate drug for study as an alternative regimen for the issue of potential anesthetic neurotoxicity (see Chapter 46). Dexmedetomidine also has neuroprotective effects in cerebral ischemia and inflammation in preclinical models [296,297]. When used as an ICU sedative, dexmedetomidine is associated with a lower incidence of delirium in children [298].

Effect on the respiratory and cardiovascular systems

A major advantage of dexmedetomidine for sedation is that it maintains normal respiratory patterns, minute ventilation, and upper airway patency at normal sedative doses. This property facilitates earlier extubation for procedures such as cardiac surgery in infants [299]. This advantage is also seen in pediatric patients with obstructive sleep apnea, where upper airway patency is maintained with less airway support compared to propofol when used for imaging studies [293].

Because of its effect to decrease sympathetic outflow from the CNS and in the peripheral nervous system, dexmedetomidine administration results in lower heart rate (HR) and mean arterial pressure (MAP) compared to baseline, with the effect generally proportional to the loading dose and infusion rate [293,300]. Decreases of up to 20–30% may be observed with rapid loading doses in less than 5 min, especially in the absence of surgical stimulation. Slower loading over 10 min lessens the magnitude of the decrease in HR and BP. Glycopyrrolate may be used to prevent or treat dexmedetomidine-induced bradycardia, although there are reports of systemic hypertension when this combination of drugs is used. High or repeated loading doses of dexmedetomidine may cause transient hypertension, presumably from binding of peripheral arteriolar α_1 receptors [293].

Dexmedetomidine lengthens all electrophysiological intervals in the cardiac conduction system, and can result in second- or third-degree heart block or junctional bradycardia [301]. In the setting of pediatric cardiovascular surgery, dexmedetomidine should be avoided in patients with these dysrhythmias. Dexmedetomidine should be used only with great caution in patients receiving digoxin, β-adrenergic blocking or calcium channel blocking drugs. Conversely, dexmedetomidine administration is associated with a lower incidence of atrial and ventricular tachydysrhythmias after cardiac surgery in children [302].

Formulation and dosing

Dexmedetomidine is freely water soluble and has a pKa of 7.1. Each mL of the undiluted solution contains 118 µg of dexmedetomidine hydrochloride (equivalent to 100 µg dexmedetomidine base) and 9 mg of sodium chloride in water. The solution is preservative free and contains no additives or chemical stabilizers [303].

As a sedative agent in the ICU setting, or as an adjunct to general anesthetic techniques, an IV loading dose of 0.5–1 µg/kg over 10 min, followed by an infusion of 0.3–1 µg/kg/h is sufficient in most settings, taking into account that other agents, i.e. benzodiazepines and opioids in the ICU, and volatile agents or regional anesthesia in the OR, will be used. Doses in neonates must be reduced by 50%, accounting for reduced hepatic metabolism [294]. As a sole IV sedative for procedural sedation for MRI, loading doses of 2–3 µg/kg, with or without infusion of 1–2 µg/kg/h, have been described as effective in children without cardiovascular disease. As an intranasal sedative or premedication, doses of 2–3 µg/kg are effective [292,304].

Dexmedetomidine has been described as a useful agent to prevent or treat tolerance and withdrawal syndromes from prolonged use of benzodiazepines or opioids in the ICU setting. Conversely, prolonged ICU administration of dexmedetomidine greater than 7 days has also been associated with a withdrawal syndrome that includes agitation, hypertension, and tachycardia [292].

Neuroapoptosis related to general anesthesia

At birth, the central nervous system is not fully developed and external interventions may alter this fragile organ. For example, detrimental plasticity has been described at the spinal cord level in neonates suffering from intense, prolonged pain [305]. In the same way, general anesthesia may induce neuroapoptosis in the developing brain [306] (Fig. 10.10).

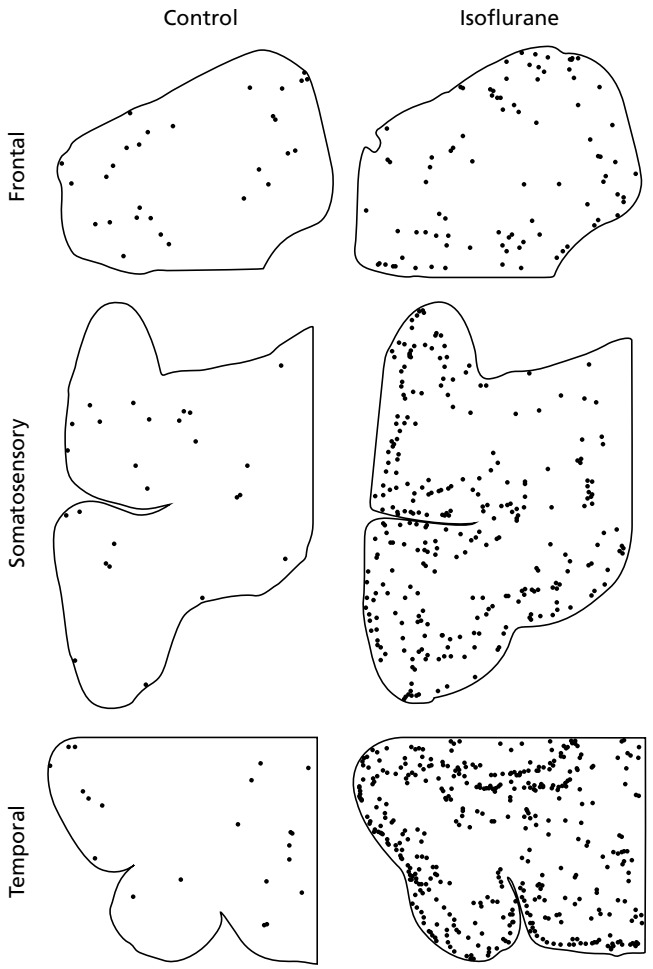

Figure 10.10 Brain sections of the neocortex in the rhesus macaque (computer reconstruction. It is clear that the number of apoptotic cells (black dots) is markedly increased in the animals exposed to 0.7–1.5 vol% end-tidal isoflurane for 5 h. *Source:* Reproduced from Brambrink et al [309] with permission of Wolters Kluwer.

To date, no clinical trial has been able to demonstrate any cognitive impairment in patients who had anesthesia in early life, but all regulatory agencies and anesthesia societies warn against unnecessary anesthesia in children up to 3 years of age. In 1999, a landmark study by Ikonomidou and colleagues demonstrated that blockade of NMDA receptors in the developing animal led to neuronal apoptosis [307]. Since then, numerous drugs have shown potential for neuroapoptosis in the developing brain, including ketamine and halogenated anesthetics, but also propofol and midazolam [95,96,265,308–310]. However, many of these animal studies have been conducted in extreme conditions, i.e. with associated hypoxia or decrease in blood pressure, which may add their confounding effects [311]. Dexmedetomidine has recently been proposed as a neuroprotectant drug, but clinical studies are needed to ascertain the results of animal studies [312]. At present, we may recommend postponing non-urgent procedures requiring general anesthesia. If the procedure is non-elective, awake regional anesthesia or regional anesthesia under light general anesthesia is certainly a good choice. If general anesthesia is mandatory, balanced anesthesia with opioids is certainly to be favored.

KEY POINTS: PHARMACOLOGY OF INTRAVENOUS AGENTS

- Propofol binds to $GABA_A$ receptors and is a versatile agent for induction and maintenance. Its effects to decrease vascular tone and interfere with mitochondrial function at high and prolonged doses are the drug's major drawbacks
- Etomidate is an imidazole derivative that binds to GABAA receptors. It is essentially devoid of cardiovascular effects, but even a single dose causes reversible adrenal suppression
- Ketamine binds to NMDA receptors and is a useful agent for induction and for IV sedation. Excessive salivation and dysphoria upon emergence are its major side-effects
- Dexmedetomidine binds to presynaptic α_2 receptors and has been used increasingly as an ICU sedative, an adjunct to general anesthesia, and for procedural sedation. It is the only commonly used IV sedative/hypnotic that does not cause neuroapoptosis in preclinical models

Opioids

Opioids interact with specific opiate receptors (μ, δ, κ). Their major sites of action include the spinal cord, the medulla, and the periaqueductal grey matter [313,314].

Two main families of opioids are currently available: long-lasting hydrophilic drugs, mainly used for postoperative or chronic pain relief, and short-acting drugs of the phenylpiperidine chemical family, used preferentially for perioperative analgesia. However, short-acting drugs are being used more and more commonly outside the operating room. These are almost pure μ receptor agonists. Except for remifentanil, the liver metabolizes phenylpiperidines.

Phenylpiperidines

Pharmacokinetics

Phenylpiperidines are weak bases that bind to AGP [29,315,316]. They are exclusively metabolized in the liver by the CYP3A4 isoform, with the exception of remifentanil, which is degraded in plasma by non-specific cholinesterases [317–319]. These cholinesterases are ubiquitous; their deficiency is lethal. Thus, all patients are able to metabolize remifentanil. Clearance of remifentanil is very rapid in neonates. The drug's clearance decreases slightly thereafter (Table 10.6). These molecules have no active metabolites. Fentanyl, alfentanil, and sufentanil undergo hepatic metabolism, which rapidly matures (Fig. 10.11) [46]. Sufentanil is a suitable choice for opioid administration by target-controlled infusion (TCI) because it has shorter, more predictable context-sensitive half-times than fentanyl or even alfentanil (see Fig. 10.9) [320]. The decrement times of remifentanil are very short and almost constant, whereas the decrement times of fentanyl markedly increase with duration of administration [21].

Effect on the central nervous system

None of these agents has a deleterious effect on cerebral hemodynamics, provided the CO_2 tension is normal. With normal $PaCO_2$, neither CBF nor ICP is increased [321–323].

Effect on the respiratory and cardiovascular systems

All opioids depress ventilation. Muscle rigidity may be a problem in younger patients, especially when the drug is rapidly injected [324]. At equipotent doses, all phenylpiperidines reduce FRC to the same extent [325,326]. When injected slowly, these agents do not significantly decrease chest wall compliance, which allows them to be used in ICUs. Interestingly, muscle rigidity has been described following remifentanil injection in the mother [327].

All phenylpiperidines have depressant effects on myocardial contractility and vascular tone [161,328–331]. They provoke marked bradycardia. Atropine does not totally restore myocardial contractility. Remifentanil causes more bradycardia than the other drugs, but at equianalgesic doses all four drugs probably have similar effects. The incidences of respiratory depression, nausea and vomiting, pruritus, and rarely urinary retention are similar for all opioids [313].

Fentanyl

Fentanyl is the oldest of these agents [46,332–336]. Its half-life is very long, particularly when it is used to sedate patients in ICUs. Fentanyl's hepatic extraction ratio is greater than 70–80% in children. Soon after birth, fentanyl's clearance from the body exceeds 50% of hepatic blood flow (see Fig. 10.11). Unfortunately, fentanyl's important volume of distribution and slow intercompartmental clearance leads to rapid increases in context-sensitive decrement times with increased duration of administration. Moreover, fentanyl is secreted into gastric fluid, and recirculation of the drug from gastric contents and deep compartments can occur long after recovery from anesthesia. The usual dosing is 2–4 μg/kg as a bolus injection and 1–2 μg/kg for reinjections. The same dose

Table 10.6 Opioids and acetaminophen. Physicochemical properties and pharmacokinetics

Drug	Molecular weight (Da)	pKa	Distribution ratio (octanol/buffer)	Protein binding %		T½ (h)	CL (mL/kg/min)	Vc (L/kg)	Vss (L/kg)	T½ke0 (min)

CL, clearance; T½, terminal elimination half-life; Vc, volume of the central compartment; Vss, steady-state volume of distribution. 1 Codeine is metabolized to morphine, which is the active molecule.

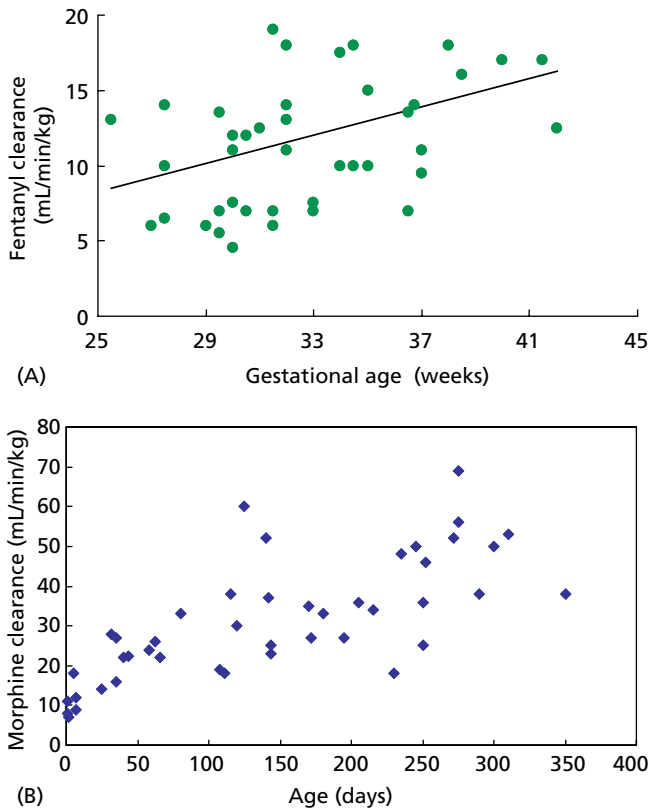

Figure 10.11 (A) Fentanyl and (B) morphine clearance as a function of age. In the younger premature infants, fentanyl clearance is relatively high (about half the liver blood flow). Maturation occurs rapidly and is almost complete at 42 weeks. Morphine clearance, on the other hand, is low at birth and maturation is complete only at the end of the first year of life. *Source:* Reproduced from (A) Saarenmaa et al [46] and (B) Lynn et al [45] with permission of Elsevier.

1–2 µg/kg/h is used for continuous IV infusion. Continuous infusion of fentanyl is not recommended during surgery if the plan is to extubate the trachea shortly after surgery. The time to peak effect is 5–6 min.

Alfentanil

Alfentanil has a short half-life, limited distribution into deep compartments, and high clearance (see Table 10.6) [335,337,338]. After an IV bolus dose of drug, alfentanil's peak effect occurs in 1–2 min. Following a prolonged infusion, decrement times increase moderately. The usual bolus dose of 10–20 µg/kg is followed by reinjections of 5–10 µg/kg for procedures of short duration.

Sufentanil

Sufentanil's half-life is of intermediate duration [335,337, 339–343]. Its effect is prolonged the least by prolonged administration, which is why its use has become very popular. Sufentanil's time to peak effect is 2–4 min. The usual bolus dose is 0.2–0.4 µg/kg at the time of anesthesia induction, followed by either reinjections (0.1–0.25 µg/kg) or an infusion of 0.1–0.5 µg/kg/h.

Remifentanil

Remifentanil is a very potent opioid that has a rapid onset (<1 min) and a very short half-life [337,344–349]. Its decrement times are constant. The context-sensitive half-time, i.e. 50% decrement time, is close to 4 min no matter how long the drug is administered. When given with propofol (3–4 mg/kg) or sevoflurane (0.5–1 MAC), excellent intubating conditions are produced in children in 20–30 sec after a bolus of 2–3 µg/kg. However, bolus doses of remifentanil are not recommended in neonates and infants because these patients may develop significant bradycardia and hypotension [327,328]. When given with 0.5–1 MAC of volatile anesthetic, a continuous infusion of 0.15–0.25 µg/kg/min (in neonates and infants) or 0.50 µg/kg/min (in children) gives excellent analgesia and stability, even for neonates who are more susceptible to the HR and blood pressure effects. However, care should be taken to (1) provide quality analgesia upon awakening and in the postoperative period because the analgesic effects of remifentanil are very short once the

drug infusion is discontinued, and (2) look for occurrence of the postoperative hyperalgesia syndrome, which follows the administration of large doses of opioids. Remifentanil and sufentanil are the drugs of choice for TIVA. The usual dose of remifentanil is 0.10 µg/kg/min in infants and 0.25 µg/kg/min in children.

Morphine

Morphine is a natural alkaloid derived from *Papaver somniferum*. It is an ampholyte, with a MW of 285 (free base), pKas of 9.85 and 7.87, an octanol:water distribution ratio of 1.42 at physiological pH, and is 35% protein bound to HSA. Morphine has four isomers, with little difference between them (codeine has the same isomeric distribution and morphine-6-glucuronide (M-6-G), the active metabolite of morphine, has two isomers).

Pharmacokinetics

Morphine (like hydromorphone) does not undergo phase 1 metabolism by cytochrome P450, but undergoes direct phase 2 metabolism by the 2B7 and to a lesser extent the 1A3 isoforms of UGT [37,39,350,351]. About 40% of morphine metabolism is extrahepatic, explaining why clearance is markedly greater than hepatic blood flow [352]. However, in patients with either a prothrombin time >40% above normal or a liver mass that decreases hepatic function by 50%, dosing must be halved (titration is unchanged) [353–355]. Although less than 10% of morphine is transformed to M-6-G, it has major importance because M-6-G has 2–8 times the potency of morphine and because its clearance is critically low [356,357]. In cases of renal failure, M-6-G elimination is impaired, and the risk of respiratory depression increases when the creatinine clearance (CrCL) is below 30 mL/min/1.73 m^2 [358]. Because the production of M-6-G is delayed, its concentration rises long after morphine administration is discontinued (Fig. 10.12). In patients with a CrCL of 15–30 mL/min/1.73 m^2, the dose of morphine should be halved. Drugs other than morphine should be given if the CrCL is <15 mL/min/1.73 m^2. Naloxone is efficacious for the treatment of narcotic-induced respiratory depression, but at times it must be infused for hours or even days. Peritoneal dialysis is poorly efficacious for removal of morphine, but hemodialysis (and usually hemofiltration) removes M-6-G. However, M-6-G may accumulate between dialysis sessions. Fentanyl and sufentanil are eliminated by hemofiltration and require the use of alternative agents in ICU patients undergoing hemofiltration.

Phase 2 metabolism is immature at birth and slowly increases during the first 6–9 months of life (see Fig. 10.11) [36,45]. This fact, together with the opioid receptor immaturity during the same period of time, explains why morphine dosing is different in young infants than in older infants and children (see Table 10.6) [35,36,359–362].

Morphine is hydrophilic and does not easily cross biological membranes. Morphine's effect concentration peaks 20 min after an IV injection (see Fig. 10.12). However, morphine concentration in the effect compartment reaches 80% of the peak concentration 6 min after an IV bolus. It remains above this concentration for 80 min. Morphine's duration of action is much longer than that of fentanyl or sufentanil.

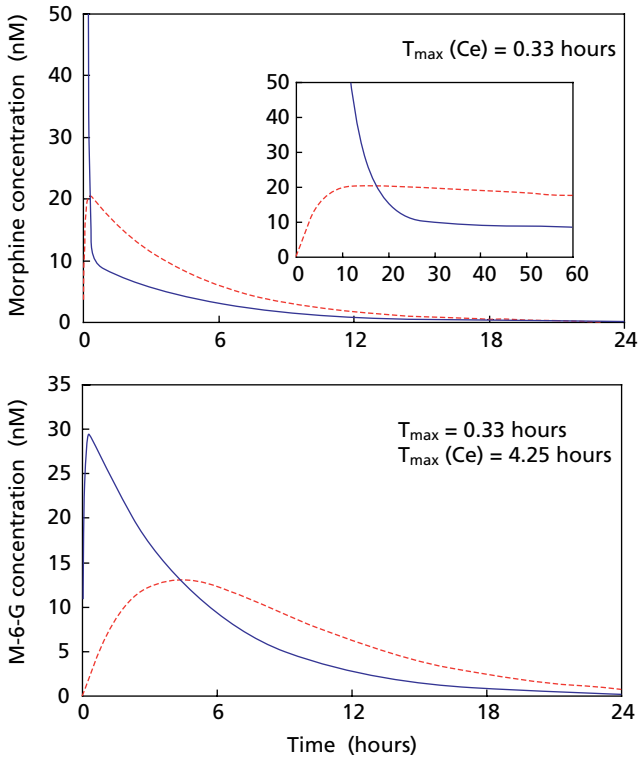

Figure 10.12 Morphine (*top*) and M-6-G (*bottom*) concentrations in the central compartment (*solid lines*) and in the effect compartment (*dotted lines*) after a single IV injection of morphine. After an IV bolus injection, morphine concentration peaks at 20 min because this hydrophilic drug slowly crosses the blood–brain barrier. M-6-G, which is more hydrophilic, peaks more than 4 h after the morphine injection. This phenomenon explains why the effect of oral morphine is delayed (part of the effect is due to M-6-G because of the first-pass effect). Adapted from Mazoit et al [356].

Pharmacodynamics

Respiratory depression is a frequent side-effect of opioids in neonates and infants. Respiratory rates decrease progressively, and respiratory depression increases. Depression is more associated with episodes of desaturation than with hypercarbia because of the associated sedation. However, sedation is difficult to appreciate in infants because they normally sleep much of the time. Monitoring by transcutaneous pulse oximetry is recommended for young infants, but clinical observation is also necessary, often in the postanesthesia care unit (PACU) or ICU. Apart from respiratory depression, the other side-effects of morphine include nausea and vomiting, urinary retention, pruritus, and constipation after 2–3 days of drug administration. Dexamethasone, droperidol, or a 5-HT3 receptor inhibitor like ondansetron best prevents postoperative nausea and vomiting (PONV).

Dosing

Morphine should be titrated in infants and young children. In neonates and infants younger than 3 months of age, a continuous IV infusion of the drug is usually sufficient. The doses are

between 10 and 30 µg/kg/h and are adjusted according to desired effect and the respiratory rate. Infants <3 months of age are very sensitive to the respiratory depressive effect of morphine. In infants older than 3–6 months and children <10 kg BW, IV titration of the drug is begun by injecting a loading dose of 50 µg/kg in those aged <12 months or 100 µg/kg thereafter. The loading dose is followed by 25 µg/kg every 5 min until the desired effect is reached. Children <40 kg usually receive 75 µg/kg every 5 min until the effective dose is reached. Children weighing more than 40 kg may receive the adult regimen, i.e. 3 mg as a bolus every 5 min. Before the age of 6–7 years, it is not appropriate to use a PCA device with the parents injecting the boluses because of safety issues. Even after this age, this method has its limits, and only a few teams continue to practice parent-controlled analgesia. Continuous infusions of opioids have shown similar benefits and similar limits as PCA, i.e. the lack of efficacy on pain with movement. The infusion regimen is between 20 and 40 µg/kg/h. After the age of 6 or 7 years, children are able to understand the principle of PCA. The dosing and rules of administration for children are similar to those for adults, i.e. boluses of 15–20 µg/kg every 5–10 min. Use of a continuous infusion of morphine along with the PCA has long been used, but this practice may induce respiratory depression. In patients receiving a continuous infusion of drug, nurse-controlled analgesia allows the injection of small boluses of drug and/or the modification of the infusion rate of morphine by increments or decrements of 5 µg/kg and is used in numerous centers. This is a good practice, provided all team members (including doctors and nurses) are well trained and follow rigorous protocols.

When pumps for continuous drug infusion or for PCA are not available, the intramuscular or (better) subcutaneous route can be used, but when this is done, the blood concentrations exhibit peaks and valleys. The oral route is also possible. However, when this route is used, the hepatic first-pass effect needs to be taken into account because part of the morphine dose is metabolized before reaching the general circulation. Only 10% of the metabolites are active (M-6-G). The concentration of M-6-G in the effect compartment is not significant before 6–9 h after initial administration of the drug (see Fig. 10.12). The oral dose of morphine is 0.2–0.4 mg/kg, with a maximum dose of 20 mg every 6 h.

Other opioids

Tramadol

Tramadol, a centrally acting analgesic, is a racemic mixture of cis and trans isomers that have few differences in activity, binding, or metabolism. It is a weak µ opioid receptor agonist that inhibits norepinephrine and serotinin reuptake [363–365]. The (+) enantiomer has greater affinity for the µ receptor and preferentially inhibits serotonin uptake while enhancing serotonin release. The (–) enantiomer preferentially inhibits norepinephrine reuptake by stimulating α_2-adrenergic receptors. The O-desmethyl metabolite (M1) is active and (+)M1 is the principal active molecule.

Pharmacokinetics

Tramadol is metabolized primarily by the CYP2D6, which is immature at birth [53,54,363,364]. Formation of M1 is impaired *in utero* and has important polymorphisms. The affinity of M1 for the µ receptor is 300–400 times greater than that of tramadol [365]. Both forms have similar half-lives [366–368]. Because M1 is at least as efficacious as the parent drug, there is a lag-time between its administration and effect. This is why the tramadol dose–effect relationship is flat and why it provides inadequate analgesia when injected immediately after surgery [369]. Hepatic failure markedly decreases the clearance of tramadol. Renal failure slightly decreases its clearance, but markedly decreases M1 clearance. CYP2D6 polymorphism may lead to inadequate analgesia in 5–6% of Caucasians because tramadol metabolism and M1 formation are reduced. In contrast, ultra-fast metabolizers of tramadol are at risk of respiratory depression. This wide variation in metabolism has resulted in the FDA issuing a warning that tramadol is contraindicated and should not be used in children less than 12 years of age for pain treatment, nor in children 12–18 years of age after tonsillectomy [370–372]. After oral administration, bioavailability of the drug is 70–90%. The T_{max} is 1–2 h, depending on the formulation (drops are more rapidly absorbed).

Pharmacodynamics

Respiratory depression with tramadol is less common than with morphine. Other side-effects include nausea, vomiting, dizziness, sweating, dry mouth, and drowsiness. However, like codeine, tramadol may induce severe poisoning in ultra-fast metabolizers [60].

Dosing

Tramadol is mainly used to treat mild to moderately severe postoperative pain and for intraoperative analgesia, although its analgesic properties are weaker than those of phenylpiperidines or morphine. Giving 2–3 mg/kg IV at the beginning of surgery can provide effective postoperative analgesia for many patients. Continuous infusions of tramadol are not recommended because the lag-time for M1 formation is long. Oral tramadol 1–3 mg/kg is given every 6–8 h.

Codeine

Codeine is a natural alkaloid from opium. It mainly acts by producing morphine, which is a minor metabolite (≈5–6% of codeine is transformed into morphine in most Caucasian subjects) [56,60]. The main metabolite, codeine-6-glucuronide, does not appear to be active. Because of CYP2D6 polymorphism, there are large variations in morphine production. For example, about 20–25% of East Asians do not metabolize codeine to morphine; 5–6% of Caucasians fail to do so. In those adults who metabolize codeine extensively, the absorption of 50 mg codeine leads to morphine and M-6-G production with C_{max} = 27 ± 23 and 41 ± 33 nM at T_{max} = 0.7 and 1.8 h respectively. The corresponding areas under the curve (AUC) compare with those obtained after 3–6 mg of oral morphine. However, some ultra-fast metabolizers have CYP2D6 gene duplication and may produce exaggerated amounts of morphine [57]. Fatalities have been reported in babies breastfed by their ultra-fast metabolizing mothers, in infants and young children treated with codeine for more than 1 day, or children with renal failure in whom M-6-G production was dramatically increased [58,59,373]. Codeine was also the subject of an FDA warning that the drug is contraindicated in children less than 12 years and in obese adolescents 12–18 years of age [370].

Dosing

Codeine is sometimes used in combination with acetaminophen. In children older than 6 months of age, dosing is 1 mg/kg/6–8 h. For day case surgery, parents should be warned against the possible lack of effect or the very rare possibility of overdosage with drowsiness or even coma and bradypnea [374].

Acetaminophen (paracetamol)

Acetaminophen has anti-inflammatory, antipyretic, and analgesic properties. Its mechanism of action is central and partly unknown [375,376]. Acetaminophen inhibits the COX-3 variant of cyclo-oxygenase. In addition, an active metabolite (p-aminophenol) may exert an effect through cannabinoid receptors.

Acetaminophen is poorly soluble in water. Mixing acetaminophen with mannitol and cysteine improves its solubility and stability. The time to peak plasma concentration is 30–60 min and 1–2 h after oral and rectal administration respectively (see Table 10.6) [377–382]. Bioavailability after oral administration is 85–95% and is usually <80% after rectal administration. Metabolism of the drug is by CYP2E1, CYP1A2, and CYP3A4 in the liver (see Table 10.1). N-acetyl p-benzoquinone imine (NAPQI) is a toxic metabolite that causes hepatotoxicity by binding to cellular proteins and forming drug adducts [33,383]. Paracetamol appears to be less metabolized in early infancy, but clearance rapidly increases after birth [381]. Neonatal icterus reduces clearance by 40%.

Exposure to acetaminophen in infancy and early childhood has been claimed to increase the incidence of asthma, but recent studies did not confirm the risk [384,385]. Intravenous paracetamol is also increasingly used to induce ductus arteriosus closure [386].

Dosing

Acetaminophen is available as tablets, an oral solution, suppositories, and a solution for IV infusion. The latter formulation is not available in all countries. For IV and oral administration, dosing is 10 mg/kg/6 h in premature infants and in neonates. Dosing is 15 mg/kg/6 h from 1 month to 2 years and 20 mg/kg/6 h from 2 to 15 years. By the rectal route, the first dose is 40 mg/kg.

Sucrose and other sweet-tasting solutions

These have shown antinociceptive properties in premature babies and neonates [387]. They are now commonly used, often in conjunction with comforting measures, to treat procedural pain and are recommended during awake regional anesthesia such as spinal anesthesia.

KEY POINTS: OPIOIDS

- Phenylpiperidine metabolism is almost fully mature in premature babies, hence increasing numbers of pediatric ICUs use fentanyl or sufentanil routinely for sedation
- Morphine metabolism is immature at birth and morphine clearance slowly increases during the first year of life. However, morphine remains the drug of choice in the postoperative period
- Codeine and tramadol mainly act via their metabolites. Some patients are ultra-fast metabolizers and are at risk of life-threatening complications. Codeine should therefore be avoided in children under 12 years, and particularly after discharge from hospital and in patients with sleep apnea syndrome

Muscle relaxants and reversal agents

The main two classes of muscle relaxants are depolarizing and non-depolarizing. Suxamethonium is the only depolarizing muscle relaxant still in use. Non-depolarizing agents include non-steroidal and steroidal agents. Both classes are non-competitive antagonists of acetylcholine (ACh).

Neuromuscular transmission

Muscle contraction is elicited by release of ACh in the synaptic cleft of the neuromuscular junction [388,389]. Calcium-dependent mechanisms are responsible for release of ACh from stores in presynaptic vesicles. In the synaptic cleft, ACh is rapidly degraded by acetylcholinesterases. There is also reuptake of some of the Ach by the motor nerve endings. Ach works by stimulating opening of muscle nicotinic acetylcholine receptors (nAChR), which allows sodium and calcium to enter the cells. The signal is further transmitted by sodium channels ($NA_V1.4$) [390], which are particularly abundant around endplates. $NA_V1.4$ density is lower in neonatal muscle. Seventeen subunits assemble numerous nAChR subtypes. Two variants of muscle type receptors, the adult $\alpha_1\beta_1\varepsilon\delta$ and the fetal $\alpha_1\beta_1\gamma\delta$, are present in humans (Fig. 10.13). During the first 2–4 years of life, the adult subtype progressively replaces the fetal subtype. Fetal receptors respond more slowly to ACh. Interestingly, fetal subtypes are re-expressed in ICU patients during prolonged periods of immobilization and inflammation. Neonates, infants, and young children also release less ACh into synaptic clefts than adults. However, the response of infants and children to muscle relaxants depends

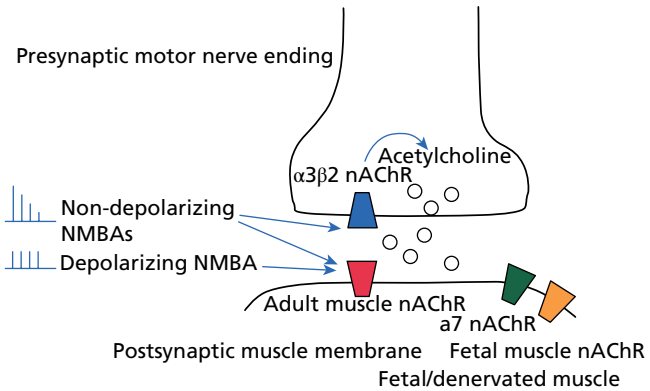

Figure 10.13 A schematic representation of the neuromuscular junction. The effect of neuromuscular blocking agents (NMBA) on the postsynaptic and presynaptic nicotinic acetylcholine receptor (nAChR) is depicted. The fetal muscle type nAChR has a lower affinity and rate of response than the usual adult receptor. *Source:* Reproduced from Fagerlund and Eriksson [389] with permission of Elsevier.

on numerous factors, such as the pharmacokinetics of the muscle relaxant and the binding capacity of the receptor. For example, the volume of distribution of succinylcholine and most non-depolarizing agents is increased in infants.

Monitoring neuromuscular blockade [391]

The only way to directly and reliably determine and prevent residual muscular blockade is by neuromuscular stimulation by acceleromyography. Acceleromyography measures the contraction of muscles in response to stimulation of their motor nerve. Single twitch measures the response height elicited by a single impulse. The train-of-four (TOF) measures the response to four successive supramaximal stimuli at 0.5 s intervals, and the height of the fourth to the first response is determined (T4/T1 ratio, that measures the amount of fade after repetitive stimulations). This ratio measures the decrease in response (fade) to repeated stimuli and is a measure of the amount of fade. Tetanic stimulation, the result of high-frequency stimulation, causes tetanic muscle contraction. Double-burst stimulation (DBS) consists of two short tetani (three impulses at 50 Hz) separated by an interval long enough to allow relaxation (usually 750 ms). Post-tetanic stimulation is the response to a single twitch or a TOF after a tetanic facilitation. Presynaptic neuronal nAChR is not inhibited by succinylcholine. Fade observed with non-depolarizing agents is related to the effect on presynaptic receptors; succinylcholine has no effect on these receptors, thus no fade is observed with this agent. This may explain why there is a lack of effect with TOF and tetanic fade [392]. All non-depolarizing drugs, on the other hand, inhibit neuronal nAChR and exhibit fade. The most common monitoring sites are the adductor pollicis (thumb), the orbicularis oculi (eyelid), and the corrugator supercilii (superciliary arch). The last is used to test for blockade of the laryngeal adductor muscles. The time course of blockade of the different muscles varies (Fig. 10.14) [393–396]. The abdominal wall and laryngeal muscles exhibit rapid onset and offset of neuromuscular blockade compared to the adductor pollicis. In addition, laryngeal adductors require higher doses of non-depolarizing drugs to achieve complete blockade than the adductor pollicis. The diaphragm is the muscle most resistant to blockade; its onset and recovery from blockade are similar to those of the adductor pollicis.

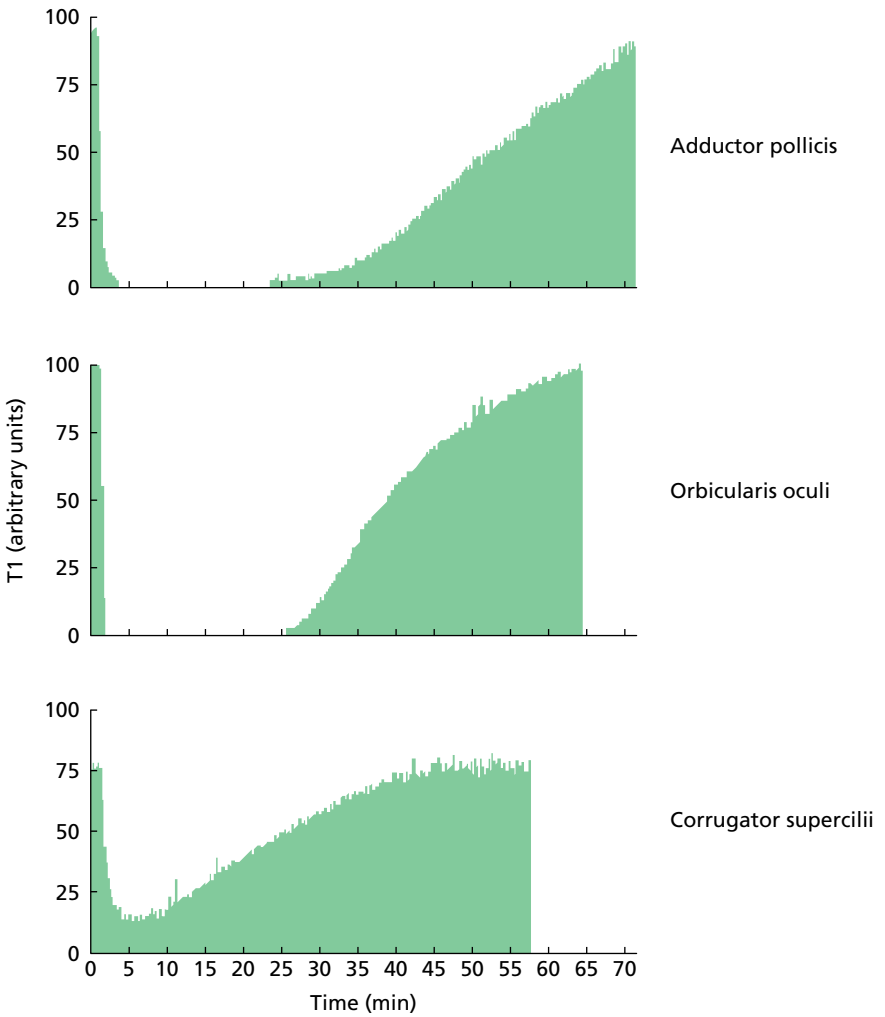

Figure 10.14 Difference in pharmacodynamics of muscles after injecting rocuronium into a patient. Train-of-four stimulations were repeated every 15 s and the T1 response is depicted in the figure. Clearly, the corrugator supercilii has a shorter delay of response, but is more resistant. Its kinetics is close to that of the laryngeal muscles. This is in perfect accordance with the 2–4-fold difference in T½ke0 reported for the adductor pollicis and laryngeal muscles after vecuronium or rocuronium injection. *Source:* Reproduced from Plaud et al [393] with permission of Wolters Kluwer.

Table 10.7 Muscle relaxants and reversal agents. Physicochemical properties and pharmacokinetics

Drug	Molecular weight (Da)	Distribution ratio (Octanol/ buffer)	Protein binding %	T½ (min)	CL (mL/kg/ min)	Vc (mL/kg)	Vss (mL/kg)	T½ke0		Ce50 (ng/mL)

Ce50, pseudo-steady-state concentration leading to half maximum effect; CL, clearance; T½, terminal elimination half-life; T½ke0, rapid equilibration half-life; Vc, volume of the central compartment; Vss, steady-state volume of distribution.

The differences in T½ke0 at different sites reflect differences in muscle physiology (Table 10.7 and Fig. 10.14). Low degrees of neuromuscular blockade cause sufficient pharyngeal dysfunction to allow easy tracheal intubation [397]. Consequently, the corrugator supercilii is the best indicator of ease of tracheal intubation, and the adductor pollicis is the best indicator of early recovery from the block. One response out of four (TOF) means that the muscular force is <10% of control. When the fourth response reappears, the force of the tested muscle has reached at least 25% of control. In clinical practice, the recovery of T4/T1 to >90% indicates that non-significant residual block remains. Reversal of muscle blockade is usually only possible if two of four responses of the TOF are present.

Succinylcholine

Despite succinylcholine (SCh) being the only depolarizing muscle relaxant available, its precise mechanism of action remains unclear. Its injection induces massive exocytosis of Ach and muscle fasciculation. The ensuing paralysis involves complex mechanisms that include desensitization of the receptor and inactivation of the sodium channels. SCh has a rapid onset and short duration of action, which makes it the agent of choice for rapid sequence induction.

SCh has low affinity for the presynaptic nAChR and causes a phase I block (decreased twitch amplitude, absence of fade, absence of post-tetanic potentiation). Large doses of SCh cause tachyphylaxis and a phase II block that resembles a non-depolarizing block.

Pharmacokinetics

Succinylcholine has two molecules of ACh linked by an ester bond. It is highly hydrophilic (see Table 10.7) [398]. Like cocaine, heroin, and ester local anesthetics, SCh is hydrolyzed in serum, red blood cells, and liver by non-specific esterases (butyrylesterases or pseudocholinesterases) [399,400]. There are many plasma cholinesterase genotypes that are responsible for wide variations in plasma cholinesterase activity. Some patients have reduced blood pseudocholinesterase activity. More than 20% of Caucasians are heterozygous for the main atypical variant. Patients with this variant have elimination half-lives that are nearly double those of patients without the variant. Patients who are homozygous for the abnormal variant may remain paralyzed for hours to days following a single injection of SCh. Determining the dibucaine number is the test for lack of pseudocholinesterase. However, lack of sensitivity, specificity, and cost make its routine use unlikely. Eskimos and Australian aborigines share the same genotype and have greater risk for prolonged paralysis with SCh.

Succinylcholine rapidly accesses the neuromuscular junction. It is rapidly degraded due to its small volume of distribution and to elimination from both the central and peripheral compartments (see Table 10.7) [401]. The elimination half-life of SCh is 1 min. However, the T½ke0 for blockade of the adductor pollicis is 12 min and is similar to that for non-depolarizing agents. The short onset of the drug's effect is aided by the high dose injected. Unfortunately, no recent data for infants and children are available [402–404]. Infants require 3 mg/kg and children 2 mg/kg to produce the same intubating conditions. It is highly probable that these differences in

drug dosage are the result of different volumes of distribution in the two groups. SCh is very hydrophilic. PK-PD data are needed in newborns, infants, and children, and should be correlated using allometric scaling.

Pharmacodynamics

Succinylcholine has numerous side-effects that have caused some anesthesiologists to abandon its use.

Effects on the central nervous system

Succinylcholine is said to increase ICP. However, recent studies have shown that this is not the case if normocapnea is maintained. It has also been thought to increase intraocular pressure by causing contraction of the extraocular muscles. Recent evidence has shown that intraocular pressures do not increase when the trachea is rapidly intubated and the lungs are ventilated [405].

Effects on the cardiovascular system

Succinylcholine can cause either tachycardia or bradycardia, but bradycardia seldom occurs with the first dose of ACh. It occurs much more commonly after a second or third dose of the drug. Bradycardia is easily prevented by atropine [406]. Although not well documented, SCh-induced fasciculations are said to increase cardiac output and $CRMO_2$. This effect does not appear to have clinical relevance.

Potassium release, effects on muscles, and malignant hyperthermia

Potassium release

Succinylcholine causes potassium release that usually is minimal and has no clinical consequence, unless the patient is hyperkalemic. Patients with Duchenne muscular dystrophy and other myopathies, paralysis (usually of spinal origin), rhabdomyolysis, and burns have a significant risk for developing arrhythmias with SCh due to receptor upregulation and phenotype changes in denervated muscle [407,408].

Masseter rigidity and malignant hyperthermia

Succinylcholine may cause masseter spasm and incomplete relaxation of the jaw, particularly when it is given during halothane anesthesia. Some authors argue that this occurs because the dose of SCh was inadequate. SCh can trigger malignant hyperthermia (see section "Pharmacokinetics and pharmacodynamics of inhaled anesthetics" and Chapter 45). This is more likely when it is used with halothane or sevoflurane.

Non-depolarizing muscle relaxants

Non-depolarizing muscle relaxants compete with ACh at both muscle and neuronal nAChR. Non-depolarizing relaxants are either aminosteroids (pancuronium, vecuronium, and rocuronium) or benzylisoquinoliniums (atracurium, cisatracurium, and mivacurium) [409]. All of these drugs produce a block of <40 min duration. Mivacurium's duration of action is the shortest.

Pharmacokinetics

All neuromuscular relaxants are highly water-soluble and have small volumes of distribution [398]. They are best described by two- or three-compartment linear kinetics (see Table 10.7) [410–419]. The volume of the central compartment is no larger than the plasma volume, and the volume of distribution at steady state (Vss) is equal to one-quarter the body weight. Clearance of non-depolarizing muscle relaxants is usually relatively low, except for mivacurium, which is hydrolyzed by the same cholinesterases as SCh.

Metabolism

Aminosteroids are principally eliminated unchanged in urine and bile by carrier-mediated processes [420,421]. Transport is by OCTs and, to a lesser extent, by P-gp. Pancuronium has major renal transport and limited hepatobiliary transport [422]. As much as 25% of a dose of pancuronium can be recovered as the 3-hydroxy metabolite, which has blocking properties half as potent as those of pancuronium. Patients with renal and/or liver failure have delayed elimination of pancuronium. Vecuronium is excreted unchanged in urine and in bile (>50% is transported in bile) [423]. Patients who have cholestasis have reduced clearance of vecuronium. Renal failure has less effect. However, patients with end-stage renal failure also exhibit decreased clearance of vecuronium and a slightly higher sensitivity to the drug than normal subjects. Small amounts of 3-desacetyl vecuronium, a moderately active metabolite, were found in plasma after prolonged administration of vecuronium. Rocuronium, a derivative of vecuronium, has a rapid onset and duration of action that are similar to those of vecuronium. Rocuronium is excreted unchanged in urine and feces; its metabolism is minimal. Rocuronium's elimination is only slightly impaired by renal failure. Excretion by transporters is less impaired than that by metabolism. For example, patients with cirrhosis have greater volumes; patients with cholestasis and jaundice have decreased clearance. The order of clearance is pancuronium < vecuronium ≈ rocuronium, which explains their durations of action.

Atracurium has ten stereoisomers [424]. The 1R-cis, 1'R-cis isomer is called cisatracurium. Both atracurium and cisatracurium are spontaneously degraded in plasma by Hofmann elimination and to a small degree by carboxylesterase activity. The Hofmann reaction is rate limited and temperature and pH dependent. The main end-product of atracurium and cisatracurium is laudanosine, which is toxic and may cause seizures. However, serum concentrations of laudanosine are always below the toxic threshold. Because cisatracurium is 3–5-fold more potent than atracurium, cisatracurium causes less histamine release and has less potential for causing convulsions.

Mivacurium is hydrolyzed in plasma by the same pseudocholinesterases that hydrolyze SCh [425,426]. It is a mixture of stereoisomers; the cis-trans and the trans-trans both have similar potency. A third isomer, the cis-cis, accounts for <6% of the total amount of metabolites and is about one-thirteenth as potent as the other two isomers. Unfortunately, the cis-cis isomer is poorly cleared; its T½ is about 20–30 times longer than that of the other two isomers. Patients who are heterozygous for plasma cholinesterase (those with the atypical AA variant, i.e. 20% of the Caucasian population) clear the major isomers 50% less well and have a prolonged T½ [400]. Patients who are homozygous for AA or other variants can have prolonged

neuromuscular blockade. Clearance of mivacurium is moderately decreased by renal failure [426].

Pharmacodynamics

For neuromuscular blocking agents, ke0 is strongly correlated with logD, the distribution coefficient. Highly hydrosoluble molecules rapidly access their receptors, producing a rapid onset of action. Ce50 is inversely correlated to logD and to molecular weight (MW). Highly hydrosoluble molecules, and those with low MW, are more potent [398]. The duration of action depends on the rate of receptor access (T½ke0) and on affinity for the receptor. Interestingly, there is a great difference between the different sites of action. T½ke0 is much slower for adductor pollicis muscles than for the laryngeal muscles [393,395]. Drug access to the laryngeal muscles is 4–6 times more rapid than to the adductor pollicis and the diaphragm. The onset of action is dose dependent. Drugs with relatively short durations of action, such as rocuronium, may require relatively large doses of drug for the onset of action to be rapid. Rocuronium has the shortest T½ke0 and a rapid onset of action. Because of its intermediate duration of action, it is possible to use high doses of rocuronium to provide excellent intubating conditions 1 min after its injection.

Specific effect on organs

Non-depolarizing agents have little effect on CBF or ICP. Atracurium, cisatracurium, and mivacurium release histamine, which, when injected rapidly, can induce bronchoconstriction, hypotension, and tachycardia [427]. Pancuronium (and occasionally rocuronium) blocks muscarinic receptors and induces moderate tachycardia.

Interactions

Volatile anesthetics and neuromuscular blocking drugs interact [428–430]. The mechanism for this potentiation remains unclear, but is likely an additive effect on the nAChR [422]. For example, sevoflurane shortens the onset and prolongs the duration of a rocuronium-induced block in children. T½ke0 and Ce50 are decreased by 60%, and the recovery time to T1 = 5% is prolonged by 25%. Acid–base disturbances, hypokalemia, and hypothermia may prolong the duration of action of muscle relaxants. Numerous drugs (volatile anesthetics, antimicrobials such as gentamicin, lithium, and calcium-channel blockers) interact with neuromuscular blocking agents and enhance the block. Magnesium sulfate potentiates the action of non-depolarizing agents by decreasing Ach release. Resistance to neuromuscular blocking drugs can be caused by phenytoin, carbamazepine, and other anticonvulsants. Giving SCh after a non-depolarizing agent prolongs the block.

Allergy to muscle relaxants

Neuromuscular blocking agents can cause severe anaphylaxis, which is different from the release of histamine commonly observed when atracurium, cisatracurium, or mivacurium are injected rapidly [431–433]. Anaphylaxis is rare in neonates and infants. The incidence of anaphylaxis increases with age and reaches its maximum in 30–60-year-old patients. Based on skin tests, rocuronium is said to cause more allergic reactions than the other drugs, but skin testing may not be the best way to determine this. Grade III (bronchospasm ± urticaria) reactions occur in about 75% of cases.

Dosing

Tracheal intubation

The intubating dose of SCh is 1 mg/kg in adults, 3 mg/kg in infants, and 2 mg/kg in children. The intramuscular dose of SCh for emergency tracheal intubation is 5 mg/kg [434].

The intubating dose for rocuronium is 0.6 mg/kg in both infants and children. This dose produces excellent intubating conditions in <1 min. Older children often require the adult dose 1.2 mg/kg for rapid sequence induction of anesthesia. This dose of drug provides excellent intubating conditions, but its duration of action is prolonged.

Pancuronium 0.08–0.1 mg/kg has an onset time of between 3 and 5 min and duration of action of more than 60 min. The reinjection dose of 0.02 mg/kg is given when T2 of the TOF returns. *Vecuronium* 0.1–0.2 mg/kg has an onset time of between 1 and 3 min and duration of action of 30–40 min. The reinjection dose is 0.1 mg/kg. A continuous infusion at 1–1.2 µg/kg/min is used for maintenance. *Rocuronium* 0.4–0.6 mg/kg has an onset of between 1 and 2 min and duration of action of 40–60 min. The reinjection dose is 0.1–0.15 mg/kg. A continuous infusion of 5–15 µg/kg is often used for maintenance. *Atracurium* 0.4–0.8 mg/kg has an onset of between 2–3 minutes and duration of action of 40–60 min. The reinjection dose is 0.1–0.2 mg/kg. A continuous infusion of 5–15 µg/kg/min is used for maintenance. *Cisatracurium* 0.1–0.2 mg/kg has an onset of between 2–3 min and duration of action of 40–60 min. The reinjection dose is 0.03–0.5 mg/kg. A continuous infusion of 1–3 µg/kg/min is used for maintenance. *Mivacurium* 0.2 mg/kg has an onset of between 1–3 min and duration of action of <30 min.

Reversal agents

Two different classes of antagonists are used to reverse neuromuscular blockade: the quaternary ammonium reversible acetylcholinesterase inhibitors, and sugammadex.

Acetylcholinesterase inhibitors

Acetylcholinesterase inhibitors (neostigmine and edrophonium) are quaternary ammoniums and are hydrophilic, ionized compounds.

Pharmacokinetics

Neostigmine and pyridostigmine are tertiary ammonium compounds that bind covalently to acetylcholinesterase and form inactive carbamylated complexes that degrade slowly (T½ ~30 min) [435]. Edrophonium forms a weak complex that degrades more rapidly, which explains why its effects are shorter than those of neostigmine. Its half-life is shorter than that of either neostigmine or edrophonium. Neostigmine is rapidly metabolized at the neuromuscular junction by acetylcholinesterases and by erythrocytes. The nearly inactive metabolites are conjugated and eliminated by the kidney [436]. Edrophonium is metabolized to an inactive glucuronide conjugate. Interestingly, although the pharmacokinetics of both drugs are poorly understood, their terminal half-lives

are longer than those of all neuromuscular blockers, including pancuronium (see Table 10.7) [437,438]. In anephric patients, elimination of neostigmine is impaired (T½ = 181 versus 80 min). The time to reach T1, T4/T1 and T2 is always shorter in children than in adults. Moreover, recovery occurs more quickly with edrophonium in children than with neostigmine [439–446]. This is true for all blocking agents studied. Neostigmine is about 12–18 times more potent than edrophonium. In pediatric patients, the doses of edrophonium required for either 50% or 80% recovery of twitch height are comparatively greater (on a weight basis) than in adults. It is unclear if this is true for neostigmine.

Pharmacodynamics

Acetylcholinesterase inhibitors have numerous side-effects that are mostly related to their muscarinic effects [427]. These include bradycardia, salivary and intestinal secretions, miosis, and bronchoconstriction. Atropine or glycopyrrolate administration can prevent or reverse these effects. In pediatric patients, atropine-induced tachycardia is rarely a problem, but bradycardia may be a problem, particularly in neonates and infants. Edrophonium causes less bradycardia than neostigmine and is preferred in pediatric patients. The bronchoconstriction induced by these drugs may be a problem, particularly in patients with asthma.

Dosing

In infants and children, the dose of neostigmine required to reverse the block varies between 0.03 and 0.07 mg/kg, depending on the neuromuscular blocking agent used. The author recommends a bolus of 0.05 mg/kg. The drug's peak effect occurs 10 min after injection. Edrophonium 0.75–1 mg/kg is given as a bolus. Its peak effect occurs 2–3 min after injection. Atropine 10–-15 µg/kg should be given *before* either drug to prevent bradycardia. Glycopyrrolate 4 µg/kg in children and up to 8 µg/kg in neonates and infants effectively prevents bradycardia.

Sugammadex

Sugammadex is a cyclodextrin that can encapsulate aminosteroid neuromuscular blockers. It has an outer hydrophilic structure and an inner hydrophobic core. The drug was designed to specifically encapsulate rocuronium and vecuronium and to a lesser extent pancuronium. Sugammadex has no effect on benzylisoquinoliniums (atracurium, cisatracurium, and mivacurium). No serious side-effects have been reported, but anaphylaxis is possible.

Pharmacokinetics

Sugammadex is eliminated unchanged by the kidney [447]. Its half-life exceeds that of all neuromuscular blockers [448,449]. Its clearance is 75–138 mL/min, which approximates the glomerular filtration rate (GFR). In patients with renal failure, the decrease in sugammadex clearance is similar to the decrease in renal clearance [450]. The affinity of sugammadex for vecuronium and rocuronium differs. T½ke0 for vecuronium is twice that of rocuronium (see Table 10.7). This difference in the rate of access is consistent with the difference in Kd, the equilibration dissociation rate constant (0.1 µM for rocuronium versus 0.175 µM for vecuronium). However, the binding capacity is similar for both drugs (the ratio of Ce50 for the sugammadex effect site is similar to the ratio of Ce50 for neuromuscular junction effect site). After a dose of rocuronium, 2 mg/kg of sugammadex is injected at reappearance of T2. The time to 90% recovery of TOF occurs after 0.6 min in infants, 1.2 min in children, and 1.2 min in adults. Doses >2 mg/kg do not hasten recovery.

Dosing

For routine reversal of a block after reappearance of T2, 2 mg/kg of sugammadex is adequate [451]. However, in an emergency (e.g. failure to intubate the trachea after a large dose of rocuronium), sugammadex doses as high as 12 mg/kg may be required.

Anticholinergic agents

Two anticholinergic agents are clinically available, atropine and glycopyrrolate [452–458]. These are non-selective competitors for ACh at the muscarinic receptors and have little or no action on nicotinic receptors.

Atropine is a natural alkaloid of *Atropa belladonna*. It is a tertiary amine with a pKa of 9.9. Atropine is highly ionized at physiological pHs and rapidly diffuses in water compartments (Vd 4.9 L/kg). Atropine has a chiral carbon (the R form is almost inactive).

Glycopyrrolate is a synthetic quaternary ammonium salt that is totally ionized at physiological pHs. Its volume of distribution is small, 0.60 L/kg. In adults, the terminal half-life of atropine is 3–4 times longer than that of glycopyrrolate (2.3–3.7 versus 0.8 h). In infants and children, glycopyrrolate's T½ is very short (20 min) due to its greater clearance (22 mL/kg/min (infants and children)versus 9 mL/kg/min (adults)). Atropine's clearance is 15.4 mL/kg/min in adults. The larger volume of distribution in neonates and infants makes the T½ longer than in adults. Atropine is metabolized in the liver; one of its metabolites, 1-hyoscyamine, is active. Glycopyrrolate is not extensively metabolized and is rapidly excreted unchanged in urine. Elimination of glycopyrrolate is impaired by renal failure. Unlike atropine, glycopyrrolate does not cross the blood–brain barrier.

Anticholinergic agents increase heart rate, inhibit secretions, and induce bronchodilation. Atropine induces mydriasis while glycopyrrolate does not. At very low doses, both drugs can cause bradycardia. Glycopyrrolate's heart rate effects are delayed compared to those of atropine (2–3 min versus 1 min). Toxicity (tachycardia, restlessness and excitement, hallucinations, delirium, and coma with paralysis) occurs at supratherapeutic doses of atropine. Hypotension and circulatory collapse may also occur.

Dosing

The IV dose of atropine is 10–15 µg/kg. That of glycopyrrolate is 4 µg/kg for children and up to 9 µg/kg for infants 1 month to 2 years old. Some preparations of glycopyrrolate contain benzyl alcohol, which is toxic to neonates and infants and should not be repeated.

Following intramuscular injection, T_{max} occurs in 15–30 min. However, drug absorption by this route varies widely. IM doses are similar to or slightly higher than IV doses.

KEY POINTS: MUSCLE RELAXANTS AND REVERSAL AGENTS

- Succinylcholine has a very large volume of distribution in infants. The intubating dose is 3 mg/kg before 1 year and 2 mg/kg from 1 to 6–8 years
- The dose of neostigmine required to reverse the block is 0.05–0.07 mg/kg in infants and children
- Atropine (10–15 µg/kg) or glycopyrrolate (5–10 µg/kg) must be administered *before* reversal in infants (bradycardia induces a major fall in cardiac output in infants)
- Aminosteroid relaxants are mostly excreted unchanged by membrane transporters, which are not all fully mature at birth and during the first years of life. Atracurium and cisatracurium are degraded by the Hofmann reaction, which is temperature dependent
- Sugammadex is a newer cyclodextrin reversal agent specific for vecuronium and rocuronium. Large doses up to 12 mg/kg can be used for emergency reversal of dense neuromuscular blockade

Local anesthetics

Local anesthetics (LA) block propagation of impulses along nerve fibers by inactivation of voltage-gated sodium channels, which initiate action potentials [459]. Some toxins (tetrodotoxin (TTX)) act on the outside of cells to block action potentials; local anesthetics have their effects on the cytosolic side of phospholipid membranes. Two main chemical compounds have been synthesized and used clinically as LAs, amino esters (2-chloroprocaine, procaine, tetracaine) and amino amides (lidocaine, bupivacaine, ropivacaine). Amino esters are degraded by pseudocholinesterases in plasma; they undergo minimal hepatic metabolism. Amino amides are more stable and are metabolized exclusively by the liver.

Pharmacokinetics [460]

Local anesthetics (LAs) are weak bases with molecular weights of 236–288 Da (Table 10.8). The pKa of all LAs is between 7.6 (mepivacaine) and 9.1 (chloroprocaine). At a pH of 7.40, 60–85% of the molecules are ionized and diffuse in the body's water compartments. LAs are also soluble in lipids and cell membranes. Bupivacaine is 10 times more soluble in membranes than lidocaine; ropivacaine is twice as soluble as lidocaine. With the exception of lidocaine, all amide LAs possess an asymmetric carbon. Although the physicochemical properties (pKa, distribution ratio) of the isomers are identical, the enantiomers have different affinities for the biological effectors (channels, receptors, proteins). Ropivacaine and levobupivacaine are pure S-(–) enantiomers. LAs are marketed as hydrochloride salts in water at pHs of 4–5 to prevent them from coming out of solution. The salts precipitate when bicarbonate is added to the solution to increase its pH.

Like most weak bases, amide LAs bind to serum proteins and red cells. This may be clinically important, especially in neonates and young infants. Neonates who have hematocrits >45% may have less unbound drug. In serum, LAs bind to both AGP and albumin. Despite its low concentration in serum (less than 1 g/L in adults), AGP is the major protein that binds LAs. During the first 6–9 months of life, AGP concentrations progressively increase and reach adult levels by 1 year of age (see Fig. 10.3) [28]. When this occurs, the free fraction of LAs decreases [461]. The decrease in free fraction may protect from LA toxicity. However, the concomitant decrease in hepatic clearance of free drug may leave clearance unchanged (see Fig. 10.4). LAs also bind to HSA, but with a very low affinity. It is only because HSA is the most abundant protein in serum that its binding capacity is significant.

Absorption

After application of topical anesthesia to the upper airway via atomizer, LAs are rapidly absorbed and can cause toxicity, particularly in children under 4 years of age. This is why it is important to use devices that deliver no more than 10 mg with each activation [462]. EMLA® (eutectic mixture of local anesthetics) cream contains equal amounts of lidocaine and prilocaine and is not absorbed in significant amounts, except in premature babies [463]. Prilocaine produces methemoglobinemia in neonates and infants, especially if they are also treated with trimethoprim–sulfamethoxazole [464]. The cream may not work in premature babies because of their very high skin blood flow.

Table 10.8 Physicochemical properties of local anesthetics

Drug	Molecular weight (Da)	pKa*	Distribution coefficient†	Protein binding	Onset of action	Duration of action	Potency‡
Esters							
Procaine	236	8.9	1.7	6%	Long	1 h	0.5
Chloroprocaine	271	9.1	9.0	?	Short	½ h–1 h	0.5–1
Amides							
Lidocaine	234	7.8	43	65%	Short	1 h 30–2 h	1
Prilocaine	220	8.0	25	55%	Short	1 h 30–2 h	1
Mepivacaine	246	7.7	21	75%	Short	1 h 30–2 h	1
Bupivacaine**	288	8.1	346	95%	Intermediate	3 h–3 h 30	4
Ropivacaine	274	8.1	115	94%	Intermediate	3 h	3.5–4

* pKa at 37°C.
** Bupivacaine = levobupivacaine.
† Octanol:buffer partition.
‡ Potency is relative to lidocaine.

Amide LAs have a bioavailability of 1 (metabolism is exclusively hepatic). Since these drugs are hydrophobic, they bind to tissues, which delays their absorption. This delay varies depending on the local conditions. For example, absorption occurs more rapidly after an ilio-inguino-iliohypogastric block than after a caudal block. In adults, 3 h after an epidural injection, only 70% of a dose of lidocaine and 50% of a dose of bupivacaine or of ropivacaine is absorbed, which is a safety factor [465]. From adult studies it is clear that the speed of drug absorption decreases from head to foot and from the thoracic to the caudal portion of the epidural space. Lidocaine and bupivacaine concentrations peak about 30 min after caudal or lumbar injection in infants and adults. The T_{max} for ropivacaine is much longer in infants than in children and in children than in adults, probably because CYP1A2, which metabolizes lidocaine and ropivacaine, is immature before 4–7 years of age [466]. This phenomenon is less important with levobupivacaine because levobupivacaine is metabolized by CYP3A4/7 [467].

Epinephrine reduces the peak concentrations of LAs. The usual concentration used in clinical practice is 5 mg/L (1/200,000), which is optimal in adults. It is possible that this concentration of epinephrine may decrease spinal cord blood flow in some infants and produce neurological deficits. Therefore, some authors suggest using no more than a 1/400,000 concentration of epinephrine in infants <1 year of age, since this concentration is also efficacious [468].

Distribution

The volume of distribution of LAs at steady state (Vss) is slightly less than 1 L/kg (Table 10.9) [469–478]. Because drug absorption is delayed, volumes calculated after administration by non-intravenous routes are markedly overestimated. Terminal half-lives are also increased compared to values obtained after an IV injection. Total body clearance of the drug is only measured accurately following extravascular administration, but sampling must take place over a prolonged period of time. It is highly probable that LAs distribute into large volumes in neonates, infants, and adults, thus preventing high serum drug concentrations from occurring after a single injection. However, this is not the case following several injections. Ropivacaine's volume of distribution is smaller than that of bupivacaine in adults and probably in pediatric patients. At similar doses, the C_{max} of ropivacaine is higher than that of bupivacaine, despite ropivacaine's delayed T_{max}.

Elimination

Liver cytochrome P450 enzymes metabolize all amide local anesthetics. Bupivacaine is predominantly metabolized into pipecoloxylidide (PPX) by CYP3A4/7 [479]. Ropivacaine is predominantly metabolized to 3′- and 4′-OH-ropivacaine by CYP1A2 and to a minor extent to PPX by CYP3A4 [47]. These enzymes are not fully mature at birth and have important differences in their developmental expression. The extraction ratios for lidocaine (0.65–0.75) are relatively high. Lidocaine is flow limited rather than rate limited for its elimination. Therefore, any decrease in cardiac output decreases hepatic clearance of lidocaine. The resultant increase in plasma concentration of LA may be toxic. Bupivacaine and ropivacaine, on the other hand, have a relatively low hepatic extraction ratio (0.30–0.35) and are rate limited for their elimination. Thus, hepatic clearance and free fraction are major determinants of total clearance. After surgery, serum AGP concentrations increase, which increases protein binding. This decreases

Table 10.9 Bupivacaine, levobupivacaine, and ropivacaine pharmacokinetics after different routes in infants and children compared to adults

		fu	Vss# (l L/kg)	CLT/f (mL/min/kg)	CLU/f (mL/min/kg)	T½# (h)

fu, free fraction; Vss, volume of distribution at steady state; CL/f, total body clearance over bioavailability (T, total fraction, U, unbound fraction); T½, terminal half-life. For adults, a mean BW of 75 kg has been assumed.

#Apparent value, T½ and volumes measured after non-intravenous injections are overestimated because of a flip-flop effect (i.e. because absorption lasts longer than elimination).

* After 3 h infusion.

‡ After 48 h infusion, CLT decreases with time because protein binding increases.

total clearance but not intrinsic clearance. This resets the total serum concentration, without changing the unbound concentration (see Fig. 10.4). Bupivacaine clearance is low at birth and increases slightly during the first 6–9 months of life. Ropivacaine clearance, which is also low in neonates and infants, increases during the first 2–6 years of life [28,461,462,466,467,474–478]. Despite the low clearance, ropivacaine concentrations remain below toxic levels, even in younger patients.

Pharmacodynamics

Local anesthetics cross membranes as free bases (unionized). Inside the cells, they become ionized and bind to specific amino acids within sodium channel pores and mechanically block the pores [479]. LAs also block potassium and calcium channels, but this requires slightly higher drug concentrations than those needed to block sodium channels. Voltage-gated potassium channels initiate repolarization. Some of these channels (including the hERG (human ether-à-go-go related gene) channel) are responsible for genetically induced arrhythmias, such as the long-QT, short-QT, or Brugada syndromes. These channels are blocked by LA concentrations just slightly higher than those needed to block sodium channels [480,481]. Unlike the CNS and heart, peripheral nerves only express a small number of potassium channels. Both sodium and potassium channel blockade are stereospecific. The S enantiomers induce a lesser block than the R enantiomers. LAs bind to L-type calcium channels, but it is unclear if blockade of these channels affects the cardiotoxicity of long-lasting LAs.

Nerve fibers are either myelinized or unmyelinized. The action potential of unmyelinated fibers propagates continuously. After initial depolarization, the sodium channels become unreceptive to stimulation (refractory period), which prevents backward propagation of impulses. Sodium and potassium channels are evenly distributed along the fibers. Conduction velocity of small fibers is low. Myelin insulates myelinated nerves, and this layer is interrupted regularly by the nodes of Ranvier. Sodium channels are concentrated at the node of Ranvier in concentrations of ≈200,000 channels/cm^2 [482,483]. Potassium channels are distributed along the myelin sheet with a higher concentration present in the juxtaparanodal region. The sudden depolarization of the node induces an electrical field, which extends to 2–3 nodes. Action potentials "jump" rapidly from one node to the next. Because the distance between nodes is greater in heavily myelinated fibers (there are 3–4 nodes/cm in Aα fibers and 20–30 nodes/cm in Aδ fibers), the conduction velocity is faster in motor and small sensory fibers than in fibers that conduct pain signals. Because the electrical field extends over a relatively long distance, nerve fibers must be "bathed" over a relatively long distance by LAs. This progressive extinction of the signal is called decremental conduction. Fortunately, the phasic block that is induced by the high firing rate of nerves reinforces the block. Small Aδ lightly myelinated fibers are blocked by less drug than is needed to block heavily myelinated fibers. This phenomenon, called *differential nerve block*, is explained by differences in internode distance between fibers [484]. It is unknown to what extent concentration gradients across the myelin sheath also participate in this phenomenon. Myelinization begins during the third trimester of pregnancy and is incomplete at birth. After birth, myelinization increases

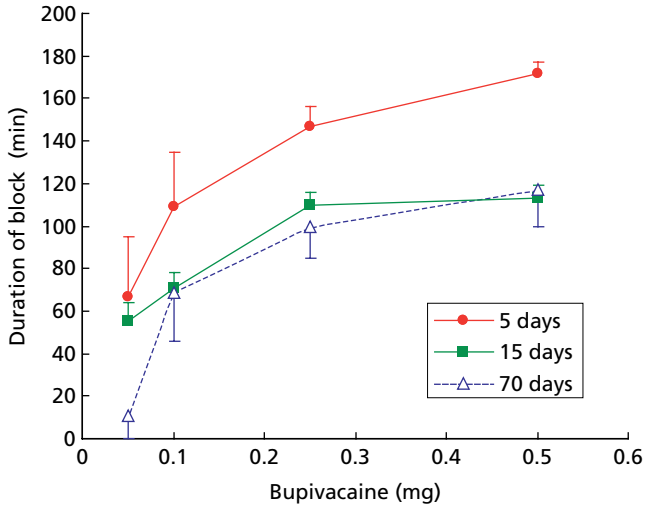

Figure 10.15 Duration of sciatic nerve blocks in rats after an injection of bupivacaine. The block is more protracted in newborn than in older rats. Duration of the block in 2- and 10-week-old rats was similar despite a marked difference in size and weight. It appears that the distance between nodes of Ranvier, which is fixed at its adult value by the age of 1–2 weeks, is the main determinant of the motor blockade. *Source:* Reproduced from Kohane et al [485] with permission of Wolters Kluwer.

rapidly and is almost complete by 3–4 years of age [483]. In rats, the nodes of Ranvier are fully mature at 2–3 weeks of age. Interestingly, the internode distance is similar between 2-week-old and adult rats. This may explain why infants and young children require larger volumes of LAs per kilogram than older children or adults (Fig. 10.15) [485]. Fortunately, lower concentrations of LA are needed to cause the block. Infants and children need larger volumes of solution with lower concentration of LAs to achieve blocks of similar intensity and duration as adults. Surprisingly, infants require larger doses of LAs for spinal anesthesia. Despite this, the duration of the spinal block is shorter. Some authors have attributed this difference to a larger volume and a more rapid turnover of CSF in neonates and infants than in older children and adults. Unfortunately, the pharmacokinetics of LAs in the CSF is particularly unknown in pediatric patients. The brain CSF volume and CSF turnover are lower in neonates and infants than in children and adults (see Fig. 10.15) [486,487]. The major factor responsible for this rapid effect seems to be pharmacodynamic. The intensity and duration of the block depend on number of nodes of Ranvier blocked (differential block). The distance between nodes is fixed soon after birth [482,483]. When this occurs, the short duration of spinal anesthesia in infants is not surprising.

Effects on the central nervous and cardiovascular systems

Like all inhibitors of sodium channels, low doses of LAs are anticonvulsive, which is why lidocaine is still used to treat intractable epilepsy in children [488]. However, the therapeutic ratio is low and the margin of safety does not favor lidocaine. At higher doses LAs may produce convulsions and coma. At similar concentrations to those that cause convulsions, long-lasting LAs can induce cardiac arrhythmias. With the exception of nodal conduction, which depends on calcium channels, impulse conduction in the heart depends on sodium

channels. This is why lidocaine is a chief class Ib antiarrhythmic agent. LAs prolong the refractory period, but the balance between the increase in effective refractory period and the decrease in the ventricular conduction velocity does not favor LAs. Long-lasting LAs, such as bupivacaine, profoundly decrease ventricular conduction velocity [489]. This phenomenon is markedly amplified by tachycardia [490]. In neonatal and adult animals, the intensity of the block is similar at similar heart rates [491]. However, because neonates and infants normally have higher heart rates than adults, they are more sensitive to local anesthetic-induced blocks than adults. LAs also impair myocardial contractility. However, to obtain the same decrease in contractile force, it is necessary to infuse 10 times more bupivacaine than is required to impair ventricular conduction. Apart from the effect of the central block-induced sympathetic blockade, LAs have direct vasoactive properties. The S enantiomers (ropivacaine and levobupivacaine) have mild vasoconstrictive properties. These properties have been advocated as the cause of ischemia after penile block, but a direct relationship between ropivacaine and ischemia in this report seems doubtful [492].

Stereospecificity

Mepivacaine, prilocaine, bupivacaine, and ropivacaine have an asymmetric carbon. Because binding to serum proteins, hepatic enzymes, or ion channels may be asymmetrical, different stereospecific properties are expected. Protein binding, pharmacokinetics, and nerve blocks have little stereoselectivity, which is why levobupivacaine has almost the same blocking properties as its racemic counterpart. In the heart, conduction is markedly stereospecific, whereas contractility is unaffected by stereoselectivity.

Local anesthetics have anti-inflammatory properties and inhibit platelet aggregation [493]. They decrease leukocyte priming and the production of free radicals [494–496]. Systemically administered lidocaine has antinociceptive effects, particularly on neuropathic pain [497]. Consequently, LAs are now used preoperatively to prevent postoperative hyperalgesia in adults [498]. Interestingly, LAs can prevent and even treat complex regional pain syndrome in adults and children by limiting the neuropathic inflammatory processes [499,500].

Toxicity of local anesthetics

At the site of injection, the minimum concentration required to produce a nerve blockade is 300–1500 μM for lidocaine and 100–500 μM for bupivacaine. In adults these concentrations of lidocaine occasionally cause cauda equina syndrome but are more likely to cause transient neurological symptoms following spinal anesthesia. LAs can also be toxic to muscles, bupivacaine being the most toxic [501,502]. Muscle toxicity is not enantioselective. Care should be taken when regional anesthesia is provided for eye surgery in adults, for children with myopathies (bupivacaine is an *in vitro* model of Duchenne myopathy), and perhaps for children with mitochondrial myopathy. Peripheral blocks are more dangerous than central blocks because it is easier to inject drug directly into muscle with peripheral blocks.

After both local and regional anesthesia, the blood concentration of LAs rises rapidly and can cause neurological or cardiac toxicity. Neurological toxicity occurs in about one case per 1000 patients [503]. Because of their low protein binding and intrinsic clearance, infants are more prone to LA toxicity than adults. General anesthesia may conceal the early signs of LA toxicity in children. In addition to pharmacokinetic factors, the rapid heart rate of children increases LA toxicity [491]. Ropivacaine and levobupivacaine (S-(–) enantiomers) are appropriate choices for younger patients because both drugs should produce less tonic block. Even if toxic events occur with ropivacaine, small doses of epinephrine should cause rapid recovery. Impaired ventricular conduction is the primary manifestation of LA toxicity. QRS widening, bradycardia, and torsades de pointe are followed by ventricular fibrillation and/or asystole [504]. The slight decrease in myocardial contractility caused by LAs is usually not a major problem. Treatment includes oxygenation, cardiac massage, correction of acidosis, and epinephrine (which is given in small incremental boluses beginning with 2–4 μg/kg) [505]. If ventricular fibrillation persists, defibrillation (2–4 joule/kg) is performed. Although resuscitation measures must be initiated immediately, the specific treatment of LA toxicity is rapid administration of Intralipid®. Numerous case reports have shown that rapid bolus injections of a lipid emulsion reverse the toxic effects of LAs [506–508]. Because one mole of Intralipid® binds >3000 times more molecules of bupivacaine than a mole of buffer, the volume of distribution suddenly increases [509]. However, a recent experiment performed in volunteers has shown that, if this lipid sink effect exists, the benefit remains less than initially expected [510] (Fig. 10.16). A direct effect of lipids on myocardium has also been advocated to explain the effect of this lipid rescue [511]. In addition, the effect is lower in less hydrophilic drugs such as ropivacaine as compared to bupivacaine or levobupivacaine [510]. Similarly, long-chain emulsions are preferable to medium- or short-chain emulsions.

The recommended dose of 20% Intralipid® for pediatric patients is 5 mL/kg by IV bolus. If cardiac function does not return, this dose (up to 10–12 mg/kg) is repeated. Rather than institute a maintenance infusion of Intralipid®, patients are closely monitored and given more Intralipid® as needed. The lipid emulsion decreases LA elimination, thus the cardiac effects may recur later.

Prevention of toxicity includes slow injection of small amounts of drug and frequent catheter aspiration. Some authors recommend injecting a solution that contains epinephrine. Continuous administration of LAs for postoperative pain is better than bolus injections because the latter may cause peaks and valleys of drug concentration and pain relief. If the catheter migrates into a blood vessel, continuous administration is safer. In older children, patient-controlled regional anesthesia (PCRA, see Chapter 37) works well. Also, the size of the boluses is small enough to avoid toxicity.

Adjuvants

Adjuvants are often used to prolong the duration of analgesia.

Epinephrine (5 μg/mL = 1/200,000) decreases C_{max} without affecting the time to peak concentration. In <6-month-old infants, 2.5 μg/mL 1/400,000 epinephrine has been recommended [468]. However, the drug is less efficacious with long-acting S-(–) enantiomers and has limited use with these solutions. Plain solutions of LAs *must* be used for penile, interdigital, and eye blocks.

Clonidine 1–2 μg/kg, either IV or in the epidural space, prolongs the duration of caudal blocks [512]. More than 2 μg/kg

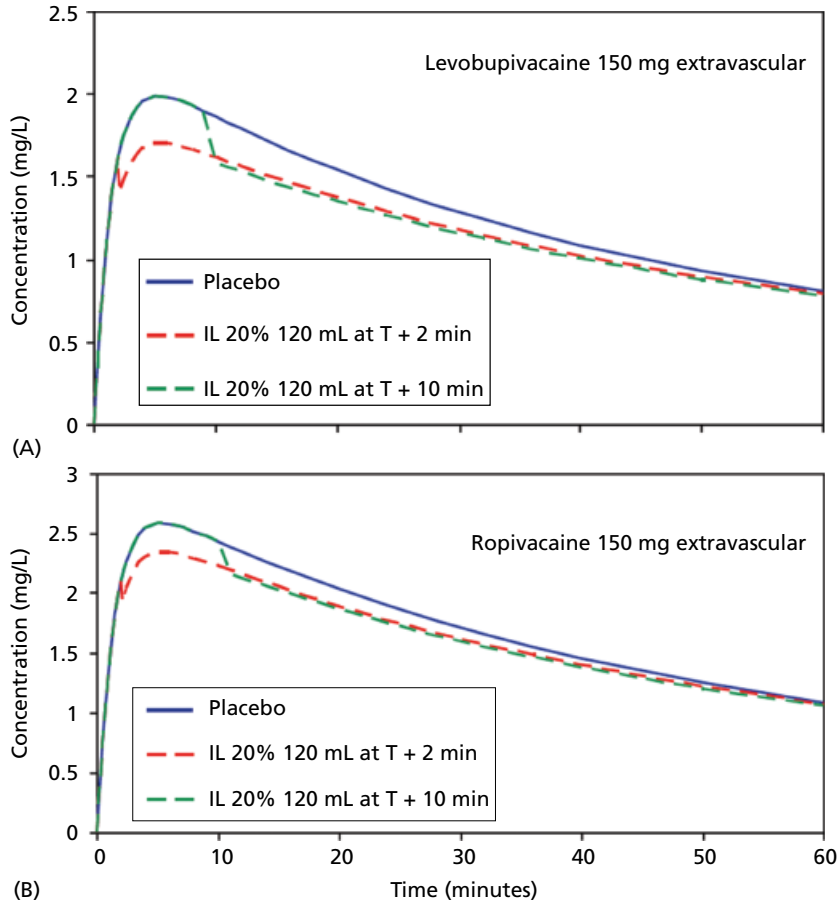

Figure 10.16 Simulations of the plasma concentration observed after extravascular injection of 150 mg levobupivacaine (A) or ropivacaine (B) followed by a bolus of 120 mL Intralipid® 20% (IL). These simulations were generated using the kinetic data obtained from 16 volunteers receiving the drugs as a short infusion and Intralipid® or placebo in a cross-over manner. Intralipid® rapidly decreases the peak concentration, but the effect is moderate. *Source:* Reproduced from Dureau et al [510] with permission of Wolters Kluwer.

may lead to hypotension. Clonidine is not recommended for infants <3 months of age because it can cause apnea in this age group.

Some clinicians use *ketamine* as an adjuvant for epidural block [513]. Both the R-(–) enantiomer and the preservative are highly neurotoxic. Even the S(+) enantiomer can be toxic. Thus it may be wise to avoid the use of ketamine as an adjuvant for epidural blocks [514,515].

Opioids are often used as adjuvants for epidural block. After 6–9 months of age, adding opioids to LAs prolongs epidural analgesia for up to 24 h. Hydrophobic agents (fentanyl, sufentanil) must be placed at the metameric level where the pain will occur [516,517]. Preservative-free morphine easily spreads rostrally and can be placed at a lower metameric level, but the risk of respiratory depression is theoretically higher. The bolus dose of morphine is 25–30 µg/kg in the epidural space, which is followed by a continuous infusion of 1 µg/kg/h. When continuous epidural administration of fentanyl or sufentanil is combined with local anesthetics, the doses are 0.2 µg/kg/h and 0.1 µg/kg/h respectively. Morphine 5–10 µg/kg can be used as the sole agent for spinal analgesia during general anesthesia.

Formulation and dosing

Plain solutions of amide LAs are preservative free; only epinephrine-containing solutions include metabisulfite [518]. The S enantiomers (ropivacaine and levobupivacaine) are safer and cause similar quality and duration of analgesia and less motor blockade than a racemic mixture of bupivacaine. When regional analgesia is used during general anesthesia, low concentrations of LAs (2–2.5 mg/mL, i.e. 0.2–0.25%) are used. The maximum dose is 2–2.5 mg/kg for the initial caudal injection, 1.2–1.7 mg/kg for lumbar or thoracic epidural injections, 0.5 mg/kg for peripheral blocks. Continuous infusion of LAs for postoperative analgesia uses low concentrations of drug (0.625–1 mg/mL) at a maximum rate of 0.20 mg/kg/h in neonates, 0.30 mg/kg for 1–6 months old, and 0.40 mg/kg beyond 6 months of age.

KEY POINTS: LOCAL ANESTHETICS

- The amide local anesthetics levobupivacaine and ropivacaine should be favored because these molecules are less toxic to the heart and because they induce less motor block than racemic agents
- In case of local anesthetic systemic toxicity with cardiac toxicity, the usual resuscitation maneuvers with lipid rescue are the basis of therapeutic intervention
- In infants older than 3 months, clonidine is commonly used as an adjuvant for caudal epidural anesthesia

Anesthetic pharmacology in obese children

The prevalence of obesity, defined as a body mass index (BMI) greater than the 95th percentile for age and gender in children 2–19 years of age in the US, has increased from 13.9% in 2000 to 17.2% in 2014 [519]. Recommendations for anesthetic drug dosing in obese children based on evidence are limited to a handful of studies. Clinical trials for dosing recommendations for drug labeling almost always exclude morbidly obese patients. Further clouding the issue, many recommendations for drug dosing are based on lean body weight (LBW), that is, the weight excluding all fat weight, which of course is unrealistic for most all patients. The ideal bodyweight (IBW), which is the BMI at the 50th percentile for age and gender, is also discussed in some dosing schema.

In children, propofol is the best-studied agent for PK and PD data for dosing recommendations in obese patients. For induction using propofol, a dose based on the IBW, rather than total body weight (TBW), seems to be most appropriate based on both processed- EEG and clinical signs (loss of eyelid reflex) [520,521]. However, for maintenance infusion, dosing based on an allometric function with an exponent of 0.75 provided the best fit to achieve and maintain a plasma concentration of about 3 μg/mL, which is associated with adequate depth of anesthesia by processed EEG criteria. This dosing regimen for a TBW 130 kg, 1.66 m adolescent, with an IBW of 78.7 kg would be 1.4 mg/kg TBW propofol for induction, followed by an infusion of 155 μg/kg/min for 20 min, 120 μg/kg/min for 20 min, and finally 85 μg/kg/min for a 60 min anesthetic.

For other anesthetic drugs, e.g. opioids, thiopental, and etomidate, pediatric data are lacking but in adults most authorities recommend that LBW be utilized as the basis for dosing [522]. For muscle relaxants, again there are no published pediatric data, but for succinylcholine, whose pharmacodynamic properties are determined by the volume of the extracellular fluid compartment, TBW should be the basis for dosing. For the other non-depolarizing muscle relaxants, either LBW or IBW is recommended. For all drug dosing in obese patients, the principle of titrating to effect is crucially important, given the paucity of data in children and the variation in the PK/PD data in adults [522].

CASE STUDY

A full-term newborn weighing 3520 g was scheduled for esophageal atresia (type 3) repair 16 h after birth. Cardiac, abdominal, and renal echography were normal. A small amount of stridor was noticed. An ENT surgeon was asked to evaluate the child and perform laryngoscopy prior to surgery. All blood tests were normal for age, except the activated coagulation test, which was slightly prolonged (45 s versus 35 s for control). Factors VIII and IX were subsequently found to be normal, as was a preoperative thromboelastogram. The physical examination showed an apparently healthy boy who was spontaneously breathing and had mild stridor. A peripheral venous catheter was in place. A suction catheter was present in the upper esophagus to aspirate saliva. Anesthesia was induced with sevoflurane (6% inspired) with spontaneous ventilation. The ENT surgeon sprayed the larynx with 10 mg of 2% lidocaine without epinephrine. No airway abnormality was found, and the trachea was intubated. Following tracheal intubation, the patient was given sufentanil (0.5 μg) and atracurium (1 mg) over 1 min. The lungs were mechanically ventilated. An epidural was performed using levobupivacaine. Because lidocaine had been administered 30 min earlier for examination of the larynx, the initial bolus of LA was reduced (5 mg or 2 mL of a 2.5 mg/mL solution). The bolus was immediately followed with a continuous infusion of 0.85 mg/h, i.e. 1.4 mL/h of a 0.0625% solution. Anesthesia was maintained with sevoflurane 1.5–2% (0.5–0.6 MAC without N_2O). Surgery was uneventful and the trachea was extubated after reversal of the muscle relaxant (neostigmine 350 μg, atropine 75 μg). In addition to the epidural, intravenous acetaminophen (50 mg bolus plus 25 mg every 6 h) was given. Unfortunately, the epidural catheter was dislodged 5 h after surgery. The anesthesiologist prescribed a continuous IV infusion of morphine 40 μg/h, but because drugs already given through the epidural catheter would provide pain relief for 1–2 more hours, no loading dose of morphine was given. Six hours later, the patient's respiratory rate progressively decreased to 16 bpm. The infusion of morphine was decreased to 30 μg/h and the respiratory rate returned to normal. The remainder of his postoperative course was uneventful.

1. Because lidocaine was used for the laryngeal examination, a smaller dose of LA was given into the epidural space. Lidocaine is rapidly absorbed following topical application to mucous membranes and may interact with levobupivacaine given for blocks.
2. Sevoflurane was used to induce anesthesia because it, plus the topical anesthesia, provided excellent conditions for the laryngopharyngeal examination. Following tracheal intubation, a phenylpiperidine opioid and a muscle relaxant were slowly injected to prevent a "stiff" chest from developing. The drugs were also injected slowly to prevent the profound hypotension that sometimes occurs when sufentanil and atracurium are injected rapidly.
3. The epidural was performed (1) to provide postoperative analgesia, allow rapid tracheal extubation, and avoid postoperative mechanical ventilation, and (2) to reduce the amount of halogenated agents used and prevent their possible deleterious CNS effects. At this age, MAC is higher than that of adults. However, MAC may differ for different variables (e.g. hemodynamic variables). Balanced anesthesia with opioids and regional anesthesia is a good choice. Levobupivacaine was chosen over ropivacaine because levobupivacaine is metabolized by CYP3A4/3A7, which is more mature at birth. Ropivacaine

is metabolized by CYP1A2, which is immature until 4 years of age. Pure S enantiomers (ropivacaine and levobupivacaine) are less toxic and induce less motor blockade, a significant problem in infants. Because the volume of distribution of hydrophilic local anesthetics is large in neonates and infants, the initial bolus dose/kg is usually the same as in older children. Since LA toxicity is additive, and because a topical spray of lidocaine was used less than 1 h before the epidural block, limited amounts of levobupivacaine (1.4 mg/kg) were injected into the epidural space. This initial bolus was followed by a continuous infusion of the drug. The infusion dose was reduced because the volume of distribution would be filled after 4–5 half-lives; at that point clearance rapidly becomes the only factor governing drug concentration. Because clearance of the unbound fraction (CLu), which is responsible for LA toxicity, is low at birth and progressively increases with age, the dose varies with age. Fortunately, infants less than 4–6 months old have excellent pain relief with smaller doses of LAs.

4. Postoperative pain control is critical, not only to relieve the pain but to also reduce respiratory complications (hypoventilation). In addition to regional anesthesia, this patient received paracetamol (acetaminophen). Because metabolism of this drug is reduced during the first month of life, the child was given about half the dose of paracetamol given to older patients. No loading dose was given.

A comprehensive review article addressing the pharmacology of dexmedetomidine in children: pharmacokinetics, pharmacodynamics, effects on major organ systems, and data on clinical uses of the drug.

393 Plaud B, Debaene B, Donati F. The corrugator supercilii, not the orbicularis oculi, reflects rocuronium neuromuscular blockade at the laryngeal adductor muscles. Anesthesiology 2001; 95: 96–101. This paper explains why T½ke0 for muscle relaxants may be so long when compared to our clinical impressions. The onset of effect and recovery times differ from one muscle to another. For example, the T½ke0 of vecuronium is four times longer for the adductor pollicis than for the laryngeal muscles. Whether one wants to monitor the onset of action for tracheal intubation or to monitor the recovery for adequate ventilation, the muscle of interest should be different. Because it is not possible in daily practice, it is important to understand this concept to adapt our understanding of the observed phenomenon.

509 Mazoit JX, Le Guen R, Beloeil H, Benhamou D. Binding of long-lasting local anesthetics to lipid emulsions. Anesthesiology 2009; 110: 380–6. Lipid rescue. This *in vitro* study shows that long-acting local anesthetics are rapidly (less than 30 s) adsorbed in lipid particles by a passive (entropy-driven) phenomenon. At 37°C and pH 7.40, the mole fraction of bupivacaine between Intralipid® and buffer was 3100, i.e. 3100 molecules of bupivacaine distributed in a mole of emulsion for every one molecule found in a mole of buffer. The consequence is an immediate increase in the volume of distribution of the LAs and a lower elimination rate. Recurrences of toxicity may then occur, inasmuch as the half-life of the chylomicrons is very short (6–7 min). Close patient monitoring for several hours after lipid rescue appears mandatory.

CHAPTER 11
Fluids, Electrolytes, and Nutrition

Peggy McNaull and Adam Suchar
Department of Anesthesiology, University of North Carolina, Chapel Hill, NC, USA

Introduction

Fluid and electrolyte management is an essential component of the care of hospitalized pediatric patients. Fluids and electrolytes, like anesthetics, must be titrated to effect based on clinical assessment and an in-depth knowledge of a wide range of organ systems. The objective of this chapter is to enhance understanding of the mechanisms underlying fluid and electrolyte regulation, examine management of their disturbances, and illustrate related anesthetic implications in children.

Physiology

Renal physiology

The kidneys are important for regulating fluid and electrolyte homeostasis. Each kidney contains 1.0 to 1.3 million nephrons, the functional units of the kidney. The afferent arteriole carries blood into the glomerulus while the efferent arteriole carries blood away. The glomerulus, a specialized cluster of capillaries, is responsible for filtration of water, amino acids, and free ions from the plasma. This tuft-like network of branching capillaries is contained within a cup-like sac called Bowman's capsule. Filtered fluid flows across the glomerular basement membrane into Bowman's capsule, to the proximal convoluted tubule, through the loop of Henle, to the distal convoluted tubule, and then exits the nephron as urine via the collecting duct. Through complex mechanisms of resorption and secretion across the renal tubules, filtered fluid is altered significantly as it traverses the renal tubular system (Fig. 11.1). Embryologically, development of the renal system begins as early as the third week of gestation. By the 10th week, the glomeruli within the nephron function and produce urine. Nephrogenesis, the formation of the functional units of the kidney, is complete by 34–36 weeks' postconceptual age. Although the term neonate has a full complement of glomeruli, the glomerular filtration rate (GFR) is only about 30% of the normal adult rate, even when adjusted for body surface area. During the first year of life, the GFR increases dramatically due to increases in glomerular and tubular size. When infants are born before 34 weeks of gestation, the formation of new nephrons continues after birth. Thus, some of the increase in the GFR in these infants will be due to the addition of more glomeruli [1–4].

The GFR is regulated by the balance of Starling forces across the capillary wall, total surface area of the capillaries, permeability of the glomerular wall, and renal blood flow. In general, fetal and neonatal renal function is characterized by low renal blood flow and a low GFR that are caused by high renal vascular resistance, low systemic blood pressure, and a smaller capillary surface area for filtration. Renal vascular resistance decreases rapidly after birth, and systemic blood pressure and capillary surface area increase as the infant ages [5]. Neonates double GFR by 2 weeks of age and triple it by 3 months. GFR reaches adult levels by 2 years of age. The GFR of premature infants is even lower at birth and increases more slowly than that of their full-term counterparts [6].

Full-term infants can conserve sodium despite a low GFR. As GFR and the filtered sodium load increase, the proximal tubule is able to increase sodium resorption [7]. Preterm infants exhibit prolonged glomerular–tubular imbalance, with GFR exceeding the tubule's ability to reabsorb sodium due to proximal convoluted tubule immaturity. Additionally, the distal convoluted tubule does not respond to aldosterone. Consequently, preterm infants are at risk for excessive sodium excretion and hyponatremia. Sodium reabsorption increases with age; at 30 weeks' postconceptional age a neonate excretes 5% of the filtered sodium load, while a full-term neonate excretes only 0.2% of the filtered sodium load [8].

Creatinine and/or creatinine clearance (either calculated directly from 24-h urine collection or indirectly from a formula) are commonly measured or calculated as a means of

Gregory's Pediatric Anesthesia, Sixth Edition. Edited by Dean B. Andropoulos and George A. Gregory.

estimating GFR. This relationship is complicated and unreliable in neonates and infants. In most infants, the plasma creatinine concentration actually increases after birth. In fact, the more preterm the infant, the higher the rise in plasma creatinine before it begins to decline to a steady-state level [2,9]. Chapter 9 presents additional information about the developmental physiology of the renal system.

Body fluid homeostasis

Conceptually, the internal environment of the body is an interconnected group of anatomical compartments among which fluids distribute. Water is the primary fluid found in the human body and accounts for 50–80% of total bodyweight. Total body water (TBW), defined as the amount of sodium-free water in the body, is distributed across two main compartments that are separated by the cell membrane: the extracellular fluid (ECF) compartment and the intracellular fluid (ICF) compartment (Fig. 11.2). The variation in water content depends on tissue type: muscle contains 75% water, whereas adipose tissue contains only 10% water. TBW decreases with age, mainly because of loss of water from the ECF compartment. For preterm and low-birth-weight infants, TBW is 80% of total bodyweight. For term infants up to 6 months, TBW equals 75% of total bodyweight. In infants greater than 6 months of age, as well as in children and adolescents, TBW is estimated at 60% of body weight [10–15]. TBW decreases and constitutes a smaller percentage of bodyweight during dehydration.

Intracellular fluid represents about two-thirds of TBW, which is equivalent to 30–40% of total bodyweight. In preterm infants the proportion of ECF is much greater than that of the ICF and reaches 60% of TBW at term [16]. In the neonate, the normal postnatal diuresis causes an immediate decrease in the ECF volume. This decrease in ECF volume is followed by continued expansion of the ICF volume because of cellular growth. The change in TBW distribution, as a function of weight, continues postnatally such that by around 3 months of life the intracellular compartment is larger than the extracellular compartment. This shift is beneficial because it allows fluid to be mobilized from ICF in periods of dehydration in

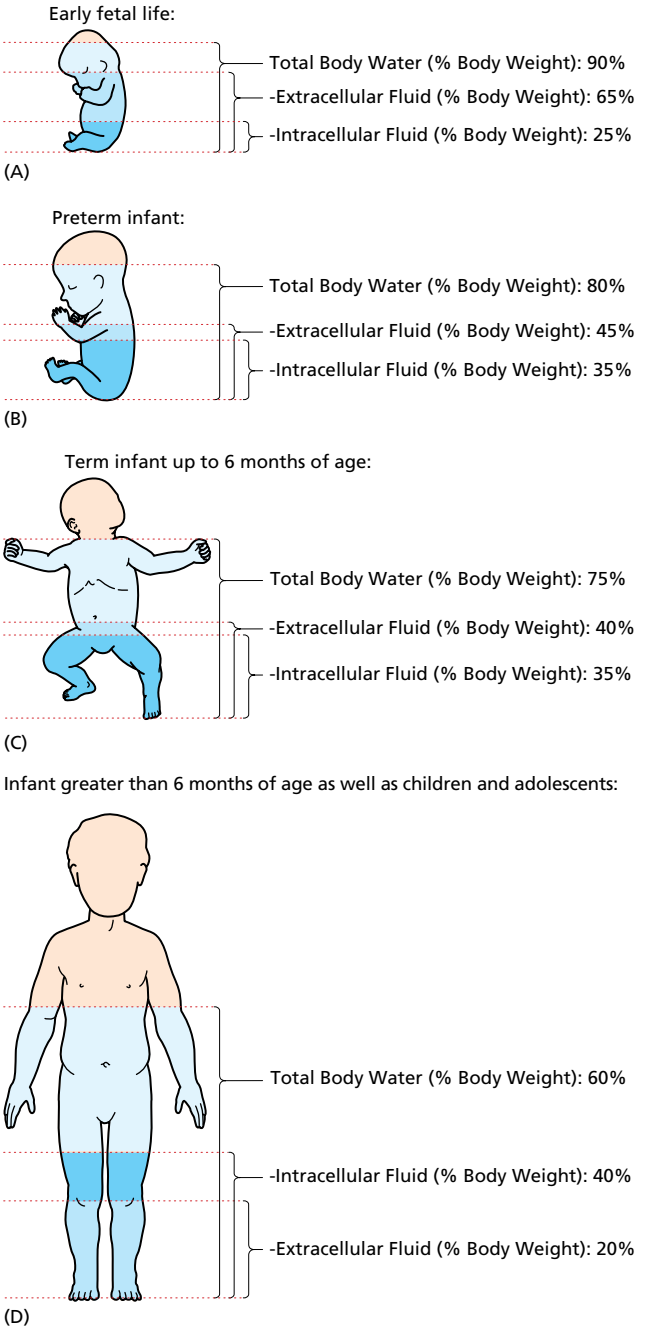

Figure 11.2 Schematic representation of body fluid compartments as a percentage of body weight in (A) early fetal life, (B) the preterm infant, (C) the term infant up to 6 months of age, (D) infants more than 6 months of age, children, and adolescents. ECF, extracellular fluid; ICF, intracellular fluid; TBW, total body water.

order to replenish intravascular volume. The non-neonate is better able than the neonate to maintain intravascular volume lost from fasting, fever, diarrhea, or other causes. The adult ratio of extracellular water (ECW) to intracellular water (ICW) is achieved by about 1 year of age (Fig. 11.3).

The ECF consists of both the plasma volume and the interstitial fluid volume. The plasma volume is relatively small, which is important to consider in the context of intravenous fluid therapy. This compartment remains constant throughout life, comprising ~5% of bodyweight. It is the milieu in which blood cells, platelets, and proteins are suspended. The interstitial fluid volume accounts for 15% of bodyweight and

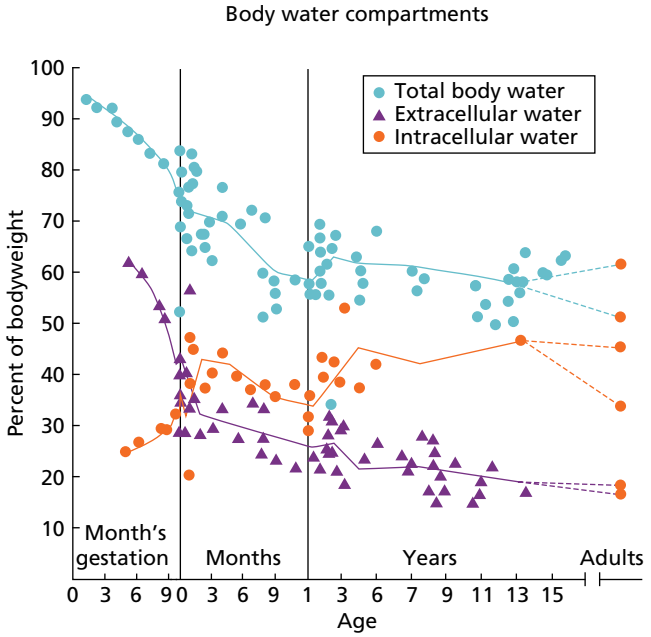

Figure 11.3 Body compartments: fetus to adult. Total body water, extracellular water, and intracellular water as a percentage of bodyweight. *Source*: Reproduced from Friis-Hansen [10] with permission of American Academy of Pediatrics.

has a solute composition almost identical to that of intravascular fluid, except for a lower protein concentration.

The solute composition of the ICF and ECF is different. Sodium and chloride are the dominant cation and anion in the ECF, respectively. Potassium is the most abundant cation in the ICF, and its concentration within the cells is approximately 30 times higher than in the ECF. Proteins, organic anions, and phosphate are the most plentiful anions in the ICF (Table 11.1) [17]. For all practical purposes, the electrolyte values in the neonatal period are the same as in the child and adult with the exception of potassium, which can be about 1–2 mmol/L higher than average for the first 2 days of life [18]. The difference in the distribution of cations – sodium and potassium – is due to the activity of the Na^+/K^+-ATPase pump, which extrudes sodium from cells and moves potassium into cells. In contrast, the dissimilarity between the anions in the ICF and the ECF is determined largely by the presence of intracellular molecules that do not freely cross the cell membrane.

Table 11.1 Composition of body fluid compartments

	Extracellular fluid	Intracellular fluid
Osmolality (mOsm)	290–310	190–310
Cations (meq/L)	155	155
Sodium (Na^+)	142	10
Potassium (K^+)	4.0	140
Calcium (Ca^{2+})	2.4	0.0001
Magnesium (Mg^{2+})	1.2	58
Anions (meq/L)	155	155
Chloride (Cl^-)	103	4
Bicarbonate (HCO_3^-)	28	10
Phosphates	4	75
Sulfate (SO_4^{-2})	1	2
Organic acids	6	–
Protein	5	40

It is important to remember that the serum concentration of a measured electrolyte does not always reflect the body content. This is because of the larger volume of ICF compared with ECF and the variation in electrolyte concentrations between these two compartments. For example, the intracellular potassium concentration is much greater than the serum concentration. A shift of potassium from the intracellular space can maintain a normal serum potassium or even cause an elevation in serum potassium, despite massive losses of potassium from the intracellular space. This is most evident in diabetic ketoacidosis, a state of significant potassium depletion that is often masked by transmembrane shifts of potassium from the ICF to the ECF.

The mathematical relationship (Starling equation) describing net water movement across a membrane between these compartments includes factors for oncotic and hydrostatic pressures on either side of the membrane (e.g. interstitial and intravascular space):

$$J_V = K_F\left(\left[P_C - P_I\right] - \delta\left[\pi_C - \pi_I\right]\right)$$

where J_v = the net flow across the membrane, K_F = fluid filtration coefficient of the membrane, P_C = capillary hydrostatic pressure, P_I = interstitial hydrostatic pressure, δ = solute reflection coefficient (permeability of solute across a specific membrane), π_C = capillary oncotic pressure, and π_I = interstitial oncotic pressure. Fluid moves as a function of the product of the permeability of the membrane and net driving pressure (hydrostatic pressure minus oncotic pressure) (Fig. 11.4). Disturbances of this relationship (e.g. when membrane trauma decreases the reflection coefficient for proteins) may cause the interstitial compartment to expand and edema to develop. In the normal patient, oncotic and hydrostatic pressures are balanced. With various disease states, the interstitial space expands at the expense of the intravascular space. For example, increased capillary permeability during sepsis (trapping protein in the interstitial space, increasing π_I) or increased venous pressure with positive pressure ventilation (increasing P_C) may produce edema and/or decrease intravascular volume.

Osmolality

An understanding of osmotic shifts between the ECF and ICF is fundamental to understanding the physiology of fluid balance. Osmolality is defined as the concentration of all of the solutes in a given weight of water. Due to permeability of the cell membrane to water, iso-osmolality, or osmotic equilibrium, is generally maintained between compartments. If the osmolality in one compartment changes, then water movement leads to a rapid equalization of osmolality. This can lead to significant shifts of water between the intracellular space and the extracellular space [19,20]. Plasma osmolality is tightly regulated and maintained at 285–295 mOsm/kg. It can either be measured directly or estimated by the following formula [21]:

$$\text{Osmolality} = 2\times[\text{Na}] + [\text{glucose}]/18 + [\text{BUN}]/2.8$$

Glucose and blood urea nitrogen (BUN) are measured in mg/dL. Division of these values by 18 and 2.8, respectively, converts the units into mmol/L. Multiplication of the sodium value by 2 accounts for its accompanying anions, principally chloride and bicarbonate. The calculated osmolality is usually slightly lower than the measured osmolality.

Urea normally contributes little to plasma osmolality. Urea is not confined to the extracellular space because it readily crosses the cell membrane, and its intracellular concentration approximately equals its extracellular concentration. Whereas an elevated sodium concentration causes a shift of water from the intracellular space, with uremia there is no osmolar gradient between the two compartments and, consequently, no movement of water. Therefore, the effective osmolality can be calculated as follows [21]:

$$\text{Effective osmolality} = 2\times[\text{Na}] + [\text{glucose}]/18$$

The effective osmolality (also called the tonicity) determines the osmotic force that is mediating the shift of water between the ECF and the ICF. Effective osmolality differs from measured osmolality in that it accounts only for osmotically active impermeable solutes rather than all osmotically active solutes, including those that are permeable to cell membranes. There are many mechanisms that influence ECF volume and osmolality including antidiuretic hormone (ADH) and thirst, renal regulation of sodium, the renin–angiotensin–aldosterone system, and atrial natriuretic peptide.

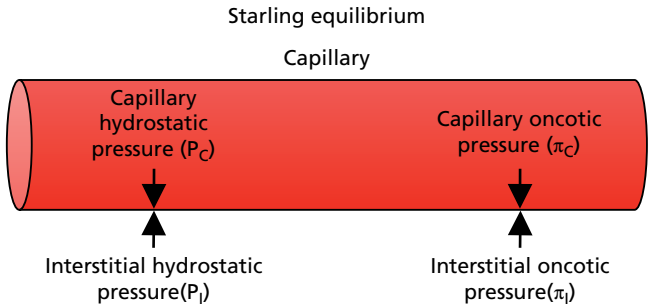

Figure 11.4 The Starling hypothesis states that fluid flux at the capillary level is controlled by a balance between hydrostatic pressure and osmotic pressure gradients between the capillaries and interstitial spaces.

Regulation of extracellular fluid volume and osmolality

Antidiuretic hormone and thirst

Osmoreceptors in the hypothalamus can detect as little as a 1% change in plasma osmolality [22]. When an elevated effective osmolality is sensed, ADH is secreted by neurons in the supraoptic and paraventricular nuclei of the hypothalamus [23,24]. The prohormone of ADH migrates along the nerve axons to the posterior pituitary gland, where it is stored as arginine vasopressin. It is released through exocytosis [25]. Circulating ADH binds to its V_2 receptors in the collecting duct cells of the kidney, and, via the generation of cyclic adenosine monophosphate, causes insertion of water channels (aquaporin-2) into the renal collecting ducts [26]. This produces increased permeability to water, permitting resorption of water into the hypertonic renal medulla. As a result, urine concentration increases and water excretion decreases. Urinary water losses are not completely eliminated because there is obligatory excretion of urinary solutes, such as urea

and sodium [27]. ADH secretion virtually disappears when the plasma osmolality is low, allowing excretion of maximally dilute urine. The consequent loss of free water (water without sodium) corrects the plasma osmolality.

The minimum urine osmolality is approximately 30–50 mOsm/kg [28,29], placing an upper limit on the kidney's ability to excrete water. Sufficient solute must be present for water loss from the kidneys. The maximum urine osmolality is approximately 1200 mOsm/kg [28]. Obligatory solute losses dictate the minimum volume of urine that must be produced, even when maximally concentrated. Obligatory water losses increase in patients with high salt intake or high urea losses, as may occur after relief of a urinary obstruction or during recovery from acute tubular necrosis. An increase in urinary solute and subsequent water losses occurs with osmotic diuresis, which occurs classically from glycosuria in diabetes mellitus and after mannitol administration. There are developmental changes in the kidney's ability to concentrate the urine. The maximum urine osmolality in a newborn, especially a premature newborn, is less than that in an older infant or child [30]. This limits the ability to conserve water and makes such a patient more vulnerable to hypernatremic dehydration.

A secondary stimulant for ADH release is a perceived decrease in intravascular volume, as sensed by baroreceptors in the left atrium, aortic sinus, and carotid sinuses. Hypovolemia, as well as hypotension, stimulates a nonosmolar release of ADH. In fact, volume depletion takes precedence over osmolality in the regulation of ADH. In other words, brisk ADH release can occur in the volume-depleted or hypotensive child even when the plasma osmolality is as low as 260–270 mOsm/L [31].

Inappropriate ADH release is associated with many other clinical scenarios, resulting from both hemodynamic and nonhemodynamic stimuli (Box 11.1). The pediatric surgical patient is at risk for increased ADH given the pain, stress, opioids, hypovolemia, and/or hemorrhage associated with the perioperative period [32,33].

Thirst is also regulated by hypothalamic osmoreceptors. These receptors are distinctly different from those that determine ADH secretion. By linking to the cerebral cortex, osmoreceptors stimulate thirst when serum osmolality increases. Thirst is not physiologically stimulated by plasma osmolality until it reaches 290 mOsm/kg, a level at which ADH levels are sufficient to induce maximal antidiuresis [34]. Additionally, thirst is frequently a response to an absence of ADH (central diabetes insipidus) or lack of responsiveness to ADH (nephrogenic diabetes insipidus), which results in the production of copious, dilute urine. Those who cannot perceive thirst develop profound problems with fluid balance. Although the mechanisms are not all clearly understood, angiotensin II, which is increased during volume depletion, and baroreceptors are also known to stimulate thirst [35].

Renal regulation of sodium

As stated previously, sodium, the principal extracellular cation, is the primary determinant of osmolality and therefore critical to the maintenance of intravascular volume. The principal extracellular anion, chloride, is also necessary, but for simplicity, sodium balance is considered the main regulator of volume status. Given the need for equal numbers of cations and anions, body content of sodium and chloride usually changes proportionally. There are, however, some situations in which chloride depletion is the dominant derangement causing volume depletion (metabolic alkalosis with volume depletion). Other situations also exist, such as volume depletion with metabolic acidosis, where sodium depletion may exceed chloride depletion.

Because there is little homeostatic control of sodium intake, the kidney determines sodium balance. Sodium homeostasis is maintained by altering the percentage of filtered sodium that is resorbed along the nephron. Normally, the kidney excretes <1% of the sodium filtered at the glomerulus. In the absence of disease, extrarenal losses and urinary output of sodium match intake, with the kidney having the capacity to adapt to large variations in sodium intake. Urinary sodium excretion, which is regulated by both intrarenal and extrarenal mechanisms, can be reduced to virtually undetectable levels when necessary. The most important determinant of renal sodium excretion is the effective intravascular volume of the child. The effective intravascular volume is the volume status that is sensed by the body's regulatory mechanisms.

Sodium resorption occurs throughout the nephron (see Fig. 11.1). While the majority of filtered sodium is resorbed in the proximal tubule and the loop of Henle, the distal tubule and the collecting duct are the main sites for precise regulation of sodium balance. Approximately 65% of the filtered sodium is reclaimed in the proximal tubule, which is also the major site for resorption of bicarbonate, glucose, phosphate, amino acids, and other substances that are filtered by the glomerulus [36]. The transport of all these substances is linked to sodium resorption by cotransporters, or a sodium–hydrogen exchanger in the case of bicarbonate. This link is clinically important for bicarbonate and phosphate because their resorption parallels sodium resorption. In patients with metabolic alkalosis and volume depletion, correction of the metabolic alkalosis requires urinary loss of bicarbonate, but the volume depletion stimulates sodium and bicarbonate retention, preventing correction of the alkalosis. Volume expansion causes increased urinary losses of phosphate, even when there is phosphate depletion [37]. Resorption of uric acid and urea occurs in the proximal tubule and increases when sodium retention increases. This arrangement accounts for the elevated uric acid and BUN measurements that often accompany dehydration, which is a stimulus for sodium retention in the proximal tubule [38]. The cells of the proximal tubule are permeable to water; thus, water resorption in this segment parallels sodium resorption.

The loop of Henle is, in terms of absolute amount, the second most important site of sodium resorption along the nephron [39]. The Na^+/K^+, $2Cl^-$ cotransporter on the luminal side of the membrane reclaims filtered sodium and chloride, whereas most of the potassium is recycled back into the lumen. This is the transporter that is inhibited by furosemide and other loop diuretics, which are highly effective at increasing sodium excretion. The ascending limb of the loop of Henle is not permeable to water, permitting sodium retention without water. ADH stimulates sodium retention in this segment; this arrangement helps create a more hypertonic medulla, which maximizes water conservation when ADH acts in the medullary collecting duct. Because loop diuretics inhibit sodium retention in this segment, their use causes a less

hypertonic medulla, preventing excretion of maximally concentrated urine in the presence of ADH.

Sodium retention in the distal tubule is mediated by the thiazide-sensitive Na^+, Cl^- cotransporter [40]. This segment of the nephron is relatively impermeable to water, and along with sodium and chloride retention, the distal tubule is important for delivery of fluid with a low sodium concentration to the collecting duct. This allows for excretion of water without sodium in patients who stop secreting ADH because of low plasma osmolality. Thiazide diuretics, by inhibiting sodium and chloride retention in this segment, prevent the excretion of water without electrolytes – partially explaining the severe hyponatremia that occasionally develops in patients receiving chronic thiazide diuretics.

The collecting duct, the final segment of the nephron, is important for the regulation of excretion of water, potassium, acid, and sodium. Even though the amount of sodium resorbed in this segment is lower than in any other segment, this is the critical site for the regulation of sodium balance. Sodium resorption occurs via a sodium channel that is regulated by aldosterone. When these channels are open under the influence of aldosterone, almost all of the sodium can be resorbed. The uptake of sodium creates a negative charge in the lumen of the collecting duct, which facilitates the secretion of potassium and hydrogen ions. The potassium-sparing diuretics, amiloride and triamterene, block these sodium channels, and the inhibition of sodium uptake decreases potassium excretion. The potassium-sparing diuretic spironolactone blocks the binding of aldosterone to its receptor; thus, it indirectly decreases the activity of the sodium channels. As highlighted previously, the collecting duct is important for the regulation of water balance because it responds to ADH by inserting water channels that increase the permeability to water, and the hypertonicity of the renal medulla allows for maximal concentration of the urine [4].

The amount of sodium filtered at the glomerulus is directly proportional to the GFR. If sodium resorption in the nephron were constant, complete resorption of sodium with a small decrease in the GFR and significant renal sodium wasting with a small increase would result. This does not occur, however, because sodium resorption in the nephron is proportional to sodium delivery, a principle called glomerular tubular balance.

Renin–angiotensin–aldosterone system

The renin–angiotensin–aldosterone system is also an important regulator of renal sodium excretion. The juxtaglomerular apparatus produces renin in response to decreased effective intravascular volume. Specific stimuli for renin release include decreased perfusion pressure in the afferent arteriole of the glomerulus, decreased delivery of sodium to the distal nephron, and β_1-adrenergic agonists, which increase in response to intravascular

volume depletion [41,42]. Renin, a proteolytic enzyme, cleaves angiotensinogen to produce angiotensin I. Angiotensin-converting enzyme then converts angiotensin I into angiotensin II [43]. The actions of angiotensin II include direct stimulation of the proximal tubule to increase sodium resorption and stimulation of the adrenal gland to increase aldosterone secretion. Through its actions in the distal nephron – specifically, the late distal convoluted tubule and the collecting duct – aldosterone increases sodium resorption. Aldosterone also stimulates potassium excretion, increasing urinary losses. Along with decreasing urinary loss of sodium, angiotensin II acts as a vasoconstrictor, which helps maintain adequate blood pressure in the presence of volume depletion [44].

Atrial natriuretic peptide

Volume expansion stimulates the synthesis of atrial natriuretic peptide (ANP), a polypeptide produced by the atria in response to atrial wall stretch. Along with increasing the GFR, ANP inhibits both renin secretion and aldosterone synthesis, which subsequently facilitates an increase in urinary sodium excretion. ANP also guards against excessive plasma volume expansion in the face of increased ECF volume by shifting fluid from the vascular to the interstitial compartment. ANP inhibits vasoconstriction induced by angiotensin II and norepinephrine and acts in the brain to decrease the desire for salt and inhibit the release of ADH. Thus, the net effect of ANP is a decrease in blood volume and blood pressure through natriuresis and diuresis [45].

Blood volume

The circulating blood volumes of neonates, infants, and children were determined in the late 1960s to mid 1970s and remain the accepted norms for estimating a wide variety of clinically important conditions and guiding therapies, such as blood loss and transfusion of blood products [46,47]. The blood volume gradually decreases (as a function of weight) with growth and development. Thus, in low-birthweight, preterm, or critically ill infants, values as high as 100 mL/kg have been measured. Blood volume increases slightly during the first few months of life, reaching its peak at 2 months of age (approximately 86 mL/kg), then returns to near 80 mL/kg and finally stabilizes at 70 mL/kg by the end of the first year of life. An estimate of the circulating blood volume is presented in Table 11.2.

Table 11.2 Estimate of circulating blood volume

Age	Estimated blood volume (mL/kg)
Premature infants	90–100
Term infants	80–90
Infants <1 year	75–80
Children	70–75
Adults	65–70

KEY POINTS: PHYSIOLOGY OF FLUID AND ELECTROLYTE REGULATION

- Immature renal development in the preterm infant can lead to excessive sodium excretion and hyponatremia
- Numerous hemodynamic and non-hemodynamic stimuli for antidiuretic hormone secretion (ADH) place virtually all hospitalized patients at risk for the development of hyponatremia
- Sodium is the dominant extracellular cation and is the primary determinant of osmolality and therefore critical to the maintenance of intravascular volume. The resorptive capabilities of the kidney determine sodium balance
- The renin–angiotensin–aldosterone system's regulation of renal sodium excretion plays a key role in maintaining adequate blood pressure in the presence of volume depletion
- Atrial natriuretic peptide (ANP) is a key regulator of sodium resorption in states of hypervolemia and its secretion ultimately results in reduction of intravascular volume and systemic blood pressure
- The circulating blood volume in preterm neonates is as high as 100 mL/kg. By the end of the first year of life, the circulating blood volume decreases to adult values of approximately 70 mL/kg

Intravenous fluid therapy

Historical perspective

Intravenous (IV) fluid therapy for the ill child was first reported in 1831 by Dr Thomas Latta in his resuscitation of patients dehydrated by cholera. Instead of infusing fluid into the colon, Latta decided to "throw it immediately into the circulation" [48]. Between 1882 and 1885 the British physiologist Dr Sydney Ringer conducted his so-called "extravital investigations" and developed a fluid that enabled a frog's heart to continue beating outside the body by using a solution comparable to blood plasma [49]. Around 1900, the Dutch physiologist Dr Hartog Jacob Hamburger developed "physiological" or "normal" saline, i.e. 0.9% sodium chloride [50]. In retrospect, the adjectives "physiological" and "normal" are misnomers. In fact, the chloride concentration of 0.9% NaCl is supraphysiological with a chloride concentration of 154 mmol/L versus a serum concentration of 100 mmol/L [51]. In 1918, Blackfan and Maxcy reported instilling 0.8% isotonic saline intraperitoneally to successfully treat an infant with diarrheal dehydration [52]. In 1931, Karelitz and Schick used an IV solution of 5% dextrose combined with either isotonic saline or Ringer's solution to "detoxify" dehydrated children [53]. In 1932, the American pediatrician Dr Alexis Hartmann modified Ringer's solution by adding the buffer lactate [54]. The fluids developed by Latta, Ringer, Hamburger, and Hartmann all qualify as crystalloids, water with electrolytes forming a solution that is capable of crystallizing. In contrast to crystalloids, colloids are fluids in which insoluble particles are suspended and not in solution. The naturally occurring colloid albumin was first used to treat trauma casualties, including burn patients after the Pearl Harbor attack in 1941 [55]. Contributions by Gamble in the 1940s detailed the anatomy of fluid and electrolyte compartments and the role of the kidney in fluid maintenance [56]. In 1950, Darrow and Pratt described the effects of potassium loss and developed regimens for replacing electrolyte deficits in children with diarrhea [57].

In 1957, Malcolm Holliday and William Segar coauthored a report that first estimated "the maintenance need for water in parenteral fluid therapy" [58]. The data from this article evolved into the "4–2–1" formula widely used to calculate the rates of hourly maintenance IV fluid requirements for hospitalized children. The authors simplified the calculation of fluid requirements by correlating insensible loses to the metabolic rate of healthy children at rest and during normal activity. They noted that the requirements for water paralleled those for energy, and that metabolic rate correlated to weight. Holliday and Segar assumed the energy requirements of a "hospitalized patient" to be "roughly midway between basal and normal levels" and constructed a curve of caloric requirement versus weight (Fig. 11.5) [58]. The basal metabolic rate and estimated total energy expenditure with normal activity curves were based on data from studies by Talbot published in 1925 [59]. Based on these plots, the authors proposed daily fluid requirements for patients weighing 0–10 kg to be 100 mL/kg, for patients 11–20 kg 1000 mL + 50 mL/kg for each kilogram between 11 and 20 kg, and for patients weighing more than 20 kg 1500 mL + 20 mL/kg for each kilogram over 20 kg. This construct was further simplified into the "4–2–1" rule. The rule suggested an hourly maintenance IV fluid rate for hospitalized children of 4 mL/kg/h for the first 10 kg of weight, 2 mL/kg/h for the next 10 kg, and 1 mL/kg/h for each kg thereafter (Table 11.3). In 1988, Lindahl found that energy expenditure in anesthetized children was 50% lower than that calculated by Holliday and Segar, but he calculated that 166 mL of water were required to metabolize 100 calories under anesthesia [60]. Thus, there was good agreement in fluid requirements between those proposed by Holliday and Segar and those by Lindahl.

In their article, Holliday and Segar further proposed that electrolytes in IV fluids should mimic those found in human milk [58]. They estimated the amount of sodium, potassium, and chloride in 100 mL of human milk and used those concentrations to determine daily requirements based on the volume of maintenance fluid. They recommended 3 meq/kg/day for sodium and 2 meq/kg/day for both potassium and chloride. This led to the practice of adding 0.2% saline to 5% dextrose for routine IV fluid. In the conclusion of their paper, the authors emphasized that their data were meant to provide only maintenance needs for water and warned against using these data to guide repair of deficits or replacement of continuing abnormal losses of water.

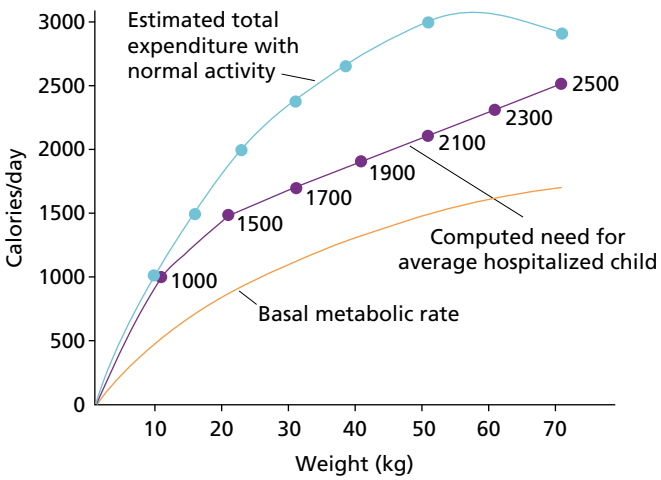

Figure 11.5 Comparison of energy expenditure in basal and ideal state. Energy expended by hospitalized patients was estimated to be approximately between that for basal and normal activity from the study by Talbot [59]. From the curve for the hospitalized patient, a 10 kg infant expends 1000 calories (requires 1000 mL/day, 100 mL/kg) and a 20 kg child, 1500 calories (requires 1500 mL/day, 100 mL/kg for 10 kg + 50 mL/kg for 10 kg). *Source*: Reproduced from Holliday and Segar [58] with permission of American Academy of Pediatrics.

Table 11.3 Hourly or daily maintenance fluid requirements of children based on bodyweight: the "4–2–1 rule"

Weight (kg)	Hourly rate	Daily volume
<10	4 mL/kg	100 mL/kg
10–20	40 mL + 2 mL/kg (for each kg between 10 and 20)	1000 mL + 50 mL/kg (for each kg between 10 and 20)
≥20	60 mL + 1 mL/kg (for each kg >20)	1500 mL + 20 mL/kg (for each kg >20)

Perioperative fluid management

Intraoperative fluid management must address fluid deficits and ongoing losses in addition to maintenance requirements. In 1975, Furman and colleagues proposed a strategy of fluid replacement whereby the preoperative deficits were calculated by multiplying the hourly rate, as dictated by the Holliday and Segar method, by the number of hours the patient was nil per os (NPO). It was then suggested that one-half of the calculated deficit be replaced in the first hour of the procedure, and one-half replaced in the subsequent 2 h [61]. This was adopted into clinical practice until 1986 when Berry proposed a simplified method of delivering a bolus of basic salt solution to otherwise healthy children over the first hour of surgery [62]. Berry concluded that children 3 years and younger should receive 25 mL/kg, whereas children 4 years and older should receive 15 mL/kg. The recommendations proposed by Furman and Berry were developed based on the assumption of a prolonged, 6–8 hr NPO time, but this has come under scrutiny with newer American Society of Anesthesiologists (ASA) NPO guidelines (Table 11.4). Current recommendations allow administration of clear liquids up to 2 h before procedures requiring anesthesia. Holliday and Segar have revised their recommendations and subsequently recommend a simpler and likely more accurate method of fluid management, which is to administer 20–40 mL/kg of a balanced salt solution during the course of the anesthetic. Postoperative fluid management should be reduced to a 2, 1, 0.5 rule: 2 mL/kg for the first 10 kg, 1 mL/kg for the next 10 kg, and 0.5 mL/kg for

Table 11.4 American Society of Anesthesiologists (ASA) NPO guidelines

Ingested material	Minimum fasting period
Clear liquids	2 h
Breast milk	4 h
Infant formula	6 h
Non-human milk	6 h
Light meal	6 h
Fried foods, fatty foods, or meat	8 or more hours

each kg above 20 kg with an isotonic fluid [63–65]. If after 12 hours the child is unable to convert to oral intake, then a standard hypotonic solution (D5 0.45% saline) is initiated at the 4–2–1 rule rate to avoid hypernatremia.

Furthermore, the idea of "third-space losses," i.e. ECF that does not equilibrate with the intravascular space and that is beyond osmotic equilibrium with the vascular space and thus non-functional, has been questioned and recent data suggest they may not exist [66]. This phenomenon was first described in 1961 by Shires and coworkers in a series of 13 adults having elective surgeries (primarily cholecystectomies). The patients were injected with ^{131}I serum albumin, ^{51}Cr-tagged red blood cells, and ^{35}S-tagged sodium sulfate to determine plasma volumes, red cell mass, and ECF volumes. Additionally, the tissue trauma associated with surgery was rated based on observed amount of necessary retraction, difficulty in exposure, and depth of anesthesia. The authors reported that the ECF volume was redistributed or sequestered into areas that no longer communicated with a functional extracellular space and that this correlated with the observed degree of surgical trauma [67]. Isotonic fluids were recommended to replace the losses from the functional extracellular space to the "third space." The Shires group had considerable impact on researchers and clinicians in the 1960s, but few other researchers have been able to replicate their findings. Several more recent studies in the adult literature have cast serious doubt on the actual existence of this "third space" [66]. These studies, using multiple blood samples and steady-state tracer kinetics, revealed that the functional fluid space is either unchanged or expanded rather than contracted after surgery [68–70].

In pediatrics, it has been proposed that, depending on the type of surgery, 1 mL/kg/h to as much as 15 mL/kg/h of additional isotonic fluids are necessary to replenish intravascular volume due to ongoing losses during surgery [71–73]. In fact, it has been stated that up to 50 mL/kg/h of replacement fluids is required for premature neonates undergoing surgery for necrotizing enterocolitis, a surgery associated with significant trauma and ischemia to bowel [74]. This ongoing fluid loss has been attributed primarily to three simultaneous physiological processes. First, anesthetic-induced relaxation of sympathetic tone produces vasodilation. Second, whole blood is lost at various rates. Third, capillary leak and surgical trauma result in extravasation of isotonic, protein-containing fluid into interstitial compartments. This third physiological process must be carefully considered because it is exacerbated by the hemodilution and increased capillary pressures caused by excessive fluid administration. In general, 1 mL of lost blood is replaced with 1 mL of colloid (5% albumin or blood) or about 1.5 mL of isotonic crystalloid such as lactated Ringer's solution (LR) [74].

Perioperative dextrose

Hypoglycemia, depending on the severity, can have devastating effects on the central nervous system, especially in neonates. Low blood glucose invokes a stress response and alters cerebral blood flow and metabolism, leading to permanent neurodevelopmental impairment if hypoglycemia goes unrecognized and untreated. In 1967, Anderson et al first described six cases of neonatal hypoglycemia and the serious clinical and pathological sequelae associated with prolonged low blood glucose [75]. Animal experiments have further demonstrated that cerebral injury is caused not only by severe prolonged hypoglycemia but also by mild hypoglycemia combined with mild hypoxia or ischemia [76]. In a 2008 study of 35 term neonates with symptomatic hypoglycemia (blood glucose level 45 mg/dL or 2.6 mmol/L), magnetic resonance imaging detected white matter abnormalities in 94%, with severe abnormalities noted in 43% of the studied population. Furthermore, at 18-month follow-up, 26 of the 35 patients studied continued to exhibit some level of impairment [77]. Hypoglycemia has also been found to be associated with an increase in morbidity and mortality in pediatric intensive care unit (PICU) patients [78].

In the last 40 years, there has been a complete re-evaluation of the place of glucose in routine intraoperative solutions. In the 1970s, research suggested that fasted children may become hypoglycemic while under anesthesia [79–82]. Administration of dextrose was deemed mandatory to avoid perioperative hypoglycemia. Unfortunately, the risk of hyperglycemia was underestimated. In 1986, Welborn et al evaluated preoperative hypoglycemia in 446 children, 1 month to 6 years old, scheduled for minor outpatient surgical procedures [83]. There were two asymptomatic children with preoperative blood glucose values of 50 mg/dL. Both of these children had fasted in excess of 17 h before presenting to the operating room. More recent studies on this topic estimate the incidence of preoperative hypoglycemia to be between 0% and 2.5% and usually associated with fast durations from 8 to 19 h, well beyond the current ASA recommended guidelines (see Table 11.4) [84].

Hyperglycemia has also been recognized as significantly detrimental for the brain. In the presence of ischemia or hypoxia, it is proposed that the impaired metabolism of excess glucose causes an accumulation of lactate, a decrease in intracellular pH, and subsequently severely compromised cellular function that may result in cell death [85]. Hyperglycemia can also induce an osmotic diuresis that may lead to dehydration and electrolyte abnormalities [74,84,86]. Furthermore, there is evidence in the pediatric literature suggesting that hyperglycemia, especially in the setting of an ischemic or hypoxic event, worsens neurological outcomes as well as morbidity and mortality statistics in the pediatric population [78,87–89].

In the 1986 study by Welborn et al, the patients were randomized to intraoperatively receive either LR or 5% dextrose in LR (D5LR). Both the LR and D5LR groups had statistically significant increases in blood glucose. However, the D5LR group had a much larger increase in blood glucose (83 ± 14 mg/dL preoperatively to 244 ± 60 mg/dL postoperatively) than the LR group (85 ± 14 mg/dL preoperatively to 111 ± 22 mg/dL postoperatively) [83].

Based on these results and those of other studies, there is a growing consensus that intraoperative dextrose should be selectively administered only in those patients at greatest risk for hypoglycemia and, in such situations, that the use of fluids with lower dextrose concentrations (e.g. 1% or 2.5%) be considered [74,84,86,90]. It should be noted that there are no IV fluids with dextrose concentrations less than 5% commercially available in the United States. The populations at highest risk of hypoglycemia include neonates, children receiving hyperalimentation, and those with endocrinopathies, in whom monitoring blood glucose levels and adjusting the rate

of infusion is also recommended [74,86,90]. Routine dextrose administration is no longer advised for otherwise healthy children receiving anesthesia.

Neonatal fluid management

Fluid needs vary according to gestational age, environmental conditions, and disease states. Assuming minimal water loss in the stool of infants not receiving oral fluids, their water needs are equal to their insensible water losses, excretion of renal solutes, and any unusual ongoing losses. Insensible water losses are indirectly related to gestational age; very immature preterm infants (<1000 g) may lose as much as 2–3 mL/kg/h, partly because of immature skin, lack of subcutaneous tissue, and a large exposed surface area [91]. Furthermore, insensible water losses are increased under radiant warmers, during phototherapy, and in febrile infants. Insensible losses are diminished when an infant is clothed, breathes humidified air, or is of advanced postnatal age. A larger premature infant (2000–2500 g) nursed in an incubator may have an insensible water loss of approximately 0.6–0.7 mL/kg/h [91].

Adequate fluid intake is essential for excretion of the urinary solute load (i.e. urea, electrolytes, phosphate). The amount varies with dietary intake and the anabolic or catabolic state of nutrition. High protein intake, formulas with a high solute load, and catabolic conditions all increase the end-products that require urinary excretion and thus increase the requirement for water. Renal solute loads may vary between 7.5 and 30 mOsm/kg. Newborn infants, especially those with very low birthweight, are also less able to concentrate urine, so they need higher fluid intake to excrete solutes.

Fluid intake in term infants is usually started at 60–70 mL/kg on day 1 and increased to 100–120 mL/kg by days 2 or 3. Smaller, more premature infants may need to start with 70–80 mL/kg on day 1 and advance gradually to 150 mL/kg/day [5]. Fluid volumes should be titrated individually, although it is unusual to exceed 150 mL/kg/day. Infants weighing <750 g in the first week of life have immature skin and a large surface area, characteristics that lead to a high rate of transepidermal fluid loss, at times requiring higher rates of intravenous fluids. Daily weights, urine output, serum urea nitrogen and sodium levels should be monitored carefully to determine water balance and fluid needs. Clinical observation and physical examination are poor indicators of the state of hydration of premature infants. Conditions that increase fluid loss, such as glycosuria, the polyuric phase of acute tubular necrosis, and diarrhea, may place additional strain on kidneys that have not yet acquired their maximal capacity to conserve water and electrolytes. The result of this may be severe dehydration. Alternatively, fluid overload may lead to edema, heart failure, patent ductus arteriosus, and bronchopulmonary dysplasia.

Due to the ongoing sodium loss secondary to the inability of the neonatal distal tubule to respond fully to aldosterone, IV fluids in the neonate must contain sodium. Given that most operations on neonates involve loss of ECF and blood, a replacement fluid with a similar electrolyte content (i.e. a balanced salt solution such as LR or Plasma-Lyte) should be used. Hypotonic solutions should not be used to replace these losses due to risk of significant hyponatremia. If a neonate presenting to the operating room is stable on a maintenance solution, it is reasonable to continue this maintenance fluid at a constant rate and add a balanced salt solution, colloid, or blood product as needed to replace operative fluid losses.

As noted earlier, appropriate glucose administration is an important issue in the fluid choice for the neonate. In most cases, maintenance fluids containing 10% glucose and 0.2 normal saline with 20 mmol/L of potassium are reasonable in the first 48 h of life. Beyond that time period, full-term infants can be changed to 5% glucose instead of 10%. Preterm infants will often require the higher glucose load for longer. Infants who have had continuous glucose infusions stopped, those who are small for gestational age, and newborns of diabetic mothers require special attention and monitoring as they have particular problems with hypoglycemia. Neonates who have been receiving hyperalimentation or supplementary glucose should continue to receive that fluid during surgery but must have their glucose levels monitored closely for hypo- or hyperglycemia.

Parenteral nutrition

Before complete enteral feeding has been established or when enteral feeding is impossible for prolonged periods, total parenteral nutrition (TPN), also called hyperalimentation, is often necessary. TPN provides fluid, calories, amino acids, fat, electrolytes, and vitamins to sustain the growth of ill infants and children. Critically ill patients often present to the operating room with hyperalimentation infusing. Infusions may be administered through a percutaneously or surgically placed indwelling central venous catheter or through a peripheral vein. The umbilical vein may also be used for up to 2 weeks. Glucose concentrations should be measured during surgery to determine if hyperglycemia is developing.

The goal of parenteral nutrition is to deliver sufficient calories from glucose, protein, and lipids to promote optimal growth. To meet nutritional needs, the infusate should contain 2.5–3.5 g/dL of synthetic amino acids and usually 10–15 g/dL of glucose (10–15% dextrose), in addition to appropriate quantities of electrolytes, trace minerals, and vitamins [92,93]. If a peripheral vein is used, it is advisable to keep the glucose concentration below 12.5 g/dL (12.5%). If a central vein is used, glucose concentrations as high as 25 g/dL (25%) may be used.

Electrolytes, trace minerals, and vitamin additives are included in amounts approximating established IV maintenance requirements. IV fat emulsion, such as Intralipid 20%, is often administered in combination with parenteral nutrition to provide calories without an appreciable osmotic load. This may decrease the need for infusions of higher glucose concentrations as well as prevent the development of essential fatty acid deficiency. Intralipid is frequently initiated at 0.5 g/kg/24 h and advanced to 3 g/kg/24 h, if triglyceride levels remain normal; 0.5 g/kg/24 h is sufficient to prevent essential fatty acid deficiency [94]. The content of each day's infusate should be determined after careful assessment of the infant's clinical and biochemical status. Slow and continuous infusion is advisable.

Neonates with >100 kcal/kg/24 h via parenteral nutrition can be expected to gain about 15 g/kg/24 h, with a positive nitrogen balance of 150–200 mg/kg/24 h, in the absence of episodes of sepsis, surgical procedures, and other severe

stress [93]. This goal can usually be achieved (and the catabolic tendency during the first week of life reversed, with subsequent weight gain) by peripheral vein infusion of 2.5–3.5 g/kg/24 h of an amino acid mixture, 10 g/dL of glucose, and 2–3 g/kg/24 h of a 20% fat emulsion [95].

Complications of IV alimentation are related to both the catheter and the metabolism of the infusate. Sepsis, the most common complication of central vein infusions, can be minimized only by meticulous catheter care and aseptic preparation of the infusate. Coagulase-negative *Staphylococcus* is the most common infecting organism [92]. Treatment includes appropriate antibiotics. If an infection persists (i.e. repeatedly positive blood culture results while the infant is receiving appropriate antibiotics), the line must be removed. Thrombosis, extravasation of fluid, and accidental dislodgment of central venous catheters also occur. Phlebitis, cutaneous sloughing, and superficial infection are the more common complications observed with peripheral infusion of hyperalimentation. Metabolic complications of parenteral nutrition include hyperglycemia, azotemia, nephrocalcinosis, hypoglycemia, hyperlipidemia, possibly hypoxemia with intravenous lipid infusions, and hyperammonemia. Metabolic bone disease and/or cholestatic jaundice and liver disease may develop in infants who require long-term parenteral nutrition and receive no enteral nutrition.

Choice of fluids

The compositions of commonly used IV solutions are presented in Table 11.5. A normal plasma osmolality is 275–290 mOsm/kg. Infusing an IV solution peripherally with a much lower osmolality can cause water to move into red blood cells, leading to hemolysis. Thus, IV fluids are generally designed to have an osmolality that is either close to 285 or greater (fluids with moderately higher osmolality do not cause problems). Normal saline (0.9% NaCl) is slightly hypertonic to plasma (308 mOsm/L) while LR solution is isotonic (273 mOsm/L) and slightly hyponatremic.

Albumin

Albumin is a natural colloid abundant in plasma and is regarded as the colloid "gold standard." Albumin is derived from pooled human plasma by the Cohn cold ethanol fractionation process: human plasma is heated to 60°C for 10 h and then sterilized by ultrafiltration, thus eliminating the risk of disease transmission [96]. Albumin has a molecular weight (MW) of approximately 69 kDa. In the United States, albumin is produced in concentrations of both 5% and 25%. A solution of 5% albumin is osmotically equivalent to an equal volume of plasma, whereas a 25% solution is osmotically equivalent to five times its plasma volume. In other words, the administration of 100 mL of 25% albumin will increase the intravascular volume up five times the amount infused while the administration of 500 mL of 5% albumin is necessary to increase the intravascular volume by a similar amount [97]. Intravascular volume expansion occurs because of fluid translocation from the interstitial compartment to the intravascular space. In subjects with increased intravascular permeability (e.g. critically ill, sepsis, trauma, and burn), this translocation of fluid between compartments may be decreased and colloids may actually leak into the interstitial space, thereby worsening edema by pulling fluid from the intravascular compartment.

Side-effects from albumin are rare. Although considered to have negligible effects on the coagulation cascade, albumin has been implicated to have weak anticoagulation effects through inhibition of platelet aggregation [98] or heparin-like effects on antithrombin III [99]. These effects are thought to be clinically insignificant if volume replacement with albumin is kept below 25% of the patient's blood volume. Allergic reactions are another possible complication of albumin administration; however, albumin is associated with significantly fewer anaphylactic reactions compared with other colloids [100].

Albumin's safety has been questioned in two separately conducted meta-analyses [101,102]. In the 2004 Saline versus Albumin Fluid Evaluation study, a 7000-patient multicenter, randomized, double-blind trial, Finfer et al noted no difference in outcomes between albumin and saline administration in adults [103]. This study showed no significant difference in mortality (726 deaths in albumin group and 729 deaths in saline group) or secondary endpoints (length of stay in the ICU or hospital, days of mechanical ventilation, and days of renal replacement therapy) between the groups. However, there seemed to be an increased mortality in a subset of patients with traumatic brain injury (TBI). A *post hoc* follow-up study was undertaken (Saline versus Albumin Fluid Evaluation–TBI study) that substantiated these findings and concluded that critically ill patients with TBI had a higher mortality rate if resuscitated acutely with albumin as opposed to saline [104].

Table 11.5 Composition of frequently used intravenous fluids [33]

Solution	Osmolality (mOsm)	pH	Na^+ (mM)	K^+ (mM)	HCO_3^- (mM equivalent)	Cl^- (mM)	Glucose (g/dL)
Plasma	275–290	7.4	140	3.6–5.1	30	100	0.07–0.11
0.9% saline	308	5	154	0	0	154	0
3% saline	1026	–	513	0	0	513	0
7.5% saline	2400	3.5–7	1250	0	0	1250	0

Non-protein colloids: hydroxyethyl starches

Hydroxyethyl starches (HES) are synthetic colloids that are modified natural polysaccharides. Natural polysaccharides are broken down by circulating amylases. HES solutions avoid this by substituting hydroxyethyl groups for the naturally occurring hydroxyl groups at carbon positions C-2, C-3, and C-6. This results in a more stable product, resistant to hydrolysis, with subsequent prolonged effectiveness.

HES colloids are classified by concentration, MW, molar substitution (MS, ratio of hydroxyethyl groups to glucose units), and C2:C6 ratios [105]. HES solutions expand the plasma volume with effects lasting 2–6 h, depending on the specific characteristics of the HES fluid. While the physical properties of HES promote longer times in the intravascular space compared to crystalloids, they also confer more side-effects, including hypocoagulability (decreased function of von Willebrand factor, platelets, and factor VIII), renal impairment, and pruritus [106,107]. The older high-MW, high-MS, first-generation HES solutions (e.g. HES 450/0.7) have more significant hemostatic side-effects compared with the newer low-MW, low-MS solutions (e.g. HES 130/0.4). HES solutions may worsen renal function by inducing renal tubular cell swelling and creating a hyperviscous urine [108–110].

In a prospective randomized study published in 2008, Standl et al compared third-generation 6% HES (Voluven – 6% HES 130/0.4 in 0.9% NaCl) and 5% albumin. In this study, there was no difference in perioperative hemodynamic stability, coagulation variables, blood gas, or other laboratory values in 81 pediatric patients undergoing elective non-cardiac surgery [111]. Also in 2008, a European prospective, multicenter, observational, post-authorization safety study that evaluated the safety of 6% HES for perioperative plasma replacement in children was published [112]. Some 316 children, aged 3–12 years, were infused with a mean volume of 11 ± 4.8 mL/kg of HES (130/0.42). Cardiovascular stability was maintained in all cases. There were no serious adverse drug reactions, such as anaphylaxis, renal failure, or clotting disorder. In this study, only pediatric patients with normal renal function and intact coagulation systems were investigated. Despite reassuring pediatric clinical trials, recent data from adult studies have demonstrated an increased risk for renal failure and mortality with HES as compared to crystalloid solutions in critically ill patients [113–116]. In June 2013, the US Food and Drug Administration (FDA) issued a warning against use of HES in critically ill patients. Given the 2013 US FDA warning and the risks of HES in adult patients, most pediatric anesthesia providers have moved away from their use in clinical practice.

Crystalloid versus colloid

The controversy regarding the perioperative use of crystalloid versus colloid fluid replacement remains an unresolved subject. Given a lack of pediatric studies, we continue to extrapolate from adult studies and use a combination of crystalloid and colloids to achieve the desired outcomes. In the most recent Cochrane database review of colloids versus crystalloids for fluid resuscitation in critically ill adult patients, the authors concluded that there is no evidence to support the use of colloids over crystalloids in the resuscitation of patients with burns, trauma, or after surgery, because they are significantly more expensive and not associated with improved survival [117]. A further meta-analysis analyzing the different colloid solutions available for fluid resuscitation concluded that when measuring mortality, blood administration, and the incidence of allergic reactions, there was no evidence to suggest that one colloid solution is more effective or safe than another [118].

KEY POINTS: INTRAVENOUS FLUID THERAPY

- The 1957 publication by Holliday and Segar first presented a practical method for clinicians to prescribe IV fluids. Their suggestions evolved into what is now termed the "4–2–1 rule" for maintenance fluid therapy in children
- No clear consensus exists on which intravenously administered fluid is associated with the best clinical outcomes. The use of traditional hypotonic fluids may cause complications, such as hyperglycemia and hyponatremia, in the postoperative surgical patient
- Routine dextrose administration is no longer advised for otherwise healthy patients. There is a growing consensus to selectively administer intraoperative dextrose only in those patients at greatest risk for hypoglycemia such as neonates, children receiving hyperalimentation, and those with endocrinopathies
- Neonatal fluid management requires a unique understanding of the developmental aspects of distribution of total body water and of age-related renal, hepatic, cardiorespiratory, and central nervous system physiology

Disorders of fluids and electrolytes

Dehydration

Dehydration is a commonly encountered problem in clinical pediatrics and is one of the leading causes of pediatric morbidity and mortality worldwide. Clinical history usually suggests the etiology of the dehydration. Viral gastroenteritis and/or diarrheal disease are the most common causes of pediatric dehydration. The first step in caring for the dehydrated child is to assess the degree of dehydration (Table 11.6), which dictates both the urgency of the situation and the volume of fluid needed for rehydration. Weight loss is the most reliable indicator of the degree of a child's dehydration. Due to the fact that water accounts for a higher percentage of bodyweight in infants, the degree of dehydration will be represented as a higher percentage of bodyweight lost. The infant or child with mild dehydration may have few clinical physical signs or symptoms, while the infant or child with moderate or severe dehydration typically has clear physical signs and symptoms. Intravascular space depletion is initially evident with an increased heart rate and reduced urine output. When the dehydrated infant has a decrease in blood pressure, the volume deficit is severe and vital organs may be inadequately perfused. Immediate and aggressive intravenous therapy is necessary.

Laboratory findings

Several laboratory findings are useful for evaluating the child with dehydration. In fact, serum sodium concentration

Table 11.6 Clinical manifestations of dehydration

	Mild	Moderate	Severe
Decrease in bodyweight	<5% (infant) <3% (older child or adult)	5–10% (infant) 3–6% (older child or adult)	>10% (infant) >6% (older child or adult)
Hemodynamic signs	Absent	Present	Present
Pulse	Normal	Slight increase	Tachycardia
Capillary refill	2–3 s	3–4 s	>4 s
Blood pressure	Normal	Normal	Low
Perfusion	Normal	Normal	Circulatory collapse
Skin			
Turgor	Normal	Decreased	Markedly decreased
Color	Normal	Pale	Markedly decreased
Mucous membranes	Dry	Dry	Mottled or gray, parched
Fluid loss			
Urinary output	Mild oliguria	Oliguria	Anuria
Tears	Decreased	–	Absent

determines the type of dehydration as serum sodium values vary depending on the relative loss of solute to water. Dehydration is frequently classified as isonatremic (also termed isotonic), hyponatremic, or hypernatremic. The most common clinically encountered pediatric dehydration state (~75–80%) is isonatremic dehydration (Na^+ 130–150 mEq/L) where there is an equal proportion of solute and water loss. Isonatremic dehydration is most frequently the result of secretory diarrhea. Hypernatremic dehydration (Na^+ >150 mEq/L) occurs in approximately 15% of dehydrated pediatric patients. This type of dehydration is common with viral gastroenteritis or in breastfeeding infants in whom diarrheal and insensible water losses are inadequately replaced. Hyponatremic dehydration (Na^+ <130 mEq/L) has an incidence of about 5%. Hyponatremic dehydration occurs in the child with diarrhea who is taking in large quantities of low-salt fluid, such as water or formula [119].

Metabolic acidosis may be a result of stool bicarbonate losses in children with diarrhea, secondary renal insufficiency, or lactic acidosis from shock. The anion gap is useful for differentiating between the various causes of a metabolic acidosis. Emesis or nasogastric losses usually cause a metabolic alkalosis. The serum potassium concentration may be low as a result of diarrheal losses. In children with dehydration as a result of emesis, gastric potassium losses, metabolic alkalosis, and urinary potassium losses all contribute to hypokalemia. Metabolic acidosis, which causes a shift of potassium out of cells, and renal insufficiency may lead to hyperkalemia. A combination of mechanisms may be present; thus, it may be difficult to predict the child's acid–base status or serum potassium level from the history alone.

The BUN value and serum creatinine concentration are useful in assessing the child with dehydration. Volume depletion without parenchymal renal injury may cause a disproportionate increase in the BUN with little or no change in the creatinine concentration. This condition is secondary to increased passive resorption of urea in the proximal tubule as a result of appropriate renal conservation of sodium and water. The increase in the BUN with moderate or severe dehydration may be absent or blunted in the child with poor protein intake, because urea production depends on protein degradation. The BUN may be disproportionately increased in the child with increased urea production, as occurs with a gastrointestinal bleed or with the use of glucocorticoids, which increase catabolism. A significant elevation of the creatinine concentration suggests renal insufficiency, although a small, transient increase can occur with dehydration. Acute tubular necrosis (acute kidney injury) is the most common etiology of renal insufficiency in a child with volume depletion, but occasionally the child may have previously undetected chronic renal insufficiency or an alternative explanation for the acute renal failure. Renal vein thrombosis is a well-described sequela of severe dehydration in infants; possible findings include thrombocytopenia and hematuria.

Hemoconcentration from dehydration causes increases in hematocrit, hemoglobin, and serum proteins. These values normalize with rehydration. A normal hemoglobin concentration during acute dehydration may mask an underlying anemia. A decreased albumin level in a dehydrated patient suggests a chronic disease, such as malnutrition, nephrotic syndrome, or liver disease, or an acute process, such as capillary leak.

Calculation of the fluid deficit

The fluid deficit is the total amount of body water lost expressed as the percent decrease in bodyweight. Determining the fluid deficit necessitates clinical determination of the percentage of dehydration and multiplication of this percentage by the patient's weight; a child who weighs 10 kg and is 10% dehydrated has a fluid deficit of 1 L. If the child's baseline weight is unavailable, the percentage of fluid deficit should be estimated by clinical signs and symptoms (see Table 11.6).

Approach to severe dehydration

The child with severe dehydration needs acute intervention to ensure adequate tissue perfusion. The resuscitation phase requires rapid restoration of the circulating intravascular volume and treatment of shock with an isotonic solution such as normal saline or LR. The child should be given a fluid bolus, usually 20 mL/kg, of the isotonic fluid. The child with severe dehydration may require multiple fluid boluses and may need to receive the boluses as quickly as possible. In a child with a known or probable metabolic alkalosis (i.e. the child with isolated vomiting), LR should not be used because the lactate may worsen the alkalosis.

The initial resuscitation and rehydration phase is complete when the child has an adequate intravascular volume.

Typically, the child shows clinical improvement, including a lower heart rate, normalization of blood pressure, improved perfusion, better urine output, and a more alert affect.

Once the patient has an adequate intravascular volume, further resuscitation should be based upon the etiology and type of dehydration. In isonatremic or hyponatremic dehydration, the entire fluid deficit should be corrected over 24 h; a slower approach should be taken for hypernatremic dehydration. Depending upon the etiology of the dehydration, the patient may be either hypo- or hyperkalemic. Potassium is not usually included in the IV fluids until the patient voids and normal renal function is documented via measurement of BUN and creatinine. Based upon the clinical situation, it is essential that children with significant ongoing losses receive an appropriate replacement solution.

Monitoring and adjusting therapy

Measurement of serum electrolyte levels at least daily is appropriate for any child who is receiving IV rehydration. As outlined previously, dehydrated children are at risk for sodium, potassium, and acid–base disorders. It is important to look at trends. For instance, a sodium value of 145 mEq/L is normal, but if the sodium concentration was 135 mEq/L 12 h earlier, then there is a distinct risk that the child will be hypernatremic in 12 or 24 h. The correction of both hypernatremia and hyponatremia will be discussed in detail later in the chapter. Clinicians must be proactive in monitoring electrolytes and adjusting fluid therapy accordingly.

Sodium

Sodium, the principal ECF cation and major determinant of plasma osmolality, is critical for the generation of action potentials in nervous and cardiac tissue. Abnormalities of sodium concentration are most often a reflection of an abnormal water balance rather than an increase or decrease in total body sodium. Plasma osmolality and sodium concentration are tightly regulated, both by thirst, which prompts water ingestion, and by ADH, also known as arginine vasopressin. ADH, which is released from the posterior pituitary gland in response to increased osmolality, decreased blood volume and/or decreased blood pressure, enhances water reabsorption from the tubular fluid in the kidneys.

Hyponatremia

Hyponatremia is one of the most common electrolyte disorders encountered in hospitalized patients. In fact, the condition affects approximately 25% of hospitalized children [120]. Hyponatremia, defined as a serum sodium level of less than 135 mmol/L (mEq/L), most frequently occurs as a result of excess free water in the setting of impaired free water excretion.

Hyponatremia can be the result of many different etiologies (Fig. 11.6). The first step in further evaluation of hyponatremia is to determine the patient's plasma osmolality. If the plasma osmolality is normal, pseudohyponatremia should be suspected. Pseudohyponatremia is a laboratory artifact that occurs in the presence of hyperlipidemia or hyperproteinemia when the sodium concentration is determined by an indirect method rather than by a direct ion-selective electrode. If the plasma osmolality is elevated, a hyperosmolar state should be suspected as it is frequently encountered with hyperglycemia or mannitol administration.

True hyponatremia is most often associated with a low plasma osmolality. If both the serum sodium and plasma osmolality are low, the patient's volume status and urine sodium concentration should be assessed. In patients with hyponatremia, evidence of volume overload, and a low urine sodium, congestive heart failure, cirrhosis, nephrotic syndrome or hypoalbuminemia are possible causes. Patients with acute or chronic renal failure frequently exhibit hyponatremia and hypervolemia with a variable urine sodium. In the setting

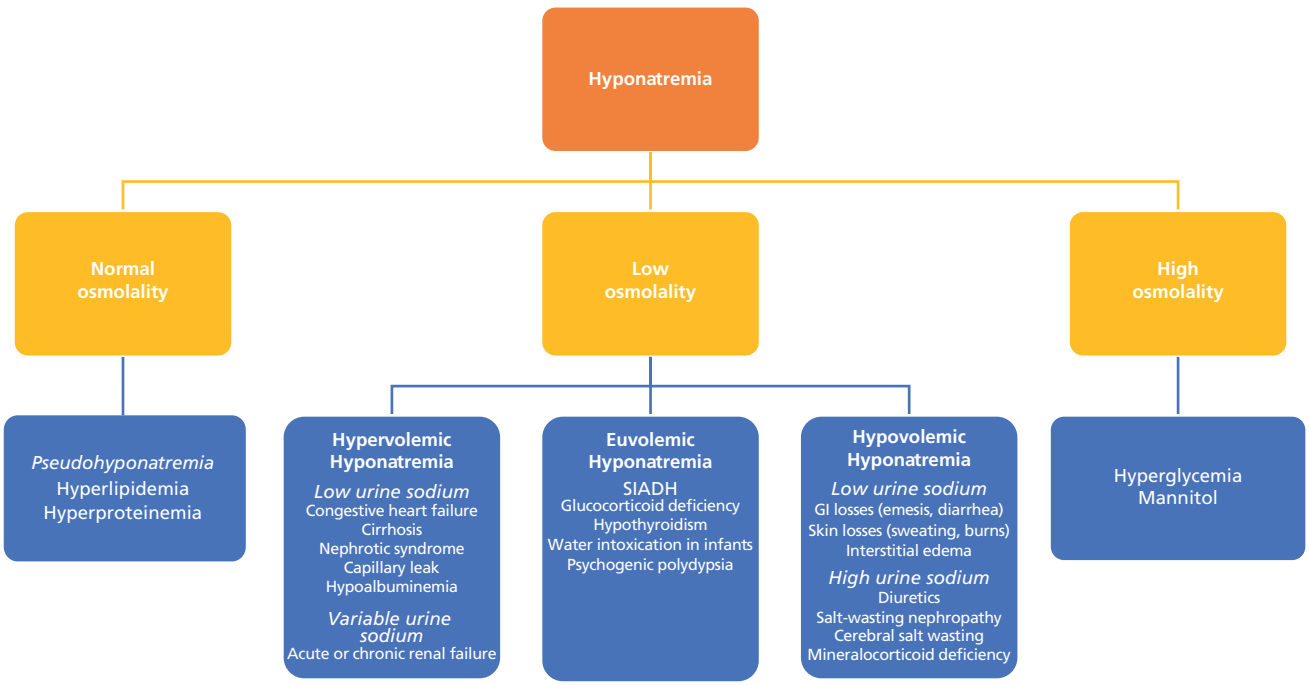

Figure 11.6 Hyponatremia. GI, gastrointestinal; SIADH, syndrome of inappropriate antidiuretic hormone secretion.

of low plasma osmolality, hyponatremia, hypovolemia, and a low urine sodium, common etiologies include emesis, diarrhea, excessive sweating, burns, and interstitial edema. Diuretics, notably thiazide diuretics, and conditions that promote renal salt wasting lead to low plasma osmolality, hyponatremia, hypovolemia, and high urine sodium.

Euvolemic hyponatremia has several potential causes including glucocorticoid deficiency, hypothyroidism, water intoxication in infants, psychogenic polydipsia, and syndrome of inappropriate antidiuretic hormone (SIADH). In postsurgical pediatric patients, SIADH is most frequently responsible for the constellation of low plasma osmolality, hyponatremia, euvolemia, and a high urine sodium. In SIADH, ADH secretion is not inhibited by either low plasma osmolality or expanded intravascular volume. ADH-mediated retention of water leads to hyponatremia, expansion of intravascular volume, and an increase in renal sodium excretion. As mentioned previously in this chapter, inappropriate ADH release occurs in many pediatric postsurgical patient populations as a result of both hemodynamic and non-hemodynamic stimuli (see Box 11.1).

In 1983, a study of children undergoing scoliosis surgery first demonstrated that hyponatremia developed frequently in the postoperative period. Investigators in this study asserted that the phenomenon was secondary to SIADH in the setting of administration of hypotonic IV fluids [121]. Since this initial report, there has been an abundance of retrospective and prospective observational studies that have demonstrated a relatively high incidence of hyponatremia in both non-surgical and postsurgical hospitalized pediatric populations and the potentially devastating consequences of that hyponatremia [122–127]. In a prospective observational study of 81 consecutive postsurgical patients admitted to a single PICU, the incidence of hyponatremia was 21% at 12 h postoperatively and 31% at 24 h [125]. There have also been many prospective randomized controlled trials comparing hypotonic versus isotonic fluid administration in hospitalized children [128–138]. A recent meta-analysis of the available literature summarized the data of 10 randomized controlled trials comparing hypotonic and isotonic maintenance fluid therapy in 855 hospitalized children. The meta-analysis showed a significantly higher risk for developing hyponatremia with hypotonic IV fluids (relative risk (RR) 2.24, 95% confidence interval (CI) 1.52 to 3.31) and severe hyponatremia (plasma Na <130 mmol/L) (RR 5.29, 95% CI 1.74 to 16.06). There was a significantly greater decrease in sodium in children who received hypotonic IV fluids (–3.49 mmol/L versus isotonic IV fluids, 95% CI –5.63 to –1.35). Moreover, there was no significant difference between the two interventions in the risk of hypernatremia (RR 0.73, 95% CI 0.22 to 2.48) [139].

Given the current clinical evidence, hospitalized children who require IV fluid therapy should receive isotonic maintenance IV fluids or IV fluids of an appropriate composition at a rate commensurate with their ongoing volume losses. When receiving IV fluid therapy, these same patients should have both daily weights and daily electrolyte monitoring with close attention to serum sodium levels [140].

Hyponatremia produces osmotic movement of free water across cell membranes from the extracellular to the intracellular compartments, with the brain being the most significantly affected organ. Children are more prone to cerebral edema from hyponatremia than are adults. This results from differences in the ratio of intracranial capacity to brain size, cerebrospinal fluid volume, and brain water and electrolyte content. The brain of a child grows rapidly, achieving adult size by age 6 years, whereas the skull continues to grow until the age of 16 years. The volume of cerebrospinal fluid, which buffers brain expansion, is relatively smaller in children than adults. Moreover, the brain intracellular concentration of sodium is approximately 27% higher in children than adults.

Clinically, cerebral edema is the most devastating consequence of hyponatremia. In the case of mild hyponatremia, patients frequently appear anxious or agitated. As the level of hyponatremia progresses, symptoms may worsen to include headaches, vomiting, ataxia, disorientation, seizures, and even coma or death. Treatment of hyponatremia and the rate of correction of the patient's sodium should depend upon the severity of the symptoms and the chronicity of the hyponatremia. Treatment options include fluid restriction, administration of oral or IV sodium chloride, and treatment of the underlying disease (Box 11.2). Considering the risk for cerebral demyelination with rapid correction or overcorrection of severe and/or chronic hyponatremia, an increase in plasma sodium of >25 mmol/L (mEq/L) over 48 h should be avoided. In the setting of symptoms suggestive of hyponatremic encephalopathy, definitive therapy with hypertonic saline is indicated (3% NaCl, 513 mEq/L) (see Box 11.1) [141].

Hypernatremia

Hypernatremia, another frequently encountered electrolyte disorder in hospitalized children, represents a deficit of water in relation to total body sodium. Defined as a serum sodium level >145 mmol/L (mEq/L), hypernatremia is the result of either a net loss of water or a gain of hypertonic sodium (Fig. 11.7). Net water losses, in either the form of pure water or hypotonic fluids, account for the majority of cases of hypernatremia. Pure water losses occur because of insensible losses through the skin or respiratory system or as a result of nephrogenic or central diabetes insipidus. There are many potential causes of hypotonic fluid losses. In infants and children, diarrhea and/or vomiting are common etiologies because this patient population often has an inability to control their own water intake and replace ongoing losses. In the hospital setting, hypernatremia is often iatrogenic secondary to either the administration of hypertonic saline or sodium bicarbonate for the treatment of metabolic acidosis [142,143].

Box 11.2: Treatment of symptomatic hyponatremia

1. 2 mL/kg bolus of 3% NaCl over 10 min. Maximum 100 mL
2. Repeat bolus 1–2 times as needed with until symptoms improve. Goal: 5–6 mmol/L increase in serum sodium in first 1–2 h
3. Recheck serum sodium following second or third bolus or every 2 h
4. Hyponatremic encephalopathy is unlikely if no clinical improvement following an acute rise in serum sodium of 5–6 mmol/L
5. Stop further therapy with 3% NaCl boluses if either:
   a. Patient is symptom free: awake, alert, responding to commands, resolution of headache and nausea
   b. Acute rise in sodium of 10 mmol/L in first 5 h
6. Correction in first 48 h should:
   a. Not exceed 15–20 mmol/L
   b. Avoid normo- or hypernatremia

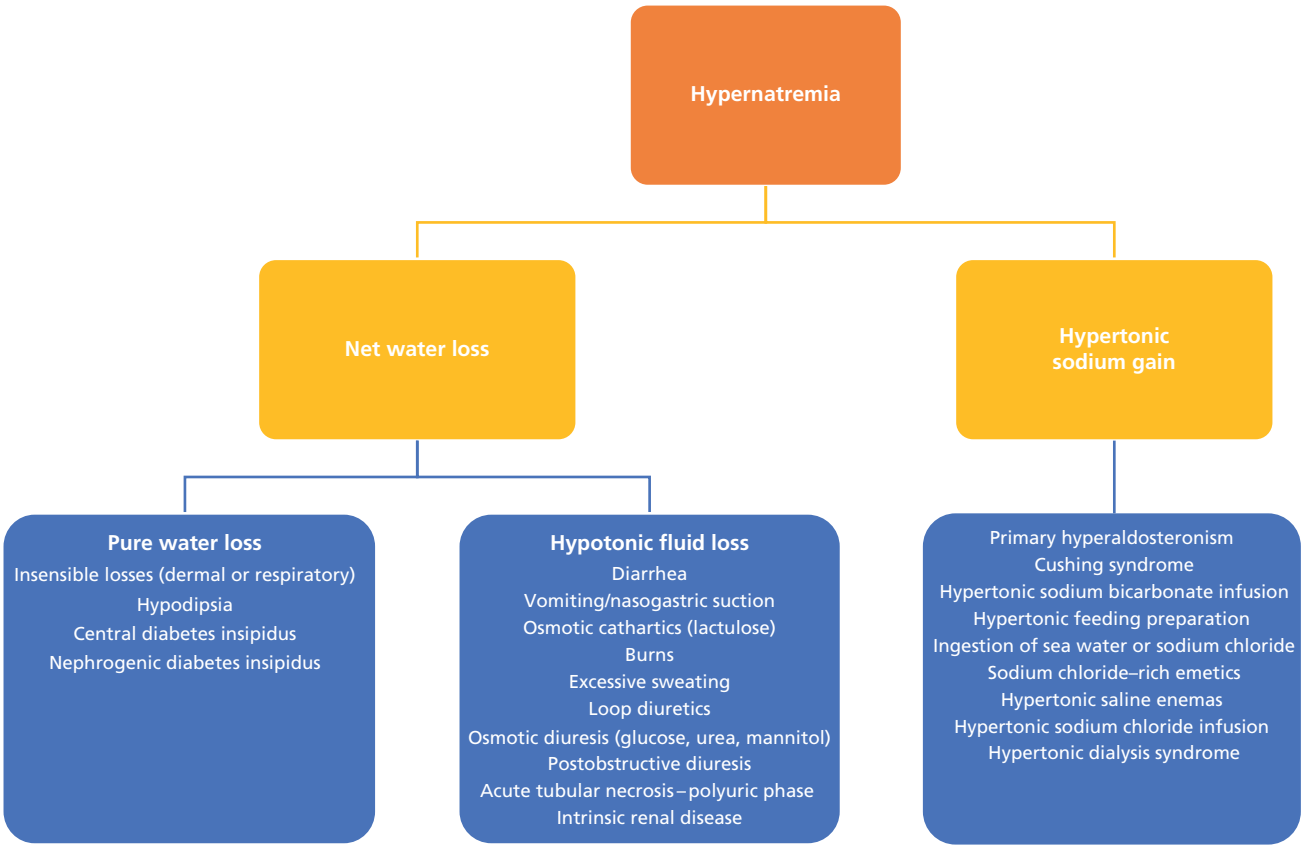

Figure 11.7 Hypernatremia.

Pure water losses that occur in the form of large volumes of dilute urine are most commonly attributable to diabetes insipidus (DI). In nephrogenic DI, there is normal ADH release and renal resistance to the water-retaining effects of ADH. In children, nephrogenic DI is more frequently inherited than acquired. Most cases of inherited nephrogenic DI occur in boys, as the disorder is an X-linked mutation of the gene for the ADH receptor. With central DI, there is a deficiency of ADH production in the hypothalamus and/or secretion from the posterior pituitary. Central DI can occur secondary to trauma, tumors, infarction, infection, or infiltrative diseases. Central DI can present in the operating room with hypernatremia, hyperosmolality, polyuria, and dehydration. The condition should be suspected in patients with the aforementioned symptoms who have suffered either an intracranial trauma or are undergoing surgery for a pituitary, hypothalamic, or optic tumor. Depending on the severity of the intraoperative central DI, these patients may require a vasopressin infusion to establish antidiuresis [144].

Clinically, cerebral hemorrhage is the most devastating consequence of hypernatremia. Severe hypernatremia, especially when associated with dehydration, induces brain shrinkage, which can cause tearing or rupture of the cerebral blood vessels and lead to cerebral hemorrhage and permanent neurological damage or death. Symptoms vary based upon both the severity of the hypernatremia and the rate at which the hypernatremia developed. Clinical manifestations in infants and children include hyperpnea, muscle weakness, restlessness, high-pitched cry, insomnia, lethargy, and even coma.

Treatment of hypernatremia and the rate of correction of the patient's sodium should depend upon the degree of associated dehydration, the severity of the symptoms, and the chronicity of the hypernatremia. In the setting of severe hypernatremic dehydration, intravascular volume should be carefully restored with isotonic IV fluids. Following re-establishment of an adequate intravascular volume, the patient's free water deficit should be calculated and the sodium level decreased by no more than 15 mmol/L per day. If hypernatremia is corrected too rapidly, cerebral edema, seizures, and death can occur [143].

Potassium

Potassium is the principal ICF cation with a normal intracellular concentration of 150 mmol/L (mEq/L) and an extracellular concentration between 3.5 and 5.5 mmol/L (mEq/L). These concentration differences are regulated by sodium–potassium adenosine triphosphate (Na^+/K^+-ATPase) pumps and lead to a transmembrane potential across the cell. Maintenance of the normal ratio of intracellular to extracellular potassium is critical to normal conductive and contractile function in the central nervous system and cardiac, skeletal, and smooth muscle cells. Total body potassium is largely dependent upon the kidneys. Potassium is freely filtered at the glomerulus and the vast majority reabsorbed before excretion in the urine. The kidneys can adjust to increased potassium ingestion by increasing excretion but cannot prevent depletion in the setting of low potassium intake. Aldosterone, the primary mineralocorticoid hormone, has an important

role in potassium homeostasis. Aldosterone primarily acts on the distal tubules of the kidneys and causes sodium and water reabsorption and potassium secretion. Disorders of potassium are typically the result of abnormal transcellular ions shifts, abnormal renal excretion, an excess or deficiency in mineralocorticoids, an exogenous or endogenous potassium load, or inadequate ingestion of potassium [145].

Hypokalemia

Hypokalemia, defined as a potassium of less than 3.5 mmol/L (mEq/L), is also commonly encountered in hospitalized children. A retrospective analysis of 512 consecutive children admitted to a single-center tertiary PICU revealed that hypokalemia affected over 40% of patients. The hypokalemia was moderate to severe (<3.0 mmol/L) in 16% of patients [146].

Hypokalemia secondary to a shift in potassium from the extracellular to intracellular fluid can occur with endogenous or exogenous β agonists, insulin, familial periodic paralysis, or barium poisoning. Alkalosis promotes hypokalemia through both potassium shifts across the cellular membrane and enhanced potassium secretion in the kidneys. Loop and thiazide diuretics, as well as acetazolamide, promote renal excretion of potassium. Children with diabetic ketoacidosis frequently have hypokalemia because of the osmotic diuresis that occurs in the setting of glycosuria. Abnormal renal losses of potassium frequently occur as a result of excess mineralocorticoids in patients with primary hyperaldosteronism, some rare forms of congenital adrenal hyperplasia and Cushing syndrome. Liddle, Barter and Gitelman syndromes also cause abnormal renal losses of potassium. Vomiting and diarrhea are the most common cause of extrarenal loses of potassium in children (Fig. 11.8).

Clinical signs and symptoms of hypokalemia are often absent or mild. With moderate to severe hypokalemia, patients may exhibit generalized weakness, lethargy, or constipation. Electrocardiographic changes include an increased P wave amplitude, prolonged PR interval, ST depression, QT prolongation, T-wave flattening or inversion, or the appearance of U waves. The risk of cardiac arrhythmias is increased in patients with heart failure or left ventricular hypertrophy. In patients with a serum potassium of less than 2.5 mmol/L, muscle necrosis can occur, and with a potassium of less than 2.0 mmol/L an ascending paralysis can occur [145].

Treatment of hypokalemia should depend upon the severity of the accompanying signs and symptoms. Whenever possible, hypokalemia should be corrected with oral supplementation. In the setting of severe symptoms (e.g. ECG changes, muscle weakness, or paralysis), IVs potassium should be administered. The rate of IV administration should not exceed 0.5–1 mEq/kg/h. IV potassium can cause pain and phlebitis when given via a peripheral vein. Potassium concentrations of 40 mEq/L or greater should be administered through central venous access.

Hyperkalemia

Hyperkalemia, defined as a potassium of greater than 5.5 mmol/L, occurs less frequently than hypokalemia in hospitalized children. The aforementioned retrospective analysis of 512 consecutive children admitted to a single-center tertiary PICU revealed that hyperkalemia affected 29% of admissions. Twelve percent of admitted PICU patients had severe hyperkalemia (K^+ >6.0 mmol/L) [146].

In children, hyperkalemia is most frequently a spurious or inaccurate measurement. Capillary sampling, blood aspiration through a small-bore needle or catheter, and a tight tourniquet can lead to hemolysis of red blood cells and release of intracellular potassium. If pseudohyperkalemia is suspected, a repeat free-flowing sample should be obtained.

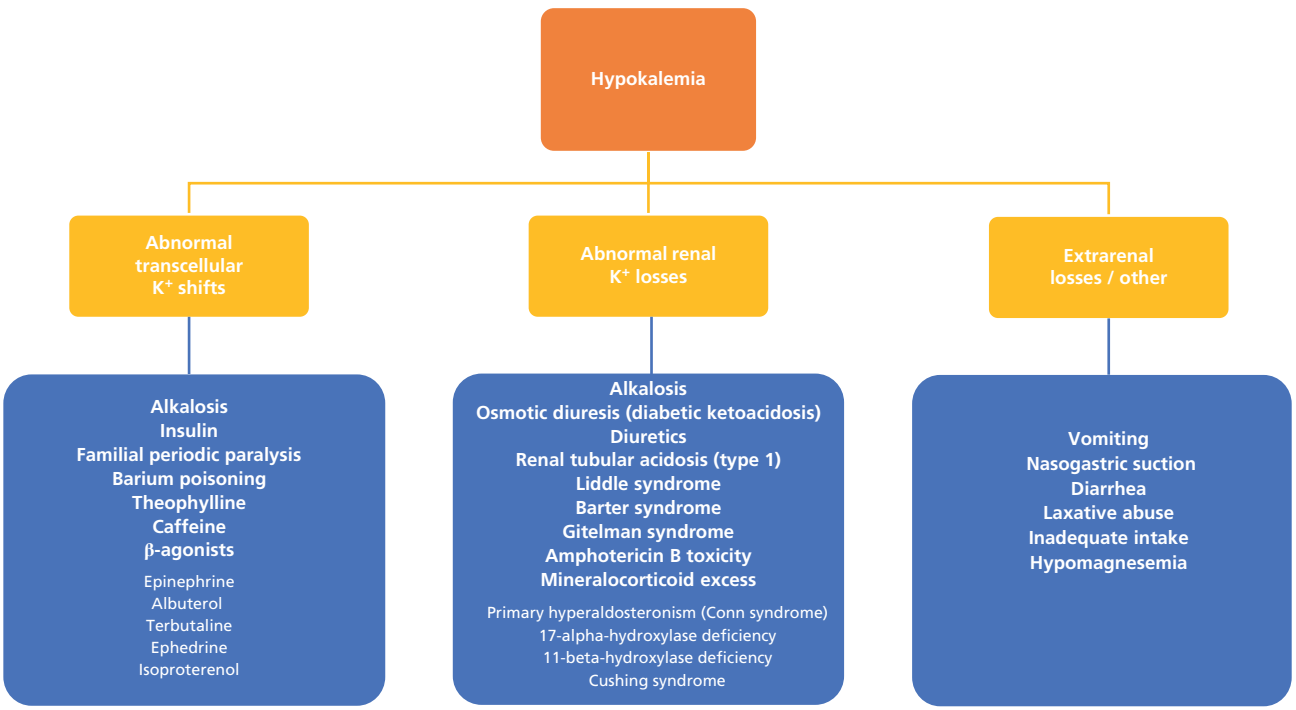

Figure 11.8 Hypokalemia.

Many clinical scenarios lead to hyperkalemia via a shift in potassium from the ICF to the ECF. Metabolic acidosis, insulin deficiency, hypertonicity, digitalis poisoning, β-blockers, succinylcholine, tumor lysis syndrome, hyperkalemic periodic paralysis, strenuous exercise, and tissue injuries from burns, trauma, or rhabdomyolysis can all cause hyperkalemia from a transcellular shift in potassium. Hyperkalemia may also occur as a consequence of acute and/or chronic renal failure. When the GFR falls below 15–30 mL/min/1.73 m^2, urinary potassium excretion is significantly impaired. Mineralocorticoid (aldosterone) deficiencies, such as Addison disease, 21-hydroxylase deficiency, or type IV renal tubular acidosis, may also cause significant hyperkalemia. A reduced effective arterial blood volume frequently leads to hyperkalemia in children via renal mechanisms. The reduced sodium delivery to the collecting ducts that occurs during hypovolemia leads to a functional impairment of urinary potassium excretion. Several medications, including spironolactone, ACE inhibitors, non-steroidal anti-inflammatory drugs, and cyclosporins, affect aldosterone and are associated with hyperkalemia. Hyperkalemia as a result of excessive intake is infrequent, especially in the setting of normal kidney function. Occasionally, it may occur following a massive blood transfusion and/or the transfusion of old banked blood (Fig. 11.9) [147].

Hyperkalemia is frequently asymptomatic in children and can go undetected until signs and symptoms of the underlying disease lead to an electrolyte evaluation. Children with potassium concentrations greater than 8 mmol/L may develop ascending muscle weakness or paralysis similar to that found in patients with Guillain–Barré syndrome. Hyperkalemia is associated with significant disturbances in cardiac conduction and, depending on the severity and the rate of development, can be associated with lethal arrhythmias. Characteristic changes seen on the ECG with increasing levels of potassium include tall, peaked T waves followed by prolongation of the PR interval, decreased or disappearing P wave, widening QRS, and amplified R wave. Finally, prior to ventricular fibrillation or asystole, there is progressive widening of the QRS complex eventually merging with the T wave to form the sine wave pattern (Fig. 11.10).

Children with muscle weakness or paralysis, ECG changes, and/or a potassium concentration >6.0–6.5 mmol/L require emergent treatment (Box 11.3). The first step in the management of hyperkalemia is to identify and remove any oral and/or parenteral sources of potassium. The next step is to stabilize the myocardium by antagonizing the effect of the extracellular potassium with either intravenous calcium chloride or calcium gluconate. Calcium exerts its effects rapidly. However, calcium's benefits may last only 30–60 min and repeat dosing may be required. Insulin in combination with glucose is indicated for symptomatic hyperkalemia. Insulin drives the extracellular potassium intracellularly while glucose prevents hypoglycemia and enhances the endogenous production of insulin. Inhaled β-adrenergic agonists and IV sodium bicarbonate should also be considered as they too promote redistribution of potassium intracellularly. Definitive therapy should be aimed at identifying the etiology of the hyperkalemia and permanently removing excess potassium from the body. Loop diuretics and enteral cation exchange resins such as sodium polystyrene sulfonate both facilitate potassium excretion through the kidneys and gut, respectively. Renal replacement therapy is indicated when conservative therapy fails.

Calcium

Calcium, a divalent cation, is the fifth most abundant element in the body and primarily stored in bone as hydroxyapatite crystal. In fact, only 1% of total body calcium is found in the

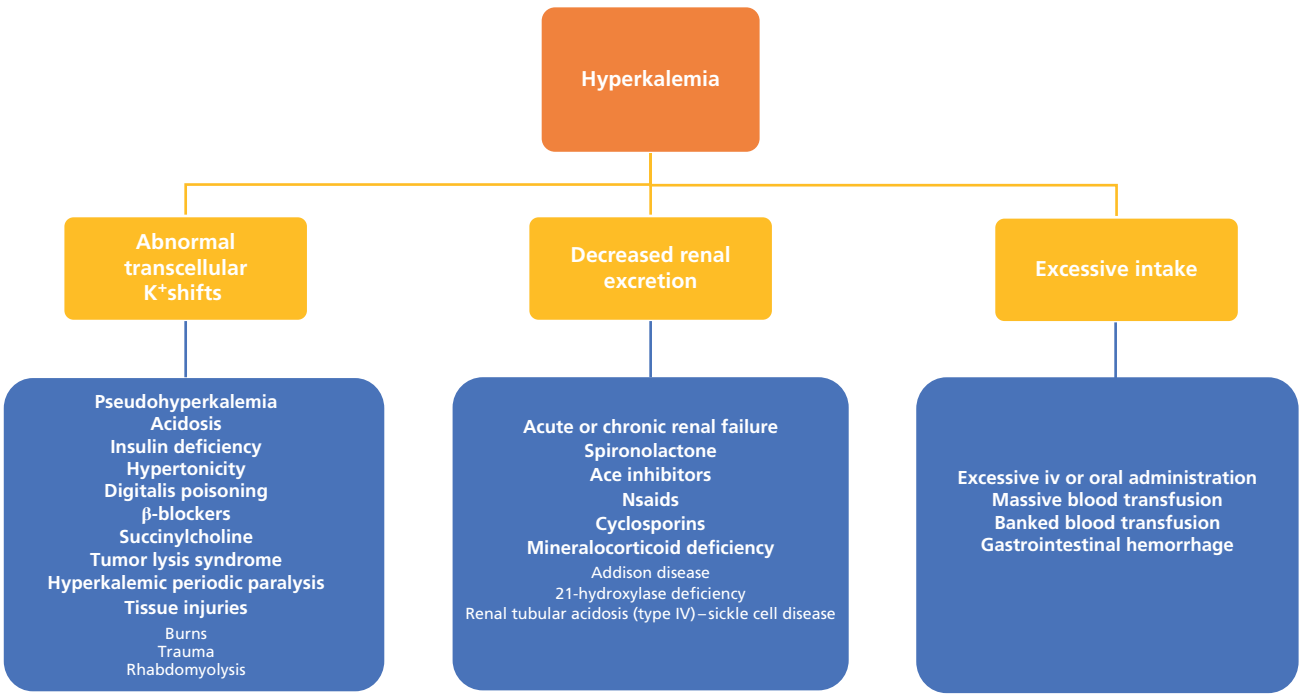

Figure 11.9 Hyperkalemia. ACE, angiotensin-converting enzyme; IV, intravenous; NSAIDs, non-steroidal anti-inflammatory drugs.

Box 11.3: Treatment of symptomatic hyperkalemia

1. Remove sources of oral or parenteral potassium intake
2. Administer calcium chloride (10–20 mg/kg IV) or calcium gluconate 10% (0.5 mL/kg IV) over 5–10 min
3. Administer regular insulin (0.1 unit/kg IV) and dextrose (0.5 g/kg IV) over 15–30 min
4. Consider administering sodium bicarbonate (1 mEq/kg IV) and/or inhaled albuterol
5. Consider administering furosemide (1 mg/kg IV) in patients with adequate intravascular volume and renal function
6. Consider administering sodium polystyrene sulfonate (oral or rectal)*
7. Renal replacement therapy when conservative therapy fails

*Contraindicated in neonates, postoperative patients, and patients with ileus or bowel obstruction.

ECF. Approximately 50% of extracellular calcium is circulated in the free ionized form while 40% is bound to protein (primarily albumin) and 10% complexed with anions. Only the free ionized form of calcium is biologically active. Calcium is critical to cardiac, vasomotor, and neurological function. Calcium concentrations are reported in various units including mg/dL, mmol/L, or mEq/L. Normocalcemia is 8.5–10.5 mg/dL (2.1–2.6 mmol/L or 4.2–5.2 mEq/L) for total calcium, and 4.0–5.0 mg/dL (1.0 –1.3 mmol/L or 2.0–2.6 mEq/L) for ionized calcium.

Parathyroid hormone, the primary regulator of calcium homeostasis, induces calcium release from bone, calcium reabsorption in the kidneys, and conversion of vitamin D to its most active form, 1,25-dihydroxyvitamin D (calcitriol). In turn, 1,25-dihydroxyvitamin D stimulates increased intestinal absorption of calcium. Calcitonin, a hormone released by the thyroid gland in response to rising levels of calcium, decreases calcium levels by decreasing bone resorption. However, an absence or excess of calcitonin does not result in either hypercalcemia or hypocalcemia, respectively [148].

Hypocalcemia

Hypocalcemia, defined as an ionized calcium of less than 4 mg/dL (1.0 mmol/L), is a relatively common electrolyte abnormality in hospitalized children. A prospective analysis of 145 pediatric patients admitted to a single-center PICU revealed 49% had a low total calcium and 17.9% a low ionized calcium [149].

Hypocalcemia observed in the ICU setting is often related to an acute illness or stress such as sepsis, cardiac surgery, rhabdomyolysis, pancreatitis, hepatitis, or tumor lysis. Insufficient parathyroid hormone (hypoparathyroidism) or insufficient responsiveness to parathyroid hormone (pseudohypoparathyroidism) both also lead to hypocalcemia. Hypocalcemia is common in infants with DiGeorge syndrome secondary to parathyroid aplasia or hypoplasia. Magnesium is required for both parathyroid hormone release and responsiveness. Consequently, hypomagnesemia may lead to low ionized calcium levels via indirect mechanisms. Deficiencies in vitamin D or impaired activation of vitamin D can both cause hypocalcemia. Hypocalcemia is common in neonates secondary to stress, immaturity of the parathyroid glands, and/or the administration of phosphorus-rich formula or cow's milk. Renal failure leads to hypocalcemia via numerous mechanisms including hyperphosphatemia. Elevated phosphorus levels often cause calcium phosphate precipitation and subsequent hypocalcemia. Respiratory and metabolic alkalosis promote the binding of calcium to albumin, thereby decreasing ionized calcium levels. Additionally, citrate, used to preserve blood products, chelates calcium and can rapidly decrease the free fraction of serum calcium.

The cardiovascular manifestations of hypocalcemia include hypotension, impaired cardiac contractility, and a prolonged QTc interval. A low ionized calcium is associated with neuromuscular excitability, which may present as seizures, tetany, muscle cramps, laryngeal stridor, and/or apnea in the newborn.

The most important aspect in the treatment of hypocalcemia is determination of the etiology of the electrolyte abnormality. In the critically ill child with symptomatic hypocalcemia, immediate treatment is indicated with IV calcium chloride or calcium gluconate, preferably through a large vein or central line. If hypomagnesemia is also present, IV magnesium sulfate should be administered. Long-term therapy, depending on the etiology of the hypocalcemia, may include oral calcium salts, calcitriol, and/or magnesium sulfa [148].

Hypercalcemia

Hypercalcemia, defined as an ionized calcium of greater than 5.0 mg/dL (1.3 mmol/L), is an uncommon electrolyte abnormality in hospitalized children. In pediatric patients, iatrogenic administration of calcium is a frequent cause of hypercalcemia. The other causes of hypercalcemia in children vary by age and include hyperparathyroidism, phosphate depletion, maternal hypocalcemia, malignancy,

hypervitaminosis D, immobilization, subcutaneous fat necrosis, and genetic or inborn metabolic disorders. Clinical features may be non-specific or in severe cases may include weakness, hypotonia, lethargy and stupor, and possibly seizures. Hypertension, bradycardia, and/or a shortened QT interval may also be present. Hypercalcemia can induce polyuria and dehydration. Damage to the kidneys from nephrocalcinosis may occur as well. In the symptomatic patient, the initial approach to treatment is to increase urinary excretion of calcium with loop diuretics while correcting the dehydration that commonly occurs with significant hypercalcemia. Beyond emergent management, long-term therapy, depending upon the etiology, can include parathyroidectomy, calcitonin, or bisphosphonates [150].

Magnesium

Magnesium, the second most abundant intracellular cation to potassium, is critical to cellular enzymatic activity. Specifically, it is a vital cofactor of any reaction powered by adenosine triphosphate. Magnesium also acts as a calcium channel antagonist and subsequently plays a key role in the modulation of intracellular calcium channel activities. Because less than 1% of total body magnesium is found in the extracellular space, serum magnesium levels may not accurately reflect total body concentrations of magnesium. Consequently, clinical symptoms of magnesium abnormalities often do not correlate with serum magnesium levels. The normal serum concentration of magnesium ranges between 1.8 and 2.3 mg/dL (0.75–0.95 mmol/L) [151,152].

Hypermagnesemia

Hypermagnesemia is rare in pediatric patients. The most common cause is iatrogenic administration of excessive amounts of magnesium, especially in the setting of renal failure. Symptoms include hyporeflexia, respiratory depression, somnolence, ECG changes, and even cardiac arrest. IV calcium reverses the neuromuscular and cardiotoxic effects of hypermagnesemia and should be administered in the symptomatic patient. Further treatment should be directed at identifying and removing exogenous sources of magnesium. In patients with renal failure, dialysis may be required.

Hypomagnesemia

Hypomagnesemia occurs with some frequency in PICU patients. In one retrospective analysis, the incidence of hypomagnesemia in critically ill children was 44% [153]. The main cause of hypomagnesemia is inadequate intake or supplementation. Other causes include gastrointestinal losses and renal losses. Many drugs promote renal wasting of magnesium including aminoglycosides, cisplatin, amphotericin B, loop diuretics, cyclosporine, and tacrolimus. Low magnesium levels frequently occur in patients with sepsis and burn injuries. Concurrent hypocalcemia and/or hypokalemia is also common.

Neuromuscular irritability including tetany, tremors, and/or seizures is often present with significant hypomagnesemia. Personality changes may be evident. Arrhythmias can occur, and may include premature ventricular beats, ventricular tachycardia, torsades de pointes, and ventricular fibrillation. Enteral or intravenous replacement of magnesium is indicated in symptomatic patients and/or in patients in whom losses of magnesium will be ongoing. IV magnesium should be given slowly as hypotension can occur with rapid infusion [151].

Phosphorus

Phosphorus, an intracellular ion primarily stored in bone, is essential to cell structure, cellular metabolism through the generation of ATP, regulation of subcellular processes such as cell signaling through protein phosphorylation of key enzymes, maintenance of acid–base homeostasis through urinary acid buffering, and bone mineralization. Phosphate homeostasis is maintained by regulation of intestinal uptake of dietary phosphate, renal phosphate reabsorption and excretion, and the exchange of phosphate between extracellular and bone storage pools. Normal serum concentrations of phosphorus vary by age, with the highest concentrations noted in infants. Higher concentrations observed in younger infants and children are likely related to more rapid rates of skeletal growth in the pediatric population [154].

Hyperphosphatemia

Hyperphosphatemia, while relatively uncommon in children, is most frequently a result of either renal failure or tumor lysis syndrome. The major clinical consequence of hyperphosphatemia is the associated hypocalcemia and abnormal deposition of calcium phosphate salts in soft tissues including the kidney. In severe cases, dialysis may be required.

Hypophosphatemia

Hypophosphatemia is relatively common in critically ill children with a reported rate as high as 61% during the first 10 days of a PICU stay [155]. The disorder frequently goes undiagnosed, as symptoms can be largely non-specific. The main clinical manifestations are metabolic acidosis, decreased levels of 2,3-DPG and ATP, hemolysis, leukocyte and platelet dysfunction, acute respiratory failure, arrhythmias, hypotension, seizures, and weakness. The most common causes and/or risk factors for the development of hypophosphatemia are malnutrition, refeeding, the use of diuretics, steroids, catecholamines and antacids, excessive parenteral glucose administration, diabetic ketoacidosis, sepsis, and respiratory alkalosis. Beyond identifying and addressing the cause of the hypophosphatemia, treatment is replacement with either enteral or IV phosphorus preparations. IV therapy is typically reserved for severe cases [155,156].

KEY POINTS: DISORDERS OF FLUIDS AND ELECTROLYTES

- The first step in caring for a dehydrated child is to assess the degree and cause of dehydration. The degree of dehydration dictates the urgency of the situation and the volume of fluid needed for rehydration
- Hyponatremia is common and is often caused by administration of hypotonic IV fluids. Children should generally receive isotonic maintenance IV fluids
- Hyperkalemia usually results from acute renal injury, acidosis, massive tissue trauma, or iatrogenic causes. Hypokalemia usually results from diarrhea or persistent vomiting associated with gastroenteritis

- Hypocalcemia is a relatively common electrolyte abnormality often related to an acute illness or stress such as sepsis. A low ionized calcium is associated with neuromuscular excitability, which may present as seizures, tetany, muscle cramps, laryngeal stridor, and/or apnea in the newborn
- Hypophosphatemia is relatively common in critically ill children. The main clinical manifestations are metabolic acidosis, decreased levels of 2,3-DPG and ATP, hemolysis, leukocyte and platelet dysfunction, acute respiratory failure, arrhythmias, hypotension, seizures, and weakness

Conclusion

Intravenous fluid therapy is a core component of the perioperative practice of pediatric anesthesia and an area in which pediatric anesthesiologists have a significant role in advising perioperative clinicians. It is important to recognize that IV fluids are medications that must be initiated, dosed, monitored, and discontinued just like any other pharmaceutical agent. The goal of IV fluid therapy is to preserve the extracellular volume while maintaining a normal electrolyte balance. Acutely ill patients frequently have conditions that impair normal water and electrolyte homeostasis, and choosing the appropriate volume and composition of fluid therapy requires great care and a thorough understanding of the physiology of fluid electrolyte regulation.

CASE STUDY

A 9-year-old previously healthy male, who was struck by a motor vehicle and thrown approximately 50 feet from the site of impact, presents to the Emergency Department with a complaint of abdominal pain and a urinalysis revealing frank blood. Glasgow Coma Scale score is 13 and a non-contrast head CT scan is negative for intracranial pathology. Further imaging reveals a left pubis fracture and underlying pelvic hematoma, left midfoot subluxation/dislocation, a left clavicle fracture, and a pulmonary contusion. On ICU day #1 he developed mental status changes requiring intubation and had an obvious peri-intubation aspiration event. His vital signs and ventilator settings remained stable and he was subsequently taken to the OR for repair of his left foot fracture and dislocation. His pelvic fracture is managed non-operatively through immobility in a pelvic brace. He is uneventfully extubated 4 days later after his respiratory status stabilized without any complications and is transferred to the general pediatric surgical floor. Two days later, he is again noted to have altered mental status and is taken for an urgent CT scan. He proceeds to have a full tonic-clonic seizure in the CT scanner and is readmitted to the PICU. On work-up, he is found be significantly hyponatremic with a serum sodium of 116 meq/dL. He is treated with 3% hypertonic saline and his sodium is slowly corrected over 2 days with hypertonic saline and fluid restriction. His hyponatremia was likely multifactorial, including iatrogenic administration of hypotonic intravenous fluids and SIADH secondary to his pulmonary contusion, aspiration, and pain from his multiple injuries.

Introduction

The hematological system is unique among all of the systems in the body. It is composed of multiple components, each of which engages in a very specific and unique function that is critical for life. This chapter will focus on one of those functions: coagulation. The coagulation process, maturational factors affecting coagulation in neonates and infants, tests of and defects in the coagulation system, and principles of transfusion therapy and blood conservation will be discussed.

The coagulation process

The coagulation system is a complex interplay of cellular elements and plasma proteins that functions to stop bleeding from an injured blood vessel and then to re-establish patency of that vessel. The process that stops bleeding is understood to occur in two phases. Primary hemostasis arrests bleeding by inducing vasoconstriction in the injured vessel and by causing the formation of a platelet plug. Secondary hemostasis then involves the circulating plasma coagulation factors and results in the formation of a fibrin clot at the site of blood vessel damage. While it is easy to think of these two phases as separate, distinct, and sequential, they are in fact highly coordinated, interdependent, and concurrent. In the end, the fibrinolytic system removes clot to re-establish blood flow and to allow wound healing [1].

Primary hemostasis involves the interaction of damaged blood vessel walls and platelets to form a platelet plug. Damage to blood vessel walls exposes subendothelial collagen. Platelets immediately *adhere* via their exposed glycoprotein Ib (GpIb) surface receptors to von Willebrand factor (vWF) that has bound to this collagen. Platelet *activation* then occurs with release of platelet agonists and coagulation factors from platelet storage granules and with changes in the shape and surface function of the platelets. Vasoconstriction of injured vessels results, and platelets *aggregate* as fibrinogen binds to exposed glycoprotein IIb/IIIa (GpIIb/IIIa) receptors on adjacent platelets (Fig. 12.1). With a platelet plug now formed, the phospholipid membrane of activated platelets provides the surface on which the process of secondary hemostasis occurs [2].

Secondary hemostasis involves the interaction of plasma coagulation factors to form a fibrin clot. Roman numerals are used to designate most of these factors in order to provide an international code for clear communication [3] (Table 12.1). The clotting factors exist in inactive precursor forms before being converted to active enzymes upon initiation of secondary hemostasis [4].

Initial explanations of secondary hemostasis involved "intrinsic" and "extrinsic" limbs of a cascade that converged on a "common" pathway leading to thrombin generation and subsequent fibrin formation [4,5] (Fig. 12.2). However, clinical and laboratory observations led to the recognition that the intrinsic and extrinsic coagulation pathways do not operate independently *in vivo*. Additionally, even the early descriptions of coagulation recognized the significant role of phospholipid acting as a surface catalyst for coagulation and postulated that the phospholipid might be derived from platelets during the clotting process [5]. Subsequently, a cell-based model has been proposed to explain secondary hemostasis. This model emphasizes the importance of cell surfaces as the platform upon which the events of secondary hemostasis occur [6].

The cell-based model describes three overlapping phases of secondary coagulation: *initiation* of coagulation on tissue factor (TF)-bearing cells in and around injured blood vessels, *amplification* of coagulation by thrombin generated on these

TF-bearing cells, and *propagation* of thrombin generation on platelet surfaces. *Initiation* of coagulation occurs when TF complexes with activated factor VII (FVIIa) from plasma to catalyze the activation of FX and FIX. Involvement of FVa from platelet degranulation allows the generation of small amounts of thrombin (Fig. 12.3A) which then stimulates the *amplification* phase. This initiation phase of the cell-based coagulation model has been compared to the classically described extrinsic coagulation pathway (Fig. 12.4A).

In the *amplification* phase, the initially produced thrombin activates additional plasma coagulation factors as well as nearby platelets. The activated platelets provide the phospholipid surfaces on which large amounts of thrombin are subsequently generated in the *propagation* phase (Fig. 12.3B).

Propagation of thrombin generation occurs on the surfaces of activated platelets. FVIIIa and FIXa form a "tenase" complex which activates FX. These actions have been compared to those outlined in descriptions of the intrinsic coagulation pathway (Fig. 12.4B). FXa and FVa then form a "prothrombinase" complex which finally catalyzes the large-scale conversion of prothrombin into thrombin (Fig. 12.3C), analogous to the common coagulation pathway where the extrinsic and intrinsic pathways converge (Fig. 12.2). Unlike the small quantity of thrombin produced in the initiation phase, the quantity of this platelet-produced thrombin is sufficient to cleave fibrinogen to fibrin and to cross-link the fibrin monomers with FXIIIa to form a stable clot [6,7].

After clotting has occurred and bleeding has been stopped, activation of the fibrinolytic system allows patency of the involved blood vessel eventually to be restored so that wound healing can proceed. Both tissue plasminogen activator (tPA) and its substrate, plasminogen, bind to fibrin surfaces. Fibrin-bound tPA then converts this localized plasminogen to its active form, plasmin, which dissolves the fibrin clot to eventually re-establish blood flow through vessels [6,7].

Table 12.1 Coagulation factor numbers and synonyms

Roman numeral	Synonyms
I	Fibrinogen
II	Prothrombin
III	Thromboplastin
	Tissue factor
IV	Calcium
V	Proaccelerin
	Labile factor
VII	Proconvertin
	Stable factor
VIII	Antihemophilic factor (AHF)
	Antihemophilic globulin (AHG)
	Antihemophilic factor A
	Factor VIII:C
IX	Plasma thromboplastin component
	Antihemophilic factor B
	Christmas factor
X	Stuart factor
	Prower factor
	Stuart–Prower factor
XI	Plasma thromboplastin antecedent
	Antihemophilic factor C
XII	Hageman factor
	Contact factor
	Surface factor
	Glass factor
XIII	Fibrin stabilizing factor
	Laki–Lorand factor

The hematological system constantly balances the ability to keep blood flowing through undamaged vessels with the ability to stop bleeding from damaged blood vessels. Under normal circumstances, the luminal surface of blood vessels is non-thrombogenic because of an intact endothelial surface and because circulating activated protein C, with its cofactor protein S, inactivates any circulating FVa and FVIIIa to attenuate thrombin generation [8]. Antithrombin (AT) neutralizes circulating FIXa, FXa, FXIa, and thrombin to prevent fibrin formation [9]. Circulating nitric oxide and prostacyclin inhibit platelet activity and release tPA to promote fibrinolysis [8]. Thus, clot formation is prevented in undamaged blood vessels while vascular damage disrupts these homeostatic mechanisms to create an environment conducive to clot formation [8]. Furthermore, when vascular damage does occur, the coagulation process is restricted only to affected vessels because the coagulation process-inducing TF is expressed only on damaged vessels and also because a host of circulating anticoagulants keep the actions of circulating activated coagulation factors in check [1,6–8]. In the end, under normal conditions, coagulation and fibrinolysis occur only where they are needed and are prevented from becoming pathological generalized problems by procoagulant and anticoagulant factors that delicately balance the system.

KEY POINTS: THE COAGULATION PROCESS

- Primary hemostasis involves the interaction of damaged blood vessel walls and platelets to form a platelet plug
- Secondary hemostasis involves the interaction of plasma coagulation factors on activated platelet surfaces to form a fibrin clot
- Fibrinolysis later reestablishes patency of involved blood vessels

Maturation of the coagulation system

Coagulation proteins, platelets, and fibrinolytic proteins do not cross the placental barrier but their synthesis by the fetus begins at approximately 11 weeks of gestational age. During the remainder of fetal development, maturation of the coagulation and fibrinolytic systems parallel each other so that a delicate hemostatic balance is maintained [10,11]. However, despite this ongoing maturation, both quantitative and qualitative deficiencies exist in these systems at birth.

Plasma levels of coagulation factors and coagulation inhibitors have been documented in detail in both healthy premature infants (30–36 weeks' gestational age) and full-term infants (>37 weeks' gestational age) from birth through 6 months of age. Plasma levels of the vitamin K-dependent coagulation factors (II, VII, IX, and X) and the contact

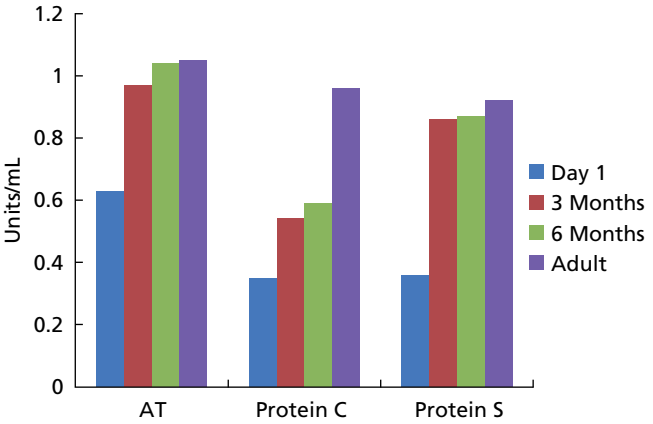

Figure 12.7 Coagulation inhibitor levels in full-term infants. AT, antithrombin. *Source:* Adapted from Andrew et al [13].

factors (XII, XI, high-molecular-weight kininogen (HMWK), and prekallikrein (PK)) are all significantly lower than adult values at 1 day of age with most rising to within adult ranges by 6 months (Fig. 12.5). This is also the situation for several coagulation inhibitors (AT, PC, and PS) and fibrinolytic factors (plasminogen and tPA) (Fig. 12.6). In contrast, levels of fibrinogen, FV, FVIII, FXIII, vWF, and platelet counts are all remarkably similar to adult values on the first day of life, as is plasminogen activator inhibitor [12–15] (Fig. 12.7).

In addition to these quantitative issues in development of the hemostatic system, qualitative issues exist. The concept of a "fetal fibrinogen" has been proposed [16,17] and evidence of impaired fibrinogen function in infants has been postulated based on thromboelastography data [18], on differences between measured activity and antigen levels of fibrinogen [19], and on differences in the microscopic structures of neonatal and adult fibrinogen [20]. Comparison of the biological activity and the plasma levels of FXII, PK, protein C, and plasminogen has suggested that these factors may also exhibit qualitative deficiencies [10,21–23] but the data are not absolute [15,19]. Finally, impairment of platelet aggregation has been documented in neonates in the first 48 h of life [24].

Coagulation tests have also been studied in infants. Activated partial thromboplastin time (aPTT) is prolonged in both term and preterm infants, maturing to adult ranges within 3–6 months. Values of prothrombin time (PT) and thrombin time (TT) are similarly prolonged at birth but reach adult ranges within several days of age [11–13,25].

Interpretation of these maturational issues of the hemostatic system is complex. There is no evidence that neonates, infants, or children have an increased risk of bleeding either spontaneously, after trauma, or during surgery compared to adults. In fact, thromboelastograms have shown intact coagulation systems even in neonates [26]. However, the alterations in coagulation factors and coagulation inhibitors in young infants result in a reduced ability to generate thrombin as well as a significant delay in thrombin generation once the coagulation system is triggered. On the other hand, deficiencies in the fibrinolytic system result in decreased plasmin generation and impairment of fibrinolysis [23,27]. Fortunately, maturation of coagulation and fibrinolysis proceeds in tandem and in accordance with gestational age, and the net effect apparently strikes the necessary balance to maintain a competent hemostatic picture. Nevertheless, while quantitative and qualitative immaturities resolve during the first year of life, normal values for plasma levels of most coagulation factors, coagulation inhibitors, and fibrinolytic proteins in young infants

must be recognized to be different from those values considered normal for adults.

KEY POINTS: MATURATION OF THE COAGULATION SYSTEM

- Quantitative deficiencies in many coagulation factor and coagulation inhibitor levels exist in early infancy
- Qualitative abnormalities may also exist in several pre- and anticoagulants
- Despite these immaturities, hemostasis seems balanced, though tenuous, in young infants

Evaluation of the coagulation system

Anesthesiologists and surgeons usually employ laboratory tests of the coagulation system to screen patients preoperatively for inherited or acquired hemorrhagic disorders or to diagnose the cause(s) and monitor the treatment of intraoperative or postoperative bleeding [28]. None of the available tests is perfect because each either reports a quantitative count with no consideration of qualitative function or is performed *in vitro* in environments that are not equivalent to *in vivo* processes. This section will describe available laboratory tests and their indications and limitations.

Evaluation of primary hemostasis

Evaluation of primary hemostasis includes quantitative and functional analysis of platelets and vWF. Platelet counts are measured by automated systems on whole blood samples. The range of normal for platelet counts is 150,000–400,000/μL. Platelet counts, however, do not assess the functional capacity of the available platelets. Bleeding time (BT) was the historical mainstay of platelet function assessment. However, because it requires making a skin cut and is very operator dependent, it has been mostly abandoned in favor of the platelet function analyzer (PFA-100, Siemens Diagnostics, Marburg, Germany). The platelet function analyzer assesses platelet adhesion to a membrane upon which either adenosine diphosphate (ADP) or epinephrine then stimulates platelet aggregation. The closure time (CT), i.e. the length of time necessary for a platelet plug to form and occlude an aperture in the membrane, is then recorded [29]. The CT is prolonged in patients with platelet counts below 50,000/μL or hematocrit below 25% and in patients with severe platelet dysfunction (Bernard–Soulier syndrome (Gp Ib receptor defect) and Glanzmann thrombasthenia (Gp IIb/IIIa receptor defect)) or severe von Willebrand disease (vWD, types 2 and 3). CT is also prolonged by aspirin, non-steroidal anti-inflammatory drugs (NSAIDs), or Gp IIb/IIIa inhibitor use [28,30,31]. The most reliable use of the platelet function analyzer is in patients with severe bleeding where a normal CT excludes quantitative deficiencies of platelets or vWF, severe platelet function disorders, and severe vWD [30,32]. However, the platelet function analyzer has a low sensitivity as a screening test for platelet function defects thus its usefulness as a preoperative screening tool is questionable [32].

While abnormal results of PFA-100 CT indicate a problem in primary hemostasis, definitive investigation and identification of the specific problem are accomplished by sophisticated tests such as platelet aggregometry, platelet secretion assays, and platelet flow cytometry. Platelet aggregometry is considered the gold standard for global platelet function testing. Platelet secretion assays measure the release of substances from platelet granules. Platelet flow cytometry uses monoclonal antibodies to diagnose defects in platelet surface glycoproteins (Bernard–Soulier syndrome and Glanzmann thrombasthenia) [31]. Appropriate use of these tests requires extensive expertise in diagnosing hemostatic disorders, thus they should be utilized under the guidance of a hematologist.

Evaluation of secondary hemostasis

Evaluation of secondary hemostasis involves examining the steps in thrombin generation and fibrin formation. Available tests include quantitative measurements of coagulation factor levels and analyses of the interactions of these factors in the coagulation process.

Measurement of fibrinogen level is the most common quantitative test performed. Standard measurement (the Clauss method) adds exogenous thrombin to diluted platelet-poor plasma centrifuged from a whole blood sample. The fibrinogen level is deduced by plotting the time until clot formation (measured by optical density) on a calibration curve drawn from reference plasma with known fibrinogen levels [33]. Normal values for fibrinogen level range between 150 and 400 mg/dL. Viscoelastic coagulation tests, thromboelastography (TEG®) and rotational thromboelastometry (ROTEM®), are being investigated as means to measure a "functional fibrinogen" level using whole blood samples. Platelet contribution to clot strength is eliminated by blocking fibrinogen-induced platelet aggregation. The independent contribution of fibrinogen to clotting can then be measured [34]. Reference ranges are being established for these measures of fibrinogen.

The interactions of coagulation factors are commonly measured with the prothrombin time (PT), activated partial thromboplastin time (aPTT), and thrombin time (TT). The PT is classically used to examine the factors involved in the "extrinsic" and common pathways of coagulation and thus is sensitive to factors VII, X, V, II (thrombin), and I (fibrinogen) (Fig. 12.8). Thromboplastin, a mixture of TF, phospholipids, and calcium, is used to initiate coagulation. The usual range for PT measurements is 10–14 s. The potency of the thromboplastin used to initiate clotting is referenced to a standard thromboplastin preparation to allow the calculation of an international normalized ratio (INR). The INR allows a more accurate comparison of PT values [33]. The PT is useful in the detection of coagulation defects due to vitamin K deficiency, intestinal malabsorption, hepatic failure, dilutional or consumptive coagulopathies, and isolated deficiencies of the factors noted above, especially factor VII. Anticoagulation with oral vitamin K antagonists (warfarin) is monitored using the PT and INR [28].

The aPTT is described as a test to evaluate the "intrinsic" and common coagulation pathways (Fig. 12.9). Only the phospholipid part of thromboplastin is used to activate factor XII, hence

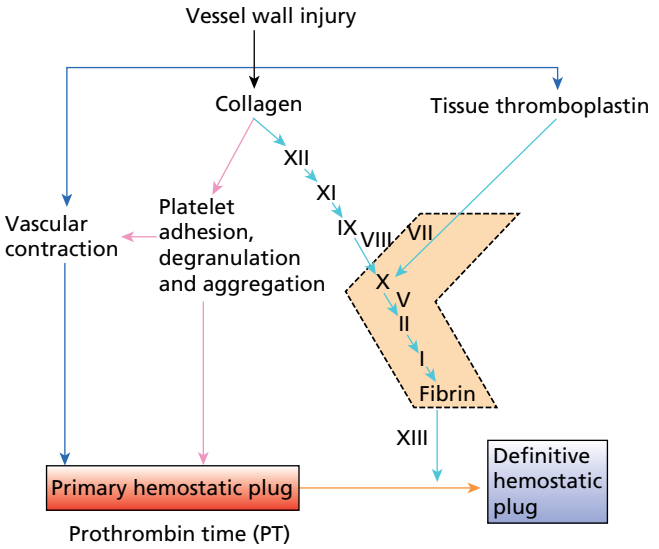

Figure 12.8 Portion of the coagulation cascade examined by the prothrombin time (PT). *Source:* Reproduced from Bleyer et al [11] with permission of Elsevier.

the term "partial thromboplastin" time, and coagulation is accelerated for this test using an activator (celite, kaolin, silica, or ellagic acid), hence the term "activated" PTT. The normal range for the aPTT is typically 21–35 s. The aPTT is prolonged by deficiencies of the contact coagulation factors (XII, XI, HMWK, and PK), factors VIII and IX, and factors of the common pathway (X, V, II (thrombin), and I (fibrinogen)). It is also prolonged in the presence of heparin and lupus anticoagulants.

Lupus anticoagulants belong to the broad family of antiphospholipid antibodies and were initially thought to occur exclusively in patients with autoimmune disorders. However, they are now known to occur in up to 1% of the normal population and may appear transiently in children after viral illnesses [35,36]. Lupus anticoagulants inhibit the proper assembly of lipid-dependent coagulation complexes such as the factor VIIIa/IXa "tenase" complex and the factor Xa/Va "prothrombinase" complex. While their presence is probably the most common cause of a prolonged aPTT [37], they do not increase the risk of bleeding. In fact, their predominant clinical manifestation is the development of thrombosis secondary to their effect on platelet–endothelial interactions and their interference with protein C and protein S activity.

Initial differentiation of a prolonged aPTT may be made by using a 50:50 mixture of the plasma being tested and normal plasma. Subsequent correction of the aPTT indicates a factor deficiency whereas ongoing prolongation suggests the presence of an inhibitor such as heparin, lupus anticoagulants, or a coagulation factor-specific inhibitor [28,33].

Thrombin time (TT) is the time required for the conversion of fibrinogen to fibrin after a patient's plasma is exposed to exogenous thrombin (Fig. 12.10). The reference range for TT is typically 10–15 s. The TT is prolonged in the presence of heparin, antibodies to thrombin, hypofibrinogenemia, dysfibrinogenemia, fibrin degradation products, lupus anticoagulant, and amyloidosis [33]. In the presence of heparin, the TT can be modified to assess fibrin formation by using reptilase, a substance derived from snake venom. Reptilase, like thrombin, will stimulate the conversion of fibrinogen to fibrin but, unlike thrombin, it is not inhibited by heparin.

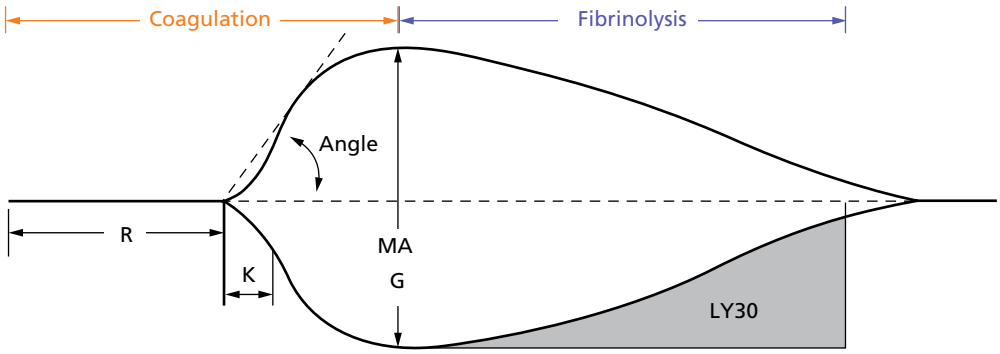
Evaluation of fibrinolysis

The occurrence of fibrinolysis can be determined either by measuring the endproducts of fibrin degradation or by directly measuring clot lysis by viscoelastic tests [33]. When fibrinolysis occurs in response to the activation of the coagulation system, plasmin degrades the resulting fibrin clots into fibrin degradation products including D-dimers, a breakdown product composed of two of the "D" fragments of cross-linked fibrin [38]. The presence of D-dimers thus specifically indicates the breakdown of FXIII-cross-linked fibrin, as may be seen in pathological conditions such as disseminated intravascular coagulation (DIC) [39]. Assays for fibrin and fibrinogen degradation products are usually performed in reference laboratories while D-dimer assays can be performed in many hospital laboratories.



R = Reaction time to first clot formation

K = Fibrin cross-linkage, fibrinogen function

Angle = Fibrinogen function

MA (mm) = Clot strength, most reflects platelets

G = MA converted to kdynes/cm^2

LY30 = Lysis 30 minutes after MA reached

The viscoelastic tests (TEG® and ROTEM®) assess hemostasis from clot formation to clot retraction and lysis as a characteristic coagulation tracing is produced in a rotating cup and pin assembly when a sample of whole blood proceeds through the clotting process [40,41] (Fig. 12.11). With the use of coagulation activators, they can provide very rapid results that can be used to immediately influence patient care [42]. These tests can identify both hypercoagulable and hypocoagulable scenarios. Additionally, any fibrinolytic activity will be dramatically displayed as the coagulation tracing produced by these tests unfolds. Viscoelastic coagulation tests have proven very useful in managing the coagulation problems associated with liver transplantation, cardiac surgical procedures, and trauma [26,43,44] and have been used to develop algorithms to guide transfusion therapy [45,46].

Use of laboratory tests

Coagulation tests typically have been used to screen patients preoperatively in an attempt to predict perioperative bleeding problems. While the rational for obtaining preoperative coagulation tests on patients with significant systemic illnesses is understandable, the rationale for routinely obtaining these tests on healthy patients who are undergoing straightforward procedures and have no history or physical signs to suggest an underlying bleeding diathesis is controversial. The main reason to obtain screening tests in this population is to detect previously undiagnosed inherited bleeding disorders such as vWD or hemophilia. However, because of the infrequent occurrence of these disorders, the routine use of coagulation tests for preoperative screening in the absence of a significant bleeding history seems unjustified from an economic standpoint [47,48]. Furthermore, the tests used for preoperative screening of patients do not provide data that reliably predict perioperative bleeding [49]. Platelet counts, for instance, are only a quantitative assessment and thus provide no information on platelet function [48]. While the CT of the PFA-100 can screen for vWD and can detect platelet function impairment due to aspirin or NSAID use, its usefulness in the perioperative setting is unproven [50]. The PT screens the "extrinsic" coagulation pathway and thus will not detect either type of hemophilia. Finally, the aPTT has not been found to predict postoperative bleeding in patients with no clinical indicators of bleeding problems [51].

The use of preoperative screening coagulation tests has been intensely scrutinized in children undergoing tonsillectomy and adenoidectomy. Approximately 2–4% of patients undergoing this surgery experience postoperative hemorrhagic complications. Results from many studies have shown no ability of the platelet count, PT, or aPTT to predict which children will bleed postoperatively [36,47,52–55]. Additionally, there are a large number of initially abnormal routine tests that return to normal on retesting thus causing unnecessary concern for parents, unnecessary delays in surgery, and increased costs [56]. Findings such as these have led some authors to state that in the absence of suspicions raised from a patient's history or physical examination, preoperative laboratory screening contributes little to patient care and should not be performed [47,56–60]. Indeed, the practice advisory published by the American Society of Anesthesiologists on preanesthesia evaluation discourages the routine use of preoperative laboratory testing in asymptomatic patients, reserving it for selected patients with pertinent findings on history or physical examination [61]. Similarly, the American Academy of Otolaryngology, Head and Neck Surgery recommends performing coagulation studies only in those patients undergoing tonsillectomy and adenoidectomy whose medical history or physical examination may indicate coagulation problems [62].

Preoperative evaluation of the coagulation system should, therefore, start with a pertinent history and physical examination. A sample of questions to ask parents and older children is outlined in Box 12.1 [47,63,64]. Pertinent findings on physical examination include petechiae, purpura, and ecchymoses with no antecedent injury [63,65]. Clinicians must always be aware, though, that the accuracy of histories and physical examinations depends on the clinician performing them and the parent and/or child answering the questions. The ability of parents and children to understand and answer medically related questions appropriately may be lacking, memories and interpretations of previous events may not be accurate, family histories may be overinterpreted, knowledge of a

Box 12.1: Questions regarding bleeding history

- Does your child have trouble with any of the following:
  - Easy bruising (larger than 2 inches)?
  - Gum bleeding with tooth brushing?
  - Frequent nose bleeds?
  - Oozing a long time from cuts or scrapes?
  - Abnormally heavy menstrual periods?
  - Bleeding into joints or muscles?
- Has your child had trouble with bleeding after:
  - Loss of teeth or dental extractions?
  - Previous surgery (including circumcision)?
  - Previous injuries?
  - When his/her umbilical cord came off?
- Is your child taking:
  - Antihistamines?
  - Aspirin?
  - Ibuprofen or other non-steroidal anti-inflammatory drugs?
  - Other over-the-counter medicines for headaches, colds, or menstrual cramps?
- Does your child take any prescribed medicines or have any chronic medical problems requiring a doctor's ongoing care?
- Has your child ever received a blood transfusion?
- Is there a family history of easy bruising or unusual bleeding after surgeries, injuries, or childbirth?
- Does anyone in your family have hemophilia, von Willebrand disease, low platelets, or any other blood disorder?

child's personal or family history by foster or adoptive parents may be deficient, ingestion of medications may be forgotten, and examinations may be incomplete [63,64]. Additionally, a negative family history may occur in up to 40% of cases of inheritable bleeding disorders because of spontaneous mutations or variable expression of the disorders in relatives. Also, young children may not have experienced an injury, undergone previous surgery, or had other experiences that would allow a bleeding problem to be revealed [63,66]. For this reason, some still advocate routine coagulation screening before tonsillectomy and adenoidectomy [54,67]. Nevertheless, the current opinion of most authorities remains that preoperative laboratory tests should only be obtained in the face of an indicative history and/or physical examination. However, one's clinical experience and judgment must be applied to the content and quality of the information obtained from the history and physical examination to make final decisions about obtaining preoperative laboratory tests.

In cases of active bleeding, quantitative assessments of platelet counts and fibrinogen levels and qualitative assessments of clotting with PT and aPTT have limitations. First, there are few agreed upon absolute values at which transfusion of blood components is indicated. Second, these tests are usually done in a central laboratory with a relatively long turnaround time. Therefore, by the time results are obtained, the clinical picture may have changed. With advances in technology, point-of-care tests have been developed and allow results to be available to the bedside clinician significantly quicker. Platelet counts, fibrinogen levels, PT, aPTT, and TT can all be obtained with this methodology but the accuracy and validation of these against conventional laboratory tests awaits confirmation [28]. The viscoelastic tests (TEG® and ROTEM®) can also provide immediate data to clinicians and have been extensively studied as aids to manage post-cardiopulmonary bypass bleeding in children [26,68]. While the use of point-of-care tests ameliorates the timeliness problem, absolute trigger values that dictate intervention are still lacking. Therefore, transfusion decisions still are heavily influenced by the clinical situation and the appearance of the operative field (and the opinions of those observing it!) while coagulation tests are used to monitor trends in the coagulation status as therapy is administered.

KEY POINTS: EVALUATION OF THE COAGULATION SYSTEM

- The indiscriminant use of screening preoperative coagulation tests may not reliably identify clinically relevant underlying coagulation abnormalities
- A pertinent history and physical exam followed by targeted coagulation tests may better identify children at risk for perioperative bleeding
- In cases of active bleeding, point-of-care tests including viscoelastic tests (TEG® and ROTEM®) may provide the most clinically useful coagulation data

Congenital hematological disorders

Congenital disorders of hemostasis can present major perioperative management challenges to anesthesiologists that extend well beyond the time when the patient is anesthetized in the operating room. Knowledge of the more common of these disorders will allow intelligent conversations with hematologists and surgeons in preparing to provide appropriate care to affected children.

von Willebrand disease

vWD is the most common inherited bleeding disorder, occurring in up to 2% of the population. The disease results from defects in the concentration, structure, or function of vWF, a large protein that plays two instrumental roles in hemostasis [69–71]. First, vWF promotes platelet adhesion and aggregation. During primary hemostasis, vWF enables platelets to adhere to injured vascular endothelium and aids in platelet aggregation through interactions with platelet GpIIbIIIa surface receptors. Second, vWF serves as a carrier protein for coagulation factor VIII, thus preventing the rapid clearance of FVIII from the circulation by activated protein C. As a result, FVIII levels and function are dependent on vWF function and activity [72]. vWF is synthesized in endothelial cells and megakaryocytes and is released from endothelial cells in response to activation of the coagulation system or to stressful stimuli such as infections, pregnancy, or physical exertion. It is also released from the α-granules of platelets upon their activation [69,73,74].

Classification of vWD is based on quantity of plasma vWF and on defects in vWF function and structure (Table 12.2).

Table 12.2 von Willebrand disease

Type	Pathology	Inheritance	Laboratory findings			
			vWF:Ag	vWF:RCo	FVIII activity	vWF multimer distribution
1	Quantitative deficiency: • Decreased amounts of otherwise normal vWF (vWF:RCo/vWF:Ag = 1.0)	Autosomal dominant	↓	↓	↓	Normal
2	Qualitative deficiency: (vWF:RCo/vWF:Ag <0.6–0.7 for 2A, 2B, and 2M)					
2A	• Failure of large vWF multimer assembly • Increased proteolysis of mutant multimers	Autosomal dominant	Normal or ↓	Normal or ↓	Normal or ↓	High and intermediate molecular weight missing
2B	• Increased binding of abnormal large vWF multimers to platelets → thrombocytopenia	Autosomal dominant	Normal or ↓	Normal or ↓	Normal or ↓	High molecular weight missing
2M	• Abnormal binding site on vWF for platelets → decreased vWF–platelet binding	Autosomal dominant	Normal or ↓	↓ or ↓↓	Normal or ↓	Normal
2N	• Abnormal binding site on vWF for FVIII → increased FVIII clearance → decreased FVIII levels	Autosomal recessive	Normal	Normal	↓ or ↓↓	Normal
3	Total deficiency: • Complete absence of vWF	Autosomal recessive	↓↓↓	↓↓↓	↓↓↓	All multimers missing
"Platelet-type" or "pseudo" vWD	Platelet abnormality: • Abnormal platelets with enhanced binding to vWF → thrombocytopenia	Autosomal dominant	Normal or ↓	↓↓	Normal or ↓	High molecular weight often missing

Ag, antigen; RCo, ristocetin cofactor assay; vWD, von Willebrand disease; vWF, von Willebrand factor.

Three major types of vWD are generally identified: partial quantitative deficiency (type 1), qualitative deficiency (type 2), and total deficiency (type 3). Type 1 is characterized by decreased amounts of normal vWF and accounts for 70–80% of patients with vWD. Type 2 is characterized by various qualitative defects in vWF and is further divided into four subtypes: 2A, 2B, 2M, and 2N. Type 3 is characterized by a complete absence of vWF and very low levels of FVIII and is the most severe form. Additionally, a "platelet-type" or "pseudo" vWD has been described where abnormal platelets demonstrate an enhanced affinity for normal vWF. Finally, an "acquired" von Willebrand syndrome has been described that is characterized by low plasma vWF levels secondary to autoantibodies against vWF, adsorption of vWF by malignant cell clones, or loss of high-molecular-weight vWF multimers under conditions of high shear stress. Possible etiologies include autoimmune disorders (such as systemic lupus erythematosus), lymphoproliferative disorders, myeloproliferative disorders, Wilms' tumor, and conditions such as congenital heart defects, aortic stenosis, bacterial endocarditis, and atherosclerotic lesions [69,75].

Clinical presentation

Clinical manifestations of types 1 and most variants of type 2 vWD are typically relatively mild and usually consist of mucocutaneous bleeding: epistaxis, gingival bleeding, gastrointestinal bleeding, menorrhagia, excessive postpartum bleeding, cutaneous bleeding, and easy bruising. These patients may have excessive bleeding after dental extractions, tonsillectomy and adenoidectomy, minor surgeries, or minor traumas. Types 2N and 3 vWD may have severe bleeding, such as the hemarthroses and intracranial bleeding seen with hemophilia patients, since these types also are associated with low FVIII levels.

Diagnosis

The diagnosis of vWD is based on a personal history of mucocutaneous bleeding, a family history of vWD, and/or coagulation tests consistent with vWD [76–78]. Screening tests for vWD may include aPTT, BT, and platelet function assay, but these tests lack sensitivity and specificity for a definitive diagnosis. Instead, assays that measure vWF quantity, function, and structure are used for both diagnosis and management (see Table 12.2). The most common tests include vWF antigen (vWF:Ag) to quantify vWF levels, vWF ristocetin cofactor assay (vWF:RCo) to assess vWF function, and FVIII assay (FVIII:C) to assess FVIII function in plasma. When interpreting vWF levels, it is important to remember that people with type O blood have mean vWF levels that are about 25% less than people with other blood types. On the other hand, inflammation and stress (i.e. during blood draws in children) can cause a falsely elevated vWF level, so repeated testing may be necessary to establish a suspected diagnosis of vWD when initial tests are normal. Measurement of FVIII activity levels is useful in establishing the diagnosis of types 2N and 3 vWD since FVIII is unbound and thus rapidly cleared in these patients. Varying degrees of thrombocytopenia due to spontaneous *in vivo* binding and consumption of vWF and platelets are seen in patients with type 2B or "platelet type" vWD [73,76,79].

Management

The goals of treatment of vWD are to restore the normal platelet adhesion of primary hemostasis and to increase abnormally low levels of FVIII. For minor surgery or tooth

extraction, levels of 40–50% of vWF:RCO and FVIII:C are considered sufficient. For patients requiring major surgery or with life-threatening hemorrhage, levels of 80–100% are desired. Postoperatively, levels greater than 50% for at least 3 days for vWF:RCo and for 5–7 days for FVIII:C are sought [77].

1-Deamino-8-D-arginine vasopressin (DDAVP, desmopressin), a synthetic vasopressin analog, releases vWF from endothelial cells and platelets and increases plasma levels of vWF and FVIII. It is effective in treating patients with type 1 vWD. It will also restore plasma levels of FVIII and vWF in many patients with type 2 vWD but the vWF will still be qualitatively deficient so primary hemostasis may continue to be abnormal. DDAVP is contraindicated in type 2B and platelet-type vWD since the release of vWF will exacerbate the thrombocytopenia common to these conditions. A trial dose of DDAVP with measurement of the subsequent vWF:RCo response is recommended in order to guide its use before a child with vWD encounters a hemostatic challenge. Replacement of vWF and FVIII will be required in patients with type 3 vWD and in those with type 2 vWD who do not respond to DDAVP [69,72,74,79].

Preoperative evaluation

Patients with a known personal or family history of vWD should undergo preoperative consultation with a hematologist at least 1 month prior to any scheduled surgery to allow time for appropriate evaluation, testing, and treatment planning. The type of vWD and the extent of surgery will determine the appropriate resources that should be available prior to the beginning of surgery.

Intraoperative management

The goal of perioperative treatment is to achieve therapeutic levels of vWF and FVIII to allow for adequate hemostasis. As noted, DDAVP-stimulated release of vWF from endothelial cells and platelets can adequately raise vWF levels for many patients with type 1 disease in anticipation of surgery. Repeated use may lead to tachyphylaxis, however, thus requiring additional intervention [69].

For patients in whom DDAVP is either contraindicated (type 2B, platelet type) or ineffective (types 2, 3 vWD, major surgery), replacement of vWF and FVIII may be required perioperatively. Options for these patients include treatment with a commercially available factor concentrate or cryoprecipitate, which contains both vWF and FVIII. Concentrates approved by the US Food and Drug Administration (FDA) include Humate-P® (human derived vWF; CSL Behring, Marburg, Germany), Wilate® (human derived vWF/FVIII complex; Octapharma USA, NJ, USA), and VONVENDI® (recombinant vWF; Shire Pharmaceutical Holdings Ireland Limited, Baxalta Incorporated, Dublin, Ireland) [72].

In patients with oral or mucosal bleeding, antifibrinolytic treatment (e.g. tranexamic acid and ε-aminocaproic acid) is an important adjuvant therapy to prevent clot lysis after hemostasis has been achieved. Antifibrinolytics are typically given for 3–7 days following the surgical procedure. If a patient continues to bleed despite adequate vWF and FVIII replacement therapy, platelet transfusions may be required. Consideration should always be given to careful surgical hemostasis, which may require topical agents such as bovine thrombin or fibrin sealant or local pressure [74,77].

Postoperative management

As patients with vWF are at increased risk for bleeding after surgical procedures, the severity of disease and hemostatic challenge should be considered when planning for postoperative monitoring and discharge. These patients may require admission or close follow-up postoperatively for possible rebleeding, electrolyte abnormalities, and volume overload after DDAVP treatment, antifibrinolytic treatment, or continued factor replacement and monitoring.

KEY POINTS: VON WILLEBRAND DISEASE

- The most common inherited bleeding disorder
- Results from defects in the concentration (types 1 and 3) or structure and function (types 2A, 2B, 2M, and 2N) of vWF
- Most variants present with mucocutaneous bleeding
- Definitive diagnosis is made with assays of vWF quantity (vWF:Ag) and function (vWF:RCo) and with assays of FVIII activity
- Management for most variants includes the use of DDAVP and/or replacement of vWF and FVIII

Hemophilia

Hemophilia is an X-linked congenital bleeding disorder caused by a deficiency of FVIII (hemophilia A) or FIX (hemophilia B or Christmas disease) [80,81]. Low levels of FVIII or IX activity prevent adequate formation of the FVIIIa/FIXa "tenase" complex on the surface of activated platelets during the coagulation process. Thus, the activation of FX and subsequent thrombin generation are blunted, resulting in defective clot formation and bleeding. Hemophilia A is more common than hemophilia B, comprising 80–85% of all cases. As an X-linked recessive trait, hemophilia generally affects males on the maternal side. However, approximately a third of patients with hemophilia have negative family histories and appear to be affected by *de novo* mutations [82–85].

Clinical presentation

Patients with hemophilia suffer from bleeding manifestations that range from prolonged oozing after minor insults to life-threatening hemorrhage after trauma or major surgery, depending on the severity of the clotting factor deficiency. In patients with mild to moderate disease, bleeding may only manifest after surgery or trauma. In contrast, those with severe disease are usually diagnosed before 2 years of age due to bleeding associated with the usual activities of life. In neonates, bleeding may occur after venipunctures, heel sticks, injections, or circumcision. Boys born to mothers known to be carriers of hemophilia thus should not be circumcised until it has been determined that they do not have the disease. Toddlers and young children may have excessive bruising associated with regular activity, mouth bleeding after tooth loss, and even muscle hematomas and joint hemorrhages. Intracranial hemorrhage is the leading cause of death related to bleeding in patients with severe hemophilia.

Another common manifestation of severe hemophilia is non-traumatic (spontaneous) intra-articular bleeding. The most frequent sites of bleeding are knees, ankles, and elbows.

Often recurrent bleeds occur in the same joint, resulting in inflammation of the synovial tissue with progressive joint damage and arthropathy. When recurrent bleeding has occurred at least four times in 6 months or 20 total times, the joint is described as a "target joint." Chronic joint pain and dysfunction may ultimately necessitate arthroscopic intervention or joint replacement. Chronic joint disease is the major cause of disability for patients with severe hemophilia [84–89].

Diagnosis

While patients usually have a family history or clinical history of easy bruising or bleeding, the diagnosis of hemophilia is made by measurement of low activity levels of FVIII or FIX with normal, functional vWF. Coagulation screening tests typically demonstrate a prolonged aPTT with a normal PT, but these tests are not consistent, sensitive, or specific enough to be used as diagnostic tools. Results of factor assays are expressed as "% activity" with 1 unit of factor per mL of plasma being equivalent to 1% activity. In families with a history of hemophilia, newborns can be diagnosed by testing plasma from cord blood, and fetal diagnosis can even be made as early as 20 weeks' gestation. Classification of both types of hemophilia is based on levels of FVIII or FIX activity and is described as severe (levels <1%), moderate (levels 1–5%), or mild (levels >5–40%). Severe hemophiliacs are usually diagnosed before 2 years of age, while those with moderate or mild forms are diagnosed later in life, usually after a hemostatic challenge [82,83,85].

Management

Management of hemophilia strives to increase the plasma concentration of the deficient factor sufficiently to control traumatic bleeding, provide hemostatic coverage for planned invasive procedures, and/or prevent spontaneous bleeding episodes [90]. In cases of mild hemophilia, where life-threatening and spontaneous bleeding are rare, administration of DDAVP may release enough vWF and FVIII from endogenous stores to overcome the mild factor deficiency [74,91]. For patients with moderate to severe hemophilia A or with hemophilia B, treatment focuses on prophylactic or "on-demand" factor replacement with recombinant or plasma-derived FVIII or FIX [84]. Prophylactic therapy may be given one to four times per week to maintain clotting factor activity level >1% to prevent bleeding. In contrast, "on-demand" therapy is used to treat acute bleeding episodes. The dose and frequency of "on-demand" therapy depend on the location and the severity of the bleeding. A minimum level of 40% factor activity should be targeted for minor oral, nasal, or urinary tract bleeding and should be maintained for several days. For bleeding in more critical anatomical areas such as the brain, retropharynx, or target joints and for severe bleeding in the gastrointestinal tract or muscle, levels of 80–100% should be achieved and then maintained for 3–14 days (depending on the severity of bleeding) [82,92,93].

Historically, treatment for hemophilia involved direct blood transfusions in the nineteenth century, which progressed to fresh frozen plasma (FFP) and cryoprecipitate by the 1950s to 1960s. By the 1990s, plasma-derived and recombinant FVIII and FIX had become the mainstay of treatment. When available, recombinant factors are the treatment of choice as they reduce the risk of transfusion-related infections. Unfortunately, most products have a short half-life (8–12 h for FVIII and 18–24 h for FIX) and thus patients require frequent transfusions [85]. Additionally, up to 30% of patients develop neutralizing IgG inhibitor alloantibodies to FVIII or FIX, thus rendering replacement therapy with plasma-derived or recombinant products ineffective [83,93]. Elimination of these antibodies by immune tolerance induction therapy, where large and frequent (usually daily) doses of FVIII or FIX are administered with or without immunosuppressants, is successful in approximately 70% of these patients [94]. Bleeding in the setting of high-titer inhibitors typically requires treatment with recombinant FVIIa or **f**actor eight **i**nhibitor **b**ypassing **a**gent (FEIBA), an activated prothrombin complex concentrate (APCC) containing factors II, VII, IX, and X [95]. Recombinant FVIIa and APCC can also be used as prophylactic agents to prevent spontaneous bleeding or to provide perioperative hemostatic coverage in hemophiliacs with inhibitors. "Bypassing" agents, however, are not a panacea. They do not normalize thrombin generation, the hemostatic response to them is less predictable than to factor concentrates, they are more costly and more difficult to monitor, and they carry a thrombotic potential [82,83,96].

Preoperative evaluation

Surgery for hemophilia patients requires advanced planning and coordination. A multidisciplinary team (surgeon, hematologist, anesthesiologist, blood bank physician, pharmacist, and laboratory personnel) is important to ensure appropriate resources are available to care for a patient with severe hemophilia [97]. Elective surgery should be scheduled early in the week and early in the day to allow for adequate personnel support in the blood bank and laboratory both intraoperatively and during the necessary postoperative healing time.

Preoperative laboratory studies include: (1) factor assays to measure factor activity; (2) inhibitor screening and inhibitor assays; and (3) type and cross for blood products. A laboratory equipped to measure clotting factor levels and inhibitor testing is required for optimal care. The pharmacy and blood bank should be notified to ensure that adequate quantities of factor concentrates and blood products are available to maintain the necessary factor levels during the entire perioperative period.

Intraoperative management

The expert help of a hematologist will be crucial in providing the best perioperative care to children with hemophilia who are scheduled for surgery. For minor surgeries, increasing factor activity levels to >30% is usually adequate. For more invasive procedures, levels greater than 50% are necessary. In the setting of life-threatening hemorrhage or surgical procedures that will result in significant blood loss, factor activity should be 80–100%. Therefore, adequate factor concentrates and blood products (red blood cells, cryoprecipitate, FFP, platelets) should be in the operating room or readily available. Laboratory personnel should be available to run factor activity assays as needed. In addition to replacing clotting factors, other measures that can reduce intraoperative blood loss include careful attention to surgical hemostasis (i.e. pressure, thrombin gel foam) and antifibrinolytics (i.e. tranexamic acid, aminocaproic acid) to prevent clot lysis [84,85,87,89].

Postoperative management

As hemophiliacs have prolonged wound healing and may have delayed or recurrent bleeding postoperatively, patients should be monitored closely for bleeding in the postoperative period. Depending on the disease severity, surgical procedure, and patient's comfort with their disease, this may be done as an inpatient or outpatient. A hematologist should be consulted to monitor factor activity levels and make recommendations regarding factor replacement requirements and duration to prevent recurrent bleeding.

KEY POINTS: HEMOPHILIA

- An X-linked recessive trait: hemophilia A is a deficiency of FVIII; hemophilia B is a deficiency of FIX
- Hemophilia is classified as mild, moderate, or severe depending on residual factor activity
- Severe disease leads to spontaneous bleeding, most frequently in joints
- Diagnosis is made by measurement of FVIII or FIX levels with normal vWF levels and function
- Management includes prophylactic or "on-demand" factor replacement with recombinant or plasma-derived FVIII or FIX or the use of recombinant FVIIa or activated prothrombin complex concentrates

Thrombophilias

Thrombosis and thromboembolism are fortunately uncommon in children, with a reported incidence of 0.07–0.14 per 10,000 children [98,99]. Predisposing clinical risk factors include indwelling central venous lines, immobility, malignancy, systemic infections, cardiac disease, nephrotic syndrome, obesity, smoking, pregnancy, and the use of estrogen-containing oral contraceptives. Medical advances that have increased the occurrence and the duration of these clinical factors are increasing the risk of occurrence of thrombotic problems. The presence of congenital prothrombotic disorders (thrombophilias) can also increase this risk [99–105].

Inherited thrombophilias include deficiencies of antithrombin (AT), protein C (PC), or protein S (PS) and mutations resulting in production of FV Leiden (FVL) and prothrombin G20210A, and reductions in methylenetetrahydrofolate reductase (MTHFR) activity. Deficiency of AT leads to reduced inhibition of thrombin, FXa, FIXa, FXIa, and FXIIa while deficiencies of PC or PS prevent the inactivation of FVa and FVIIIa. FVL is a mutant FV that is resistant to inactivation by PC. The prothrombin G20210A mutation leads to an increased production of prothrombin. MTHFR gene mutations lead to elevated blood levels of homocysteine which can induce endothelial cell injury and dysfunction. All of these potentially allow the development of a hypercoagulable state. Deficiencies of AT, PC, and PS are the least common of these but carry the highest risk for thrombosis development [96,100,101,103,104,106–112].

The presence of "lupus anticoagulants" may also pose a risk factor for thrombosis. "Lupus anticoagulant" is a term applied to antibodies produced against phospholipids in cell membranes and mitochondria or against antigens that then bind to phospholipid. Lupus anticoagulants may occur in patients with autoimmune disorders or transiently with malignancies or viral infections. As previously noted, they cause a prolonged aPTT by preventing the proper assembly of lipid-dependent coagulant complexes such as the FVIIIa/FIXa "tenase" complex and the FXa/FVa "prothrombinase" complex. More importantly, lupus anticoagulants alter platelet–endothelial interactions and inhibit the PC/PS system thus predisposing patients to thrombosis [96,109,113–115].

Clinical presentation

Neonates and adolescents are the children most at risk for thrombotic problems. Neonatal issues usually center around indwelling central catheters and are more common in the upper venous system. Adolescents are more likely to have concurrent medical risk factors or be taking estrogen-containing oral contraceptives or abusing tobacco. Additionally, affected adolescents are more likely to have an inherited thrombophilia (21% versus 6% in neonates). Their thromboses more likely involve the lower venous system [99,101,103]. PC deficiencies are more often seen in children less than 2 years old whereas AT and PS deficiencies are found more in school-aged children [105]. FVL and MTHFR mutations have been linked to recurrent pregnancy losses due to abnormal clotting in small placental vessels [116]. The vast majority (85%) of thromboses in children develop during a hospitalization [99].

About two-thirds of thrombotic episodes in children are symptomatic. Clinical manifestations depend on the location of the thrombus or embolus. Headache, vomiting, and seizures can occur with intracranial episodes, chest pain, and tachypnea with pulmonary emboli, hematuria with renal thromboses, and superior vena cava (SVC) syndrome and chylothoraces with SVC obstruction [99].

Diagnosis

Diagnostic tools include ultrasonography, including echocardiography, where the diagnosis may be incidentally made while evaluating cardiac issues. CT angiography and ventilation–perfusion scans are also useful tools [99,102].

Management

Avoidance of thrombosis development obviously is the goal and should center on minimizing clinical risk factors and promoting healthy lifestyle choices. Specific therapies may be helpful in identified inherited factor deficiencies. Recombinant AT concentrate is available for AT-deficient patients. FFP may replace AT, PC, and PS. A PC concentrate is also available.

A difficult question in dealing with thrombophilias is, "Who should be screened?". Interpretation of thrombophilia screening tests requires expert insight. Indiscriminant use of these tests is discouraged, but the infrequency of these abnormalities makes controlled trials to determine who should be screened difficult. Test results may be useful in determining ongoing management and in advising asymptomatic relatives. General guidelines based mostly on expert opinions suggest screening individuals who present with thrombotic events unprovoked by concurrent clinical risk factors (especially at early ages) and those with recurrent thromboses or strong family histories of thromboses. Long-term anticoagulation is often advised in patients with "high risk" thrombophilias, i.e. those with AT, PC, or PS deficiencies, those homozygous for FVL, and those with multiple coexisting defects [101,117,118].

Anesthetic implications

The anesthetic implications of thrombophilias are mainly those of awareness of their existence, pathophysiological mechanisms, and potential for long-term anticoagulant use. Heparin may be ineffective until adequate AT levels are restored in deficient patients. Nitrous oxide should be avoided in patients with MHTFR mutations as it interferes with vitamin B12/homocysteine metabolism, thus further increasing plasma homocysteine levels [119]. The advice of an experienced hematologist is invaluable in preparing a perioperative plan for this group of patients.

KEY POINTS: THROMBOPHILIAS

- Predisposing clinical risk factors are the most common contributors to thrombosis in children
- Neonates and adolescents are most at risk
- Congenital prothrombotic disorders (thrombophilias) increase this risk
- Screening is advised in cases of unprovoked thrombosis or strong family histories

Sickle cell disease

Sickle cell disease (SCD) is a genetic disorder of hemoglobin and is the most common inherited red blood cell disorder [120]. Hemoglobin molecules are composed of two pairs of globin chains, each possessing an Fe^{2+}-containing heme group. Hemoglobin A is composed of two α and two β chains and accounts for 95% of normal adult hemoglobin. Hemoglobin S (HbS) contains abnormal β chains as a result of a single nucleotide substitution of valine for glutamic acid in the sixth position of the β chain. Populations and descendants from sub-Saharan Africa, the Middle East, Southeast Asia, the Mediterranean, and parts of South and Central America have the highest prevalence of HbS. In developed countries, neonatal diagnosis, vaccinations, penicillin prophylaxis, disease-modifying medications (i.e. hydroxyurea), and blood transfusion allow people with SCD to survive into their fifth or sixth decades, but 50–90% of those born in developing nations die before age 5 [121,122].

The genes coding for the β chains of hemoglobin are codominant so a person who is heterozygous for normal and sickle β chains produces both HbA and HbS. This predominantly benign carrier state is termed sickle cell trait (SCT). SCT is considered to have persisted in some populations because it offers protection from the fatal complications of *Plasmodium falciparum* malaria. Homozygotes for the sickle β chain produce only HbS. Unlike SCT, this condition (HbSS disease) may be associated with significant clinical manifestations [123–125]. The term SCD includes HbSS disease as well as conditions with a combination of HbS and HbC (lysine substituted for glutamic acid in the sixth position of the β chain) and those with a combination of HbS and a hemoglobin molecule with decreased (β^+ thalassemia) or absent (β^0 thalassemia) β chains. Of these genotypes, HbSS and HbS/β^0 disease produce the most severe clinical manifestations while the symptoms of HbSC disease are more moderate and those of HbS/β^+ disease are mild [121,125–127].

The instability of HbS results in the polymerization, accelerated denaturation, and breakdown of the hemoglobin molecule, leading to red blood cell (RBC) membrane damage and RBC rigidity. During periods of low oxygen, the erythrocyte becomes stiff and "sickle shaped," preventing easy passage through capillary beds. These deformed RBCs block blood flow to organs and tissues, resulting in a vaso-occlusive event, end-organ damage, and severe pain for the patient. Due to the instability of the HbS molecule, sickle RBCs also have a shorter life span (10–12 days) than normal RBCs (120 days) resulting in hemolytic anemia. The chronic intravascular hemolysis is associated with increased chronic vascular inflammation, pulmonary hypertension, and ischemic strokes [121,125,126,128]. Surgical interventions are common in SCD patients, and the seriousness of the pathology associated with SCD necessitates a multidisciplinary approach to plan appropriate perioperative management.

Clinical presentation

Intermittent painful vaso-occlusive crises are the clinical hallmark of SCD. Infection and surgical stress as well as physical exertion and emotional stress can trigger these "sickle cell crises" [127,129]. However, more than half of all events do not have an obvious cause. In young children, the initial manifestation of the disease is often dactylitis, a painful swelling of the hands and feet. The most severe complications in SCD are vaso-occlusive pain crises, acute chest syndrome (ACS), ischemic stroke, and splenic sequestration. However, the disease affects all organ systems, resulting in a variety of long-term morbidities (Table 12.3).

ACS is the leading cause of death in patients with SCD. ACS is defined as a new pulmonary infiltrate in combination with fever, chest pain, or respiratory symptoms. Etiologies include infections and fat emboli from necrotic bone marrow. Treatment includes the administration of a broad-spectrum antibiotic, the use of incentive spirometry, bronchodilators, and supplemental oxygen if hypoxia is present, the restoration and maintenance of adequate hydration, and the appropriate management of pain. If there is no improvement from the initial interventions, then exchange transfusion should be implemented. Repeated episodes of ACS often lead to chronic lung injury and pulmonary hypertension. Asthma and pulmonary emboli are additional issues that accompany SCD [126,127,130,131].

Neurological complications, including transient ischemic attacks and strokes, are common with HbSS disease. In instances of ischemic cerebral infarctions, emergent exchange transfusion to reduce the level of circulating HbS to less than 30% may be undertaken upon presentation. Chronic transfusion regimens are then useful to prevent recurrences [128,131].

Splenic sequestration or aplastic crises may cause acute exacerbations of compensated chronic anemia. Splenic sequestration may occur in children under 4 years of age in association with a viral illness and may lead to severe anemia, hypovolemia, and even shock. Management often requires aggressive volume resuscitation, emergent transfusion, inotropic support, and urgent splenectomy. Splenic involution usually occurs by 5 years of age, thus eliminating this problem beyond that age. Aplastic crises are usually the result of a parvovirus B19-mediated temporary suppression of bone marrow function and may also result in the need for RBC transfusion [125–127,130,132].

Table 12.3 Organ system involvement in sickle cell disease

System	Clinical manifestations	Treatment
Neurological	TIA, ischemic stroke	Emergent exchange transfusion (decrease HbS to <30%); hydration
Pulmonary	ACS, PHTN, pulmonary infarction, asthma, RAD	Acute: broad-spectrum antibiotics, supplemental O2, bronchodilators, hydration, pain management, exchange transfusion Chronic: diuretic, pulmonary vasodilator
Cardiac	Vaso-occlusion of coronary arteries, cardiac autonomic dysfunction, right heart dysfunction	Supplemental O_2, inotropic support as necessary
Genitourinary	Priapism, papillary necrosis, renal failure, nocturnal enuresis	Priapism: hydration, pain control, injection of α-agonists Other: dialysis, renal transplant
Skeletal	Avascular necrosis, septic arthritis, osteomyelitis, osteoporosis, vertebral collapse	Acute: antibiotics, pain management Chronic: pain management, physical therapy, osteotomy, joint replacement
Hematological	Hemolytic anemia, acute aplastic anemia, splenomegaly or splenic sequestration, iron overload	Emergent transfusion, splenectomy, chelation therapy
Gastrointestinal	Acute/chronic cholecystitis, gallstones, hepatomegaly	Cholecystectomy
Other complications	Retinopathy, chronic pain, leg ulcers	Pain management consultation, ophthalmological consultation

ACS, acute chest syndrome; PHTN, pulmonary hypertension; RAD, reactive airway disease; TIA, transient ischemic attack.

Long-term morbidities from vaso-occlusive crises include avascular necrosis of the femoral and humeral heads, osteomyelitis, osteopenia, retinopathy, and cholelithiasis/cholecystitis. Renal and genitourinary problems range from nocturnal enuresis to priapism to renal failure requiring dialysis. These patients should be followed by a team that specializes in managing treatment for acute and chronic manifestations of SCD [126,127,133].

Diagnosis

Hemoglobinopathies can be diagnosed by hemoglobin electrophoresis or high-performance liquid chromatography. Patients with SCT as well as those with SCD will show positive results from sickle hemoglobin solubility testing (Sickledex). Currently, newborns in the United States are screened by this method shortly after birth. This early identification of affected children in combination with the use of prophylactic penicillin and vaccinations has increased the survival rates of patients with HbSS disease to 93.9% at 18 years. Older patients from regions where HbS occurs frequently should be tested if there is concern based on clinical presentation [121,126,130,134].

Management

Current treatment strategies are aimed at reducing acute crises, decreasing long-term complications, and improving survival. The only FDA- approved drug for SCD is hydroxyurea, which has significantly decreased acute crises and improved mortality rates in adults and children with SCD. Hydroxyurea augments the release of nitric oxide thus promoting vasodilation, attenuating pulmonary hypertension, and inhibiting platelet aggregation. It also induces the production of fetal hemoglobin (HbF). HbF inhibits the polymerization of HbS and thus helps to reduce sickling of RBCs. For some patients, stem cell transplantation is an option that, if successful, essentially restores normal production of erythrocytes and prevents further morbidity. Additionally, gene therapy may be on the horizon for some cases [120,122,126,129].

Chronic RBC transfusions are a mainstay of maintenance therapy. SCD patients are usually anemic, so transfusions treat anemia and increase the concentration of HbA while suppressing endogenous production of new RBCs containing HbS. RBCs chosen for transfusion should be sickle negative and negative for all antigens against which the patient has pre-existing antibodies. Phenotypic matching of RBCs for C, E, and Kell antigens has been shown to decrease rates of RBC alloimmunization and ultimately to decrease rates of hemolytic transfusion reactions in patients with SCD [135]. Thus, RBCs chosen for transfusion should also ideally be phenotypically matched for these antigens. However, transfusing non-phenotypically matched RBCs (or RBCs from donors whose sickle status is not known) is acceptable in urgent situations.

Treatments for an acute sickle cell crisis include oxygen supplementation for hypoxemia, aggressive hydration, correction of acidosis, administration of antibiotics, promotion of normothermia and good perfusion, adequate pain control, and possible transfusion (simple or exchange to decrease concentration of HbS). Pain control in SCD can be difficult but includes treatment with acetaminophen, NSAIDs, narcotics, and possibly regional anesthetic techniques. Guidelines for pain management in children with SCD are available from the American Pain Society [136].

Preoperative evaluation

The complications from SCD mean that patients often require a variety of surgical interventions. Cholecystectomy is the most frequently performed procedure because of gallstone formation in the face of persistent hemolysis [127]. Splenectomy and orthopedic, neurosurgical, cardiac, and obstetric procedures are also commonly undertaken. Preoperative evaluation should include a multidisciplinary team (surgeon, anesthesiologist, and the primary physician managing the SCD) to aid in the prevention and management of perioperative complications.

Co-morbidities and the severity of the patient's SCD should be established during a thorough history and physical examination (Box 12.2). Important preoperative studies will be

Box 12.2: Preoperative evaluation of patients with sickle cell disease

- When was the last acute sickle cell crisis?
- How frequently does the patient have crises?
- Is there a specific trigger for acute crisis?
- What is their current treatment for SCD (i.e. hydroxyurea, chronic blood transfusions)?
- When was their last blood transfusion?
- What is their pain regimen during a crisis?
- Who is the primary physician who manages their SCD?

determined by the severity of an individual patient's disease and may include hematocrit, hemoglobin, blood urea nitrogen (BUN), creatinine, chest X-ray, and possibly electrocardiogram or echocardiogram if there is concern for pulmonary hypertension [127]. SCD patients should be scheduled early in the day to avoid prolonged nil per os (NPO) times, as hypovolemia and dehydration may precipitate a crisis. Surgery for superficial procedures on patients with stable disease may be scheduled on an outpatient basis but requires thoughtful consideration.

Prophylactic preoperative RBC transfusions have been shown to decrease the incidence of perioperative complications by diluting the abnormal RBCs with normal ones. Aggressive transfusion regimens aim to decrease the HbS concentration to less than 30% while conservative regimens aim to increase the hemoglobin level to 10 g/dL without concern for HbS concentrations. The conservative regimen has been found to be as effective as the aggressive approach in preventing perioperative SCD-associated complications while significantly reducing transfusion-associated risks [137]. Preoperative transfusion may be foregone in children undergoing minor superficial elective surgical procedures but is important prior to major surgical procedures (including thoracotomies, laparotomies, orthopedic procedures, and tonsillectomies and adenoidectomies) [138,139].

Intraoperative management

Intraoperative anesthetic management includes exercising caution about adequate oxygenation, hydration, thermoregulation, and acid–base balance. Postoperative pain control is often a challenge for these patients. Therefore a multimodel approach, including regional anesthetic techniques, may be useful both intraoperatively and postoperatively for pain control [127].

Orthopedic and cardiac surgery presents several challenges for SCD patients. The use of tourniquets for orthopedic procedures is controversial [140,141], but their uncomplicated use has been documented in patients after preoperative exchange transfusions [142]. Similarly, cardiac surgery involving cardiopulmonary bypass (CPB) has been safely conducted after performing preoperative and intraoperative exchange transfusions [143,144]. No consensus exists on the appropriate body temperature to be maintained during CPB or on the use of cold cardioplegia, but the maintenance of normothermia seems intuitive.

Postoperative management

No evidence exists to support the prolonged postoperative administration of supplemental oxygen in the absence of hypoxemia. However, pulse oximetry should be monitored and oxygen therapy should be used to maintain normal oxygen saturations. Aggressive pulmonary toilet and early ambulation postoperatively may limit pulmonary complications. Adequate postoperative pain management is critical. As mentioned above, the use of acetaminophen, NSAIDs, narcotics and regional anesthesia may provide good postoperative pain control. Consultation with pain management specialists may be needed in more complex patients.

KEY POINTS: SICKLE CELL DISEASE

- The most common inherited red blood cell disorder
- Intermittent painful vaso-occlusive crises ("sickle cell crises") are the clinical hallmark
- Acute chest syndrome is the leading cause of death
- Cholecystectomy is the most frequently performed surgery in these patients
- Prophylactic preoperative red blood cell transfusions to a hemoglobin of 10 g/dL (conservative) or to a hemoglobin S level <30% (aggressive) may be used before more invasive surgeries

Transfusion therapy

Transfusion medicine has played a major role in propelling medical and surgical advances that have benefitted the pediatric patient population. This section will describe the basic principles of transfusion therapy, the blood products available for transfusion, the logistics of transfusion, the indications and triggers for administering blood products, and the potential adverse effects that can accompany transfusion of these products. It is important to realize that most medical centers have a Blood Bank Medical Director or Transfusion Specialist available for consultation on these topics.

Principles of transfusion therapy

ABO blood group system

Blood is classified into groups based on the presence or absence of specific inherited RBC surface antigens. The International Society of Blood Transfusion recognizes 30 major blood group systems, the most important of which is the ABO system. The ABO system defines an individual's "blood type" by the presence or absence of A and/or B antigens on RBC surfaces. The homozygous presence of alleles coding for the A or B antigen produces group A or group B. Additionally, the heterozygous presence of one of these alleles in combination with the O allele, which codes for no antigen production, also produces group A or B. The heterozygous presence of both A and B alleles produces both antigens and yields group AB. Finally, the homozygous presence of O alleles produces no antigen and thus group O (Table 12.4). Ethnic and racial differences exist in the distribution of ABO blood groups across the world. In the United States, approximately 44% of the population has type O, 42% has type A, 10% has type B, and 4% has type AB blood.

Individuals naturally develop antibodies against the ABO antigen(s) not present on their own RBCs during the first year

Table 12.4 ABO blood group system

ABO type				
	A	**B**	**O**	**AB**
Allele combinations	AA AO	BB BO	OO	AB
ABO antigen present	A	B	None	A and B
ABO antibody present	Anti-B	Anti-A	Anti-A Anti-B	None

Table 12.5 ABO compatibility

Recipient ABO type				
	A	**B**	**O**	**AB**
Compatible donor RBCs (contain antigens)	A O	B O	O	A B AB O
Compatible donor plasma-containing products (contain antibodies)	A AB	B AB	O A B AB	AB

of life. This occurs even without exposure to blood transfusions, probably in response to exposure to antigens from bacteria, viruses, or plants that are structurally very similar to the ABO antigens. Thus, those with type A blood develop anti-B antibodies (IgM type), those with type B blood develop anti-A (IgM type), those with type O blood develop both anti-A and anti-B (IgM and IgG types), and those with type AB blood develop no anti-ABO antibodies (see Table 12.4). IgG-type anti-A and anti-B antibodies in type O mothers can cross the placenta and cause hemolysis in children with A or B antigens on their RBCs.

Rh blood group system

The Rh blood group system is second in importance after the ABO group. An RBC antigen in the Rhesus macaque monkey, designated as "Rh factor," was reported in 1940 after the finding that the serum of rabbits immunized with RBCs from this monkey agglutinated about 85% of human RBCs. A serologically similar antigen, termed a D antigen, was subsequently identified on these human RBCs. Consequently, people whose RBCs have this D antigen are referred to as being "Rh positive" whereas those whose RBCs do not carry this antigen are designated as "Rh negative." As noted, approximately 85% of the US population is Rh positive.

In contrast to the ABO blood group system, anti-Rh antibodies only develop in Rh-negative individuals after exposure to Rh-positive blood by a blood transfusion or by placental exposure during pregnancy. Once anti-Rh antibodies have developed, repeat exposure to Rh-positive RBCs can result in hemolysis. Since anti-Rh antibodies are of the IgG class, they can cross the placenta. This can be of grave importance to sensitized Rh-negative mothers carrying an Rh-positive child. These mothers may have been sensitized by the feto-maternal transfer of Rh-positive RBCs during a previous pregnancy with an Rh-positive child. Transplacental transfer of the sensitized mother's IgG anti-Rh antibodies to her second Rh-positive child can lead to hemolytic disease of the newborn (erythroblastosis fetalis) as the unborn child's Rh-positive RBCs are hemolyzed.

Transfusion compatibility between recipients and donors

The presence of RBC surface antigens and circulating plasma antibodies to these antigens mandates immunological compatibility between recipients and donors of blood products. Since whole blood (WB) contains both ABO antigens and antibodies, it can be transfused only to ABO-identical recipients. Packed RBCs (PRBCs) contain antigens expressed on the surfaces of the RBCs with minimal amounts of antibody-containing plasma, so donors and recipients do not have to be ABO identical. However, patients can only receive PRBCs whose ABO surface antigens will not react with the patient's circulating anti-ABO antibodies. For example, type O patients with no A or B antigens on their RBC surfaces but with anti-A and anti-B antibodies in their plasma may receive only type O RBCs (no antigens). In contrast, type AB patients with both A and B antigens on their RBC surfaces but with no antibodies in their plasma may receive A, B, AB, or O RBCs (Table 12.5). Thus, when transfusing PRBCs, type O individuals are universal donors whereas type AB patients are universal recipients.

Conversely, plasma-containing products (including FFP and platelets), which contain negligible RBCs, contain anti-ABO antibodies so patients can only receive plasma-containing products whose anti-ABO antibodies will not react with the patient's ABO surface antigens. Type AB patients may receive only type AB plasma and platelets because the plasma from any other blood type will contain antibodies to the A or B antigens present on their RBCs. In contrast, type O patients may receive plasma-containing products from A, B, AB, or O donors since these patients have no RBC antigens (see Table 12.5). Therefore, when transfusing plasma-containing products, type AB individuals are universal donors whereas type O patients are universal recipients.

Rh antigen status must also be considered when transfusing blood products. Rh-positive individuals may receive PRBCs from either Rh-positive or Rh-negative donors and plasma-containing products from donors without anti-Rh antibodies (either Rh-positive or previously untransfused Rh-negative donors).

Rh-negative individuals preferentially should receive Rh-negative PRBCs since exposure to Rh-positive RBCs invokes the production of anti-Rh antibodies in 30–80% of these recipients. This matching is especially important if these recipients will be receiving further PRBCs in the future or are females who may bear children in the future. Although platelets contain ABO antigens, they do not contain Rh antigens. However, RBCs contaminate all platelet preparations to some extent. Thus, Rh-negative patients should preferentially receive Rh-negative platelets. If transfusion of Rh-positive platelets to Rh-negative recipients is necessary, Rho(D) immune globulin can be given within 72 h to the high-risk populations previously identified to prevent the development of anti-Rh antibodies that may be induced by contaminating RBCs. Since FFP is an acellular product, Rh-negative individuals can receive plasma from either Rh-positive or Rh-negative donors.

Available blood products

Collection techniques

A variety of blood products are available for transfusion (Table 12.6) and can be collected via two processes. Whole blood (WB) can be collected from a single donor as a 450–500 mL aliquot. While being collected, the blood is mixed with 70 mL of an anticoagulant/preservative solution. Basic "CPD" solutions contain citrate for anticoagulation, phosphate to buffer the acidosis that develops during storage, and dextrose to serve as a source of energy for the RBCs. These CPD anticoagulant/preservative solutions allow RBC-containing products to be stored for 21 days when kept at 1–6°C. The addition of adenine to the solution (CPDA-1) supports the synthesis of ATP by the RBCs and prolongs the shelf-life to 35 days. Newer adenine–saline additive solutions, such AS-1 (Adsol), AS-3 (Nutricel), and AS-5 (Optisol), add various additional amounts of phosphate, dextrose, adenine, mannitol, and saline and further extend the shelf-life to 42 days [145–147].

Most units of WB are subsequently separated into various components. This practice allows several patients to benefit from one blood donation, optimal storage of the different components, and focused administration of specifically indicated components. Centrifugation of one unit of WB ultimately can provide one unit each of PRBCs, plasma, and platelets. In the majority of centers in North America, a unit of WB is separated initially into PRBCs and platelet-rich plasma. The platelet-rich plasma is then further separated into plasma and platelets. Cryoprecipitate and other human-derived products including albumin and fibrin glue can subsequently be obtained from plasma.

Alternatively, individual components can be specifically collected from a donor by apheresis. In this process, blood from the donor is drawn into an external circuit and a specific component is separated by centrifugation based on its specific gravity and removed from the whole blood while the remaining components are returned to the donor. This process can be used to collect RBCs, platelets, plasma, or granulocytes. Its use can minimize donor exposures for blood product recipients by providing larger quantities of a desired component from one donor than WB separation techniques can provide [145].

Whole blood

WB is obtained from donors with a hematocrit of at least 38% [146] and is used not only to support hemoglobin levels but also to provide coagulation factors [148]. The ability of WB to raise hemoglobin levels, however, is limited by the hemoglobin level of the donor. Its use may be advantageous in neonatal exchange transfusions and in controlling bleeding after complex cardiac surgeries requiring CPB in children less than 2 years old and after massive blood loss and transfusion [145,149]. However, only relatively "fresh" WB (i.e. less than 24–48 h old) is useful in correcting coagulopathic bleeding. During storage at 1–6°C, the activities of the temperature-sensitive labile coagulation factors, V and VIII, progressively diminish in WB [145]. Additionally, storage at this temperature rapidly and dramatically alters platelet survival. After 3 h of storage at 4°C, platelet viability drops to 62%, then to 12% after 24 h, and to 2% after 48 h [150]. However, the logistics of timely acquiring, testing, and transporting WB so that it is available for use at many facilities within 24–48 h of its collection pose major barriers to its regular availability. Because of these practical considerations as well as the previously mentioned benefits of separating WB into components, WB is rarely used today.

Packed red blood cells

PRBCs are the component most commonly used to raise hemoglobin levels and thus increase the oxygen-carrying capacity of blood. They can be prepared by separation from WB or by apheresis. Like WB, PRBCs are stored at 1–6°C in an anticoagulant/preservative solution. If CPDA-1 is the solution used, the hematocrit of the unit of PRBCs is 65–80%, the volume is approximately 250 mL, and the shelf-life is 35 days. If one of the additive solutions (AS-1, AS-3, or AS-5) is used, the volume of the unit is increased to approximately 350 mL, the hematocrit is decreased to 55–65%, and the shelf-life is extended to 42 days [145,146,148]. PRBCs can be further processed by freezing, washing, irradiation, or leukocyte reduction as necessitated by the recipient's condition and previous tolerance of transfusions.

Table 12.6 Available blood products

	Storage	Shelf- life	Special preparations (reasons)
Whole blood	1–6°C	21–35 days*	
Packed red blood cells	1–6°C	21–42 days*	Leukocyte reduction** (febrile HTRs, alloimmunization, CMV reduction, TRIM) Irradiation (immunocompromised, neonates, blood relatives, TAGVHD) Washing (removes potassium)
Frozen packed red blood cells	≤–65°C	10 years	Thawing Washing (removes glycerol and potassium)
Fresh frozen plasma	≤–18°C (within 8 h of collection)	1 year	Thawing
Plasma frozen within 24 hours	≤–18°C (after 8 but within 24 h of collection)	1 year	Thawing
Cryoprecipitate	≤–18°C	1 year	Thawing
Platelets	20–24°C	5 days	Leukocyte reduction** (as with PRBCs) Irradiation (as with PRBCs)

* Depending on storage solution used.

** Typically performed at collection before storage CMV, cytomegalovirus; HTRs, hemolytic transfusion reactions; PRBCs, packed red blood cells; TAGVHD, transfusion-associated graft versus host disease; TRIM, transfusion-related immunomodulation.

PRBCs with unique phenotypes or RBCs collected for autologous use that need to be stored for more than 42 days can be frozen for up to 10 years at -65°C or lower after adding glycerol as a cryoprotective agent. After these frozen PRBCs have been thawed for transfusion, they must be transfused or frozen again within 24 h. The glycerol is removed by washing the RBCs with progressively lower concentrations of sodium chloride-containing solutions. Unfortunately, this process may cause cell volume loss, resulting in a product with a lower baseline hematocrit. Washing RBC units removes plasma proteins, inflammatory mediators such as cytokines, and other plasma contaminants. Washed RBCs are indicated to prevent severe recurrent allergic reactions caused by foreign plasma proteins, to remove excess potassium from older units of PRBCs or from those that have been irradiated, and to remove plasma IgA prior to transfusion to IgA-deficient patients who have developed anti-IgA antibodies. After washing, PRBC units must be used within 24 h if stored at 1– 6°C or within 4 h if stored at 20–24°C since the hermetic seal of the unit will have been broken [146].

Irradiation of PRBCs (or WB) with γ-irradiation using a cesium (^{137}Cs) source or with X-rays using a linear accelerator is performed to inactivate viable lymphocytes, thus preventing transfusion-associated graft versus host disease. Irradiation is indicated when PRBC (or WB) recipients are immunocompromised, are first- or second-degree blood relatives of the donor, or are neonates. The shelf-life of PRBCs after irradiation is reduced to 28 days if the anticoagulant/preservative-dictated shelf-life still exceeds 28 days at the time of irradiation. Potassium and free hemoglobin leak from the RBCs into plasma after irradiation so washing of irradiated PRBCs may be considered when there is an extended length of time between irradiation and transfusion [145–147].

Leukocyte reduction of PRBCs is performed to decrease the incidence of febrile non-hemolytic transfusion reactions, to decrease the incidence of alloimmunization of recipients to HLA antigens, to reduce the risk of transmission of cytomegalovirus (CMV) and other infectious diseases transmitted by white blood cells (WBCs), and possibly to reduce the effects of transfusion-related immunomodulation. Leukocyte reduction is typically performed before storage at the time of collection of the blood but can be performed post storage in the laboratory or at the bedside. Poststorage leukocyte reduction has been reported to cause unexpected severe hypotension in some recipients (especially those taking angiotensin-converting enzyme (ACE) inhibitors) due to bradykinin activation. Additionally, inflammatory mediators released by leukocytes during storage are not removed by poststorage leukoreduction. Given these considerations, more than 80% of RBCs transfused in the United States are leukoreduced before storage, with leukoreduction filters removing more than 99% of leukocytes [145,146,151].

Plasma

Plasma is prepared by separation from the platelet-rich plasma component of WB or by apheresis. The volume of a unit of plasma derived from WB is 170–250 mL whereas a unit obtained by apheresis measures up to 500 mL. To be labeled as "fresh frozen plasma" (FFP), the plasma has to be stored at -18°C or colder within 8 h of collection. This prevents the inactivation of the temperature-sensitive "labile" coagulation factors, V and VIII, and allows a shelf-life of 1 year. If plasma is not frozen within 8 h of collection, the activity of factors V and VIII will diminish, but the plasma can still be frozen at or below -18°C within 24 h, labeled "plasma frozen within 24 hours," and stored for up to 1 year. By definition, each mL of FFP contains 1 international unit (IU) of each coagulation factor. FFP also contains 2–4 mg of fibrinogen per mL. No cryoprotectant is included in the unit and, therefore, the majority of leukocytes are killed or rendered non-functional. As a consequence, irradiation to prevent transfusion-associated graft versus host reaction and leukocyte reduction to prevent CMV infection are not necessary for FFP. Prior to administration, FFP is thawed in a waterbath at 30–37°C for approximately 20–30 min. The unit should then be infused immediately or it may be stored at 1–6°C and transfused within 24 h. If it is not used within this 24 h window, it can be stored for an additional 4 days at 1–6°C but it must be relabeled as "thawed plasma" and it will have diminished, although still hemostatic, levels of factors V and VIII [145,146,152].

Cryoprecipitate

Cryoprecipitated antihemophilic factor, or "cryoprecipitate," is the cold-insoluble white precipitate that forms when a unit of FFP is thawed only to 1–6°C. Once prepared from FFP, cryoprecipitate must be refrozen at -18°C or colder within 1 h and then has a shelf-life of 1 year. Each unit of cryoprecipitate contains concentrated amounts of fibrinogen (150–250 mg), FVIII (80–150 IU), vWF (40–70% of original plasma concentration), FXIII (30% of original plasma concentration), and fibronectin (30–60 mg) in approximately 5–15 mL of plasma. The plasma remaining after extraction of cryoprecipitate is relabeled as "cryoprecipitate reduced plasma." Since this plasma is deficient in the previously mentioned coagulation factors, it should not be used as a substitute for FFP.

Once thawed in preparation for transfusion, cryoprecipitate must be administered within 6 h to prevent loss of FVIII activity. If several cryoprecipitate units are pooled, transfusion must take place within 4 h to minimize risks from potential contamination. Since cryoprecipitate, like FFP, is stored at temperatures below –18°C, irradiation and/or leukocyte reduction are not necessary before cryoprecipitate transfusions. Additionally, since cryoprecipitate contains no RBCs and only small amounts of plasma (thus, minimal amounts of anti-ABO antibodies), ABO and Rh compatibility are not required before its use in adults [145,146,152,153]. However, the small amount of plasma in cryoprecipitate units may be significant relative to the blood volume of infants and young children, so pediatric centers often administer cryoprecipitate whose plasma is ABO compatible with the recipient.

Platelets

Platelets are prepared by separation from the platelet-rich plasma component or the buffy coat layer of WB or by apheresis. Platelet units prepared from WB are termed "random donor platelets" and contain a minimum of 5×10^{10} platelets in 50–70 mL of plasma. Platelet units obtained by apheresis are designated as "single donor platelets" and contain at least 3.5×10^{11} platelets in 200–400 mL of plasma. One single donor apheresis platelet unit is equivalent to 6–8 units of random donor platelets. Apheresis platelet units have become the primary source of platelets for transfusion in the United States

since their use minimizes donor exposures to recipients. Platelet units are stored at 20–24°C with continuous gentle agitation to prevent aggregation. Because of the risk of bacterial contamination at this temperature, platelet units in the United States currently have a shelf-life of only 5 days. Since platelet units are not subjected to the extremely cold temperatures at which plasma and cryoprecipitate are stored, they (like WB and PRBCs) must be irradiated to kill viable lymphocytes in clinical situations where transfusion-associated graft versus host disease is a concern and must be leukocyte reduced when transmission of CMV is a risk [145,146].

In adult centers, type compatibility may not be required between recipients and donors of platelet units for small-volume transfusions. However, platelets express multiple surface antigens, including ABO and platelet-specific antigens, so ABO-identical platelets may be needed if survival of ABO-incompatible platelets is decreased. With the significant amount of plasma contained in platelet units, though, compatibility between donor plasma and recipient ABO type is necessary in infants and children. Additionally, since a small amount of RBCs remain in both random and single donor platelets, Rh-negative patients preferentially should be transfused with platelets from Rh-negative donors to prevent Rh alloimmunization, especially in females or in patients who may receive future transfusions [145,154].

Factor concentrates

Several factor concentrates were developed for clinical use in specific diseases, such as hemophilia. However, as clinicians seek alternatives to allogenic blood products to aid in perioperative hemostasis, the off-label use of factor concentrates such as fibrinogen concentrate (FC), recombinant activated FVII (rFVIIa), and prothrombin complex concentrates (PCC) is increasing. Proponents of these alternative procoagulant adjuncts emphasize the benefits of small-volume infusions, immediate availability (they do not require thawing or cross-matching), decreased infectious and immune risks, and cost-effectiveness. However, few studies have evaluated the safety and efficacy of these products. Therefore, it is important to consider thrombotic risk when using these adjuncts in perioperative hemostasis management.

rFVIIa (rFVIIa; NovoSeven ®, RT, Novo Nordisk, Bagsvaerd, Denmark), synthesized from hamster cells, was developed specifically for hemophiliacs who developed inhibitors against exogenous FVIII or FIX. rFVIIa works by both TF-dependent and independent mechanisms to activate FXa on platelet surfaces. These complexes catalyze a large thrombin burst, which promotes fibrin generation and thus dense clot formation [155,156]. Although rFVIIa was FDA approved for hemophilia A and B patients with inhibitors against FVIII and FIX, this medication has been used off-label in adults and pediatric patients as a rescue for massive bleeding associated with trauma, intracranial hemorrhage, liver transplantation, and cardiac surgery [157–161]. Despite demonstrating some efficacy in reducing transfusion, it has been associated with increased thromboembolic complications and mortality in some studies [162–166].

There are several commercially available PCCs that have been FDA approved for various uses. These are lyophilized products from human plasma that contain all the factors to promote coagulation [167]. Each PCC has a different composition and function, but most include the vitamin K dependent factors (FII, FVII, FIX, FX), while some also contain PC, PS, antithrombin, and heparin. Three-factor PCCs contain low levels of inactivated FVII and therapeutic levels of FII, FIX, and FX. In contrast, four-factor PCCs contain therapeutic levels of all the vitamin K dependent factors. PCCs are most commonly used for replacement in patients with congenital or acquired factor deficiencies or reversal of anticoagulants, such as warfarin [168]. As with rFVIIa, the "off-label" use of PCCs to manage bleeding associated with trauma and post-bypass bleeding is increasing. There are some reports of increased thrombotic complications, but so far there are no studies examining the appropriate dose, dosing regimen, thrombotic complications, or mortality associated with off-label use.

Fibrinogen concentrate (RiaSTAP, CSL Behring, Marburg, Germany) is purified fibrinogen derived from adult plasma. It is FDA approved for patients with congenital hypofibrinogenemia, but is being used as a fibrinogen replacement instead of cryoprecipitate or FFP. Of note, FC does not contain other factors (vWF, FVIII, and FXIII) found in cryoprecipitate [168,169].

Logistics of transfusion

Typing, screening, and cross-matching

Preparation for transfusion begins with determining the blood type and Rh status of the intended recipient and the prospective donor unit. ABO group is defined using forward and reverse typing. Forward typing confirms the presence of certain antigens on the recipient's RBCs while reverse typing tests for the presence of naturally occurring antibodies in the recipient's plasma to A and B antigens not present on the recipient's RBCs. Therefore, blood group is defined by identifying the ABO antigen(s) and anti-ABO antibody(ies) present. Neonates typically do not develop anti-ABO antibodies until 4–6 months of age; therefore, forward typing is primarily utilized to determine their blood type. Rh status is defined by testing RBCs for the presence of the D antigen using anti-D-containing reagent.

The plasma of the intended recipient is then screened for the presence of unexpected antibodies to antigens of any of the other blood group systems that can be present on RBC surfaces. This is accomplished by incubating the recipient's plasma with screening RBC panels composed of three or four group O RBCs selected in such a way that most common non-ABO antigens capable of inducing the production of significant antibodies that could cause hemolysis are represented on at least one screening cell. Antihuman globulin is then added to agglutinate any RBCs to which an antibody has attached (indirect Coombs test). If an antibody is detected, the screen is considered positive and further investigation must be undertaken to identify the specific antibody present. Antibody screening must be repeated if RBCs are ordered and 3 days have elapsed since the last antibody screen or if the patient was discharged from the facility in the 3 days since obtaining the initial screen. An exception is in neonates where, due to the immaturity of their immune systems, an initial negative screen does not have to be repeated during the same hospitalization until after 4 months of age [145].

Cross-matching of recipient plasma and donor RBCs is the next step prior to PRBC transfusions. If the recipient has a negative antibody screen, only ABO compatibility between the recipient and the donor RBCs must be verified. This can be done with an immediate spin cross-match to provide serological verification (mixing the recipient's plasma with the donor's RBCs to ensure there is no agglutination or hemolysis) or with an electronic cross-match that uses a series of computer algorithms to select a suitable PRBC unit that is in stock in the blood bank. Either of these cross-matching techniques can be used to have PRBCs ready for transfusion in 5–10 min for recipients with negative antibody screens. However, if the recipient has a positive antibody screen, a more detailed serological cross-match, called an antihuman globulin (AHG) or "full Coombs" cross-match, must be performed to verify compatibility of the recipient's plasma against clinically significant non-ABO antigens that may be present on donor RBC surfaces. This process requires up to 45 min to perform, although identifying the recipient antibody and finding compatible donor RBCs may take considerably longer.

In contrast to PRBCs, cross-matching is not necessary prior to plasma, cryoprecipitate, or platelet transfusions. For each of these products, units whose plasma is ABO-compatible with the recipient's RBCs are administered. FFP and cryoprecipitate can be thawed and available for transfusion in approximately 20–30 min. Since platelets are stored at room temperature, they can be immediately available for transfusion when required.

Administration of blood products

The process of transfusing blood products begins with the proper identification of the recipient, verification that the product to be transfused has been assigned to that recipient, and confirmation that the ABO type and Rh status of the blood product is appropriate for that recipient.

RBC products transfused intraoperatively may need to be warmed since they will have been kept at 1–6°C in the blood bank or stored on ice in the operating room. This may be accomplished by warming the WB or PRBC unit in a temperature-controlled water bath or by warming the RBCs as they flow through the intravenous (IV) tubing by using circulating water, forced air, or a heat exchanger. Warming these products prior to their administration attenuates not only the development of hypothermia but also any vasoconstriction and/or coagulopathy that may accompany hypothermia [170]. Care must be taken, however, to prevent excessive warming as this can lead to hemolysis [146]. FFP and cryoprecipitate will be warmed in the blood bank prior to their release, and platelets are stored at room temperature so further warming is not usually necessary prior to their administration.

If PRBCs need to be diluted to expedite their flow through IV tubing, 0.9% NaCl (normal saline) should be used. Calcium-containing solutions such as Ringer's lactate should be avoided for this purpose because calcium in excess of the chelating ability of the citrate anticoagulant in the PRBC unit will cause the formation of small clots. Hypotonic solutions should also be avoided because they may cause hemolysis of the RBCs. No medicines or other IV solutions should be infused through the same IV tubing being used for any blood products [146].

Screening filters with pore sizes of 170–200 μm should be used in the transfusion of WB, PRBCs, FFP, cryoprecipitate, and platelets to remove clots and aggregates. These filters are incorporated into all standard blood administration sets. There are no firm indications for using microaggregate filters (pore size 20–40 μm), although these are commonly used when reinfusing blood processed through a cell saver device. Microaggregate filters will trap platelets so should definitely not be used when transfusing platelet units. Finally, once any blood product is accessed for transfusion, its administration should be completed within 4 h to minimize the risk of bacterial contamination [146].

Indications/triggers for blood product transfusion

Blood products are used for the correction of anemia to improve oxygen-carrying capacity and for the treatment of coagulopathies to attenuate bleeding. The administration of blood products, however, is accompanied by infectious, immunological, and non-immunological risks that must be weighed against the anticipated benefits of their use. Therefore, insightful thought processes should guide any decision to transfuse these products [148].

Packed red blood cells

There is no single minimum hemoglobin level that serves as a transfusion trigger for all patients in all clinical scenarios [148,152,171]. To complicate this problem for pediatric caretakers, there is a dearth of randomized controlled trials on RBC transfusion thresholds for neonates, infants, and children [145]. Surveys of pediatric intensive care units (PICUs) have shown significant variations in hemoglobin levels that trigger RBC transfusion [172] as well as a variety of clinical factors other than hemoglobin level that are used to help make this decision [173]. The "10/30" rule for transfusion that was introduced in the 1940s has fallen into disfavor based on risk:benefit analyses [148], and hemoglobin levels are currently allowed to fall to levels much lower than 10 g/dL before PRBCs are administered in many clinical situations. Physiological signs such as tachycardia, hypotension, and, if available, low mixed venous oxygen saturations, increased oxygen extraction ratios, or development of lactic acidemia and metabolic acidosis are useful in providing objective evidence of the need to correct a given level of anemia [148].

In addressing specific hemoglobin levels, data from adults have shown that at a hemoglobin level less than 6 g/dL, coronary artery blood flow reserve may be exceeded and oxygen extraction may be compromised [148]. Studies in both adults and children in intensive care units using a restrictive transfusion strategy of only administering PRBCs when hemoglobin levels drop below 7 g/dL have shown reductions in number of patients transfused and units given with unchanged or improved morbidity and mortality rates when compared to more liberal strategies of transfusing at hemoglobin levels of 9.5 or 10 g/dL [174,175]. With these data in mind, recommendations to transfuse PRBCs for hemoglobin levels less than 7 g/dL seem appropriate. Transfusion for levels greater than 10 g/dL is probably unnecessary in the absence of ongoing blood loss or complicated clinical scenarios. Transfusions for hemoglobin levels between 7 and 10 g/dL should be triggered

by objective physiological signs of inadequate oxygen delivery to tissues [176]. These guidelines require modification for premature infants and for children with cyanotic congenital heart disease, congestive heart failure, or significant co-morbidities. Indeed, although not without controversy [177], the use of a restrictive transfusion threshold in premature infants may be associated with an increase in neurological morbidities that have been postulated to result from decreased oxygen delivery to the brain [178]. Practice parameters for these infants and children are even less evidence based than those previously described.

It typically has been taught that transfusing 10–15 mL of PRBCs per kg of bodyweight will raise the hemoglobin level by approximately 3 g/dL or the hematocrit by 10% [145]. Formulas have been developed to add more precision to determinations of volume of PRBCs to be transfused. One such formula is:

Volume of PRBCs to be transfused = total blood volume × (desired hemoglobin − actual hemoglobin) / hemoglobin of PRBC unit

Assumptions of total blood volume (TBV) are based on the age of the recipient: 90–100 mL/kg for preterm neonates, 80–90 mL/kg for full-term neonates, 80 mL/kg from 6 months to 2 years of age, and 70 mL/kg for children older than 2 years [179]. The hemoglobin of the PRBC unit depends on the anticoagulant/preservative solution used to store the unit [145]. The actual/predicted hemoglobin rise using this formula is 0.61–0.85 and is influenced by the TBV and PRBC hemoglobin values used. A new formula developed from a regression analysis of volume of PRBCs transfused versus bodyweight results in an actual/predicted hemoglobin rise of 0.95 that is valid across different age groups [180]:

$$\text{Volume of PRBCs to } be \text{ transfused} = 4.8 \times \text{weight}\,(kg) \times \text{desired rise in hemoglobin}\,(\text{g}/dL)$$
$$\text{or} = 1.6 \times \text{weight}\,(kg) \times \text{desired rise in hematocrit}\,(\%)$$

Use of this new formula may minimize the need for repeat transfusions.

Plasma

Generally agreed upon indications for transfusing FFP include the treatment of active microvascular bleeding associated with an acquired coagulopathy (disseminated intravascular coagulation, liver disease, massive transfusion, cardiac surgery, or liver transplantation) in the presence of an INR >2.0 or an aPTT >1.5 times normal or when an INR and an aPTT cannot be obtained in a timely manner; replacement of rare congenital coagulation factor deficiencies (II, V, X, XI, XIII, protein C) when specific concentrates are not available; emergent reversal of the anticoagulant effects of warfarin; replacement of AT deficiency in patients with heparin resistance when AT concentrate is not available; and replacement of C1 esterase inhibitor in patients with hereditary angioedema. FFP is not indicated for volume expansion, to augment albumin concentration, or when specific factor concentrates are available to correct documented deficiencies [145,152,176,181]. "Cryoprecipitate reduced plasma" is sometimes used in the management of thrombotic thrombocytopenic purpura (TTP), a condition where the breakdown of large multimers of vWF is inhibited thus leading to microvascular thromboses and tissue infarctions. Transfusion of this plasma product, which is devoid of vWF, replenishes the deficient enzyme (ADAMTS13) responsible for cleaving vWF and ameliorates the complications of TTP [145,146,182].

Ten to 15 mL of FFP per kg of bodyweight is the conventional volume transfused for the previously mentioned indications. This amount is reported to increase plasma levels of coagulation factors by 25–30% [1,3] and thus to exceed the factor level thresholds required for hemostasis (15% for factor V and 30% for all other factors) [183].

Cryoprecipitate

Transfusion of cryoprecipitate is indicated in the presence of microvascular bleeding when the fibrinogen level is <80–100 mg/dL or when the fibrinogen level cannot be measured in a timely fashion and in actively bleeding patients with congenital fibrinogen deficiencies. Cryoprecipitate is rarely indicated when the fibrinogen level exceeds 150 mg/dL but its use may be prudent with fibrinogen levels between 100 and 150 mg/dL when there is a risk of bleeding into a confined space such as the brain or the eye. Cryoprecipitate is not indicated as a first-line treatment for hemophilia A or B, factor XIII deficiency, or vWD, but may be used when purified or recombinant factor concentrates are not available or when vWD is unresponsive to the administration of DDAVP. In small children, 1 unit of cryoprecipitate per 5 kg of bodyweight is estimated to raise the fibrinogen level by 100 mg/dL. In older patients, one unit per 10 kg should increase the fibrinogen level by approximately 50–70 mg/dL [145,152,176].

Platelets

Platelet transfusions may be required because of low platelet counts or because of abnormal platelet function regardless of the number of platelets present. Controlled trials are lacking, and only general guidelines are available to help guide platelet replacement therapy. In the face of active bleeding in the perioperative period, it is prudent to maintain platelet counts above 50,000/μL. When microvascular bleeding is present, this level should probably be raised to 100,000/μL. When active bleeding occurs in the setting of platelet dysfunction (uremia, thrombasthenias, or ingestion of antiplatelet drugs), platelet transfusion will be required regardless of platelet counts. Even in the absence of bleeding, platelets are often transfused prophylactically when counts fall below 50,000/μL in the setting of sepsis, antibiotic use, or other coagulopathies, or when counts fall below 10,000/μL in patients who do not have these additional risk factors. Platelet counts greater than 30,000/μL are felt to be a safe level for most neonatal ICU patients if they have no other risk factors or previous intraventricular hemorrhage. Prior to invasive procedures such as surgery, central line placement, thoracentesis, endoscopy, or lumbar puncture, platelet counts should be raised to greater than 50,000/μL. For neurosurgical or ophthalmological procedures, or if bleeding in the central nervous system has occurred, platelet counts above 100,000/μL are preferred. Platelet transfusions are not typically indicated prior to bone marrow biopsies or in scenarios of increased platelet destruction (idiopathic thrombocytopenic purpura). Platelet administration will increase the risk of thrombosis in patients with TTP and heparin-induced thrombocytopenia [145,152,176,181].

When transfusing random donor platelets, 5–10 mL of platelets per kg of bodyweight in neonates and 0.1–0.2 units/kg in older infants and children should result in a platelet increment of 50,000–100,000/μL. When single donor apheresis platelet units are being transfused, a general rule is to administer 10 mL/kg to neonates, ¼ unit to children <15 kg, ½ unit to children between 15 and 30 kg, and a whole unit to children >30 kg. Response to these transfused volumes varies among patients and according to the platelet content of the unit transfused. Failure to achieve expected platelet increments after transfusion should prompt a search for causes of platelet refractoriness and may require the use of phenotypically matched platelets for future transfusions [145].

Massive transfusion

Trauma is the leading cause of death in children, and hemorrhage is the leading cause of preventable death in trauma victims [184]. Resuscitation of these patients, as well as patients with non-traumatic severe intraoperative bleeding, may require massive transfusion, classically (though arbitrarily) defined in children as the transfusion of one blood volume (70–80 mL/kg) in a 24 h period [185,186]. This amount of transfusion often follows significant crystalloid infusion and often is associated with a trauma-induced coagulopathy, part of the "lethal triad" of coagulopathy, acidosis, and hypothermia that often results in death in these patients [187,188]. Data derived from combat situations have shown that the use of fresh WB as part of "damage control resuscitation" attenuates this coagulopathy and improves survival rates in these patients [189]. Since WB is difficult to obtain in civilian settings, a balanced transfusion approach using predetermined ratios of RBCs, plasma, and platelets has been introduced and similarly found to reduce mortality in adult trauma victims [186,190]. Consequently, massive transfusion protocols (MTPs) have been proposed for use in hemorrhaging pediatric (mostly trauma) patients [191].

Goals of pediatric MTPs include maintenance of platelet counts above 50,000/μL and hemoglobin levels above 10 mg/dL and achievement of normal coagulation assays [192]. However, several questions surround the use of MTPs in the pediatric arena. Objective data to trigger the initiation of MTPs are elusive, but clinical concern for acute imminent blood loss or acute transfusion of 40 mL/kg of blood, a threshold shown to reliably predict mortality in children, has been suggested [193,194]. Variations in age, gender, and weight of children complicate the creation of universally applicable MTPs [184]. Optimal plasma and platelet to PRBC ratios have not been determined although 1:1 ratios of FFP and PRBCs are commonly sought, with platelets and cryoprecipitate included in subsequent rounds of the protocols [189,191,192,194] (Fig. 12.12). Benefits of using MTPs include not only allowing bedside physicians to focus on immediate patient care instead of the tedium of ordering blood products based on laboratory tests whose untimely results may no longer reflect the current clinical picture but also allowing the blood bank to more rapidly provide safe blood products for transfusion [186,195].

Neonate (1–5 kg)

Package	RBC	Plasma	PLTs	Cryo
1	½ unit	½ unit		
2	½ unit	½ unit	¼ apheresis	
3	½ unit	½ unit		1 unit
4	½ unit	½ unit	¼ apheresis	
5	½ unit	½ unit		1 unit

Infant (6–10 kg)

Package	RBC	Plasma	PLTs	Cryo
1	1 unit	1 unit		
2	1 unit	1 unit	½ apheresis	
3	1 unit	1 unit		2 units
4	1 unit	1 unit	½ apheresis	
5	1 unit	1 unit		2 units

Younger child (11–25 kg)

Package	RBC	Plasma	PLTs	Cryo
1	2 units	2 units		
2	2 units	2 units	1 apheresis	
3	2 units	2 units		4 units
4	2 units	2 units	1 apheresis	
5	2 units	2 units		4 units

Older child (26–50 kg)

Package	RBC	Plasma	PLTs	Cryo
1	3 units	3 units		
2	3 units	3 units	1 apheresis	
3	3 units	3 units		6 units
4	3 units	3 units	1 apheresis	
5	3 units	3 units		6 units

Adolescent (>50 kg)

Package	RBC	Plasma	PLTs	Cryo
1	5 units	5 units		
2	5 units	5 units	1 apheresis	
3	5 units	5 units		8 units
4	5 units	5 units	1 apheresis	
5	5 units	5 units		8 units

Figure 12.12 Pediatric massive transfusion protocol. Cryo, cryoprecipitate; PLTs, platelets; RBC, red blood cells. *Source:* Reproduced from Hendrickson et al [191] with permission of John Wiley & Sons.

MTP use in pediatric patients does not increase total blood product use and is not associated with morbidity from increased plasma or platelet transfusions. However, its use also has not yet been demonstrated to reduce overall mortality in massively transfused children [191,194].

KEY POINTS: TRANSFUSION THERAPY

- Blood groups are based on the presence or absence of inherited RBC surface antigens
- Cross-matching is required before PRBC transfusions but not before transfusions of plasma, cryoprecipitate, or platelets
- Specific factor concentrates may provide more targeted correction of coagulation problems while minimizing some transfusion-related issues
- Weight-adjusted massive transfusion protocols may be useful in resuscitating children during significant hemorrhage

Potential adverse effects of transfusion

The transfusion of blood products is not without risks. Additionally, the incidence of adverse reactions during blood product transfusion is three to four times greater in children compared to adults [196,197]. Transmission of infectious diseases and non-infectious immune- and non-immune-mediated hazards of transfusion are sources of ongoing concern and investigation (Box 12.3). Advances in blood donor selection, infectious disease testing of donated blood products, use of leukoreduction filters, and irradiation of blood components in defined situations have made today's blood supply safer than ever [145,198,199]. Nevertheless, vigilance must be maintained to identify known risks and to anticipate emerging risks in today's blood supply.

Transmission of infectious diseases

While the public may be unaware of many of the risks of transfusion, the risk of contracting an infectious disease from a blood product transfusion has not escaped its attention. Potentially transmissible agents include bacteria, viruses, parasites, and prions (Box 12.4).

Bacterial contamination is the most prevalent infectious risk. Platelet units are the most frequently contaminated blood product since they are stored at room temperature. *Staphylococcus* species are the most common contaminants of platelet units whereas gram-negative bacteria such as *Yersinia enterocolitica* that can replicate at cold temperatures are more commonly found as contaminants in PRBC units. The major sources of contamination are the donor's skin at the venipuncture collection site, donor bacteremia that is asymptomatic or undetected, unsterile collection packs, and violations of sterility during processing procedures [151,152,200–202].

Despite this, transmission of viral infections by blood product transfusions is more concerning because of potential long-term implications. Currently, donated blood products are regularly tested for human immunodeficiency virus (HIV), human T-lymphotrophic virus (HTLV), hepatitis B virus (HBV), hepatitis C virus (HCV), West Nile virus, and Zika virus using serological assays or nucleic acid amplification tests (NATs) [200,203–205] (Table 12.7). Early detection of viral DNA or RNA by NATs shortens the window period of these viruses, i.e. the time after a blood donor has become infected but before any donor screening tests are positive [151]. Consequently, the risk of transmitting several of these viruses through blood product transfusions has been drastically reduced [151,201,203,206]. NATs are not currently routinely performed for HBV detection since their use would reduce

Box 12.3: Potential hazards of transfusion

- Transmission of infectious diseases
- Immune-mediated risks
  - Hemolytic transfusion reactions
  - Febrile non-hemolytic transfusion reactions
  - Allergic reactions
  - Transfusion-related acute lung injury
  - Transfusion-associated graft versus host disease
  - Post-transfusion purpura
  - Transfusion-related immunomodulation
  - Alloimmunization
- Non-immune-mediated risks
  - Septic transfusion reactions
  - Non-immune hemolysis
  - Transfusion-associated circulatory overload
  - Metabolic derangements
  - Red blood cell storage lesions
  - Mistransfusion

Box 12.4: Infectious agents/diseases potentially transmissible by blood product transfusion

Viral
- HIV 1/2
- HTLV I/II
- Hepatitis A virus
- Hepatitis B virus
- Hepatitis C virus
- Hepatitis G virus
- Cytomegalovirus
- Epstein–Barr virus
- Parvovirus B19
- Human herpesvirus-8
- West Nile virus
- Enterovirus
- Zika virus

Bacterial
- Syphilis (*Treponema pallidum*)
- Rocky Mountain spotted fever (*Rickettsia rickettsii*)

the window period only marginally compared to the most sensitive HBsAg screening tests [151,198]. Current estimated risks of transmitting some of these viral pathogens through blood product transfusion are detailed in Box 12.5.

Hepatitis A virus (HAV) is rarely transmitted by blood products because individuals are usually symptomatic when infected and thus excluded from donation, no chronic carrier state exists, and many people have developed antibodies either naturally from previous infection or by vaccination. The risk of CMV transmission to immunocompromised patients has been reduced by the use of leukoreduced cellular blood products (termed "CMV safe") or the use of CMV-seronegative cellular blood products [151]. Potential blood donors are also screened for *Treponema pallidum*, the causative agent of syphilis, and *Trypanosoma cruzi*, the parasite that causes Chagas disease, using serological tests to detect antibodies to these organisms [203,207].

The transfusion-associated transmission of other infectious agents for which no screening tests are currently available is also a concern. This includes human herpesvirus-8 (a causative agent of Kaposi sarcoma) and most of the parasitic diseases (malaria, babesiosis, toxoplasmosis, and leishmaniasis) [152,198,199,208]. Fortunately, transmission of parasitic diseases is rare in developed countries. However, potential transmission of hepatitis G virus, other as yet unknown viruses, and the prion causing variant Creutzfeldt–Jakob disease, the human equivalent of bovine spongiform encephalopathy ("mad cow disease"), is a significant concern [209]. Currently, potential blood donors who visited European countries affected by bovine spongiform encephalopathy between 1980 and 1996 are deferred from donating [203].

The risks of transfusion-associated transmission of infectious agents are not static because new agents continue to emerge and old agents change their properties and epidemiological patterns. A recent example is the development of a Zika virus screening test, and mandated testing of all blood donations in the United States for this virus [210].

Pathogen reduction technologies effective against most viruses, bacteria, and parasites are being developed to improve future safety, as are prion-retention filters [203,210]. Additionally, performance of NAT on individual units of blood rather than on minipools of samples, as is currently done, could be of benefit but would be extremely expensive [208]. Nevertheless, currently used screening methods are effective enough that non-infectious hazards of transfusion have now emerged as the leading complication of transfusion therapy [151,201,211].

Immune-mediated hazards of transfusion

Immune-mediated transfusion risks include hemolytic transfusion reactions, febrile non-hemolytic transfusion reactions, allergic reactions, transfusion-related acute lung injury, transfusion-associated graft versus host disease, post-transfusion purpura, transfusion-related immunomodulation, and alloimmunization [201] (Table 12.8).

Hemolytic transfusion reactions

Immune-mediated hemolytic transfusion reactions (HTRs) are caused by the transfusion of RBCs to patients with preexisting antibodies to antigens on those RBCs. The most serious HTRs are caused by the transfusion of ABO-incompatible RBCs and result in acute intravascular hemolysis. Clerical error is the most common cause of this mishap and, therefore, most are preventable. Electronic identification systems, including barcode scanning, have been demonstrated to reduce the incidence of transfusion of incompatible blood products [212].

Awake patients may manifest chills, fever, nausea, anxiety, and chest and flank pain but these may be masked in anesthetized patients. Tachycardia, hypotension, microvascular bleeding, and hemoglobinuria may be seen but need to be recognized as resulting from an HTR as opposed to a myriad of other potential causes in anesthetized patients. Once an acute immune-mediated HTR is suspected, the transfusion should be immediately stopped, the unit of blood should be returned to the blood bank for investigation, and steps should be taken to prevent or ameliorate acute renal failure and coagulopathy.

Delayed immune-mediated HTRs result from the transfusion of RBCs containing a non-ABO antigen to which the recipient has developed an antibody because of a previous transfusion or pregnancy. The antibody is usually present at such low levels that it is undetected during the screening procedure. However, a rapid anamnestic response follows the transfusion. A delayed HTR presents 3–10 days after transfusion as a falling hemoglobin level. No treatment is usually indicated but recognition of the problem, identification of the recipient's antibody, and future transfusion of blood negative for the corresponding antigen are necessary [145,152,201,203].

Table 12.8 Immune-mediated hazards of transfusion

	Etiology	Causative products	Prevention
Hemolytic transfusion reactions	Recipient antibodies to donor RBCs	Acute: ABO incompatible RBCs Delayed: non-ABO antigens on donor RBCs (anamnestic)	Acute: clerical error prevention Delayed: transfusion history and history of antibodies
Febrile non-hemolytic transfusion reactions	Leukocyte-derived cytokines in donor products Recipient antileukocyte antibodies against donor leukocytes	Platelets most commonly	Prestorage leukocyte reduction
Allergic reactions	Recipient antibodies against soluble donor plasma antigen Recipient anti-IgA antibodies against donor IgA	Plasma-containing products (FFP, apheresed platelets, and RBCs)	Washing cellular products (RBCs and platelets) to remove plasma Use of IgA-deficient plasma
Transfusion-related acute lung injury	Donor antileukocyte antibodies against recipient leukocytes Donor cytokine- or interleukin-induced activation of recipient leukocytes sequestered in lungs	Plasma rich products (FFP and apheresed platelets)	Avoidance of plasma products from multiparous female donors
Transfusion-associated graft versus host disease	Donor immunocompetent lymphocytes engraft in recipient	Cellular blood products (RBCs, platelets, granulocytes)	Irradiation of cellular blood products
Post-transfusion purpura	Recipient antibodies against donor platelet antigens	Platelets, RBCs, FFP	
Transfusion-related immunomodulation	Leukocytes?		Prestorage leukocyte reduction
Alloimmunization	Recipient antibodies to donor minor RBC, platelet, or leukocyte antigens	Cellular blood products (RBCs, platelets, leukocytes)	Extended antigen phenotyping Irradiation of HLA-matched platelets

FFP, fresh frozen plasma; RBC, red blood cells.

Febrile non-hemolytic transfusion reactions

A febrile non-hemolytic transfusion reaction (FNHTR) is defined as a 1°C increase in body temperature into the febrile range during or soon after a transfusion. These reactions are typically caused by leukocyte-derived cytokines that have been released into the blood product during storage or by the reaction of recipient antileukocyte antibodies (developed after previous transfusions or pregnancies) against donor leukocytes. They are most commonly seen in association with platelet transfusions but can also accompany RBC or plasma administration. FNHTR is a diagnosis of exclusion after other transfusion-associated causes of fever, such as acute HTRs, septic transfusion reactions, or transfusion-related acute lung injury, have been ruled out. The use of prestorage leukocyte reduction has significantly reduced the occurrence of these reactions [145,201,203].

Allergic reactions

Allergic reactions are the most common of all acute transfusion reactions and result from the reaction of an antibody in the recipient to a soluble plasma antigen in the donor. Leukocyte reduction of cellular blood products, therefore, does not decrease the occurrence of these reactions. However, pretransfusion washing of PRBCs or platelets removes plasma and associated antigens and thus does decrease the occurrence of allergic reactions. Treatment of allergic reactions involves stopping the transfusion and administering antihistamines. Some of these reactions are anaphylactic in nature and will require aggressive treatment, possibly including steroids, antihistamines, and epinephrine. IgA deficiency of the recipient should be considered after a severe allergic transfusion reaction has occurred. IgA-deficient individuals can develop anti-IgA antibodies that react with donor IgA resulting in an anaphylactic reaction. Use of IgA-deficient plasma or washed cellular products will be necessary for any future transfusions to recipients known to have IgA deficiency and anti-IgA antibodies [145,201].

Transfusion-related acute lung injury

Transfusion-related acute lung injury (TRALI) has historically been a leading cause of transfusion-related deaths [201]. TRALI is defined as new acute lung injury occurring during or within 6 h after a transfusion with a clear temporal relationship to the transfusion in patients with or without alternative risk factors for acute lung injury [213]. TRALI can occur after the administration of all types of blood components but is more likely after the transfusion of plasma-rich components such as FFP and apheresis platelets [214]. Two pathophysiological mechanisms have been proposed. In the "classical antibody mediated" mechanism (approximately 85% of cases), donor antileukocyte antibodies react with recipient leukocytes resulting in the release of inflammatory mediators that damage pulmonary alveolar epithelium and vascular endothelium leading to non-cardiogenic pulmonary edema. In approximately 15% of cases, however, no antibody can be detected. Systemic inflammatory conditions secondary to clinical scenarios such as major surgery, sepsis, trauma, aspiration, or massive transfusion lead to activation of leukocytes and pulmonary endothelium with subsequent leukocyte sequestration in the lungs. "Bioactive factors" such as cytokines, interleukins, or lipids in transfused products may then activate these sequestered leukocytes leading to lung injury and non-cardiogenic pulmonary edema [214].

The clinical presentation of TRALI mirrors that of acute respiratory distress syndrome (ARDS). Treatment is primarily supportive with recovery usually occurring within 96 h although the mortality rate is 5–10%. Diuresis does not improve symptoms and the role of steroids is unproven [152,214]. Plasma products from multiparous women have been implicated in the majority of cases of antibody-mediated TRALI because these donors may develop antileukocyte antibodies during pregnancies. Eliminating or minimizing the use of plasma products from these donors dramatically decreases the incidence of TRALI [145,214].

Transfusion-associated graft versus host disease

Transfusion-associated graft versus host disease (TA-GVHD) occurs when immunocompetent $CD8^+$ lymphocytes in transfused cellular blood products (RBCs, platelets, or granulocytes) engraft in a recipient, proliferate, and attack host tissues. This occurs when the recipient is immunocompromised and cannot eliminate the donor lymphocytes or when the recipient does not recognize the donor lymphocytes as foreign (biologically related donors or HLA-matched products) and thus does not eliminate them. Clinical manifestations include fever, rash, diarrhea, liver dysfunction, and pancytopenia and occur 1–6 weeks after transfusion. The diagnosis can be made by detecting donor DNA in a skin biopsy or in circulating lymphocytes taken from the recipient. Irradiating RBCs and platelets before their administration renders donor lymphocytes incapable of proliferating and thus eliminates the risk of the development of TA-GVHD. TA-GVHD is nearly uniformly fatal, with mortality rates approaching 90% [201,203].

Post-transfusion purpura

Post-transfusion purpura (PTP) is the development of severe thrombocytopenia after a transfusion in recipients who have developed antibodies against platelet-specific antigens as a result of previous transfusions or pregnancies. While PTP is a rare event, it can occur 5–10 days after the administration of RBCs, FFP, or platelets. Both transfused and autologous platelets are destroyed in this process thus severely decreasing the recipient's platelet count, even to below 10,000/μL. Recovery is usually spontaneous although treatment with steroids and IV immune globulin is indicated with plasmapheresis being a second-line intervention. Platelet transfusions are usually ineffective in raising the platelet count but, if felt necessary in the face of severe bleeding, may need to be administered in large doses since many of the transfused platelets also will be destroyed [201].

Transfusion-related immunomodulation

While the exact mechanism of transfusion-related immunomodulation (TRIM) has yet to be elucidated, modulation of the recipient's immune responses after transfusion may have both beneficial and harmful effects. Improved survival of transplanted kidneys has been documented in patients transfused before transplantation, as has survival of cardiac and liver transplant patients after pretransplant transfusion of donor-specific or HLA-DR-shared RBCs. TRIM may also decrease the recurrence rate of Crohn disease and of miscarriages in women who share HLA antigens with their mates. Evidence linking increased incidences of postoperative infections and cancer recurrence with transfusions, however, is controversial and not definitely proven. Theories of the etiology of TRIM indict leukocytes as major participants so harmful effects of transfusion that are blamed on TRIM may be ameliorated by prestorage leukocyte reduction of blood products [171,201,215].

Alloimmunization

Alloimmunization is the development of antibodies to minor RBC antigens or to platelet or leukocyte antigens after exposure by transfusion or pregnancy. Subsequent transfusion of blood products containing these antigens results in delayed HTRs or platelet refractoriness. Approximately two-thirds of clinically significant alloantibodies are directed toward Rh and Kell antigens on RBC surfaces. Up to 40% of children with sickle cell disease who are managed with chronic transfusion protocols develop alloantibodies. These children, therefore, should undergo extended RBC antigen phenotyping prior to the initiation of chronic transfusion therapy. Provision of PRBCs phenotypically matched for Rh and Kell antigens has been shown to decrease rates of alloimmunization from 3% per unit transfused to 0.5% per unit transfused [135]. Similarly, HLA-matched platelet units may be necessary for patients with platelet refractoriness and anti-HLA alloantibodies. These matched platelets, however, must be irradiated prior to transfusion to eliminate the risk of TA-GVHD due to the HLA similarity between donor and recipient [145,201,203].

Non-immune-mediated hazards of transfusion

Non-immune-mediated hazards of transfusion include septic transfusion reactions, non-immune hemolysis, transfusion-associated circulatory overload, metabolic derangements, complications from RBC storage lesions, and mistransfusion [201].

Septic transfusion reactions

Transfusion-associated bacterial sepsis occurs much less frequently than bacterial contamination of blood products. However, this is the most frequent cause of death from infectious agents acquired from blood product transfusion [202]. Gram-negative organisms are more likely to cause fatal infections. The institution in 2004 of mandatory testing of platelet units for bacterial contamination has resulted in a significant decrease in the incidence of post-transfusion sepsis. Ongoing improvements in blood component collection techniques and in the handling and storage of blood products have reduced this transfusion-related risk [151,152,200,201].

Non-immune hemolysis

Non-immune hemolysis of RBCs can result from improper storage of the blood unit, inadequate deglycerolization of frozen RBCs, thermal injury to RBCs by malfunctioning blood warmers, exposure of RBCs to hypotonic or hypertonic IV solutions, rapid transfusion through small-bore IV catheters, or processing techniques used during RBC salvage. This problem is usually preventable by strictly following established guidelines for storing, preparing, and transfusing RBCs [201].

Transfusion-associated circulatory overload

Transfusion-associated circulatory overload (TACO) is the development of cardiogenic pulmonary edema from volume

overload during transfusion. Infants and patients with cardiopulmonary compromise and renal failure are particularly susceptible to this risk. Diuretic administration, as well as slowing down the blood administration rate, may minimize TACO symptoms [201].

Metabolic derangements

Hyperkalemia, hypocalcemia, and hypothermia can accompany the transfusion of blood products. Hyperkalemia is a potential problem with PRBC administration because RBCs leak potassium into their storage solution over time. Potassium concentrations reach an average of 12 mEq/L after 7 days of storage and 32 mEq/L after 21 days of storage. Hyperkalemia can be a particular problem when transfusing neonates or in instances of massive transfusion because of the relative volume of PRBCs administered. Hyperkalemic cardiac arrest and deaths have been reported, due to faster rate of blood transfusion, rather than the total volume transfused [216].

The use of fresher PRBCs (<14 days old), transfusion into IV lines further away from the right atrium, correction of acidosis, administration of calcium to stabilize the myocardium, and administration of glucose and insulin to lower potassium levels are helpful with prevention and treatment.

Hypocalcemia from "citrate toxicity" may be a problem with administration of large volumes of plasma and platelets. These components have high citrate concentrations in their anticoagulant solutions. Citrate exerts its anticoagulant effect by binding ionized calcium. Neonates and infants are particularly prone to the development of hypocalcemia because their intracellular calcium reserves are limited. Treatment consists of the administration of calcium and slowing the infusion rate of the blood products. Citrate undergoes rapid hepatic metabolism so hypocalcemia associated with transfusion is a transient problem.

Hypothermia is a consequence of the rapid infusion of large amounts of inadequately warmed blood products. Hypothermia not only potentiates the cardiac toxicity of hyperkalemia and hypocalcemia but also is a component of the "lethal triad" of coagulopathy, hypothermia, and acidosis that can occur during massive hemorrhage and transfusion. Therefore, its occurrence should be aggressively prevented and/or treated [201].

Red blood cell storage lesions

The ability to store RBCs for up to 42 days provides blood distribution centers significant flexibility in managing the blood supply [199]. However, during this storage period, detrimental changes occur in RBCs themselves and in the RBC product as a unit. RBCs lose their deformability and increase their adhesiveness so that their passage through capillaries is impaired. Levels of 2,3-DPG fall so that the oxygen affinity of hemoglobin increases. Finally, concentrations of nitric oxide fall, possibly impairing vasodilation of blood vessels. Therefore, even though raising the hemoglobin level by transfusing RBCs allows more oxygen to be transported by blood, the sum of these effects may actually reduce the availability of this oxygen to tissues. These effects may be minimized by using PRBCs that are less than 14 days old [170,185,201].

Mistransfusion

Mistransfusion is the transfusion of the incorrect blood product to the incorrect recipient. It is the most common non-infectious complication of blood product transfusion. Approximately 30% of the errors leading to mistransfusion occur in the blood bank while 50% occur in clinical areas. Meticulous attention to detail when labeling blood samples and identifying blood products and recipients is critical to avoid the occurrence of this preventable hazard of blood transfusion [151,201]. As noted previously, electronic barcode identifying systems significantly reduce the incidence of this complication.

KEY POINTS: POTENTIAL HAZARDS OF TRANSFUSION

- Infectious disease transmission is now rare, but periodically new pathogens emerge, e.g. Zika virus
- Serious immune-mediated hemolytic transfusion reactions are most commonly due to clerical errors and can largely be prevented by electronic identification systems like barcoding
- Febrile non-hemolytic transfusion reactions, allergic reactions, transfusion-related acute lung injury, transfusion-associated graft versus host disease, transfusion-associated circulatory overload, and hyperkalemic cardiac arrest are additional risks of blood transfusion

Blood conservation

In light of the potential hazards posed by transfusing allogeneic blood products, efforts to minimize the necessity for transfusions should always be considered. These efforts may be especially important in patients who, for religious reasons (Jehovah's Witnesses), refuse blood product transfusion. Proactive blood conservation plans tailored to individual patients and their anticipated surgical procedures are essential for success but require significant forethought. Combining preoperative, intraoperative, and postoperative modalities will offer the best chance for a positive impact.

Preoperative modalities

Personal and family histories of bleeding disorders should be sought and investigated prior to surgery. Indicated laboratory tests should be performed well enough in advance to allow preoperative action based on the results. Causes of anemia should be investigated. Anticoagulant and antiplatelet drugs should be discontinued, if feasible, for an appropriate interval before surgery.

Preoperative anemia is a major risk factor in determining the need for perioperative allogeneic blood transfusion [171,217]. This risk may be reduced by the preoperative administration of erythropoietin, a hormone produced by the kidneys that acts on erythroblast precursor cells in the bone marrow to accelerate the production of mature erythrocytes and thus increase hemoglobin levels [218]. Recombinant human erythropoietin has been shown to increase preoperative hemoglobin levels in infants and children prior to a variety of surgical procedures [218–220]. However, it is expensive, it must be repeatedly injected intravenously or subcutaneously over a period of several weeks preoperatively, and its

use must be accompanied by iron supplementation. The most significant preoperative use of erythropoietin may be to increase hemoglobin levels in anticipation of preoperative autologous blood donation or intraoperative acute normovolemic hemodilution [220–223].

Preoperative autologous blood donation (PABD) is the preoperative collection of blood for transfusion back to the same donor in the perioperative period. PABD may be useful in children undergoing elective surgical procedures in which the likelihood of transfusion is substantial and in children who have rare blood groups or alloantibodies to high-incidence antigens. PABD decreases exposure to allogeneic blood products and has been used in a wide variety of surgical procedures in children as young as 3 months of age [221,224–226]. As with erythropoietin, the use of PABD requires time and forethought. Depending on the size of the child and the anticipated surgical blood loss, several donations may be collected but the donations should be completed far enough in advance of surgery to allow the patient's hemoglobin level to recover prior to surgery. Estimations of the volume of blood to be collected at each donation have been based on a percentage (15%) of estimated blood volume (EBV), a defined amount (10 mL) per kg bodyweight, a weight-corrected proportion of an adult unit of blood ([weight/50 kg] × 450 mL), and on formulas to keep the child's postdonation hematocrit above 30% (EBV × [initial Hct − 30]/average Hct with average Hct = (initial Hct − 30)/2) [224]. PABD should not be used in children with active infections, anemia, or limited cardiopulmonary reserves. Vascular access issues may limit the use of PABD in young infants [220,221]. This problem has been circumvented in some children prior to cardiac surgery by obtaining autologous blood from the large-bore vascular sheaths used during preoperative diagnostic catheterization [226]. The use of blood collected from PABD still carries risks from clerical errors and bacterial contamination, so appropriate indications should dictate its retransfusion while its automatic administration back to the donor without indications should be avoided [227].

Intraoperative modalities

Surgical technique obviously plays a role in limiting intraoperative blood loss and exposure to allogeneic blood transfusions. Direct control of bleeding vessels is essential and infiltration of local vasoconstrictors into surgical wound edges, use of tourniquets, patient positioning to elevate the surgical site, and use of topical clotting agents may all be important [215].

Anesthesiologists can also play helpful roles in minimizing perioperative exposure to allogeneic blood products. Maintenance of normothermia is important to prevent hypothermia-induced dysfunction of platelets and coagulation factors. Controlled hypotension techniques may help reduce intraoperative blood loss. Reinfusion of RBCs salvaged from the operative field may minimize effective blood loss but should not be used during cancer surgery, in patients with active infections, or after application of topical clotting agents. Tolerating lower hemoglobin levels and basing decisions to initiate transfusion on indicators such as the development of lactic acidosis or hemodynamic lability may avoid transfusion in some cases. Administration of increased inspired oxygen concentrations will increase dissolved oxygen in blood and help maintain adequate oxygen delivery to tissues when lower hemoglobin levels are being allowed. The use of acute normovolemic hemodilution (ANH) or antifibrinolytic agents may also be considered [171].

ANH involves the intraoperative collection of blood for reinfusion at the end of surgery. Blood is withdrawn from a patient after anesthetic induction while isovolemia is maintained by infusing crystalloid (3:1 volume replacement) and/or colloid (1:1 volume replacement). Subsequently, blood with a lower hemoglobin level is lost intraoperatively and safe, fresh autologous blood with a higher hemoglobin level and functioning coagulation factors and platelets is available for reinfusion once blood loss is controlled. The amount of blood to be withdrawn can be calculated using the formula EBV × (initial Hct − target Hct)/average Hct where average Hct = (initial Hct − target Hct)/2 [227]. ANH may be considered when surgical blood loss is anticipated to exceed 15% of a child's EBV and the child has a baseline hematocrit exceeding 35% and adequate cardiopulmonary reserve to tolerate lowering of the hematocrit. ANH has been used in children as young as 7 months of age and in surgeries ranging from posterior spinal fusions to abdominal surgery, cancer surgery, and bone marrow harvesting [224]. ANH offers advantages over PABD in that it may be performed on the day of surgery for both elective and emergency procedures, it may be performed after adequate vascular access is obtained in an anesthetized child, and it is associated with lower administrative costs [228]. Blood withdrawn during ANH may be stored for up to 8 h at room temperature and, if more than one bag of blood was withdrawn, should be reinfused in the reverse order of collection [224]. Therefore, blood with the highest hematocrit (the first unit collected) will be reinfused after bleeding has been controlled.

Antifibrinolytic agents include aprotinin and the lysine analogs, ε-aminocaproic acid (EACA) and tranexamic acid (TA). Although aprotinin, a serine protease inhibitor, is remarkably effective in reducing perioperative blood loss and transfusion exposure, its marketing was suspended in 2007 after concerns about adverse renal, cardiovascular, and cerebrovascular effects and increased postoperative mortality were raised in adults in whom it was administered during cardiac surgery [229–232]. Studies in neonates and children undergoing cardiac surgery have not documented similar concerns [233–236], and aprotinin has been relicensed for use in myocardial revascularization procedures in Europe and Canada [237]. We are still awaiting reconsideration of its use in children.

EACA and TA exert their antifibrinolytic effect most importantly by binding with the lysine-binding sites of plasminogen and plasmin. This reversible binding alters plasminogen's conformation, precludes its association with fibrin, and prevents its conversion to its active form, plasmin, while also inhibiting the activity of plasmin on fibrin [238,239]. These drugs have been shown to decrease blood loss and allogeneic blood transfusion in cyanotic children undergoing cardiac surgery [240–243], in children undergoing repeat sternotomies for cardiac surgery [142], and in children undergoing posterior spinal fusion for idiopathic or secondary scoliosis [244–246]. They have also been shown to have beneficial effects in adults undergoing liver transplantation [247,248] and total knee

replacement [249,250] and thus would probably be beneficial for similar types of surgeries in children. These drugs may also be helpful in preventing clot lysis in patients with vWD or hemophilia after hemostasis has been achieved with appropriate factor replacement therapy, especially with bleeding from mucous membranes [71,82]. Evidence points to TA being more effective than EACA in its hemostatic effects [251]. Appropriate dosing regimens remain an unresolved issue for both of these drugs. While no thrombotic complications have been reported with their use, an increased incidence of postoperative seizures has been reported with TA use in adults undergoing cardiac surgery [252,253].

Postoperative modalities

Efforts to minimize exposure to allogeneic blood products should continue into the postoperative period. Useful strategies include limiting blood sampling to necessary tests and continued use of restrictive transfusion thresholds to trigger RBC transfusions. Reinstitution of postoperative anticoagulant or antiplatelet therapies should begin only after correction of coagulopathies acquired intraoperatively. Future considerations include development of appropriate coagulation test-based transfusion algorithms to guide blood component use and the development of safe artificial oxygen carriers to limit RBC transfusions.

KEY POINTS: BLOOD CONSERVATION

- Combining preoperative, intraoperative, and postoperative blood conservation strategies creates maximal impact
- Preoperative approaches include the use of erythropoietin and autologous blood donation
- Intraoperatively, acute normovolemic hemodilution, RBC salvage, antifibrinolytic drugs, and controlled hypotensive techniques may be helpful
- Postoperative efforts include the use of restrictive transfusion thresholds and transfusion algorithms to guide component use

Introduction

Pediatric cardiac arrest is not a rare event. While cardiac arrest survival outcomes have improved over the last decade, more than half of these children who initially have return of spontaneous circulation (ROSC) do not live to hospital discharge, and new significant neurofunctional morbidity is common among survivors [1–7]. Death from cardiac arrest accounts for the loss of up to 400,000 quality of life years annually in the United States. While research and quality improvement projects continue to improve the field, less than 5% of existing pediatric cardiopulmonary resuscitation (CPR) guidelines are supported by high-quality evidence [8]. Furthermore, despite mounting evidence that the immature brain's response to acute injury is markedly different than that of the mature brain, there is a paucity of research investigating secondary injury mechanisms specific to infants and children following cardiac arrest. This chapter focuses on pediatric cardiac arrest, cardiopulmonary resuscitation, and other therapeutic interventions that have been specifically designed to improve outcomes from pediatric cardiac arrest.

Epidemiology of pediatric cardiac arrest

Cardiovascular disease remains the most common cause of disease-related death in the United States, resulting in approximately one million deaths per year [9]. It is estimated that more than 400,000 Americans will suffer a cardiac arrest each year, nearly 90% in prehospital settings. The true incidence of pediatric cardiac arrest is difficult to determine due to inconsistencies in reporting, as well as difficulties with identifying and defining pediatric cardiac arrest. Specifically, the determination of pulselessness in children with poor perfusion is difficult [10] and the indication for beginning CPR for bradycardia with poor perfusion complicates definitions pertaining to pediatric in-hospital cardiac arrest (IHCA) [11]. Regardless, based on cardiac arrest registries and administrative databases, more than 6000 children receive CPR in the United States annually [12,13]. This amounts to 0.77 children receiving CPR per 1000 hospital admissions [12]. Due in part to the widespread implementation of rapid response systems in most children's hospitals [14–16] and the recognition of at-risk inpatients, >95% of CPR events in the United States occur in intensive care units (ICUs) [2]. The prevalence of CPR among one cohort of academic children's hospitals was 1.4% from 2010 to 2013, compared to 1.8% reported in the 1990s [13]. In pediatric cardiac ICUs, however, cardiac arrests are reported in 3–6% of patients [17,18].

Survival to hospital discharge following pediatric IHCA improved from 13.7% in the 1990s [13] to 22% in an American Heart Association (AHA) Get With The Guidelines-Resuscitation (GWTG-R) registry study from 2006 [19]. Additional GWTG-R data demonstrated an improvement in rates of ROSC from 39% to 78%, and survival to hospital discharge from 24% to 43% between 2001 and 2009 [4]. A more recent multicenter study of IHCA events in pediatric ICUs revealed that 78% of children attained ROSC and 45%

Gregory's Pediatric Anesthesia, Sixth Edition. Edited by Dean B. Andropoulos and George A. Gregory.

survived to hospital discharge [1]. Furthermore, while the likelihood of survival falls with increasing duration of CPR, the decision to end resuscitative efforts during a prolonged CPR event is complicated for practitioners. Due to improvements in CPR techniques, it is now clear that prolonged CPR is not uniformly futile. Factors that influence outcome from pediatric cardiac arrest include: (1) the pre-existing condition of the child; (2) the environment in which the arrest occurs; (3) the initial electrocardiographic (ECG) rhythm detected; (4) the duration of no-flow time (the time during an arrest without spontaneous circulation or CPR); (5) the quality of the life-supporting therapies provided during the resuscitation; and (6) the quality of life-supporting therapies following resuscitation [19–22].

The underlying etiologies of cardiac arrest and initial rhythm are closely related and have a substantial impact on outcome [1,20]. Whereas adult cardiac arrest is frequently associated with coronary ischemia and primary ventricular arrhythmias [23], pediatric IHCAs are most often due to progressive respiratory insufficiency and circulatory shock [1,20]. Additionally, the initial rhythm in pediatric CPR events is most commonly asystole, pulseless electrical activity (PEA), or bradycardia with poor perfusion [4,20]. Ventricular fibrillation (VF) or pulseless ventricular tachycardia (pVT) occurs as the initial cardiac arrest rhythm in 10–15% of pediatric IHCAs [4,20,24,25]. Notably, VF or pVT occurs as a secondary rhythm in approximately 15% of pediatric IHCAs. Whereas primary VF and pVT are favorable rhythms that are associated with improved rates of survival when compared to asystole or PEA, secondary VF or pVT carries the highest relative risk of mortality [20,25].

Not surprisingly, outcomes after pediatric out-of-hospital arrests are much worse than those after in-hospital arrests [26–36]. This may be due to the fact that there is a prolonged period of no flow in out-of-hospital arrests, where many of the pediatric cardiac arrests are not witnessed and only 30% of children are provided with bystander CPR. As a result of these factors, less than 10% of pediatric out-of-hospital cardiac arrests (OHCA) survive to hospital discharge, and among those who survive, severe neurological injury is common. These findings are especially troublesome given that bystander CPR more than doubles patient survival rates in adults [37]. An exciting prospective, nationwide, population-based cohort study from Japan similarly demonstrated more than doubling of survival rates for children who had OHCA and received bystander CPR either with conventional CPR (with rescue breathing) or chest compression-only CPR compared to no bystander CPR [38]. The same study then further stratified outcomes for OHCA into "cardiac" and "non-cardiac" causes for arrest, and defined the relative value of rescue breathing during CPR by bystanders. Pediatric patients who had OHCA with non-cardiac causes and received bystander conventional CPR (including rescue breathing) had an association with a higher frequency of favorable neurological outcomes at 1 month after arrest compared to compression-only bystander CPR or no bystander CPR. For pediatric arrests defined as "cardiac" in nature, bystander CPR (conventional or compression-only) was associated with a higher rate of favorable neurological outcomes 1 month after arrest compared to no bystander CPR. Interestingly, the two types of bystander CPR (conventional or compression-only) seemed to be similarly effective for pediatric cardiac arrests with cardiac causes, consistent with animal and adult studies [38].

Survival outcomes after IHCA are higher in the pediatric population compared with adults: 27% of children survive to hospital discharge compared with only 17% of adults [20]. For both children and adults, outcomes are better after arrhythmogenic arrests, from ventricular fibrillation/ventricular tachycardia (VF/VT). Importantly, pediatric IHCAs are less commonly caused by arrhythmias (10% of pediatric arrests versus 25% of adult arrests), and approximately one-third of children and adults with these arrhythmogenic arrests survive to hospital discharge. Interestingly, the superior pediatric survival rate following IHCA reflects a substantially higher survival rate among children with asystole or pulseless electrical activity (PEA) compared with adults (24% versus 11%). Further investigations have shown that the superior survival rate seen in children is mostly attributable to a much better survival rate among infants and preschool age children compared with older children [19]. Although speculative, the higher survival rates in children may be due to improved coronary and cerebral blood flow during CPR because of increased chest compliance in these younger arrest victims, with improved aortic diastolic pressure and venous return [39,40]. In addition, survival of pediatric patients from IHCA is more likely in hospitals staffed with dedicated pediatric physicians [41].

KEY POINTS: EPIDEMIOLOGY OF PEDIATRIC CARDIAC ARREST

- Cardiac arrest is reported in 1.4% of patients in pediatric ICUs, versus 3–6% of patients in pediatric cardiac ICUs
- Some 78% of children attained ROSC and 45% survived to hospital discharge after cardiac arrest in pediatric ICUs
- Due to improvements in CPR techniques, it is now clear that prolonged CPR is not uniformly futile
- The superior pediatric survival rate following in-hospital cardiac arrest reflects a substantially higher survival rate among children with asystole or pulseless electrical activity compared with adults (24% versus 11%)

Phases of resuscitation

The four distinct phases of cardiac arrest and CPR interventions are: (1) prearrest, (2) no flow (untreated cardiac arrest), (3) low flow (CPR), and (4) postresuscitation/arrest. Interventions to improve outcome of pediatric cardiac arrest should optimize therapies targeted to the time and phase of CPR, as suggested in Table 13.1.

Prearrest

The prearrest phase refers to any relevant pre-existing conditions of the child (e.g. neurological, cardiac, respiratory, or metabolic problems) and precipitating events (e.g. respiratory

Table 13.1 Phases of cardiac arrest and resuscitation

Phase	Interventions
Prearrest (Protect)	Optimize community education regarding child safety
	Optimize patient monitoring and rapid emergency response
	Train in-hospital METs and Rapid Response Teams
	Recognize and treat respiratory failure and/or shock to prevent cardiac arrest
	Transfer patients to skilled pediatric centers
Arrest (no-flow) (Preserve)	Minimize interval to BLS and ACLS (organized response)
	Minimize interval to defibrillation, when indicated
Low-flow (CPR) (Resuscitate)	Push hard, push fast
	Allow full chest recoil
	Minimize interruptions in compressions (15:2)
	Avoid overventilation
	Titrate CPR to optimize myocardial blood flow (coronary perfusion pressures and exhaled CO_2)
	Consider ECPR if standard CPR/ACLS not promptly successful (within 2–5 min) if available
Postresuscitation short-term (Metabolic Delivery)	Optimize cardiac output and cerebral perfusion
	Treat arrhythmias, if indicated
	Avoid hyperglycemia, hyperthermia, hyperventilation, hypoxemia, and hyperoxia
	Treat fever aggressively
	Continual quality improvement for future responses to emergencies
Postresuscitation phase	Early intervention with physical medicine and rehabilitation
Longer-term rehabilitation (Regenerate)	Bioengineering and technology interface
	Possible future role for stem cell transplantation

ACLS, advanced cardiac life support; BLS, basic life support; CPR, cardiopulmonary resuscitation; ECPR, extracorporeal membrane oxygenation assisted cardiopulmonary resuscitation; METs, medical emergency teams.

failure or shock) uncoupling metabolic delivery and metabolic demand. Pediatric patients who suffer an IHCA often have changes in their physiological status in the hours leading up to their arrest event [42,43]. Therefore, interventions during the prearrest phase focus on preventing the cardiac arrest, with special attention to early recognition and targeted treatment of respiratory failure and shock. Early recognition plays a key role in identifying a prearrest state in children, who unlike adults may be able to mount a prolonged physiological response to a worsening clinical picture. Medical Emergency Teams (METs) (also known as Rapid Response Teams) are in-hospital emergency teams designed specifically for this purpose. Front-line providers, and even parents, are encouraged to initiate evaluation by METs based on physiological protocol-driven parameters or even intuition. Patients are assessed by the METs and those at high risk of clinical decompensation are transferred to a pediatric intensive care unit if necessary, with the goal to prevent progression to full cardiac arrest or to decrease the response time to initiation of advanced life support, thereby limiting the no flow state. Implementation of METs decreases the frequency of cardiac arrests compared with retrospective control periods before MET initiation [16,44,45]. While early recognition protocols cannot identify all children at risk for cardiac arrest, it seems reasonable to assume that transferring critically ill children to an ICU early in their disease process for better monitoring and more aggressive interventions can improve resuscitative care and clinical outcomes. The caveat is that prearrest states must be identified to initiate monitoring and interventions that may inhibit the progression to an arrest. While a significant amount of research dollars and resources are spent on the other phases of cardiac arrest, particular focus on the prearrest state may yield the greatest improvement in survival and neurological outcomes.

In highly monitored settings such as a pediatric cardiac ICU, new approaches using real-time predictive analytics may be able to identify patients at highest risk for cardiopulmonary deterioration. Using a retrospective analysis of high-resolution physiological recordings, a risk index consisting of heart rate and heart rate variability, respiratory rate variability, ST segment variability, and SpO_2, a logistic regression model was created in 25 single-ventricle infants after neonatal cardiac surgery, mostly Stage I palliation for hypoplastic left heart syndrome. Twenty cardiorespiratory deterioration events (respiratory failure or arrest, or cardiac arrest) were identified in 13 patients, and an increased risk index 1–2 h before the event could detect an impending arrest with high reliability (receiver operator curve (ROC) area 0.91) [46]. In the same group of patients, utilizing three-dimensional ST-segment vector magnitude and instability alone in the 4 h window before arrest also predicted the event (ROC area 0.81) [47]. If these algorithms were validated prospectively to predict cardiac arrest in these vulnerable patients, crucial improvements in early warning could occur in monitored settings.

No flow/low flow

In order to improve outcomes from pediatric cardiac arrest, it is imperative to shorten the no-flow phase of untreated cardiac arrest. To that end, it is important to monitor high-risk patients to allow early recognition of the cardiac arrest and prompt initiation of basic and advanced life support. Effective CPR optimizes coronary perfusion pressure (by elevating aortic diastolic pressure relative to right atrial pressure) and cardiac output to critical organs to support vital organ viability (by elevating mean aortic pressure) during the low-flow phase. Important tenets of basic life support are: push hard, push fast, allow full chest recoil between compressions, and minimize interruptions of chest compression. The myocardium receives blood flow from the aortic root, mainly during diastole, via the coronary arteries. When the heart arrests and no blood flows through the aorta, coronary blood flow ceases. However, during chest compressions, aortic pressure rises at the same time as right atrial pressure and with the subsequent decompression phase of chest compressions, the right atrial pressure falls faster and lower than the aortic pressure, which generates a pressure gradient that perfuses the heart with oxygenated blood. Therefore, full elastic recoil (release) is critical to create a pressure difference between the aortic root and the right atrium. A coronary perfusion pressure (CPP) below 15 mmHg during CPR is a poor prognostic factor for ROSC. Higher values are associated with increased likelihood of ROSC in experimental and clinical settings

[48–51]. Thus, while chest compressions primarily serve to provide an interim source of cardiac output during cardiac arrest, vasopressor administration specifically targets the augmentation of systemic vascular resistance to increase CPP and facilitate ROSC. Achieving optimal CPP, exhaled CO_2 concentration, and cardiac output during the low-flow phase of CPR is consistently associated with an improved chance for ROSC and improved short- and long-term outcome in mature animal and human studies [48,51–57]. There is a critical need for research evaluating goal-directed CPR, both in immature animal models and pediatric patients. Other measures essential for truncating the no-flow phase during VF and pulseless VT are rapid detection and prompt defibrillation. Clearly, CPR alone is inadequate for successful resuscitation from these arrhythmias. For cardiac arrests resulting from asphyxia and/or ischemia, provision of adequate myocardial perfusion and myocardial oxygen delivery are the critical elements for ROSC.

Postarrest/resuscitation

The postarrest/resuscitation phase includes coordinated, skilled management of the immediate postresuscitation stage, the next few hours to days, and long-term rehabilitation. The immediate postresuscitation stage is a high-risk period for ventricular arrhythmias and other reperfusion injuries. Goals of interventions implemented during the immediate postresuscitation stage and the next few days include: adequate tissue oxygen delivery, treatment of postresuscitation myocardial dysfunction, and minimizing postresuscitation tissue injury (e.g. preventing postresuscitation hyperthermia and hypoglycemia; and, perhaps, initiating postresuscitation therapeutic hypothermia, preventing hyperglycemia, and avoiding hyperoxia). This postarrest/resuscitation phase may have the greatest potential for innovative advances in the understanding of cell injury (excitotoxicity, oxidative stress, metabolic stress) and cell death (apoptosis and necrosis) ultimately leading to novel molecular-targeted interventions. The rehabilitation stage concentrates on salvage of injured cells and support for reengineering of reflex and voluntary communications of these cell and organ systems to improve long-term functional outcome.

The specific phase of resuscitation dictates the focus of care. Interventions that improve outcome during one phase may be deleterious during another. For instance, intense vasoconstriction during the low-flow phase of cardiac arrest improves coronary perfusion pressure and the probability of ROSC. The same intense vasoconstriction during the postresuscitation phase increases left ventricular afterload and may worsen myocardial strain and dysfunction. Current understanding of the physiology of cardiac arrest and recovery allows us only to crudely manipulate blood pressure, oxygen delivery and consumption, body temperature, and other physiological parameters in our attempts to optimize outcome. Future strategies likely will take advantage of increasing knowledge of cellular injury, thrombosis, reperfusion, mediator cascades, cellular markers of injury and recovery, and transplantation technology, including stem cells.

KEY POINTS: PHASES OF RESUSCITATION

- The four phases of cardiac arrest and CPR are: (1) prearrest, (2) no flow (untreated cardiac arrest), (3) low flow (CPR), and (4) postresuscitation/arrest
- Interventions during the prearrest phase focus on preventing cardiac arrest, with early recognition and treatment of respiratory failure and shock
- The important tenets of basic life support are: push hard, push fast, allow full chest recoil between compressions, and minimize interruptions
- Goals during the postresuscitation stage include: adequate tissue oxygen delivery, treatment of myocardial dysfunction, and minimizing tissue injury (e.g. preventing hyperthermia and hypoglycemia, and preventing hyperglycemia and avoiding hyperoxia)

Interventions during the cardiac arrest (no-flow) and cardiopulmonary resuscitation (low-flow) phases

The components of high-quality CPR are: (1) ensuring adequate rate of chest compressions; (2) ensuring adequate depth of chest compressions; (3) allowing full chest recoil between chest compressions; (4) minimizing interruptions in chest compressions; and (5) avoiding excessive ventilation [58].

A-B-C or C-A-B

For OHCA victims, "compression-only" CPR has been associated with improved outcomes [59,60]. This is now the recommended modality for emergency medical service dispatcher instructing bystander CPR [61]. In a recent Japanese study, children with OHCA due to a primary cardiac etiology displayed an equivalent survival rate between compression-only CPR and classic CPR with rescue breaths. However, only 29% of patients had a cardiac cause of OHCA. Those with non-cardiac etiology in the overall cohort had a significantly worse survival rate with compression-only CPR, as compared to classic CPR with rescue breaths [40]. Additionally, in another nationwide Japanese OHCA registry study, compression-only CPR was superior to no bystander CPR at all but not to conventional CPR [62]. In a recent American OHCA registry study, children who received conventional bystander CPR with chest compressions and rescue breaths had improved rates of overall survival and survival with favorable outcomes as compared to those who did not receive CPR, whereas those receiving compression-only CPR did not fare any better than children not receiving CPR [63]. Thus, compression-only CPR is not recommended for children in either the inpatient or out-of-hospital setting, except in situations in which "rescuers are unwilling or unable to deliver breaths" [58].

Regardless, the prioritization of initial interventions during CPR has shifted from Airway-Breathing-Circulation ("A-B-C") to Circulation-Airway-Breathing ("C-A-B") in order to prevent harmful delays in the initiation of chest compressions and due to the relative complexity of the tasks involved in providing assisted ventilation. This is endorsed by both the

2010 and 2015 AHA BLS Guidelines [58,64]. However, a 2015 International Liaison Committee on Resuscitation consensus statement identified a paucity of pediatric-specific evidence to support this recommendation [65]. In our opinion, the approach is physiologically sound, especially given the association of delayed chest compression initiation with poor outcomes. With that said, the pediatric provider must consider the predominance of asphyxia and hypoxemia as precursors to cardiac arrest [1,20]. This is especially true in the ICU and operating room, where personnel and other resources frequently allow for simultaneous circulatory support with high-quality chest compressions as well as the provision of assisted ventilations by experienced personnel.

Airway and breathing

Establishing an airway with effective gas exchange as soon as possible is critical for the success of resuscitation. Establishing a patent airway with bag-valve-mask ventilation and 100% oxygen is an initial step in resuscitation, followed by endotracheal intubation as soon as possible, with minimal interruption in chest compressions. Colorimetric CO_2 detectors for exhaled gas are standard of care for pediatric CPR [41]. Absence of CO_{2in} exhaled gas may mean the endotracheal tube is in the esophagus, or that CPR is ineffective and there is no, or very low pulmonary blood flow for gas exchange to occur. If CO_2 is absent, direct laryngoscopy by an experienced clinician is performed immediately. If the tube is properly positioned in the trachea, attention is turned to the effectiveness of chest compresions. Persistence of adequate levels of end-tidal CO_2 during CPR is a favorable prognostic factor for ROSC [42,43].

During CPR, cardiac output and pulmonary blood flow are approximately 10–25% of those during normal sinus rhythm; therefore, a lower minute ventilation is necessary for adequate gas exchange from the blood traversing the pulmonary circulation. Animal and adult data indicate that hyperventilation ("overventilation" from exuberant rescue breathing) during CPR is common and can substantially compromise venous return and subsequently cardiac output [66–68]. These detrimental hemodynamic effects are compounded when one considers the effect of interruptions in CPR to provide airway management and rescue breathing and may contribute to worse survival outcomes [69–72]. While overventilation is problematic, in light of the fact that most pediatric arrests are asphyxial in nature (90% of arrests begin with respiratory insufficiency), immediate initiation of *adequate* ventilation is still important. The difference between arrhythmogenic and asphyxial arrests lies in the physiology. In animal models of sudden VF cardiac arrest, acceptable PaO_2 and $PaCO_2$ persist for 4–8 min during chest compressions without rescue breathing [73,74]. This is in part because aortic oxygen and CO_2 concentrations at the onset of the arrest do not vary much from the prearrest state with no blood flow and minimal aortic oxygen consumption. The lungs act as a reservoir of oxygen during the low-flow state of CPR; therefore, adequate oxygenation and ventilation can continue without rescue breathing. Several retrospective studies of witnessed VF cardiac arrest in adults have also shown that outcomes are similar after bystander-initiated CPR with either chest compressions alone or chest compressions plus rescue breathing [49]. However, during asphyxial arrest, peripheral and pulmonary blood flow continues during the prearrest state resulting in significant arterial and venous oxygen desaturation, elevated lactate levels, and depletion of the pulmonary oxygen reserve. Therefore, at the onset of CPR, there is substantial arterial hypoxemia and resulting acidemia. In this circumstance, rescue breathing with controlled ventilation can be a life-saving maneuver. In contrast, the adverse hemodynamic effects from overventilation during CPR combined with possible interruptions in chest compressions to open the airway and deliver rescue breathing are a lethal combination in certain circumstances such as VT/VF arrests. In short, the resuscitation technique should be titrated to the physiology of the patient to optimize patient outcome, with rapid, efficient, skilled airway management with minimal interruption of chest compressions a cornerstone of success in pediatric resuscitation.

Circulation

Optimizing blood flow during low-flow cardiopulmonary resuscitation: push hard, push fast

When the heart arrests, no blood flows to the aorta and coronary blood flow ceases immediately [49]. At that point, provision of high-quality CPR (push hard, push fast) is vital to re-establish coronary flow. The goal during CPR is to maximize the myocardial perfusion pressure (MPP). Related by the equation MPP = aortic diastolic blood pressure (AoDP) minus right atrial pressure (RAP), myocardial blood flow improves as the gradient between AoDP and RAP increases. During the downward compression phase, aortic pressure rises at the same time as RAP with little change in the MPP. However, during the decompression phase of chest compressions, RAP falls faster and lower than the aortic pressure, which generates a pressure gradient perfusing the heart with oxygenated blood during this artificial period of "diastole." Several animal and human studies have demonstrated, in both VT/VF and asphyxial models, the importance of establishing MPP as a predictor for short-term survival outcome (ROSC) [51,75–78]. Because there is no flow without chest compressions, it is important to minimize interruptions in chest compressions. To allow good venous return in the decompression phase of external cardiac massage, it is also important to allow full chest recoil and to avoid overventilation (preventing adequate venous return because of increased intrathoracic pressure).

Based on the equation in the previous paragraph, MPP can be improved by strategies that increase the pressure gradient between the aorta and the right atrium. As an example, the inspiratory impedence threshold device (ITD) is a small, disposable valve that can be connected directly to the tracheal tube or facemask to augment negative intrathoracic pressure during the inspiratory phase of spontaneous breathing and the decompression phase of CPR by impeding airflow into the lungs. Application in animal and adult human trials of CPR has established the ability of the ITD to improve vital organ perfusion pressures and myocardial blood flow [72,79–83]; however, in the only randomized trial during adult CPR, mortality benefit was limited to the subgroup of patients with PEA [83]. Additional evidence that augmentation of negative intrathoracic pressure can improve perfusion pressures

during CPR comes from the active compression-decompression device (ACD). The ACD is a handheld device that is fixed to the anterior chest of the victim by means of suction similar to a household plunger that can be used to apply active decompression forces during the release phase, thereby creating a vacuum within the thorax. By actively pulling during the decompression phase, blood is drawn back into the heart by the negative pressure [84]. Animal and adult studies have demonstrated that the combination of ACD and ITD acts in concert to further improve perfusion pressures during CPR compared to ACD alone [81]. In the end, while novel interventions such as the ITD and ACD are promising adjuncts to improve blood flow during CPR, the basic tenets of *push hard, push fast, allow full chest wall release, minimize interruptions, and don't overventilate* are still the dominant factors to improve blood flow during CPR and chance of survival.

Chest compression depth

The pediatric chest compression depth recommendation of at least one-third anterior–posterior (AP) chest depth (approximately 4 cm in infants and 5 cm in children) is based largely upon expert clinical consensus, using data extrapolated from animal, adult, and limited pediatric data. In a small study of six infants, chest compressions targeted to one-half AP chest depth resulted in improved systolic blood pressures compared to those targeted at one-third AP chest depth [85]. While only a small series with qualitatively estimated chest compression depths, this is the first study to collect actual data from children supporting the existing chest compression depth guidelines. In contrast, two studies using computed axial automated tomography (CT) [86,87] suggest that depth recommendations based on a relative percentage of AP chest compression depth are deeper than those recommended for adults, and that a depth of one-half AP chest depth will result in direct compression to the point of fully emptying the heart and requisite shifting of the heart because of inadequate AP diameter reserve in most children. Future studies that collect data from actual children and that associate quantitatively measured chest compression depths with short- and long-term clinical outcomes (arterial blood pressure, end tidal CO_2, ROSC, survival) are needed.

Compression/ventilation ratios

The amount of ventilation provided during CPR should match, but not exceed, perfusion and should be titrated to the amount of circulation during the specific phase of resuscitation as well as the metabolic demand of the tissues. Therefore, during the low-flow state of CPR when the amount of cardiac output is roughly 10–25% of normal, less ventilation is needed [88]. However, the best ratio of compressions to ventilations in pediatric patients is largely unknown and depends on many factors including the compression rate, the tidal volume, the blood flow generated by compressions, and the time that compressions are interrupted to perform ventilation. Recent evidence demonstrates that a compression/ventilation ratio of 15:2 delivers the same minute ventilation and increases the number of delivered chest compressions by 48% compared to CPR at a compression/ventilation ratio of 5:1 in a simulated pediatric arrest model [89,90]. This is important because, when chest compressions cease, the aortic pressure rapidly decreases and coronary perfusion pressure falls precipitously, thereby decreasing myocardial oxygen delivery [49]. Increasing the ratio of compressions to ventilations minimizes these interruptions, thus increasing coronary blood flow. The benefits of positive pressure ventilation (increased arterial content of oxygen and CO_2 elimination) must be balanced against the adverse consequence of decreased circulation. These findings are in part the reason why the AHA now recommends a pediatric compression/ventilation ratio of 15:2 for two rescuers and 30:2 for a single rescuer.

Duty cycle

In a model of human adult cardiac arrest, cardiac output and coronary blood flow are optimized when chest compressions last for 30% of the total cycle time (approximately 1:2 ratio of time in compression to time in relaxation) [91]. As the duration of CPR increases, the optimal duty cycle may increase to 50%. In a juvenile swine model, a relaxation period of 250–300 ms (duty cycle of 40–50% at a compression rate of 120 per min) correlates with improved cerebral perfusion pressures compared with shorter duty cycles of 30% [92].

Circumferential versus focal sternal compressions

In adult and animal models of cardiac arrest, circumferential (vest) CPR has been demonstrated to dramatically improve CPR hemodynamics [93]. In smaller infants, it is often possible to encircle the chest with both hands and depress the sternum with the thumbs, while compressing the thorax circumferentially (thoracic squeeze). In an infant animal model of CPR, this "two-thumb" method of compression with thoracic squeeze resulted in higher systolic and diastolic blood pressures and a higher pulse pressure than traditional two-finger compression of the sternum [94]. Although not rigorously studied, our clinical experience indicates that it is very difficult to attain adequate chest compression force and adequate aortic pressures with the two-finger technique, so we fully support the AHA guidelines for healthcare providers to perform CPR on infants with the two-thumb encircling hands technique [95].

Open-chest cardiopulmonary resuscitation

In animal models, high-quality standard, closed-chest CPR generates myocardial blood flow that is >50% of normal, cerebral blood flow that is approximately 50% of normal, and cardiac output ~10–25% of normal [49,76,96,97]. By contrast, open-chest CPR can generate myocardial and cerebral blood flow that approaches normal. Although open-chest massage improves coronary perfusion pressure and increases the chance of successful defibrillation in animals and humans [98–100], performing a thoracotomy to allow open-chest CPR is impractical in many situations. A retrospective review of 27 cases of CPR following pediatric blunt trauma (15 with open-chest CPR and 12 with closed-chest CPR) demonstrated that open-chest CPR increased hospital cost without altering rates of ROSC or survival to discharge. However, survival in both groups was 0%, indicating that the population may have been too severely injured or too late in the process to benefit from this aggressive therapy [101]. Open-chest CPR is often provided to children after open-heart cardiac surgery and sternotomy. Earlier institution of open-chest CPR may warrant reconsideration in selected special resuscitation circumstances.

Vascular access

Obtaining vascular access is obviously crucial to the success of resuscitation. Standard peripheral venous access is the first technique to consider. Ultrasound for guidance may also be used with teams that are proficient in the method. Infants and children, especially hospitalized children and those with multiple previous medical interventions, often have poor peripheral venous access, and it is not uncommon, even with IHCA, to encounter a patient without venous access. In this situation intraosseous (IO) infusion has become the recommended practice, supported by decades of animal study and clinical use [41,81]. Intraosseous needles (14, 16, and 18 gauge) should be kept on all CPR carts, and the flat surface of the proximal tibia is utilized. The needle is placed perpendicular to the bone and inserted with a twisting, "boring" motion until a loss of resistance heralding perforation of the bony cortex into cancellous bone. In infants and young children, active bone marrow hematopoiesis is occurring, and removal of the IO needle stylet and aspiration of bone marrow signifies successful placement. After rapid flush of 5–10 mL normal saline, resuscitation drugs and fluids can be administered IO, all followed by rapid flush with saline. These drugs include epinephrine, atropine, antiarrhythmic agents, naloxone, and dextrose. Fluids and blood can also be administered and blood samples can be obtained for laboratory studies. Caution must be exercised to detect extravasation of fluid into surrounding tissues. Standard venous access must be obtained as soon as possible. Central venous access is often difficult to obtain during resuscitation, and IO access is preferred. Venous access attempts should not interfere with chest compressions. See Chapter 19 for additional information about IO access.

Medications used to treat cardiac arrest

While animal studies have indicated that epinephrine can improve initial resuscitation success after both asphyxial and VF cardiac arrest, there are no prospective studies to support the use of epinephrine or any other medication to improve survival outcome from pediatric cardiac arrest. A variety of medications are used during pediatric resuscitation attempts including vasopressors (epinephrine and vasopressin), antiarrhythmics (amiodarone and lidocaine), and other drugs such as calcium chloride and sodium bicarbonate. Each will be discussed separately in this section.

Vasopressors

Epinephrine (adrenaline) is an endogenous catecholamine with potent α- and β-adrenergic stimulating properties. The α-adrenergic action (vasoconstriction) increases systemic and pulmonary vascular resistance. The resultant higher AoDP improves coronary perfusion pressure and myocardial blood flow even though it reduces global cardiac output during CPR; as noted above, adequacy of myocardial blood flow is a critical determinant of ROSC. Epinephrine also increases cerebral blood flow during good-quality CPR because peripheral vasoconstriction directs a greater proportion of flow to the cerebral circulation [102–104]. However, recent evidence suggests that epinephrine can decrease local cerebral microcirculatory blood flow at a time when global cerebral flow is increased [105]. The β-adrenergic effect increases myocardial contractility and heart rate, and relaxes smooth muscle in the skeletal muscle vascular bed and bronchi; however, the β-adrenergic effects are not observed in the peripheral vascular beds secondary to the high dose used in cardiac arrest. Epinephrine also increases the vigor and intensity of VF, increasing the likelihood of successful defibrillation. High-dose epinephrine (0.05–0.2 mg/kg) improves myocardial and cerebral blood flow during CPR more than standard-dose epinephrine (0.01–0.02 mg/kg) in animal models of cardiac arrest and may increase the incidence of initial ROSC [106,107]. However, prospective and retrospective studies have indicated that the use of high-dose epinephrine in adults or children does not improve survival and may be associated with worse neurological outcome [108,109]. A randomized, blinded, controlled trial of rescue high-dose epinephrine versus standard-dose epinephrine after failed initial standard-dose epinephrine in pediatric IHCA demonstrated a worse 24 h survival in the high-dose epinephrine group (1 of 27 survivors versus 6 of 23 survivors, $p < 0.05$) [110]. Based on these clinical studies, high-dose epinephrine cannot be recommended routinely for either initial or rescue therapy. Importantly, these studies indicate that high-dose epinephrine can worsen a patient's postresuscitation hemodynamic condition and likelihood of survival.

Vasopressin is a long-acting endogenous hormone that acts at specific receptors to mediate systemic vasoconstriction (V_1 receptor) and reabsorption of water in the renal tubule (V_2 receptor). Vasoconstrictive properties are most intense in the skeletal muscle and skin vascular beds. Unlike epinephrine, vasopressin is not a pulmonary vasoconstrictor. In experimental models of cardiac arrest, vasopressin increases blood flow to the heart and brain and improves long-term survival compared with epinephrine. However, vasopressin was formerly recommended as an alternative to epinephrine in adult cardiac arrest [111], but was removed from 2015 guidelines due to a lack of survival advantage over epinephrine alone [112,113]. Due to a paucity of pediatric data and an association with lower rates of ROSC in an AHA GWTG-R study [114], vasopressin has not been recommended during cardiac arrest in children. Although there are potentially candidates with epinephrine-refractory low systemic vascular resistance during CPR that could benefit from the addition of vasopressin, this has not yet been elucidated.

Antiarrhythmic medications

Amiodarone has been the long-standing first-line agent for shock-refractory VF or pVT [115]. In a 2014 GWTG-R registry study, the use of lidocaine in these circumstances was associated with an increased likelihood of ROSC [116]. It is still unclear if one therapeutic has a clear advantage over the other. Current AHA guidelines now recommend either amiodarone or lidocaine for shock-refractory VF or pVT [8].

Calcium

Calcium is used frequently in cases of pediatric cardiac arrest, despite the lack of evidence for efficacy. In the absence of a documented clinical indication (i.e. hypocalcemia, calcium channel blocker overdose, hypermagnesemia, or hyperkalemia), administration of calcium does not improve outcomes from cardiac arrest [117–125]. To the contrary, three pediatric studies have suggested a potential for harm, as routine calcium administration was associated with decreased survival rates and/or worse neurological outcomes [117–125]. Despite limited clinical

data to support the use of calcium during CPR, it is reasonable to consider calcium administration during CPR for cardiac arrest patients at high risk of hypocalcemia (e.g. renal failure, shock associated with massive transfusion) and in combination with laboratory values obtained during arrest.

Buffer solutions

There are no randomized controlled studies in children examining the use of sodium bicarbonate for management of pediatric cardiac arrest. Two randomized controlled studies have examined the value of sodium bicarbonate in the management of adult cardiac arrest [126] and in neonates with respiratory arrest in the delivery room [127]. Neither study was associated with improved survival. In fact, one multicenter retrospective in-hospital pediatric study found that sodium bicarbonate administered during cardiac arrest was associated with decreased survival, even after controlling for age, gender, and first documented cardiac rhythm [124]. Therefore, the routine use of sodium bicarbonate is not recommended during pediatric cardiac arrest resuscitation. Clinical trials involving critically ill adults with severe metabolic acidosis do not demonstrate a beneficial effect of sodium bicarbonate on hemodynamics despite correction of acidosis [128,129]. This is somewhat surprising in light of data that severe acidosis may depress the action of catecholamines and worsen myocardial function [130,131]. Nevertheless, the common use of sodium bicarbonate during CPR is not supported by clinical data. Pediatric patients with implanted cardiac pacemakers may have an increased threshold for myocardial electrical stimulation when acidotic [132], therefore administration of bicarbonate or another buffer is appropriate for management of severe documented acidosis in these children. Administration of sodium bicarbonate also is indicated in the patient with a tricyclic antidepressant overdose, hyperkalemia, hypermagnesemia, or sodium channel blocker poisoning. The buffering action of bicarbonate occurs when a hydrogen cation and a bicarbonate anion combine to form carbon dioxide and water. Carbon dioxide must be cleared through adequate minute ventilation; thus, if ventilation is impaired during sodium bicarbonate administration, carbon dioxide build-up may negate the buffering effect of bicarbonate. Because carbon dioxide readily penetrates cell membranes, intracellular acidosis may paradoxically increase after sodium bicarbonate administration without adequate ventilation. Therefore, bicarbonate should not be used for management of respiratory acidosis.

KEY POINTS: INTERVENTIONS DURING CARDIAC ARREST AND CPR

- Compression-only CPR is not recommended for children, except in situations in which "rescuers are unwilling or unable to deliver breaths"
- Resuscitation technique should aim to optimize patient outcome, with rapid, efficient, skilled airway management and minimal interruption of chest compressions
- The basic tenets of CPR are: *push hard, push fast, allow full chest wall release, minimize interruptions, and don't overventilate*
- Current AHA guidelines recommend either amiodarone or lidocaine for shock-refractory VF or pVT

Postresuscitation interventions

Temperature management

Observational studies of children treated with therapeutic hypothermia have not demonstrated improvement in mortality or neurological outcomes [133,134], although fever after cardiac arrest is common and associated with worsened neurological outcomes [135]. The Therapeutic Hypothermia After Cardiac Arrest (THAPCA) trial in pediatric OHCA reported no improvement with hypothermia as compared to normothermia, although there was a non-significant trend toward improved rates of survival with hypothermia [136]. The IHCA arm of THAPCA likewise failed to demonstrate a benefit in survival with favorable functional outcome with hypothermia as compared to normothermia, and was terminated because of futility [137]. Current pediatric advanced life support (PALS) guidelines for the temperature management of comatose patients call for the aggressive treatment of post-ROSC fever (>38°C) and 5 days of normothermia (36–37.5°C). In OHCA specifically, 2 days of hypothermia (32–34°C) followed by 3 additional days of normothermia can be considered, although evidence is lacking to support hypothermia over normothermia. Continuous temperature monitoring and aggressive treatment of post-ROSC fever are Class I recommendations [8].

Glucose control

Both hyperglycemia and hypoglycemia following cardiac arrest are associated with worse neurological outcome [138–141]. While it seems intuitive that hypoglycemia would be associated with worse neurological outcome, whether hyperglycemia *per se* is harmful or is simply a marker of the severity of the stress hormone response from prolonged ischemia is not clear. In critically ill adult patients, tight glucose control using an insulin infusion was associated with improved survival [142,143]. However, subsequent studies of non-surgical adult populations and neonatal/pediatric trials have demonstrated no survival benefit and the potential for harm from attempts at tight glucose control because of high rates of inadvertent hypoglycemia [138,144–150]. In summary, there is insufficient evidence to formulate a strong recommendation on the management of hyperglycemia in children with ROSC following cardiac arrest. If hyperglycemia is treated following ROSC in pediatric patients, blood glucose concentrations should be carefully monitored to avoid hypoglycemia.

Blood pressure management

A patient with ROSC may have substantial variability in blood pressure following cardiac arrest. Postarrest/resuscitation myocardial dysfunction is very common and is often associated with hypotension) [151–162]. In addition, hypertension may occur, especially if the patient receives vasoactive infusions for postarrest myocardial dysfunction. Optimization of blood pressure post arrest is critical to maintain adequate perfusion pressure to vital organs that may have already been injured from the "no-flow" and "low--flow" states during initial cardiac arrest and CPR. Cerebral blood flow in healthy patients is tightly controlled over a wide range of mean arterial blood pressure via the cerebral neurovascular bundle

(autoregulation); however, adults resuscitated from cardiac arrest have demonstrated impaired autoregulation of cerebral blood flow and this may also be the case in children [163]. Dysautoregulation of the cerebral neurovascular bundle following cardiac arrest may limit the brain's ability to regulate excessive blood flow and microvascular perfusion pressure, thereby leading to reperfusion injury during systemic hypertension. However, in animal models, brief induced hypertension following resuscitation results in improved neurological outcome compared with normotensive reperfusion [164,165]. Conversely, systemic hypotension may perpetuate neurological metabolic crisis following ischemic injury by uncoupling bioenergetic demand and delivery. Therefore, a practical approach to blood pressure management following cardiac arrest is to attempt to minimize blood pressure variability in this high-risk period following resuscitation.

Postresuscitation myocardial dysfunction

Postarrest myocardial stunning and arterial hypotension occur commonly after successful resuscitation in both animals and humans [151–162]. Animal studies demonstrate that postarrest myocardial stunning is a global phenomenon with biventricular systolic and diastolic dysfunction. Postarrest myocardial stunning is pathophysiologically and physiologically similar to sepsis-related myocardial dysfunction and post-cardiopulmonary bypass myocardial dysfunction, including increases in inflammatory mediators and nitric oxide production [154,157,158,160]. Because cardiac function is essential to reperfusion following cardiac arrest, management of postarrest myocardial dysfunction may be important to improving survival. The classes of agents used to maintain circulatory function (i.e. inotropes, vasopressors, and vasodilators) must be carefully titrated during the postresuscitation phase to the patient's cardiovascular physiology. Although the optimal management of post-cardiac arrest hypotension and myocardial dysfunction has not been established, data suggest that aggressive hemodynamic support may improve outcomes. Controlled trials in animal models have shown that dobutamine, milrinone, and levosimendan can effectively ameliorate post-cardiac arrest myocardial dysfunction [151,152,166,167]. In clinical observational studies, fluid resuscitation has been provided for patients with hypotension and concomitant low central venous pressure, and various vasoactive infusions, including epinephrine, dobutamine, and dopamine, have been used to treat the myocardial dysfunction syndrome [155–159,161,162]. In the end, optimal use of these agents involves close goal-directed titration, and the use of invasive hemodynamic monitoring may be appropriate. General critical care principles suggest that appropriate therapeutic goals are adequate blood pressures and adequate oxygen delivery. However, the definition of "adequate" is elusive. Studies in large animals have shown that with even optimal resuscitation there is still persistent mitochondrial and metabolic injury from ischemia and reperfusion [168,169]. Reasonable interventions for vasodilatory shock with low central venous pressure include fluid resuscitation and vasoactive infusions. Appropriate considerations for left ventricular myocardial dysfunction include euvolemia, inotropic infusions, and afterload reduction.

Neuromonitoring

Continuous neuromonitoring and goal-directed intervention following cardiac arrest is an exciting frontier with great promise in improving neurological outcomes post-cardiac arrest [170]. Continuous electroencephalography (cEEG) monitoring is an increasingly instituted modality for neuromonitoring of critically ill patients, especially to diagnose non-convulsive seizures (NCS) and seizures in patients receiving muscle relaxants. cEEG monitoring is non-invasive, performed at the bedside, and permits continuous assessment of cortical function. Interpretation of continuous EEG is usually performed by a neurologist from a remote location, and not bedside critical care physicians. However, advances in quantitative EEG tools may allow bedside caregivers to identify important electrographic events, such as seizures or abrupt background changes, to potentially permit real-time analysis and intervention [171]. In a prospective study of cEEG in children, non-convulsive seizures were detected in 39% (12 of 31) children following cardiac arrest [172]. In a partially overlapping cohort of 19 children, NCS were common in children undergoing therapeutic hypothermia after cardiac arrest [172]. NCS seems to be a common occurrence following cardiac arrests in children. Although the relationship of NCS to worse outcomes has not been established in pediatric patients following cardiac arrest, it has been associated with worse outcomes among critically ill adults and neonates [173–179]. We believe that cEEG should be considered for children post-cardiac arrest and that patients with NCS (especially status epilepticus with NCS) should be treated with anticonvulsant medication. Further study is warranted to better establish frequency of NCS and potential benefit in outcomes with anticonvulsant therapy.

Oxidative injury may be greatest in the early phases of postresuscitation therapy following cardiac arrest [180]. Interestingly, the use of 100% oxygen (compared to room air) during and immediately following resuscitation in animal models may potentiate oxidative injury to key mitochondrial enzymes (pyruvate dehydrogenase or manganese superoxide) or mitochondrial lipids (cardiolipin) and is associated with worse neurological outcomes [181–184]. Experimental protocols in large animals using peripheral pulse oximetry to titrate oxygenation in the postresuscitation phase can reduce postresuscitation hyperoxia and significantly improve neuropathology and neurobehavioral outcomes [185]. Consistent with these experimental findings, arterial hyperoxia (PaO_2 ≥300 mmHg) was independently associated with in-hospital mortality compared with either hypoxia or normoxia in an observational study among critically ill adult patients admitted to the ICU within 24 h of a cardiac arrest [186]. We believe it is prudent to titrate oxygenation during and following pediatric cardiac arrest. Although the optimal SpO_2 is not known, we recommend titration of FiO_2 to the lowest amount necessary to assure SpO_2 >94%. Perhaps the future of postarrest care will include more aggressive neurocritical care monitoring, such as near-infrared spectroscopy, cerebral microdialysis, brain tissue oxygen saturation ($PbtO_2$), cerebral blood flow, and even bedside analysis of mitochondrial dysfunction. A non-invasive technology, cerebral oximetry, uses near-infrared (NIR) light to measure brain tissue perfusion [187]. Commercially available near-infrared spectroscopy (NIRS) devices emit a continuous wave of light from a source probe

and measure the returning light at a detector probe on the patient's forehead. Cerebral oximetry monitoring during cardiac arrest may be feasible and may not necessarily distract from high-quality CPR [188–191]. Parnia and colleagues performed a multicenter prospective observational study in 2016, representing the largest cohort of adults with cerebral oximetry in place during cardiac arrest [192]. Patients with sustained ROSC had higher overall rSO_2 during CPR (51.8% versus 40.9%, p <0.0001) during this study involving IHCA. Furthermore, patients who survived to hospital discharge with a favorable neurological outcome had higher rSO_2 than those who died in hospital but obtained ROSC (mean rSO_2 56.1% and 50.6%, respectively, p<0.001) and no patients with rSO_2 <25% achieved ROSC. In a meta-analysis performed by Sanfilippo and colleagues in 2015 which included mostly OHCA patients, average rSO_2 for those who achieved ROSC was 44.9%, compared to 29.4% in those who did not have ROSC [193]. Given the variety and technical limitations of commercially-available devices, rSO_2 measurements should be interpreted cautiously. Optimal values of cerebral oxygen saturation are not known. These devices have not been validated against gold-standard measures in the cardiac arrest setting and may not be accurate during periods of diminished blood flow and oxygenation [193–196].

KEY POINTS: POSTRESUSCITATION INTERVENTIONS

- Continuous temperature monitoring and aggressive treatment of post-ROSC fever are Class I recommendations
- If hyperglycemia is treated following ROSC in pediatric patients, blood glucose concentrations should be carefully monitored to avoid hypoglycemia
- Systemic hypotension may perpetuate neurological metabolic crisis following ischemic injury by uncoupling bioenergetic demand and delivery
- General critical care principles suggest that appropriate therapeutic goals are adequate blood pressures and adequate oxygen delivery
- Although the optimal SpO_2 is not known, we recommend titration of FiO_2 to the lowest amount necessary to assure SpO_2 >94%

Other considerations

Quality of cardiopulmonary resuscitation

Despite evidence-based guidelines, extensive provider training, and provider credentialing in resuscitation medicine, the quality of CPR is typically poor. CPR guidelines recommend target values for selected CPR parameters related to rate and depth of chest compressions and ventilations, avoidance of CPR-free intervals, and complete release of sternal pressure between compressions [197]. Slow compression rates, inadequate depth of compression, and substantial pauses are the norm. The approach "*push hard, push fast, minimize interruptions, allow full chest recoil and don't overventilate*" can markedly improve myocardial, cerebral, and systemic perfusion, and will likely improve outcomes [71]. Quality of postresuscitative management has also been demonstrated to be critically important to improve resuscitation survival outcomes [155]. The importance of measuring the quality of CPR and avoiding overventilation during cardiac arrest resuscitation has recently been re-emphasized by consensus of the International Liaison Committee on Resuscitation and the American Heart Association [198]. Although the correct amount, timing, intensity, and duration of ventilation required during CPR are controversial, there is no controversy that measurement and titration of the amount of ventilation to the amount of blood perfusion are desirable. Thus, additional technology that is safe, accurate, and practical would improve detection and feedback of the "quality of CPR."

Recent technology has been developed that monitors quality of CPR by force sensors and accelerometers and can provide verbal feedback to the CPR administrator regarding the frequency and depth of chest compressions and the volume of ventilations. Recent pediatric data illustrate that intensive training and real-time corrective feedback can help chest compression quality approach age-specific AHA CPR guideline targets [199–201]. Moreover, improvements in postresuscitation care can improve resuscitation survival outcomes [155].

Extracorporeal membrane life-saving cardiopulmonary resuscitation

The use of extracorporeal membrane oxygenation (ECMO) life-saving (extracorporeal life support – ECLS) devices as a rescue therapy for refractory cardiac arrest (ECPR) is an exciting topic in resuscitation science. In children with medical or surgical cardiac diseases, ECPR has been shown to improve survival to hospital discharge [202] and can be effective even after more than 50 min of CPR [203]. However, at this time observational data have not consistently demonstrated a survival benefit of ECPR compared to conventional CPR across broad populations [204,205]. Children with primary cardiac disease may have a survival advantage due to these disease processes being amenable to a bridge with ECLS – either to recovery, surgery, or transplantation. There may be an underlying advantage for these patients as well, stemming from predominantly single-organ failure compared to patients with non-cardiac etiologies of cardiac arrest, allowing for a greater chance of full recovery after resuscitation [206]. Importantly, in these observational studies, ECPR is used as a rescue therapy in patients who likely would have died with continued conventional resuscitation efforts [206]. In fact, in a GWTG-R study that looked at both cardiac and non-cardiac patients with >10 min of CPR, those who received ECPR had improved survival and favorable neurological outcome at discharge [207]. The finding of a lack of survival advantage across broad populations in observational studies, even when controlling for confounding factors, is flawed by the nature of these studies [208]. In the absence of randomized controlled trials that specifically compare early initiation of ECPR and conventional CPR, it is probably reasonable to consider ECPR as a rescue therapy in patients with potentially reversible underlying disease processes. However, as noted in PALS guidelines, any

reasonable chance of success requires a setting with "existing ECMO protocols, expertise, and equipment" [8], and dedicated teams that train for efficient cannulation under difficult circumstances. Therefore, timely, quality ECPR may be an exciting adjuvant to conventional CPR for pediatric patients. Future frontiers will define patient populations and optimize the clinical approach to extracorporeal support; however, clinicians providing CPR should consider ECPR early in the course of a resuscitation not responding to conventional CPR. Perhaps after failure to attain ROSC within 5 min, clinicians should ask themselves: (1) does the patient have a potentially reversible process, (2) would ECMO be a "bridge" to a potentially good outcome, and (3) do we have the personnel and resources to provide EMCO promptly? If the answers to all three are "yes," prompt implementation of ECPR should be considered.

Ventricular fibrillation and ventricular tachycardia in children

Pediatric VF or VT has been an underappreciated pediatric problem. Recent studies indicate that VF and VT (i.e. shockable rhythms) occur in 27% of IHCAs at some time during the resuscitation [25]. In a population of pediatric cardiac ICU patients, as many as 41% of arrests were associated with VF or VT [208]. According to the National Registry of Cardiopulmonary Resuscitation (NRCPR) database (https://www.heart.org/en/professional/quality-improvement/get-with-the-guidelines/get-with-the-guidelines-resuscitation/get-with-the-guidelines-resuscitation-overview), 10% of children with IHCA had an initial rhythm of VF/VT. In all, 27% of the children had VF/VT at some time during the resuscitation [209]. The incidence of VF varies by setting and age [210]. In special circumstances, such as tricyclic antidepressant overdose, cardiomyopathy, post cardiac surgery, and prolonged QT syndromes, VF and pVT are more likely.

The treatment of choice for short-duration VF is prompt defibrillation. In general, the mortality rate increases by 7–10% per minute of delay to defibrillation. Because VF must be considered before defibrillation can be provided, early determination of the rhythm by electrocardiography is critical. An attitude that VF is rare in children can be a self-fulfilling prophecy with a uniformly fatal outcome. The recommended defibrillation dose is 2 J/kg, but the data supporting this recommendation are not optimal and are based on old monophasic defibrillators. In the mid-1970s, authoritative sources recommended starting doses of 60–200 J for all children. Because of concerns for myocardial damage and animal data suggesting that shock doses ranging from 0.5 to 1 J/kg were adequate for defibrillation in a variety of species, Gutgesell et al evaluated the efficacy of their strategy to defibrillate with 2 J/kg monophasic shocks. Seventy-one transthoracic defibrillations in 27 children were evaluated. Shocks within 10 J of 2 J/kg resulted in successful defibrillation (i.e. termination of fibrillation) in 91% of defibrillation attempts. More recent data demonstrate that an initial shock dose of 2 J/kg terminates fibrillation in <60% of children, suggesting that a higher dose may be needed [30, 211]. Despite five decades of clinical experience with pediatric defibrillation, the optimal dose remains unknown.

Pediatric automated external defibrillators

Automated external defibrillators (AEDs) have improved adult survival from VF [212,213]. AEDs are recommended for use in children 8 years or older with cardiac arrest [95,214]. The available data suggest that some AEDs can accurately diagnose VF in children of all ages, but many AEDs are limited because the defibrillation pads and energy dosage are geared for adults. Adapters having smaller defibrillation pads that dampen the amount of energy delivered have been developed as attachments to adult AEDs, allowing their use in children. However, it is important that the AED diagnostic algorithm is sensitive and specific for pediatric VF and VT. The diagnostic algorithms from several AED manufacturers have been tested for such sensitivity and specificity and therefore can be reasonably used in younger children.

Simulation and pediatric cardiopulmonary resuscitation

Simulation has achieved an increasingly important place in medical education and training in pediatric anesthesiology and critical care, with resuscitation scenarios among the most frequent programs provided by pediatric simulation centers [185]. Simulation scenarios can reveal gaps in knowledge and technique for physicians. In a study of 20 anesthesia residents in a scenario of hyperkalemic cardiac arrest during anesthesia for a craniotomy for tumor incision in a 1-year-old patient weighing 10 kg resulting in pulseless electrical activity, only one-third of the residents performed chest compressions properly and administered the correct dose of epinephrine. Only one-fourth of the residents considered hyperkalemia as a cause of the arrest, and none asked for dosing aids [186]. In a study of *in situ* simulation training for effective chest compressions in a pediatric ICU, healthcare providers with more frequent exposure to these sessions correctly demonstrated proper chest compressions in significantly less time than those with less frequent exposure to these sessions [169]. See Chapter 47 for a thorough discussion of simulation in pediatric anesthesia.

Intraoperative cardiac arrest

See Chapter 45 for a detailed discussion of the causes of intraoperative cardiac arrest.

When should cardiopulmonary resuscitation be discontinued?

Several factors determine the likelihood of survival after cardiac arrest, including the mechanism of the arrest (e.g. traumatic, asphyxial, progression from circulatory shock), location (e.g. IHCA or OHCA), response (i.e. witnessed or unwitnessed, with or without bystander CPR), underlying pathophysiology (i.e. cardiomyopathy, congenital defect, drug toxicity, or metabolic derangement), and the potential reversibility of underlying diseases. These factors should all be considered before deciding to terminate resuscitative efforts. Continuation of CPR has been traditionally considered futile beyond 15 min or when more than two doses of epinephrine are needed [215]. Presumably in part because of improvements in CPR quality and postresuscitation care, improved outcomes from in-hospital CPR efforts beyond 15 min or two doses of epinephrine are increasingly the norm [20,21]. The potential for excellent outcomes despite prolonged CPR has been highlighted by the ECPR data noted previously [203,216–219]. Recently, Berg and colleagues reported 98% rates of ROSC in patients receiving 1–3 min of CPR as compared to 56% in patients receiving >30 min of CPR. At hospital discharge, survival rates were 66% and 28%, respectively [1]. In a GWTG-R study, children with CPR lasting >35 min had a 16% chance of survival to hospital discharge [220]. While these data may seem discouraging, it is important to consider that these children requiring prolonged CPR actually have better outcomes than pediatric IHCA victims with average durations of CPR just a decade earlier [4]. Thus, we believe that decisions regarding futility of continuing resuscitation efforts should not be based on duration alone.

Quality improvement in cardiac arrest

The 2015 Institute of Medicine report, *Strategies to Improve Cardiac Arrest Survival: A Time to Act*, recommended the adoption of continuous quality improvement programs to improve outcomes from cardiac arrest [221]. Use of quality improvement strategies has been associated with improved outcomes [222]. For example, the provision of formalized non-punitive feedback and the implementation of multidisciplinary postarrest debriefing have been effective at improving CPR quality and are associated with improved rates of survival to discharge in pediatric IHCA [223,224].

Postarrest prognostication

Following ROSC, a number of findings have been associated with survival and neurological outcomes. These include pupillary responses [225,226] serum biomarkers such as neuron-specific enolase and S100B [227,228], serum lactate levels [229], EEG findings [225,230], somatosensory evoked potentials [231], neuroimaging studies [232], non-invasive cerebral tissue oxygenation [192,233], and the presence or absence of hypotension [234]. Importantly, the data supporting the application of these tools as prognosticators are not as robust in children as they are in adults, and each patient's overall clinical status after cardiac arrest must be considered over any one finding.

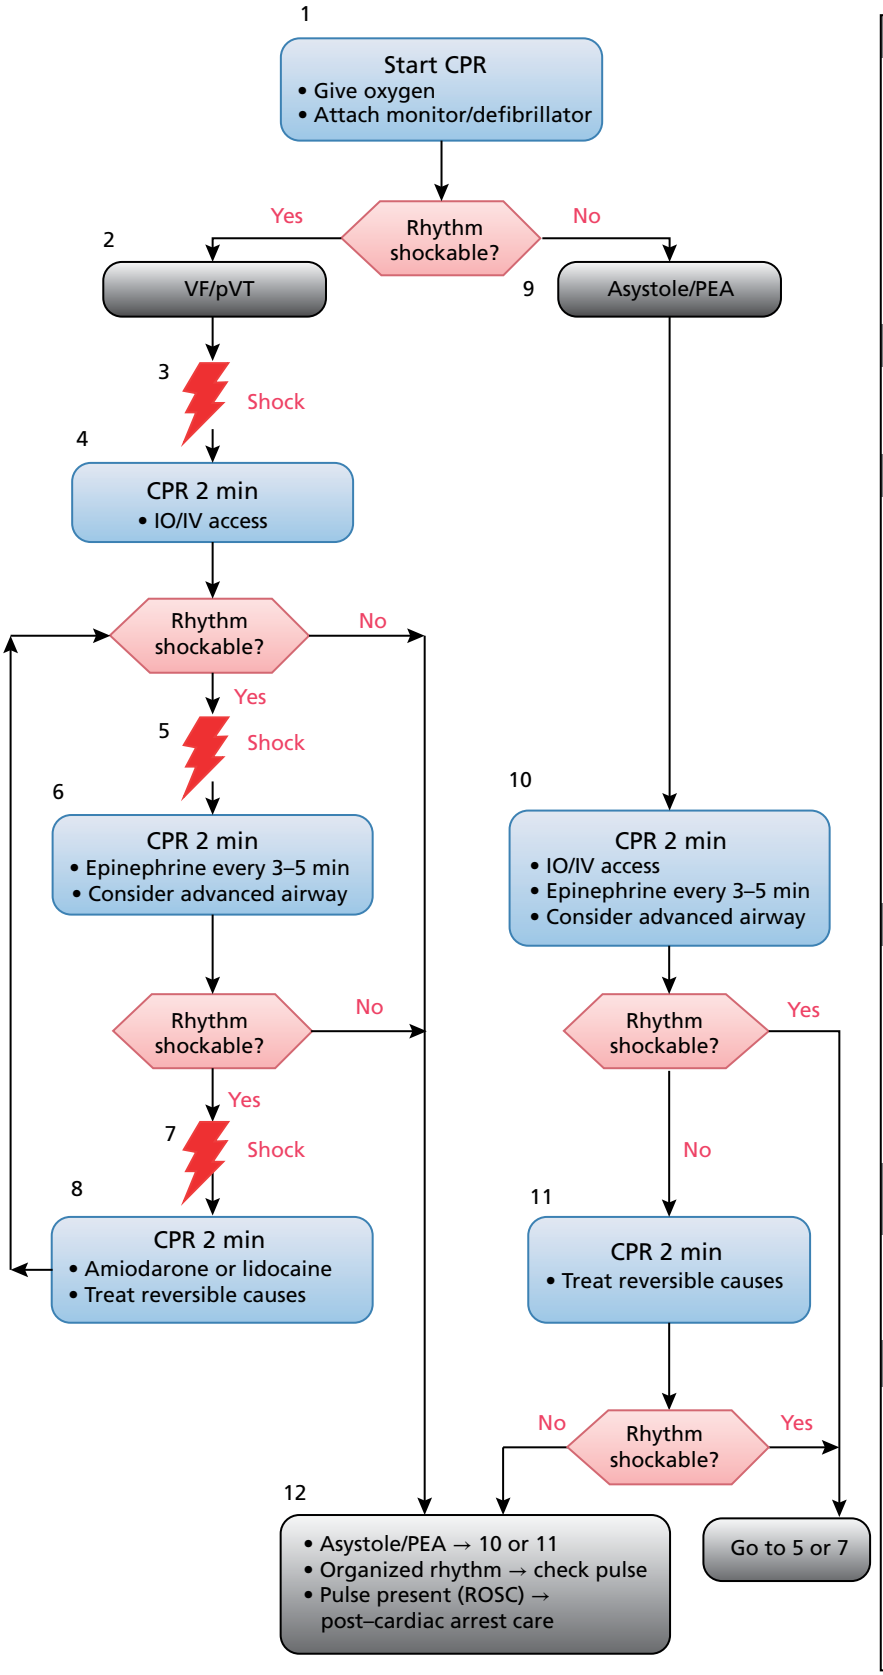
KEY POINTS: OTHER CONSIDERATIONS

- Quality ECPR may be an exciting adjuvant to conventional CPR, and future frontiers will define patient populations and optimize the clinical approach to extracorporeal support
- An initial shock dose of 2 J/kg terminates fibrillation in <60% of children, suggesting that a higher dose may be needed
- Some AEDs can accurately diagnose VF in children of all ages
- Children with CPR lasting >35 min had a 16% chance of survival to hospital discharge
- Non-punitive feedback and postarrest debriefing have been effective at improving CPR quality and are associated with improved rates of survival to discharge

Conclusion

Figures 13.1 through 13.8 summarize the most recent American Heart Association guidelines for PALS (2015) [235]. The reader is advised that new guidelines are published every few years, and the most recent guidelines should be sought out and followed.

Outcomes from pediatric cardiac arrest and CPR appear to be improving, however many patients are still left with devastating neurological injury. Perhaps the evolving understanding of pathophysiological events during and after pediatric cardiac arrest and the developing fields of pediatric critical care and pediatric emergency medicine have contributed to these apparent improvements. In addition, exciting breakthroughs in basic and applied science laboratories are on the immediate horizon for study in specific subpopulations of cardiac arrest victims. ECPR and CPR optimized to the individual patient and pathophysiology is the future of resuscitation. By strategically focusing therapies to specific phases of cardiac arrest, there is great promise that critical care interventions will lead the way to more successful cardiopulmonary and cerebral resuscitation in children.



CPR Quality

- Push hard (≥⅓ of anteroposterior diameter of chest) and fast (100–120/min) and allow Complete chest recoil.
- Minimize interruptions in compressions.
- Avoid excessive ventilation.
- Rotate compressor every 2 minutes, or sooner if fatigued.
- If no advanced airway, 15:2 compression-ventilation ratio.

Shock Energy for Defibrillation

First shock 2 J/kg, second shock 4 J/kg, subsequent shocks ≥4 J/kg, maximum 10 J/kg or adult dose

Drug Therapy

- **Epinephrine IO/IV dose:** 0.01 mg/kg (0.1 mL/kg of the 0.1 mg/mL concentration). Repeat every 3–5 minutes. If no IO/IV access, may give endotracheal dose: 0.1 mg/kg (0.1 mL/kg of the 1 mg/mL concentration).
- **Amiodarone IO/IV dose:** 5 mg/kg bolus during cardiac arrest. May repeat up to 2 times for refractory VF/pulseless VT.
- **Lidocaine IO/IV dose:** Initial: 1 mg/kg loading dose. Maintenance: 20–50 mcg/kg per minute infusion (repeat bolus dose in infusion initiated >15 minutes after initial bolus therapy).

Advanced Airway

- Endotracheal intubation or supraglottic advanced airway
- Waveform capnography or capnometry to confirm and monitor ET tube placement
- Once advanced airway in place, give 1 breath every 6 seconds (10 breaths/min) with continuous chest compressions

Return of Spontaneous Circulation (ROSC)

- Pulse and blood pressure
- Spontaneous arterial pressure waves with intra-arterial monitoring

Reversible Causes

- **H**ypovolemia
- **H**ypoxia
- **H**ydrogen ion (acidosis)
- **H**ypoglycemia
- **H**ypo-/hyperkalemia
- **H**ypothermia
- **T**ension pneumothorax
- **T**amponade, cardiac
- **T**oxins
- **T**hrombosis, pulmonary
- **T**hrombosis, coronary

CASE STUDY

A 5-year-old girl was found floating at the bottom of a swimming pool after not being seen by her parents for approximately 10 min. She was pulled from the water by a lifeguard. He noted that she was apneic and had no signs of life. Rescue breaths were given and chest compressions were initiated. The lifeguard gave rescue breaths coordinated with chest compressions at a cycle of 15:2 while emergency medical services (EMS) were called. Upon arrival of EMS, an endotracheal tube was placed while in-line neck stabilization was provided. Following intubation the child was hand ventilated at a rate of 10–12 breaths per min and received compressions at a rate of 100 per min simultaneously. An AED was placed and did not advise shocking. The EMS providers placed a cervical collar and inserted an intraosseous needle in her proximal right tibia. They infused an intraosseous bolus of 2 mL epinephrine 1:10,000 (0.1 mL/kg based on a presumed weight of 20 kg) every 3 min × 3. She was transported to an outside hospital emergency department (ED), with return of spontaneous circulation noted on arrival.

In the ED she had a rectal temperature of 36°C, a heart rate of 170 beats per minute, a blood pressure of 120/60, and SpO_2 of 100% with FiO_2 1.0. Her end-tidal CO_2 was 65 mmHg. Her pupils were 4 mm bilaterally and reactive and she had intermittent extensor posturing with stimulation, but no purposeful movement. Two peripheral intravenous lines were placed. Her initial venous blood gas revealed a pH 6.9, PCO_2 65 mmHg, PaO_2 25 mmHg, bicarbonate 12 meq/L, a base deficit of -22 meq/L, and an ionized calcium of 1.02 mmol/L. A complete blood count had a white blood cell count of 15,000/mm^3 hemoglobin of 12 g/dL, and a platelet count of 242,000/mm^3. A chemistry panel showed a sodium of 138 meq/L, potassium 7 meq/L, chloride of 103 meq/L, BUN of 15 mg/dL, and a creatinine of 0.3 mg/dL. The glucose was 345 mg/dL. The initial chest x-ray showed an endotracheal tube in the mid trachea with bilateral hazy infiltrates. Secondary to hyperkalemia in the face of a severe metabolic and mild respiratory acidosis, the patient was hyperventilated at a rate of 22 breaths per minute. She received 2 meq/kg of sodium bicarbonate as well as 50 mg/kg of calcium gluconate intravenously. She also received 20 mL/kg of normal saline, 20 µg of fentanyl, and 1 mg of midazolam for posturing and twitching with resolution of her twitching. The head CT showed no intracranial injury. She was then transferred to the ICU for further management.

On arrival in the ICU her vital signs were notable for a rectal temperature of 35.5°C, a heart rate of 150 beats per min, a blood pressure of 90/40, and a SpO_2 of 100% on FiO_2 1.0 with hand ventilation. She had an end tidal CO_2 of 50 mmHg. She was placed on initial ventilator settings of tidal volume 160 mL, a positive end expiratory pressure of 10 cmH_2O and a rate of 22 breaths per min with FiO_2 1.0. To avoid hyperoxia, her supplemental oxygen was weaned to maintain her SpO_2 >94%. Her ventilation rate was titrated to maintain normocarbia.

Simultaneously she had an esophageal and bladder temperature probe placed for core temperature monitoring. The esophageal probe was placed through the mouth and measured to terminate at the distal end of the esophagus. The temperature-sensing Foley catheter was placed for urinary output monitoring as well as continuous core temperature monitoring. A 5 French, 12 cm triple lumen right subclavian catheter was placed under sterile conditions. This catheter was placed for continuous medication administration as well as co-oximetry monitoring and central venous pressure monitoring. A repeat chest x-ray was obtained which showed the catheter to terminate at the right atrial–superior vena caval junction. There was no evidence of pneumothorax and the esophageal probe terminated at the distal esophagus. She also had a right radial arterial line placed under sterile conditions for continuous arterial blood pressure monitoring and frequent lab sampling.

Following these procedures, the patient remained tachycardic with a heart rate of 140 bpm, and became hypotensive with a blood pressure of 70/40. Her central venous pressure was 2, and her repeat venous blood gas was pH 7.13/PCO_2 45/PO_2 38/base deficit -12/lactate 6. She received another 20 mL/kg of normal saline × 2 with improvement in her central venous pressure to 6, however despite fluid boluses she remained persistently hypotensive at 80/40. At that time the intensivist decided to initiate vasopressor therapy to improve her cerebral perfusion pressure. Dopamine was infused at 5 µg/kg/min, resulting in a blood pressure of 102/55 mmHg and a urine output of approximately 5 mL/kg/h.

Labs were sent to further evaluate end-organ perfusion. Her troponin was 1.5 µg/L, creatine kinase (CK) was 2023 units/L and her CK-myocardial band percentage was 7%. Her amylase, lipase, aspartate aminotransferase (AST), and alanine aminotransferase (ALT) were within normal limits. Her glucose was 327 mg/dL. She remained comatose with a Glasgow Coma Score of 7 Total (Eye opening 1, Verbal response 0 (intubated), Motor response 5).

At that time the clinical team placed her on a cooling blanket with the goal of maintaining her temperature between 36 and 37°C to avoid hyperthermia. She was initiated on maintenance fluids without dextrose due to hyperglycemia. An insulin infusion was ordered to start at 0.01 units/kg/h

to maintain her blood glucose <180 and prevent excessive urine output from osmotic diuresis. Because of hypotension and the known risk of post-cardiac arrest myocardial depression, an echocardiogram was obtained at the bedside, which showed a shortening fraction of 40% and a hyperdynamic myocardium. Because of intermittent posturing and tachycardia, which resolved after IV midazolam treatment, a continuous electroencephalogram was performed to monitor for post-cardiac arrest seizure activity. The neurologist noted non-convulsive seizure activity on the electroencephalogram, and the patient was loaded with 20 mg/kg of intravenous fosphenytoin. She was sedated with fentanyl and midazolam infusions to decrease metabolic demand immediately post arrest.

During the 3 days following her cardiac arrest, her temperature was maintained between 36 and 37°C, her blood pressure was maintained within normal limits for age, and she was weaned off dopamine, her $PaCO_2$ was maintained in the 40s, and her SpO_2 was maintained >95%. Within 36 h post arrest, trophic feeds were initiated and slowly titrated to goal caloric needs via a naso-duodenal feeding tube. On post-cardiac arrest day 3, her neurological exam revealed: bilateral reactive pupils, a cough and gag, spontaneous respiratory effort, and she was localizing to noxious stimuli. Her seizures were controlled with phenytoin and EEG monitoring was discontinued at 72 h with no new seizures evident. On day 4 post arrest her temperature-sensing Foley and esophageal probes were removed so that she could go to MRI for evaluation of her brain and cervical spine. Her cervical spine showed no evidence of bony or ligamentous injury and her cervical collar was removed. Her brain MRI showed evidence of subtle acute hypoxic ischemic injury in the cerebral cortex bilaterally. On day 5 her sedation infusions were discontinued and she was extubated. On day 6 her central line and arterial line were discontinued and she was transferred to the inpatient rehabilitation ward for intensive therapies.

Three months following her cardiac arrest she was verbal and interactive. She was able to ambulate with assistance. She had had no seizures and was maintained on phenytoin with plans to wean it off at 6 months post arrest if there was no new seizure activity.

1. The chain of survival includes early, good-quality CPR, early defibrillation if appropriate, aggressive postresuscitative care and rehabilitation services.
2. Prompt bystander CPR was provided with chest compressions and rescue breathing.
3. Postresuscitative care requires a multidisciplinary approach and focus on details of avoiding secondary injuries from hyperoxia, hyperthermia, hypotension, and acidosis.
4. Post cardiac arrest, patients often exhibit intravascular volume depletion and have a systemic inflammatory response syndrome (SIRS) and myocardial depression. Therefore, close hemodynamic monitoring and cardiovascular supportive care are necessary for optimal postresuscitative care.

CHAPTER 14

Anxiety, Psychological Preparation, Awareness, and Behavior Change

Michelle Wright and Mike Sury

Department of Anaesthesia, Great Ormond Street Hospital for Sick Children, London, UK

Introduction

Millions of children undergo general anesthesia (GA) and, regrettably, many experience perioperative anxiety [1]. Sometimes the anxiety is severe enough to increase analgesic requirements and to cause psychological or behavioral disturbances; for a few patients, these problems may continue long after discharge from hospital [2].

Delivering healthcare in the 21st century is no longer limited to optimization of physiological parameters and clinical treatment of disease. The World Health Organization defines health as: "A state of complete physical, mental and social well-being not merely the absence of disease" [3]. This promotes a holistic approach to caring for patients of all ages [4]. Part of our role, as anesthesiologists, is to try to both reduce the distress of anxiety and prevent its long-term consequences.

Figure 14.1 illustrates the important interactions observed between perioperative anxiety, awareness, behavioral changes, and the potential value of psychological preparation. For example, perioperative anxiety may lead to behavioral changes later on, which may have been prevented or minimized by preoperative psychological preparation. Also, experiences of accidental awareness under general anesthesia (AAGA) itself may lead to anxiety about future anesthetics and other psychological consequences.

This chapter explores some important issues surrounding anxiety related to GA including the main causes and associated factors, and how psychological preparation can help. We will address the special problem of AAGA and consider its severity and how the related distress can be managed. Finally the behavioral consequences of GA and their significance in both the short and long term will be discussed.

Anxiety

Anxiety is defined as an *uncomfortable feeling of nervousness or worry about something that is happening or might happen in the future* [5]. It is an unpleasant emotional experience but it is an inevitable part of normal everyday life. It is estimated that 30–50% of children undergoing GA will be distressed preoperatively [6,7] and up to a quarter require some degree of physical restraint at induction [8].

The consequences of perioperative anxiety can be far-reaching. There is a strong association with emergence delirium [9] and other negative behavioral changes in recovery which may persist for weeks and months [10]. An anxious child is likely to worry already apprehensive parents which, in turn, can heighten the anxiety of the child. Anesthetizing a child who is anxious, distressed, and uncooperative requires consideration of interventions such as non-pharmacological techniques (i.e. play therapy and other behavioral and psychological interventions) and anxiolytic or sedative premedication. Such interventions however are time-consuming and impact on the efficiency of operating schedules. If all children were anxious, all would need these interventions and operating lists would be more predictable. However, in the authors' experience, only a few children are anxious enough to need special management and these children cannot always be identified beforehand. The behavior of children is notoriously difficult to predict and this leads to inevitable difficulties within a busy operating room schedule.

Anxiety may be associated with physical complications. In adults, pre-existing anxiety or depression increases the probability of developing a wound complication after undergoing common orthopedic or general surgical procedures [11]. This may be caused by stress-related elevations in glucocorticoid

Gregory's Pediatric Anesthesia, Sixth Edition. Edited by Dean B. Andropoulos and George A. Gregory.

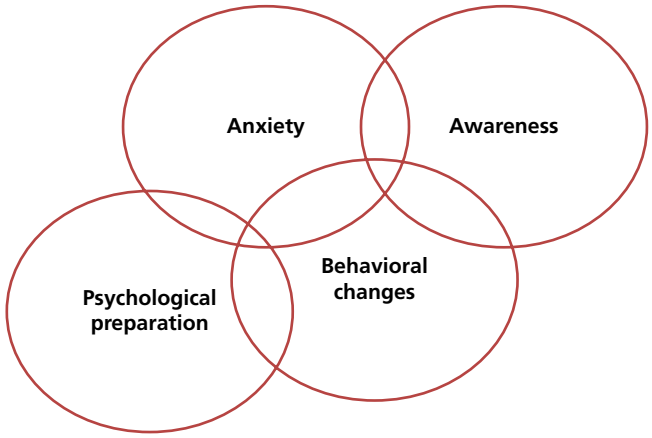

Figure 14.1 Interactions between perioperative anxiety, awareness, behavioral changes, and psychological preparation.

and catecholamine hormones, which suppress the immune system [12,13]. Additionally, increased anxiety may reduce tolerance of pain [14].

Risk factors

The ability to predict preoperative anxiety is important if it is to be effectively managed. In the past 20 years there has been much research not only to measure the frequency, range, and severity of anxiety but also to identify risk factors that could be used to predict behavior and guide interventions. Box 14.1 identifies internal and external risk factors.

Age

Children of differing ages, and thus developmental stages, have distinct triggers for their anxiety and require different management.

Infants (0–1 year)

Infants are too young to appreciate the circumstances and become anxious. Preoperative fasting is more likely to be a cause of crying than fear. Separation anxiety may become a factor after 6 months of age [15] but this will be nullified if parents remain with them during induction of GA. Parental anxiety is a related but separate problem.

Preschool children (1–5 years)

Preschool children are more likely to experience distress and anxiety during admission to hospital for an operation than any other age group [15]. There may be many reasons for this. They are less able to rationalize the reasons for their operation than older children and they have a unique perception of the world related to their imagination. They may therefore develop imaginary concepts and fears about reasons for their admission [16]. In a study of 90 4- to 6-year-olds, 90% reported at least one hospital-related fear and more than a third reported at least seven separate triggering factors for anxiety. The majority of these fears related to pain (e.g. of injections), being left alone, imaginary fears (such as monsters), noises, unfamiliar surroundings, and separation from their parents [16]. Children in this age group have a thinking style that is syncretic in nature in that they do not make deductions or reason beyond what is seen or experienced. They lack rational thought and therefore cannot understand the reasons why they are in hospital. In our experience most children in this age group, and many older children too, can be calmed by the presence of kind and friendly hospital staff in an environment that suits the needs of the child. For small children, a play area staffed by "play specialists" is extremely useful.

Box 14.1: Risk factors for perioperative anxiety in children[7,57,91]

Internal
- Younger age
- Child temperament

External
- Previous experiences in hospital
- Parental anxiety levels

School-aged children (5–12 years)

Children of this age have developed language skills and begin to apply logical thinking to situations [4]. Their anxieties include those related to their condition or the procedure (GA and/or operation). They want information and participation. Simple explanations can help to reassure younger children, while older children will ask questions and require more complex descriptions [15].

Adolescents

Adolescents are high-functioning individuals who can skilfully analyze situations and apply abstract thought [4]. However, their ability to cope and make decisions independently varies considerably depending on their maturity. They will often rely on the support of caretakers but will need to be fully involved in any discussion and decision-making including and especially that related to the method of anaesthetic induction. Adolescents have a fully developed body image and their privacy should be respected. Their fears are consistent with those of adults and these include loss of control, pain, and AAGA [15].

Child temperament

Children who display a greater degree of sociability and social-adaptive capacity are less likely to be anxious [17]. Those who are emotional, impulsive, and socially inhibited are more likely to have preoperative distress and postoperative negative behavioral changes [9]. Moreover, it is accepted that those with higher levels of baseline anxiety (so-called "trait" anxiety) are more likely to experience higher levels of anxiety during times of stress (so-called "state" anxiety) [18].

Previous experience

Children (4- to 6-year-olds) who have been admitted to hospital in the past have more hospital-related fears than their counterparts with no prior experience [16]. Moreover previous traumatic hospital experiences or distress after vaccinations have been shown to be significant predictors for preoperative anxiety [19]. These risk factors can be cumulative [20].

Parental anxiety

Parental anxiety has been consistently associated with distress at induction [7]. This is most pronounced in young

children, and may be a result of a phenomenon called "social referencing" when a child follows a parent's facial expression to guide their own behavior in an unfamiliar situation. It has been demonstrated when infants observe their mother taking part in a stressful interaction with a stranger; they will mirror these responses in their own interaction with this individual [21]. It may therefore be beneficial to use an intervention to calm parents before anesthesia. For example, the children of mothers who received auricular acupuncture compared to sham control acupuncture 30 minutes prior to induction were calmer and more compliant [22]. That a parent's anxiety is the main cause of their children's anxiety, however, is difficult to prove.

Other factors

The type of induction may be a risk factor but evidence remains inconclusive. When 100 children, sedated with midazolam and separated from their parents, were randomized to receive either an inhalational or intravenous induction, significantly more were anxious in the intravenous group [23]. This study was in children having routine ear, nose, and throat surgery and may not be applicable to other groups. In another study, unpremedicated children aged 2–10 years were equally anxious about an inhalational or intravenous induction [24]. In both studies parents were not present at induction, which may or may not have been important.

The location of the induction may also be relevant. In the UK almost all hospitals use separate anesthetic rooms (AR) next to the operating room (OR). To date, no difference has been demonstrated between using an AR or OR in respect of either children's distress or the parents' satisfaction. Furthermore, no difference has been demonstrated in operating schedule efficiency [25]. A change in a child's disposition is often observed as they enter the OR or the AR and we believe that any unfamiliar environment, especially if it involves separation from parents and apprehension about forthcoming events, is the main trigger for anxiety-related behavior. When faced with a frightened child the anesthesiologist needs to be patient, sympathetic, and able to distract and entertain the child while being skilful in the chosen induction technique.

Assessment and measurement

Various scales and scoring systems have been developed to measure and evaluate anxiety. These are not only valuable in a clinical setting but also important tools in providing quantitative data for statistical analysis in research studies.

The State-Trait Anxiety Inventory for Children (STAIC) has long been considered the gold standard for assessing perioperative anxiety. It consists of a self-report scale with 40 statements assessing how the child feels at a particular moment in time (state) and their tendency to feel anxious (trait) [26]. However, this scale may not be practical for anxiety related to induction as it takes approximately 5–10 min to complete. Also, because it is completed by the patient, only children over 5 years old can use it. It is probably impractical in a high-turnover operating schedule and in children who are extremely anxious.

Consequently, The Yale Preoperative Anxiety Scale (YPAS) was developed and revised by Kain et al [27] to become the modified YPAS (mYPAS). The mYPAS is a rapid observational scoring tool that can be applied to children over 2 years of age at any stage of the patient perioperative journey. It had, initially, five categories: activity, emotional expressivity, state of arousal, vocalization, and use of parents. The latter category was eliminated in the mYPAS because of content overlap and inconsistencies with parental presence at time of scoring. It was initially applied at four points during the perioperative period but has since been rationalized to waiting in the preoperative holding area and at the time of showing the child the anaesthetic mask: this creates the mYPAS-Short Form (mYPAS-SF) [28] (Table 14.1).

Compared with the STAIC scoring system, the mYPAS demonstrated good observer reliability and validity for anxiety throughout the perioperative period [27]. Even though the

Table 14.1 mYPAS short form

Category	Scores
Activity	1. Looking around, curious playing/reading. Moves around room toward toys/parents
	2. Not exploring/playing. May look down/fidget/suck thumb. May sit close to parent. Play has a manic quality
	3. Moving from toy to parent in unfocused manner/frenzied/squirming movements. May push mask away/cling to parent
	4. Actively trying to escape using all four limbs. Not engaging with toys. Desperate clinging to parent
Vocalization	1. Reading, asking/answering questions, laughing, babbling (as appropriate to age)
	2. Responding to questions but only whispering/head nodding
	3. Quiet, no responses to adults
	4. Whimpering, moaning, silent crying
	5. Crying or screaming
	6. Sustained loud crying or screaming
Emotional expressivity	1. Happy/smiling or playing contentedly
	2. Neutral, no facial expression
	3. Worried, frightened, or tearful
	4. Distressed, extremely upset
State of arousal	1. Alert, looks around, notices what anesthesiologist does
	2. Withdrawn, sitting still, may have face turned into adult
	3. Vigilant, looking around quickly. Eyes wide, body tense
	4. Panicked, may be crying, pushing others away

mYPAS scoring system is simple it still requires time to assess the child. Using the FACES pain scale instead is quicker and has been proposed as a rapid screening tool to identify anxious children at the preoperative assessment clinic [18]. When tested against the STAIC scoring system, this method demonstrated poor specificity and sensitivity, but it may be useful in identifying extremely anxious children [18].

Induction of anesthesia in the uncooperative child

Despite efforts to identify and prepare anxious children, it is common for children to be unexpectedly distressed and difficult to manage at induction. In this situation, the first option available to the anesthesiologist that must be considered, albeit carefully, is postponement of the procedure to allow adequate psychological preparation. A discussion should take place at this stage with the operating team and the parents about what is in the best interests of the child. Delaying the procedure may not be sensible in many circumstances, for example those involving oncological, cardiac, or acute neurological conditions. Long waiting times and financial implications for families traveling significant distances for specialized treatment are other reasons not to delay. This is a challenging scenario and the anesthesiologist should endeavor to safely induce anesthesia while minimizing distress. The following methods of reducing distress may be considered.

Non-pharmacological

A range of behavioral techniques and psychological approaches are possible. Many of these are time consuming and may not be effective although the specialist pediatric anesthesiologist should have some knowledge and experience of simple behavioral methods to reduce anxiety. These will be appropriate to the age of the child and the reader is referred to a full discussion of the subject elsewhere [29]. Parents should also be helped to deal with this difficult situation as they will need to agree with any proposed course of action.

Pharmacological

A full discussion of the range of sedative and anxiolytic drugs can be found in *Pharmacology for Anaesthesia and Intensive Care* [30]. In the authors' hospital, four groups of drugs, used either alone or in combination, are in current use. In children predicted to need premedication, midazolam is usually given orally (to be swallowed or held in the mouth) as a first-line agent. Other potentially useful drugs (all oral) include morphine, clonidine, and ketamine. We think that it is important to maximize the chance of the premedication being effective by ensuring the timing is appropriate to gain the maximum sedative effect (e.g. oral midazolam may have a window of effective time between 30 and 60 min after its administration). Also, the child should, ideally, be first on the operating schedule to make premedication timing easier, avoid the anxiety of waiting, and minimize the period of fasting. In the scenario of an unexpected need for sedation in the OR, midazolam (sublingual or nasal) and ketamine (nasal) are sometimes necessary.

If intravenous anesthesia is not possible because the child is too uncooperative, induction of anesthesia will usually involve inhalation of sevoflurane. If this is impractical then an intramuscular injection may be considered. Ketamine, at a dose of 4–5 mg/kg, provides effective sedation to facilitate an intravenous cannula insertion or inhalational induction within 5 min, but the injection is itself painful and should be necessary only in very rare circumstances [31].

Physical restraint

Physical restraint varies according to the size of the child and may only involve tight cuddling of an infant or a toddler [32]. Physical restraint of older children should only be attempted as a last resort. Situations where it may be considered include vital and urgent surgery for a child with behavioral problems who cannot be reasoned with, who does not respond to non-pharmacological methods, and in whom pharmacological methods are impractical or ineffective. In the UK, the Department of Health has published guidelines for restraint of children in a healthcare setting [33].

The issue of physical restraint remains controversial. This was demonstrated in surveys in the UK and US that revealed a wide range of opinions as to what constitutes restraint and when it may be appropriate. In general, the tendency for it to be utilized decreased with increasing age of the child [34,35].

Parents also express general dissatisfaction after being involved in restraining their child for an anesthetic, with 62% of parents in one survey stating they would prefer a sedative premedication for their child in future [36]. Nevertheless, restraint may be appropriate to some situations. In our hospital a recent feedback survey showed that out of over 700 children approximately 20% of parents reported they needed to restrain their child to help the anesthesiologist and fewer than 5% thought that this was not the best approach [37].

Legality

Laws vary around the world; here we present the situation relevant to the UK and some principles that may be applicable widely. In the UK, a child who does not have capacity can be anesthetized against their will providing there is parental consent [34]. Capacity is defined as the ability to use and understand information to make a decision, and communicate any decision made [38]. Young children, usually, do not have capacity, but "people aged 16 years or over are entitled to consent to their own treatment, and this can only be overruled in exceptional circumstances" [38]. Children younger than 16 can also consent provided they have capacity. This is usually termed "assent" in a child younger than legal age of consent, and for developmentally normal children the age at which they are assumed to have capacity to give assent is usually 7 years. Refusal to give consent is more complicated. If a child has capacity their refusal should be respected and the GA and operation should be delayed. It may take time to persuade the child and every effort should be made to do so. In extreme circumstances caretakers can follow a legal process which would enable them to act in the best interests of the child albeit against their wish. If consent is withdrawn during induction the anesthesiologist is permitted to proceed if they believe that stopping would be unsafe[34].

Summary

Anxiety prior to GA is a complex, varied, and challenging problem occurring in up to half of all children [6,7]. Anxiety is a normal and appropriate behavioral response and only a few

children show appreciable distress and need a special intervention. Distress caused by anxiety is often multifactorial; management begins with identifying vulnerable children beforehand. A poor patient experience may influence the child's reaction to future admissions.

KEY POINTS: ANXIETY

- Preoperative anxiety can have clinical and psychological consequences
- A large proportion of children experience anxiety preoperatively
- The healthcare environment and caretakers should be child friendly
- Only a minority of children need a special intervention
- Children at risk should be identified
- Previous encounters have important influences on future experiences
- Restraint is a last resort in the non-compliant, combative child

Psychological preparation

The effect of preoperative anxiety and a negative perioperative experience can have important short- and long-term effects. It has been estimated that a 10-point increase in the mYPAS score is associated with an increase in emergence delirium or maladaptive behavioral changes by 10% and 12.5% respectively [9]. The following strategies may be useful before children arrive in the OR to help them to adapt more effectively to potentially intimidating and bewildering situations thus reducing anxiety and negative behaviors. The strategies covered include not only non-pharmacological techniques of calming a child but also the pharmacological methods (anxiolytic premedication drugs) in common use.

Non-pharmacological

A Cochrane review in 2015 of various non-pharmacological interventions included 28 trials and a total of 2681 children. It found that there were major inconsistencies in the measured effects of non-pharmacological interventions [39]. Many of the studies had small sample sizes and were not adequately blinded, leading to a risk of bias. This shows that high-quality research is rare and probably very difficult in this area. Conclusions should therefore be drawn cautiously. Nevertheless, some of the strategies show promising results and are worthy of having their wider application tested.

Coping

Coping is the patient's ability to manage and minimize stress. There are various coping strategies appropriate to age and maturity of the child. Children less than 4 years of age can use distraction such as play. This is a type of "emotion-focused" coping which involves trying to directly reduce the negative feelings associated with a stressful event. More mature children may use "cognitive" coping where the perception of the situation guides the individual's ability to cope [4]. As the child grows, he or she will ask more questions and attempt to have "cognitive mastery" of a situation. For example, if they are attached to a heart monitor they seek reassurance by learning about the heart and the monitor [17]. Mature children try to problem-solve and will begin to seek support from their peers rather than their parents [16]. All of these coping methods are more likely to be effective if they are discussed before the day of surgery [40].

Preoperative preparation programs

Many hospitals offer preparation leaflets and videos to children and their parents to explain what will happen to them during their admission. A visit to the hospital may help the child to gain familiarity with the surroundings. There is some evidence to support preoperative visits and programs but the types of intervention and their effects vary. Generally, they are considered useful but they require parent involvement and extra healthcare resources.

In the Advance trial [41], a preoperative program was developed which consisted of a group of family-centred interventions 5–7 days prior to surgery, including information videos and leaflets and the opportunity to practice an inhalational induction by playing with a facemask, followed by distraction therapy on the morning of surgery and at induction with parents being present the entire time. There were 400 children aged 2–12 years randomized to control groups (consisting of standard care with or without parent presence or midazolam premedication) or to receive the intervention. Children in the Advance group were significantly less anxious in the holding area, had less emergence delirium and lower analgesic requirements, and were discharged from recovery earlier than those children in any of the three control groups [41]. Anxiety levels at induction were comparable to those receiving premedication with midazolam and lower than those receiving standard care with or without parental presence. The two elements with the greatest impact on reducing anxiety were practicing with the facemask at home and the parents' adherence to the agreed distraction methods [42].

In another study, age-appropriate comic-book leaflets were given to the children 1 week beforehand and this significantly reduced the anxiety scores compared to a control group [40]. Third, in support of preparation programs, a further study showed that when an illustrated children's book was provided at the preoperative visit, parents were less anxious and children were calmer during the admission [43]. Finally, attendance at a preoperative workshop 2 weeks beforehand, at which toy models and figurines were used to explain the perioperative process, was associated with less preoperative anxiety and fewer postoperative negative behavior changes [44].

Preoperative explanation and communication also helps parents [41]. Parents want in-depth information about GA, and this has been shown to reduce their own anxiety [45]. Likewise, children are inquisitive by nature and studies generally support the concept that children want more, not less, information. In a US study of 143 children, anxious children wanted more information, especially about pain; children less than 12 years said they wanted to know more about the operating theatre environment [46]. At the preoperative visit the anesthesiologist may focus on communication with the parent, possibly with the intention of not discussing potentially distressing details with the child. Evidence, however,

suggests that information does not usually upset children and could be helpful to them to improve their coping.

Overall, the evidence supports that negative behavioral changes can be decreased by preoperative programs and preparation [41,44], however the grade of evidence is not strong due to problems with randomization and selection bias.

Distraction therapy

Distraction therapy, for example using clown doctors, has been shown to significantly reduce anxiety in 5- to 12-year-olds [47]. It is unclear, however, whether it is specific distraction or general interaction that is effective. Other distraction techniques using entertainment videos played during induction [48,49] have been shown to reduce anxiety scores when compared with controls or with parental presence alone. Conversely, other studies have shown no effect. In one study video distraction therapy failed to calm children of 2–7 years [50]. This may have been because the children were too young and too anxious. Interventions therefore may be valuable for some children, but not universally applicable. In a study of 84 ASA I and II patients aged 4–8 years, children receiving a smartphone with age-appropriate applications to play with in the preoperative holding area and continued until inhaled induction was completed had significantly lower mYPAS scores than children who received no preparation but whose parents had verbal and written orientation to the anesthetic procedures [51]. In another study of 135 patients aged 2–12 years, children were given a portable digital video disk (DVD) player in the preoperative holding area to watch age-appropriate animated movies and compared to a group who received oral midazolam premedication and a third group with both DVD and oral premedication. There was no difference in mYPAS and visual analog score for anxiety, from the holding area until parental separation, between groups [52].

The environment is also potentially important. Anesthetizing children in a dimly lit room with soft background music and only one person talking to the child can reduce anxiety scores [53]. Music, alone, has not been shown to be of appreciable benefit. Interestingly there is also a "therapist effect" [54] in that some people are more able to calm children than others. Hypnotherapy may be helpful and has been associated with fewer children having negative behaviors postoperatively [55].

Parental presence

Anxious parents make their children more anxious [56,57]. Calm parents ought to reduce anxiety in their children, however research has consistently failed to demonstrate this [39]. In the UK, almost all parents want to accompany their child to the anesthetic room and are present until the child is asleep. Parental satisfaction is generally higher when they accompany their children, even (or especially) when the surgery is high risk. In one study, 97% of parents thought that being present was a positive experience for both themselves and their children [58]. In the UK, parental presence is generally seen as a positive experience for all; although it has not been shown to dramatically reduce anxiety in the child, it does not have a negative impact and increases parental satisfaction. The family's expectations may need to be discussed beforehand. Having a separate anesthetic induction room removes any barrier to parental presence. In our view, parents should be made welcome and helped with guidance and preparation.

Timing and selection

A preoperative visit on the day of surgery may have little effect on a child's anxiety [40], probably because the need for psychological preparation is related to many factors [59] and the timing of a psychological intervention may be relevant. In an observational study of 143 children undergoing day-case surgery, a preoperative preparation program had no effect overall. However a reduction in anxiety was seen in children who had participated in the program 5–7 days before admission. Children who had participated only 1 day before admission were made more anxious by the program [59]. In addition, children under 3 years old who had had previous experience of hospitalization seemed to be made more anxious by the program irrespective of the time [59]. These findings contrast with those of a study in Sweden which found that psychological preparation was most successful in children younger than 5 years old with a previous experience of hospitalization [20]. The methodological differences between the studies may be important. In the Swedish study all children had premedication intramuscularly, which was identified by the researchers at the time to be a major triggering factor in itself for development of anxiety. The timing of the preparation program varied and the psychological preparation was based on role play which may not be suitable for all ages of children [20]. These points show that it is difficult to be certain of the efficacy of psychological interventions and indicates the importance of tailoring different strategies to different children.

The person who delivers a psychological intervention may also be very important. A study in Sweden showed that if the nurse who had met the child at the preoperative assessment was present at induction and in the recovery unit, salivary cortisol levels (a potential biological marker for anxiety) were significantly lower compared to children who were seen by different healthcare professionals [60]. This supports the idea that trust and rapport are important factors.

Pharmacological

Despite our best efforts, anxiety may need to be managed with an anxiolytic or sedative "premedication" drug. An ideal agent for premedication should have the following properties:

- rapid onset time
- short recovery period
- no airway effects
- no cardiovascular instability
- analgesia and amnesia
- no paradoxical agitation
- simple and painless administration
- pleasant taste and smell
- no nausea or vomiting.

The perfect agent does not exist but the common classes of anxiolytic premedication in current use include benzodiazepines, opioids, α_2-agonists and N-methyl-D-aspartate (NDMA)-receptor antagonists. The principles by which the drugs may be selected are discussed below and a summary of important pharmacological effects can be found in Table 14.2. Dose ranges are provided but the correct dose depends upon

Table 14.2 Comparison of classes of drugs available for premedication [31,133–140]

Class of drug	Advantages	Disadvantages
Benzodiazepines	Rapid onset/offset time	Intranasal burning/bitter taste
Midazolam	Amnesia	Potentiates opioid-mediated respiratory depression
Oral 0.5 mg/kg		
Buccal 0.2–0.3 mg/kg		Paradoxical disinhibition
Intranasal 0.3 mg/kg		No analgesia
Rectal 0.3–0.5 mg/kg		Hiccups
Opioid	Analgesia	Respiratory depression
Morphine		PONV
Oral (0.2 mg/kg)		
Fentanyl		
Transmucosal 15–20 μg/kg		
α_2 agonists	Preserved airway reflexes	Cardiovascular depression – hypotension/bradycardia
Clonidine	No respiratory depression	
Intranasal 2 μg/kg	Tasteless	Prolonged onset and duration of action
Oral 2–4 μg/kg	Reduction in PONV	
Dexmedetomidine	Sedation more similar to sleep	
Intranasal 1–2 μg/kg	No disinhibition	
	Reduced shivering	
	Analgesia	
	Antisialagog	
NDMA receptor antagonists	Analgesia	Excess salivation
Ketamine	Preserved airway reflexes	PONV
Oral 3–8 mg/kg	No respiratory depression	Hallucinations
Intramuscular 4–5 mg/kg		

NMDA, N-methyl-D-aspartate; PONV, postoperative nausea/vomiting.

many factors and the reader should consult their hospital formulary for guidance.

Benzodiazepines

Benzodiazepines act via the gamma-aminobutyric acid-A ($GABA_A$) receptor, GABA being the main inhibitory neurotransmitter in the central nervous system. The most common member of the class of drugs used for premedication is midazolam because it is water soluble and has a rapid onset and short half-life [30]. Given orally, this drug is usually effective within 30 minutes. Occasionally children have paradoxical excitement, and this can be reversed with flumazenil.

α_2 Agonists

The main α_2 agonists available are clonidine and dexmedetomidine. Dexmedetomidine has eight times greater affinity for the α_2 receptor than clonidine. It acts at the locus coeruleus (LC) in the pons [61] which is the nucleus responsible for promoting arousal. The majority of noradrenaline synthesis in the brain is at the LC where there is a dense array of excitatory projections to the cerebral cortex inhibiting input to GABAergic neurons [62]. The inhibition of the release of noradrenaline at this location will therefore produce sedation. Dexmedetomidine acts at the LC to cause a natural, physiological sleep quality in contrast to propofol and midazolam [61]. This is supported by EEG findings that show that dexmedetomidine produces EEG patterns similar to natural sleep [61]. Clonidine has some analgesic properties.

NDMA-receptor antagonists

Ketamine is a phenylcyclidine derivative and a non-competitive inhibitor at the N-methyl-D-aspartate (NMDA) receptor, where glutamate, the brain's main excitatory neurotransmitter, acts. It is a potent analgesic and usually creates a calm state. Occasionally it causes distressing hallucinations. It can be administered into the nose using an atomizer or spray device and this method has rapid effect. By mouth the drug has a slow and variable onset. The intramuscular route is most reliable for this drug, but the injection itself is painful, distressing and, in our opinion, should be used only in exceptional circumstances. Others have suggested that, in the scenario of an uncooperative child, a ketamine injection has advantages over a forced inhalational induction with sevoflurane because it may be performed on the admission ward and the sedation is more rapidly achieved, thus minimizing duration of restraint [15].

Opioids

Opioids are rarely a first-line choice for anxiolysis, mainly due to the increased risk of respiratory depression and the side-effects of nausea and vomiting. They may however be useful for anxious older children who may need a combination of two drugs.

Studies comparing these drug classes show that α_2 agonists are superior to benzodiazepines in terms of greater sedation, reduced emergence delirium, and improved postoperative pain relief [63]. Intranasal dexmedetomidine (2 μg/kg) can produce similar sedation to oral midazolam (0.5 mg/kg) [64], but 1 μg/kg of dexmedetomidine has a slower and less reliable onset [65].

There are problems to consider and overcome if a premedication drug is ordered. It may be difficult to persuade a child to take the anxiolytic premedication, especially if they have a behavioral disorder. Once taken, the drugs can take 30–45 min to achieve their full effect and this will have an impact on the operating schedule. All the drugs have a variable effect and some children may become too deeply sedated with standard

doses. It is important to be aware that a sedated child can develop airway obstruction and respiratory depression (cardiovascular compromise is rare but possible in dehydrated children or those with severe cardiac dysfunction). All sedated children should be monitored and observed by a vigilant person trained to prevent, recognize, and manage complications. Other premedication problems are disinhibition, delayed emergence, and postoperative drowsiness.

Summary

There are many tools at our disposal to prevent or minimize negative psychological effects of hospital admissions. However, the efficacy of the interventions is variable and patient selection is important. Preschool children have the greater chance of being anxious and having emergence delirium, and further research is needed to help this patient group. Premedication still plays a significant part in facilitating the induction process for many children.

KEY POINTS: PSYCHOLOGICAL PREPARATION

- Children adapt to stressful situations differently according to their age and maturity
- Psychological preparation programs can be valuable for some children
- Parental presence at induction may be expected by parents and their children
- Premedication should be reserved for children for whom other strategies have been ineffective

Awareness

General anesthesia is the abolition of consciousness, memory, and involuntary reflexes in order to create safe, stable surgical operating conditions and prevent pain and distress. Accidental awareness during general anesthesia (AAGA) is defined as the explicit recall of intraoperative events. The manifestations of AAGA are broad and vary from minor auditory and tactile sensations to major horrific pain and a feeling of being unable to move. The distress and psychological consequences of AAGA will vary. Children commonly recall tactile and auditory experiences but, fortunately, the severe distress of pain and immobility is reported rarely [66].

Incidence

The incidence of AAGA depends on the method used to identify recall. AAGA is a well-reported subject in adults and the common method to identify it is by a postoperative interview of consecutive patients using a series of questions devised by Brice et al [67]. The postoperative questionnaire, known as the Brice questionnaire [67], is typically administered on the first postoperative day and again on day 3–7 and day 30. It is thought to be the best method of detection of AAGA [68]. Using the Brice method in adults, the overall incidence has been reported to be between 0.1 and 0.2% [69–71]; this rate varies however with types of patients and operations (Box 14.2). The 5th National Audit Project of the Royal College of Anaesthetists and the Association of Anaesthetists of Great Britain and Ireland (NAP 5) was a survey of spontaneous first reports in UK National Health Service patients over 12 months in 2012–2013. It is the largest and most comprehensive audit of AAGA to date and it found that the overall incidence was 0.005%. This incidence, being of spontaneous reporting, is strikingly lower than the postoperative interview method [72] and this difference suggests that only a minority of patients who have AAGA spontaneously disclose it.

Box 14.2: Risk factors for awareness under general anesthesia

Patient risk factors
- Hemodynamic instability
- Difficult airway
- Advancing ASA grade
- Obesity
- Female gender
- Younger age (not including children)

Anesthetic risk factors
- Total intravenous technique
- Neuromuscular blockade
- Junior anesthesiologist

Surgical risk factors
- Cardiothoracic
- Obstetrics
- Emergency surgery

Fewer data are available concerning pediatric AAGA. There are five recent cohort studies using the postoperative interview method. Combining data from these, the overall rate of AAGA in children was 0.74% [66], which is much higher than rates reported for adults. Interestingly, the NAP5 study found that AAGA was reported much less frequently (0.002%) by children than by adults [73] (Fig. 14.2). This suggests that an even smaller proportion of children who have AAGA report it spontaneously.

In our own survey of patient feedback in our hospital, in which 241 children completed a confidential written questionnaire, we found that 16.2% reported something that they thought took place after the induction and before the end of the operation [37]. That all these methods yield different

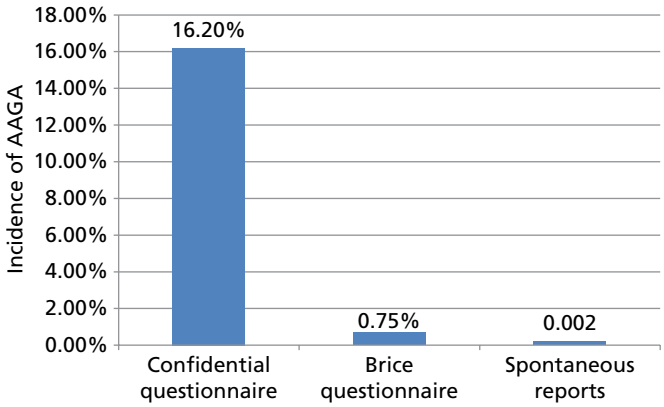

Figure 14.2 Comparison of incidences obtained from differing methods of accidental awareness under general anesthesia detection in children.

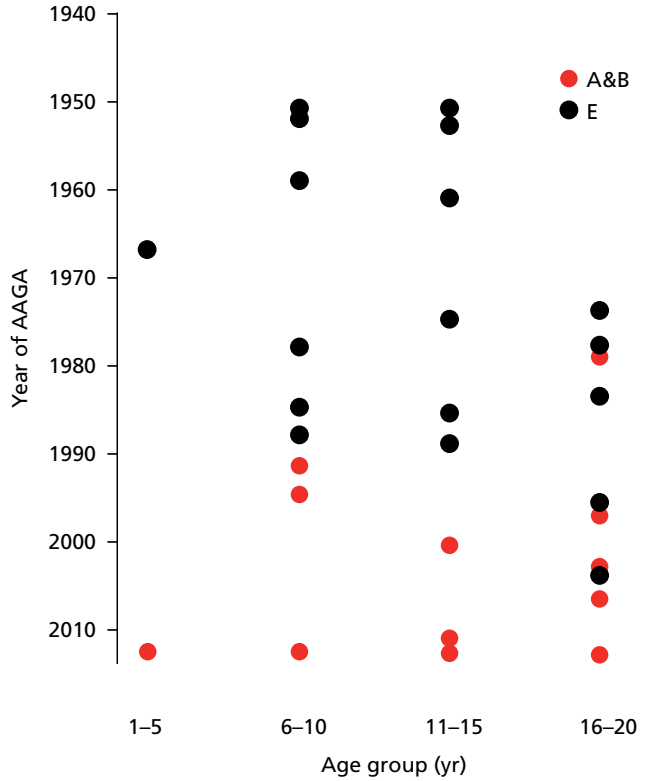

Figure 14.3 Year of accidental awareness under general anesthesia first reported to the National Audit Project 5 in 2013 [72]. Red circles, accepted and verifiable reports; black circles, not verifiable as records not available. *Source:* Reproduced with permission from the Royal College of Anaesthetists. Originally published in the report and findings of the 5th National Audit Project: Accidental Awareness during General Anaesthesia in the United Kingdom and Ireland, September 2014.

results may be explained if children are too frightened to reveal or report AAGA; on the other hand, the questionnaire method, without an interview, may not distinguish the experience of awakening in recovery from that of true AAGA [74].

The timing of the AAGA report in relation to the GA is particularly interesting in children. NAP5 found that there is often a long delay, perhaps 30–40 years. This supports the idea that some children are reluctant to report AAGA [73,75] (Fig. 14.3). The reasons why many children do not report their experiences and why others delay their disclosures are unclear. It may be that the experiences are not considered important by the child or it may be that the experiences are too distressing. A few children were not believed by their parents. Furthermore, a child's ability to correctly interpret their experiences, thereby appreciating the significance and meaning of such an event, distinguish them from dreams, and form explicit memory is dependent on age and individual cognitive abilities. Younger children may also struggle to express these events to adults due to a limited vocabulary.

Furthermore, AAGA requires a patient to recall intraoperative events; however, it is possible that memory and consciousness become uncoupled during GA and a patient could be aware but not be able to recall the experience [68]. This is illustrated by studies using the isolated forearm technique in which the patient's arm is kept free from the effects of a neuromuscular blocking drug (NMB). As the anesthetic is lightened (albeit to a dose that is considered compatible with unconsciousness) the patient responds to commands by moving their isolated arm, yet they cannot recall doing so [76]. In a survey of children under isoflurane anesthesia Andrade and colleagues found that only 2 of 181 children responded and neither had memory of it [77].

Memory

The ability to process information and retain memories is closely linked. It is generally accepted that a wide variety of new information is selected for cerebral processing and is held in the area of the brain dealing with short-term or working memory. The interpretation of new information will be dependent on prior knowledge and previous experiences already held in the long-term memory [78]. Key to this process are a child's age, cognitive abilities, and prior experiences. Children's brains are rapidly developing and growing and their cognitive abilities and proficiency in forming memory are therefore evolving.

Implicit memory

Implicit memory is that which occurs subconsciously and manifests as changes in behavior. It develops early and stabilizes by 3 years old [79]. Age has little effect thereafter. Implicit memory is hard to demonstrate in young children. One example is that when children of 3 years old are read a children's book, 3 months later they show no recognition of the pictures they had seen before, but can point to blurred similar images of the same pictures more quickly than children in a control group [80]. Infants are thought to have implicit memory before their explicit memory has developed [81].

Explicit memory

Explicit memory involves the conscious recollection of true events. Explicit memory develops throughout childhood. Few adults can recall events of their childhood before the age of 5 years. Nevertheless there is evidence of explicit memory developing in infants and toddlers. Groups of infants aged 8–10 months have been observed to imitate the sequence of actions with toys to generate a rewarding outcome, for example the finding of a toy behind a door [82]. The advancement in explicit memory may be a continuous steady process or it may have abrupt development phases [83].

Episodic memory

Episodic memory is a form of explicit memory of specific events and contextual features such as times, places, and people. It has been demonstrated in children by asking them to recall facts presented a week previously. Recollection of the facts (and the circumstances of when, where, and who told them the fact) improves markedly between the ages of 4 and 6 years [84]. The specific areas of brain development leading to these changes are thought to be related to the maturity of the medial temporal lobe including the hippocampus and the neural connections with the frontal cortex [79].

Dreaming

There may be a weak association between dreaming under GA and AAGA. Huang et al, in a prospective cohort study of 864 5- to 12-year-olds, found an incidence of dreaming of

10.4%. It was significantly more common in younger children and associated with anxiety in their parents [85]. Children in this study who did dream were significantly more likely to have also experienced AAGA. This may be because dreaming occurs under shallow depths of anesthesia [85]. Dreams, however, were not associated with negative behaviors [85].

Implications

What does this mean for anesthesiologists? How can higher awareness rates in children be explained and how can we reduce the probability of AAGA? The existence of explicit, specifically episodic, memory is pertinent in children as it relates to the child's ability to recall personal experiences. Based on current understanding, children of preschool age are unlikely to retain memories of AAGA. The implicit memory is functional at this age and unpleasant AAGA may contribute, in theory, to anxiety and other negative behaviors later. Reliable detection of AAGA with certainty in this population of children, however, is not possible.

Studies have failed to identify specific risk factors for children [75]. In contrast to adults, NMBs are not associated with AAGA [66,75]. In one prospective study, six out of 928 children reported awareness, and although four of these received a NMB, none reported being unable to move [75]. Davidson et al analyzed anesthesia factors in 4486 children and found associations with the use of tracheal tubes and nitrous oxide [66]. Associations, however, are not necessarily causation.

Reducing accidental awareness under general anesthesia

The higher awareness rates in children suggest we should be more proactive to reduce AAGA. The use of EEG monitoring such as Bispectral Index (BIS) is, to some, a logical step and it is used increasingly in the UK. Evidence of efficacy however is not compelling. The B-aware trial of 2004 [86] found that using BIS significantly reduced the rate of AAGA awareness in high-risk adults. In contrast, the B-unaware trial in 2008 [71] showed that expired breath monitoring of volatile anesthetics was equivalent to BIS. A Cochrane review in 2014 [87] concluded that BIS may provide some protection from awareness when clinical signs alone are used, but it was not superior to expired breath monitoring. In the UK, BIS is being used most frequently in adults receiving a total intravenous technique and NMBs [88].

The BIS algorithm was developed from EEG data from adults. Its validity in children has therefore been questioned. Given the limited use of BIS in predominantly volatile-based GA, this mode of monitoring may only have a small role to play in preventing awareness in children.

The NAP5 project concluded that the causes of AAG were likely to be the same in children and adults. Common causes were mistakes in technique and related to NMBs at induction and emergence [73].

Management

When a child reports AAGA, a meeting with the child and parents should be offered as soon as possible. The child should be believed although other explanations unrelated to AAGA may be considered. An apology and an explanation are courteous and appropriate, and not necessarily an admission of fault. The timing of the awareness should be checked against the anesthetic record. NAP5 suggests that there are four signs that may indicate psychological sequelae: nightmares, flashbacks, new anxiety, and depression. These should be sought in the first 24 hours and followed up at 2 weeks. A referral to a psychologist should be made if these signs persist [88,89]. AAGA in children tends to be less distressing in the short term than AAGA in adults [75].

KEY POINTS: AWARENESS

- Implicit memory develops by 3 years of age, but explicit memory begins to develop later
- AAGA rates, as detected by interviews, are higher in children
- Children are less likely to report awareness than adults
- Specific risk factors for children are unknown
- Children are less likely to suffer psychological sequelae in the short term than adults

Behavior change

Short-term negative behavioral change

Negative behavioral change in children after GA has been acknowledged since the 1940s [90]. Despite improvements in quality of anesthesia care, this problem has continued. Common short-term behavioral problems include separation anxiety, defiance towards authority, temper tantrums, nightmares, and nocturnal enuresis [1], which may persist for over 12 months in 7.3% of children [1]. Longer-term consequences are unknown.

Evaluating behavioral change of children relies on the completion of questionnaires by parents. The Post-Hospitalization Behavior Questionnaire (PHBQ) was developed over 50 years ago and is still in use. Examples of questions include: Does your child have bad dreams at night or wake up and cry? Does your child follow you everywhere around the house? [91]. The following studies show interesting and consistent results.

In a large cohort study of over 800 children, significant negative behavior changes (i.e. seven or more changes reported with the PHBQ) were noted in 24% of children aged 3–12 years undergoing a variety of surgical procedures. These changes persisted to 30 days in 8%. Anxious parents, older siblings, being young, and a previous bad hospital experience were associated factors [92].

Behavioral changes were demonstrated amongst 551 children in Finland aged 4 months to 13 years. Problems occurred in 47% and mostly in children aged 1–3 years. Associated factors were postoperative pain and previous negative experience of healthcare. Nine percent of children still had problems 4 weeks after the operation [10].

A study from three UK hospitals involving 131 2- to 12-year-olds showed that pain and behavioral change were still evident in 25% and 32%, respectively, by 4 weeks. Again, younger age, anxiety, pain, and poor previous hospital experience were associated factors [93].

Furthermore, 80% of children had negative behavioral changes the day after tonsillectomy or adenoidectomy, which remained in 30% 2 weeks later [92]. Apathy and withdrawal were more common than other problems in the first few days and separation anxiety predominated at 7–14 days. Postoperative pain was the strongest risk factor [94].

Behavioral changes may also be related to culture or community. Hispanic Spanish-speaking parents have reported significantly fewer negative behavioral changes than White English-speaking parents [95].

Identifying children at risk of postoperative negative behavior change could help to focus preventative strategies. Certainly pain at home is often undermanaged by parents and this could be improved with out-of-hospital support [96].

Even though associated "risk" factors have been identified in these studies, it is not possible to be sure about whether the anesthesia is responsible or whether it is the surgery or even the hospital episode overall that is more important. Certainly, the method of induction of GA, either inhalational or intravenous, made no difference to behavioral disturbances 2 weeks postoperatively [23].

Psychological instabilities have been demonstrated in children after a medical admission not involving GA. A study found no difference in incidence of problem behaviors in children who had caustic esophageal injury (requiring repeated dilatations under GA) compared with children with chronic renal disease requiring hemodialysis. Neither group, however, may have been comparable with children undergoing minor elective surgery [97]. Disruption of family life and chronic pain are probably important factors generating stress and behavioral problems [97].

Emergence delirium

Emergence delirium (ED) occurs on awakening from GA and was first described in the 1960s [98]. It is characterized by a state of dissociation with inconsolable crying, excitation, and agitation. It lasts for less than 15 min in 70% of cases but can continue for up to an hour [99]. The child is always distressed and may be restless enough to cause self-injury, including damage to the surgical site. Negative behaviors are weakly associated with ED: one study found that children were 1.43 times more likely to develop negative behavior if they had ED [9].

Assessment

Children awakening after GA may be in pain or hungry or confused (possibly related to hypoxia, hypoglycaemia, or drugs) which is often difficult to distinguish from ED. Studies have shown considerable variation in the incidence of ED, ranging from 10% to 80% [100]. To help evaluate ED the following scoring systems have been developed.

Pediatric Anesthesia Emergence Delirium (PAED) scale

The PAED scale (Table 14.3), developed in 2004, is considered to be a reliable and validated tool. It is more detailed than other ED scales and hence its main limitation is that it takes time to complete [101]. A score of 10 was shown to have reasonable sensitivity and specificity for ED [99]. Given that there is overlap in the behavioral items of ED and pain, observers have suggested that lack of eye contact and lack of awareness of surroundings are important markers of ED [99,102].

Cravero scale

The Cravero scale has five levels, each combining consciousness, crying, and restlessness. ED is defined as crying and restlessness lasting more than 5 min [103].

Watcha scale

The Watcha scale has four points and a simple design [104]. It defines ED as inconsolable crying or agitated and thrashing behavior for any length of time [105]. This scale correlates best with the PAED scale [105].

Potential risk factors

Age

ED is most common in toddlers and young children, and this may relate to their psychological maturity and cognitive ability [106]. Eighteen percent of 3- to 7-year-olds have ED [106].

Preoperative anxiety

The rate of ED increases by 10% for every increment of 10 points in the child's mYPAS score [9]. This suggests that modification of anxiety may reduce ED.

Type of anesthesia

ED can occur after any GA technique but sevoflurane is considered to be the most commonly associated drug [107]. A Cochrane review in 2014 concluded that within 158 studies involving 14,045 children ED was more common in anaesthetics maintained with sevoflurane as opposed to halothane or propofol, with it occurring in 50–75% more cases when sevoflurane was used. There was no conclusive evidence indicating the effect of maintenance with desflurane or isoflurane [108].

Table 14.3 The pediatric anesthesia emergence delirium (PAED) scale

Behavior	Not at all	Just a little	Quite a bit	Very much	Extremely
The child makes eye contact	4	3	2	1	0
The child's actions are purposeful	4	3	2	1	0
The child is aware of their surroundings	0	1	2	3	4
The child is restless	0	1	2	3	4
The child is inconsolable	0	1	2	3	4

Reverse scoring applied for items 1 and 2.
Source: Reproduced from Bajwa et al [105] with permission of Elsevier.

Rapid awakening was thought to be a possible factor [106]. However, desflurane has a shorter duration of action than sevoflurane and has not been shown to have higher rates of ED [108–110]. When 110 children induced with sevoflurane were randomized to receive sevoflurane or isoflurane for maintenance, there were significantly more children with ED in the group who were continued with sevoflurane for the entire anesthetic with awakening times similar on average [111]. In a study in which the emergence time of sevoflurane was controlled, the incidence of ED was the same irrespective of fast or slow emergence [112]. Depth of anesthesia is also not thought to be a major factor in the development of ED [113].

Given that induction GA with sevoflurane often has an excitement phase, some have suggested that sevoflurane may have a paradoxical excitatory effect at emergence also [114]. Contrary to this, however, ED existed long before the introduction of sevoflurane [98].

Postoperative pain

In a study of children undergoing inguinal hernia repair, fewer had ED after an effective caudal local anesthesia block [115]. Surgical pain is not an essential or even an important factor in the causation of ED because ED is also common after anesthesia for painless imaging [107].

Non-surgical site pain such as sore throat, headache, or the pain from a cannula site may be contributory. Although pain is not a causative factor, its presence may heighten central nervous system excitation thus lowering the threshold for agitation.

Type of surgery

The rates of ED are highest in children undergoing ophthalmic and ENT procedures [106].

Prevention

ED may be reduced if anxiety and pain are minimized [115]. Meta-analyses have shown that the administration of supplemental bolus doses of propofol, fentanyl, ketamine, clonidine, or dexmedetomidine just before emergence reduces the rate of ED [108,116]. As with all meta-analyses, their validity is limited both by the quality and power of the included studies and by the inability to include unpublished data.

Propofol

Propofol has a beneficial role either when given as a continuous infusion to maintain GA [117] or when given as a bolus at the end of the procedure [118]. A single bolus dose shortly after induction was shown to be ineffective [116].

Benzodiazepines

Midazolam given before or after induction has not been shown to reduce ED [116]. The 2014 Cochrane review concluded that midazolam has a positive effect when given as a bolus at the end of the procedure [108].

Opiates

A small (1 μg/kg) dose of fentanyl just before the end of a painless imaging scan reduces ED [103]. The contribution of analgesia in reducing ED is uncertain.

α_2 Agonists

Children undergoing circumcision with sevoflurane and a penile block developed significantly less ED if they received an intravenous bolus of clonidine at the start of the procedure [119]. Intranasal dexmedetomidine may be better than clonidine in reducing ED although recovery times are longer [120]. In a randomized trial, intranasal dexmedetomidine was shown to significantly reduce ED rates in a dose-dependent manner [121]. Dexmedetomidine may be better than propofol in reducing ED [122].

Ketamine

During eye surgery ketamine has been shown to be superior to midazolam [123] and similar to dexmedetomidine [124] in reducing ED.

Others

A magnesium infusion has been shown to significantly reduce the occurrence of ED in a study of 70 children, apparently without delaying recovery [125]. Acupuncture may be useful too: anesthetized children randomly assigned to have wrist stimulation during surgery had significantly less ED [126].

Management

The initial challenge is correct diagnosis. It is important to treat pain if it exists and to be sure that the child is not confused from an organic cause, e.g. hypoxemia or hypoglycemia. The treatment of ED will depend on its severity and whether the child is in danger of harm by his/her restlessness. Parents themselves seem to have a calming effect for many children. If ED requires treatment, small doses of sedative agents, for example propofol, fentanyl, midazolam, or dexmedetomidine, may be considered. Little evidence exists for the superiority of one drug over another to treat ED. The authors recommend subanesthetic doses of propofol (managed, always, by trained personnel).

Post-traumatic stress disorder

AAGA, in adults, has resulted in significant and long-term psychological sequelae such as anxiety, sleep disturbances, nightmares, flashback, and post-traumatic stress disorder (PTSD) [127]. Children may suffer similarly although the evidence for PTSD after GA (with or without AAGA) is sparse [128]. There is evidence to suggest that PTSD from all causes, including those unrelated to anesthesia, occurs less commonly than in adults. The British National Survey of Mental Health reported that of over 10,000 children 0.4% of those aged 11–15 years had PTSD and in those less than 10 years it was very rare [129]. Also, the diagnosis of PTSD in children less than 5 years old is uncertain because of communication difficulties [128].

Lopez et al followed up seven children 1 year after AAGA and found no psychological symptoms. Furthermore, none had negative descriptions of the events in question, in contrast to adults who often offer accounts of helplessness, pain, and fear [130]. In the five cohort studies of AAGA in children, approximately 25% of children reported fear or pain at the time of AAGA but they were not distressed afterwards [66]. Phelan and colleagues interviewed four

families whose child experienced AAGA and all denied significant psychological impact [131]. In the NAP5 report 12 adults reported AAGA remembered from when they had their GA as a child. Of these, five were anxious about future anesthesia and two had complex anxiety symptoms and recurrent nightmares [71]. This is supported by Osterman et al, who reported adults with PTSD who had had AAGA in childhood [132].

Summary

Negative changes in behavior are observed frequently after GA. Some anxious children and those who had previous poor hospital experiences may be at higher risk. Other factors such as the fear of surgery and pain may also be important. Attention to good-quality anesthesia and analgesia is important to prevent these problems. ED can occur after any anesthesia technique but is most common after sevoflurane: its incidence and severity can be reduced by other sedative and analgesic agents. PTSD does occur in children, but is rare after AAGA [75,128]. Nevertheless, PTSD related to anesthesia may occur in adults and could be related to AAGA suffered in childhood.

KEY POINTS: BEHAVIOR CHANGE

- Negative behavioral changes are associated with younger age, anxiety, previous negative experiences, and emergence delirium
- Emergence delirium:
  - is usually short-lived and self-limiting
  - is more likely with sevoflurane
  - may be reduced by good-quality analgesia and sedative agents
- PTSD after AAGA in children is rare but psychological effects may be delayed until adulthood

Conclusion

A holistic approach to anesthetic care not only focuses on the physiological and pharmacological requirements of the child but also attends to the psychological implications these events may elicit due to high levels of anxiety, unintended awareness, and negative behavioral changes. Consequently, our responsibility to the children we anesthetize extends to the prevention, evaluation, and alleviation of anxiety and distress throughout the perioperative period.

We must identify those children with increased vulnerability and implement appropriate strategies to promote coping strategies and facilitate resilience in all children we treat.

The challenge of pediatric anesthesia is to establish relationships with children and their families based on trust and humanity. Such an approach should be the foundation of promoting cooperation and reducing anxiety in children.

CASE STUDY

A healthy 4-year-old girl presents to your pre-assessment clinic with her parents 2 weeks prior to an admission for an inguinal hernia repair. Her parents describe a stormy perioperative course 18 months ago during an admission for a tonsillectomy.

According to her mother she was extremely distressed in the preoperative ward, and worsened on entering the OR. She clung to her mother and hid her face in her shoulder. She was resistant to encouragement by anesthesiologists and nurses and screamed when the mask was held to her face until she fell asleep.

When she awoke, her mother reports being told by the recovery nurses that she cried from when she opened her eyes. When her parents saw her in the recovery area she was thrashing around on her bed and pulled out her intravenous cannula. She was inconsolable by her parents and they both report that she did not seem to recognize them for the first hour. This episode only resolved when the anesthesiologist returned to review her. Her cannula had to be re-inserted, which caused further distress, and he gave an intravenous medication that settled her after a few minutes.

Two weeks after the procedure she was still displaying some signs of separation anxiety and sleep disturbance with some minor disobedient behavior out of character for her. Her parents felt guilty after this overall experience and are feeling extremely anxious about the forthcoming admission. On further questioning you elicit that when she had her vaccinations at 1 year old she was a lot more distressed than her older brother. Your summary of the situation is that the child has suffered a severe case of emergence delirium after her previous surgery with some longer-term behavioral changes, possibly contributed to by her anxiety prior to entering the anesthetic room and a previous negative experience in a healthcare setting. You feel that she is at high risk of a difficult induction and recovery this time which may be exacerbated by her parents' heightened anxiety on this occasion.

You arrange for a tour of the operating room complex and ward she will be admitted to, in order to familiarize her with the environment. You also provide her parents with a cartoon-based children's book explaining the perioperative process, which you advise they should read with her two or three times prior to admission. You discuss the option of premedication on the day of surgery and advise the parents to engage her in distractive activities on admission with toys or a tablet computer which should be continued in the OR. You make a note that due to the likelihood of emergence delirium she may benefit from a bolus dose of propofol, fentanyl, or an α_2 agonist prior to emergence.

CHAPTER 15

Principles of the Pediatric Perioperative Surgical Home

Lynne Ferrari[1,2]

[1] Department of Anesthesiology, Critical Care and Pain Medicine, Boston Children's Hospital, Boston, MA, USA

[2] Harvard Medical School, Boston, MA, USA

Introduction

The perioperative surgical home (PSH) is a patient-centered, innovative model of delivering healthcare during the entire patient surgical/procedural experience, from the time the decision for surgery is made until the patient has recovered and returned to the care of his or her patient-centered medical home or primary care provider. High-performing care coordination addresses interrelated medical, social, developmental, behavioral, educational, and financial needs to achieve the best possible health and wellness outcomes [1]. The modern concept of the pediatric perioperative surgical home (PPSH) renders obsolete the old practice of asking the primary care pediatrician to "clear" the patient for surgery and anesthesia. Instead the patient is evaluated in the context of an overarching perioperative episode which integrates the care provided by the perioperative care team with the patient's ongoing providers for the benefit of the family, patient, and health system [2–4]. A PPSH model must organize around each patient's condition rather than each physician's medical specialty and allow successful transition for the patient between outpatient care and episodes of procedural care. Care must be integrated across specialties and facilities, with the patient and family positioned at the center, so that the shift from volume to value may be achieved. This is especially important in the population of children with chronic conditions, an important segment of the population for whom care delivery is often fragmented.

Traditional volume-based care for a discreet surgical procedure has resulted in fragmentation of care and a diminished patient experience throughout the entire surgical or procedural episode. Too often, perioperative care plans are variable and disjointed. The need for surgery frequently disconnects patients from their routine medical care and as a result surgical patients may experience lapses in care, duplication of tests, and preventable harm. Costs rise, complications occur, physicians and other healthcare team members are frustrated, and the patient and family experience a lower quality of care. The transition back from perioperative surgical care to medical home or primary care may also be accompanied by lapses [5,6]. The goals defined for future healthcare are represented in the triple aim of high-quality care, a focus on population health, and reduced expenditures. The redesign of practice models represents a disruptive innovation in which the benefits offered are simpler, less expensive, and of equal or higher quality than current fee-for-service models [7]. A key strategy for meeting these goals is the implementation of measurable, evidence-informed, standardized activities that provide optimization of care coordination.

Goal and objectives

A comprehensive PSH provides coordination of care throughout all of the clinical microsystems of care and embeds the strategic principles outlined previously into its framework. The key elements of the PSH as defined in the literature are illustrated in Figure 15.1. As these new practice models evolve, it will be essential to monitor progress and performance by designing measures that will successfully gauge the value provided by the portfolio of care coordination activities and functions, as the guidelines for reimbursement tie payment to provision of coordinated care of all providers in the continuum. Physician leaders are drawn from an organization's anesthesiologists, surgeons, and hospitalists to achieve the goal of consistent application of evidence-informed and leading practices across specialty lines. The early identification of patients at risk for perioperative complications and subsequent readmission is an important concept so that these patients may be optimized preoperatively in an attempt to mitigate postprocedural morbidity. Tracking of patients' progress through all of the stages of the episode of surgical care provides an overarching assessment that directs the clinical management and closes the loop to transition back to primary care and the medical home. This model considers a patient's

Gregory's Pediatric Anesthesia, Sixth Edition. Edited by Dean B. Andropoulos and George A. Gregory.

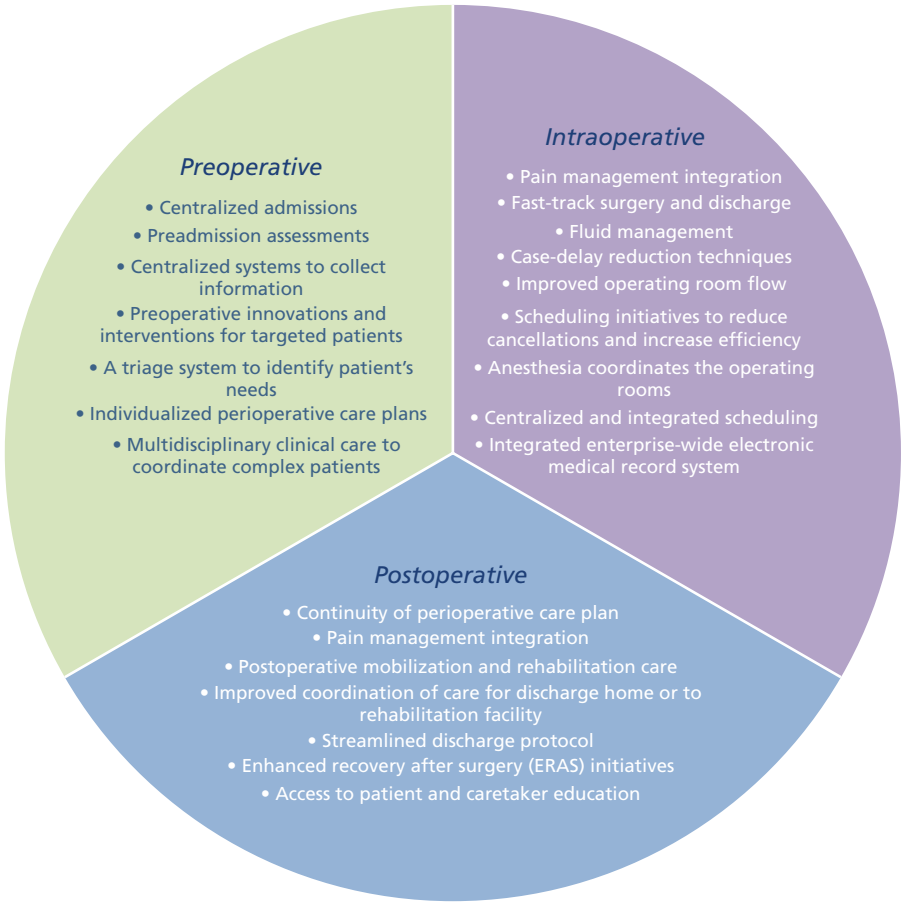

Figure 15.1 Elements of the pediatric perioperative surgical home.

Box 15.1: The goals of the perioperative surgical home

- Provide a portal of entry to perioperative care and ensure continuity
- Stratify and manage patient populations according to acuity, co-morbidities, and risk factors
- Deliver evidence-informed clinical care before, during, and after the procedure
- Manage, coordinate, and follow up on perioperative care across specialty lines
- Measure and improve performance and cost efficiency

preferences and values in all healthcare decisions, which has been associated with better outcomes and decreased postsurgical complications [8] (Box 15.1).

The PPSH is a team-based patient-centered model designed to improve the delivery of healthcare and reduce the cost of care overall. These goals are achieved through continuity of care for surgical patients, shared decision making with patients and family, and integration of care throughout the entire surgical episode of care. The components of this practice model include optimal preoperative testing and preparation together with the right care at the right place and at the right time utilizing evidence-based care principles to reduce unexplained variability, intraoperative inefficiency, complications, redundancy, and cost of care. Also included are efforts to standardize physician preference items, to reduce supply costs as well as to decrease the utilization of expensive tests and procedures.

$$\text{Value} = \frac{\text{Quality} + \text{Safety} + \text{Satisfaction}}{\text{Cost of surgical episode of care}}$$

Figure 15.2 Value equation for the surgical episode of perioperative care.

Postprocedural care initiatives include care coordination and transition planning which are defined prior to the procedure itself. This type of care coordination and integration within primary care pediatric practice is associated with a decrease in non-urgent emergency room visits, enhanced family satisfaction, reduced unplanned hospitalizations, lower out-of-pocket expenses, fewer school absences, and less impact on parental employment [9–11].

The value proposition

Fee for service rewards the quantity but not the quality or efficiency of medical care [12]. An alternative is an improved mechanism to pay for healthcare which rewards providers for delivering superior value to patients and achieving better health outcomes at lower cost. The move toward "value-based reimbursement" is accelerating. In healthcare, value is defined as the health outcomes achieved that matter to patients relative to the cost of achieving those outcomes

[13] (Fig. 15.2). It is essential for providers to have accurate cost information that includes understanding the cost of each component of care and how cost is related to the outcome achieved. To determine value, providers must measure the cost of each condition or procedure by tracking the expenses in treating the patient over the full cycle of care. This requires an understanding of the resources required, the capacity cost of supplying each resource, and the support costs associated with the care such as information technology and administration [14].

The broad phrase "value-based reimbursement" encompasses two radically different payment approaches: capitation and bundled payments. In capitation, the healthcare organization receives a fixed payment per year per covered life and must meet all the needs of a broad patient population. In a bundled payment system, by contrast, providers are paid for the care of a patient's medical condition across the entire care cycle including all the services, procedures, tests, drugs, and devices used to treat a patient with a specific disease or surgical procedure [15].

In healthcare the goal of efficiency includes elimination of waste. The three basic categories of waste are production-level waste, case-level waste, and population-level waste. The first category involves inefficiencies in producing "units of care" such as drugs, laboratory tests, radiographs, hours of nursing support, and any other item consumed in patient treatment. It accounts for about 5% of total healthcare waste. The second category, which comprises about half of all waste in care delivery, is unnecessary or suboptimal use of care during a hospital stay, an outpatient visit, or some other treatment episode, or "case." The third category, which accounts for about 45% of total waste, involves cases within a patient population that are unnecessary or preventable [16]. Failure of care coordination and integration contributes to the waste that ensues when patients receive fragmented care which may result in complications, hospital readmissions, and a decline in functional status of the patient [17] (Box 15.2).

Innovation and new care delivery methods are one solution to combating waste in medical care. Demonstrating the value of the PPSH to surgical colleagues, administrators, patients, policymakers, and payors will be needed to justify implementation of a new model which will require rigorous evaluation. In addition, it is likely that the type of PSH developed will vary based on institutional needs, payment structures, and discreet patient base. In all cases, however, the commonality of patient- and family-centered care and optimizing value are essential [18]. Specific elements inherent to the preoperative, intraoperative, and postoperative phases that reflect the added value should be identified. In addition to the development of outcome metrics and institutional assessment tools, health information technologies and methodologies for comparative effectiveness research will be needed to validate the impact of the PPSH on patient-centeredness, evidence-based practice, quality, safety, and value [19,20].

Integration with the medical home and primary care providers

As in the patient/family-centered medical home, the PPSH model must organize around each patient's condition rather than each physician's medical specialty and allow successful transition for the patient between outpatient care and episodes of procedural care. Care must be integrated across specialties and facilities, with the patient and family positioned at the center [21]. This is especially important in the population of children with chronic conditions, an important segment of the population for whom care delivery is often fragmented. The prevalence of children in the US with special healthcare needs, defined as physical, developmental, behavioral, or emotional conditions requiring health services beyond those of the general population, has increased by 18% between 2001 and 2010 and now represents 15.1% of the total population under 18 years of age [22,23].

It is well appreciated that preoperative risk reduction will result in reduction in the cost of care [23]. Especially in this patient population, integrated patient care should be coordinated across professionals, facilities, and support systems; continuous over time and between visits; tailored to the patients'/families' needs and preferences; and based on shared responsibility between the patient/family and caregivers for optimizing health [24]. Ideally the patient would transfer from a patient-centered medical home to the PPSH and back again in a continuum of care that provides seamless integration [6]. The National Quality Forum has endorsed care coordination as a "function that helps ensure that the patient's needs and preferences for health services and information sharing across people, functions, and sites are met over time" [8]. The conceptual framing for assessing care coordination includes five domains: a healthcare "home"; a proactive plan of care and follow-up; communication across team members; supportive information systems; and structured transitions of care (i.e. handoffs) [25,26]. The transfer of care using standard protocols ensures that essential information is communicated to primary care providers, subspecialists, and other providers.

KEY POINTS: GOALS AND OBJECTIVES OF THE PPSH

- Integration which is organized around each patient's condition rather than the physician's medical specialty
- Care which is integrated across specialties
- Patients transfer from a patient/family-centered medical home to the PPSH and back again in seamless integration
- Value is defined as the health outcomes achieved that matter to patients relative to the cost of achieving those outcomes

Box 15.2: Value-based transformation

Value-based care
- Patient-centered medical home
- Clinical integration
- Care management
- Post-acute care
- Electronic health record
- Data analytics

Value-based payment
- Care transformation costs
- Care management payment
- Shared savings
- Episode of care payment
- Global payment

Critical steps for implementation

Managing organizational transformation, in the words of Scott Keller and Colin Price in the *Harvard Business Review*, is like trying to change the wheels on a bike while you are riding it. The leaders of change bear the brunt of taking the organization apart and putting it together in a new way while keeping the process running [27]. Physician organizations are being asked to lead a cultural shift toward a lower-cost, higher-value healthcare delivery system. The modern physician organization must be large enough to manage population health, nimble enough to cultivate collaboration across multiple specialties, and small enough to create a "home" for each patient's healthcare needs [28]. Creating an environment of enthusiasm is one of the most important considerations in making the case for support. The problem and opportunity for improvement that will be the focus of the PPSH must be identified early with a clearly defined scope, a measurable outcome, and a surgeon champion collaborator. Examples might include identifying a discreet preoperative intervention to decrease cancellations in a specific patient population such as the preoperative insulin regime for diabetic adolescents. Another example would be proposing a decrease in length of stay for teenagers with idiopathic scoliosis undergoing spinal fusion or putting processes in place to decrease postoperative readmissions in tonsillectomy patients [29,30].

When gathering the implementation team the critical roles and stakeholders on the team should be identified. Front-line staff is critical and choosing high performers increases the potential for success. Stakeholders should be invited to identify the problem and outline a plan for improvement. The project should have a defined scope and a measurable outcome that matters to the institution. The team should include anesthesia providers, surgeons, nurses, information technology experts, an executive sponsor, staff from the institutional quality improvement division, and a parent/patient representative when feasible. The scope of the project should be established, timelines determined, and outcomes to be measured defined. (Fig. 15.3) Members of the team should be assigned specific tasks so that appropriate protocols are developed, data are collected in an efficient manner, and education is planned.

The desired changes should be fully developed, piloted, tested, and refined. One method is to begin with one part of the overall plan and measure the specific metrics as well as overall outcome. A detailed education plan should include building clinical pathways and order sets, nursing education, as well as patient and staff education. The initial project phase begins with data collection and establishing the current state. A small change should be implemented by means of one surgery, one protocol, with the goal of one small win. Results should be brought to the identified stakeholders, especially the executive sponsors, to demonstrate the success of the model and solicit ideas for the next focus. The cycle is then repeated with additional protocols and service lines [31].

Overcoming institutional barriers

Successful implementation of a PPSH requires sufficient institutional support and resources. There is a need for physician protected time to complete the administrative activities and explore other ongoing institutional efforts to partner with (neonatal/pediatric intensive care unit, etc.). The information technology role cannot be emphasized enough and dedicated

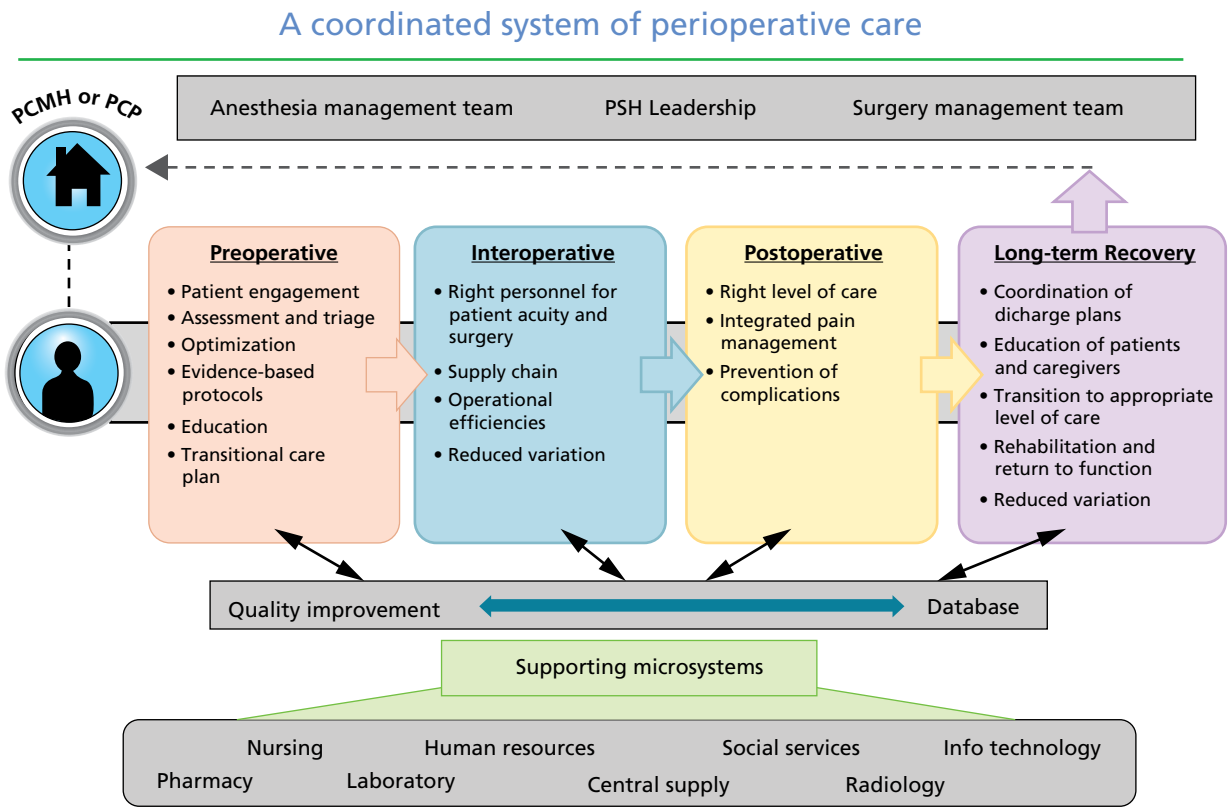

Figure 15.3 Structure of the perioperative surgical home (PSH). PCMH, patient-centered medical home; PCP, primary care physician.

teams must be created to build the tools for implementation, data analysis, and reporting of key metrics. Some of the most significant barriers might be within the anesthesia department itself as skeptical colleagues resist the adoption of innovation until much of the uncertainty has been removed and the value of change has been demonstrated [13,32,33]. Knowing the driving forces (e.g. quality, patient experience, and cost for a given institution) may be helpful in targeting the areas for change. Engagement of surgical colleagues and institutional leadership should be considered so that change may be facilitated throughout the institution. For each PPSH population a surgical champion is an important partner. It is helpful to have an "elevator speech" which is a short description of the PPSH and its advantage and value that can be communicated in its entirety during an elevator ride. This is especially useful in communicating with the institutional "C" suite consisting of the Chief Medical Officer, Chief Operating Officer, and Chief Nursing Officer. Finally, there is a need to have access to financial metrics which include both costs and charges.

Care coordination

Care coordination and integration is a complex set of functions that facilitates the provision of comprehensive health promotion, planned activities, and effective communication strategies [34]. The integration and coordination of care begins prior to the scheduling of a surgical procedure as soon as the decision for surgery is made. Involvement in the decision for surgery during the prescheduling phase in collaboration with surgical colleagues permits a multidisciplinary discussion regarding the right patient, right procedure, right place, and right provider which is especially valuable when considering children with complex or chronic health issues [5,35]. The preoperative evaluation phase provides a portal of entry to the perioperative care pathway and cost-effective preprocedure testing and consultation including "prehabilitation" interventions to optimize preoperative condition. A subtle but effective component of the preprocedural process is risk stratification to predict complications and prospective planning for length of stay and discharge so that discharge and transition planning occurs before the acute episode of care. Standardization of perioperative practice reduces variability and improves quality, and the coordination of multimodal therapy preoperatively and plan for intraoperative care may all be initiated during the preprocedural phase. Optimization of organ function to reduce the effect of co-morbidities is an important component of the preprocedural phase, as is the coordination of regional anesthesia adjuncts when appropriate. Team-based and evidence-driven care during and after surgery is an essential component of the PPSH.

Metrics, measurements, quality, and safety

The majority of pediatric readmissions are due to progression of chronic disease rather than surgical procedure and the readmission rates for infants and children are lower than in the adult population so determining the appropriate metrics for the PPSH is a challenge [36]. The demonstrated outcomes may be divided into several categories as noted in Table 15.1. Providers participating in the PPSH will be required to monitor the quality of care delivered using both internal measures and external reporting.

Types of procedures for pediatrics

The factors that distinguish pediatric heath issues from those of adult patients are referred to as the "Five Ds": *d*evelopmental trajectory, *d*ependency on adults, *d*ifferential epidemiology of chronic disease, *d*emographic patterns of poverty, and *d*iversity and overall healthcare dollars spent on the healthcare needs of children [37,38]. Additionally, the family/parent is the driver of healthcare for pediatric patients rather than the individual adult patient. The PPSH as it applies to infants and children will encompass many but not all of the competencies and functions included in overall pediatric care coordination. Overlapping functions relevant to surgery include the completion and analysis of assessments, development of care plans, management and tracking of tests, referrals, and outcomes, integration of critical care information, facilitation of care transitions, use of health information technology to manage continuous communications, and engagement of patients and families [39,40]. High-yield case types that are most suited to the PPSH model should be prioritized by determining those procedures with the greatest relative burden of preventable complications and cost variation (Fig. 15.4).

The highest-cost surgical procedures in pediatric patients according to a recent Pediatric Health Information Systems (PHIS) analysis include adenotonsillectomy, appendectomy, and spinal fusion. Other procedures that are well suited to the PPSH process are pectus excavatum repair, placement of gastrostomy tube, ventriculoperitoneal shunt insertion, laryngeal cleft repair, other otolaryngology procedures, and correction of bladder extrophy.

To understand the distribution of healthcare cost it is important to note that 75% of the pediatric population is generally healthy and incurs approximately 5% of healthcare expense, whereas 25% of the pediatric population has chronic disease consuming 70% of healthcare expense and the remaining 0.5% of the pediatric population has complex disease and requires 25% of healthcare expense [40] (Fig. 15.5). It then follows that children with medical complexity have a substantial impact

Table 15.1 Outcomes of the pediatric perioperative surgical home

Domain	Metric
Patient-centered outcomes	• Patient/family satisfaction • Success of the planned procedure • Return to prior or improved functional status
Internal operational efficiency outcomes	• Appropriateness of preoperative testing • Case delays • Case cancellations • Inpatient length of stay • Timeliness of discharge
Clinical and safety outcomes	• Unanticipated upgrade of care • Complications, morbidity, mortality • Readmissions within 30 days • Post-acute functional status
Economic outcomes	• Total cost of the episode of care • Utilization of hospital resources

on the healthcare system [41]. These children have lifelong chronic conditions with associated medical co-morbidities related to impairment of multiple organ systems and experience frequent costly hospitalizations which include surgery to improve their quality of life. Surgery in these children may be complicated and have a high likelihood of perioperative adverse events and suboptimal outcomes. Identification of those co-morbidities that have the strongest association with health outcomes and use of expensive hospital resources is an important consideration in creating a plan for a PPSH.

The adult community has fully implemented the Perioperative Surgical Home for total joint replacement surgery whereas spinal surgery is the first procedure to be an appropriate platform for pediatric patients [42]. For example, children with neuromuscular disease undergoing spinal fusion surgery exhibit an array of chronic conditions which include co-morbidities in the digestive, neurological, respiratory, and renal systems. As each patient's number of chronic conditions increases, the length of hospital stay, cost of surgical episode of care, and likelihood of readmission with 30 days increase. The most significant increase in postoperative length of stay due to a chronic condition has been noted in children with chronic respiratory insufficiency, bladder dysfunction, and epilepsy. Acute illnesses associated with increased length of stay, hospital cost, and readmission include the presence of decubitus ulcer, hypertension, and respiratory arrest. For example, urinary tract infection adds approximately $14,000 to the cost of the surgical episode of care and 3.5 days to the length of stay [41]. Adolescent idiopathic scoliosis is a condition that is associated with one of the highest annual cumulative costs in pediatric inpatient care and the implementation of a PPSH for this patient population has been shown to decrease the median length of stay from 5.2 days to 3.4 days ($p < 0.001$) as well as decreasing the rate of readmission within 30 days [29,43]. Other chronic diseases that affect a significant portion of the surgical population include cerebral palsy, myelodysplasia, congenital facial abnormalities, trisomy 21, neoplastic disease, congenital heart disease, and hydrocephalus.

Many of the metrics that define value in the domains of quality, safety, and patient/family satisfaction in adult surgical patients may apply to pediatric practice as well. These include hospital cost, length of stay, readmission, same-day cancellations, postoperative pain, nausea and vomiting, unplanned upgrade of care, actual discharge disposition, and mortality. Although inpatient length of stay and 30-day readmission are metrics that may be applied to both populations, the use of home health aides, skilled nursing, or post-acute transfer to rehabilitation facilities is not widely applicable to the pediatric population. Readmission rates are being used as an indicator of the quality of care by hospitals, clinicians, and payors. The Center for Medicare and Medicaid Services has proposed to reduce payments to hospitals with excessively high readmission rates [44]. The Pediatric Quality Measures Program, established by the Children's Health Insurance Program Reauthorization Act, has identified pediatric readmissions as an important measure and children with medical complexity have the highest rates of readmission [45,46]. The overall rate for unplanned readmissions within 30 days of discharge is approximately 6.5% with 2% occurring in children following ambulatory surgery [47]. As opposed to adults, pediatric postoperative care involves home care with family as the primary provider and in recent studies up to 29.5% of readmissions were potentially preventable [30]. Compared to adults, the reasons for readmission of pediatric patients within 30 days of discharge are significantly different and include dehydration, electrolyte imbalance, gastritis, constipation, seizures, pneumonia, anemia, upper respiratory infection, appendicitis,

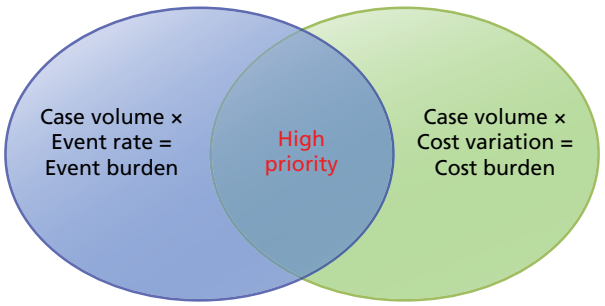

Figure 15.4 Determination of case types with the greatest yield from a pediatric perioperative surgical home model.

sickle cell crisis, and ventriculoperitoneal shunt malfunction [36,48] (Box 15.3).

Box 15.3: Most prevalent diagnoses for readmission

- Seizures
- Pneumonia related to asthma
- Bronchiolitis
- Anemia/neutropenia
- Sickle cell crisis
- Upper respiratory infection
- Acute asthma
- Diarrhea/dehydration
- Gastroenteritis/electrolyte disturbance
- Abdominal pain after appendectomy
- Neurological abnormalities after ventriculoperitoneal shunt surgery

KEY POINTS: CRITICAL STEPS FOR IMPLEMENTATION OF THE PPSH

- Pediatric health issues differ from those of adult patients
- Greatest cost variation and complication rate define the group to study
- Subsets of the highest-cost surgical procedures performed in children are defined
- Children with complex and chronic medical co-morbidities incur substantial healthcare cost

Enhanced recovery after surgery

Both the PSH and enhanced recovery after surgery (ERAS) initiatives share the goal of reducing cost while providing improvement in clinical outcomes, however the approach between the two modalities is different. ERAS is a multimodal perioperative care pathway designed to achieve early recovery for patients undergoing major surgery. ERAS represents a paradigm shift in perioperative care and is a defined clinical protocol that relies on specific elements which are implemented in every patient in a specific service line. The key areas of focus in ERAS protocols include the need for parenteral analgesia, the need for intravenous fluids secondary to gastrointestinal dysfunction, complications due to bed rest caused by lack of mobility, and carbohydrate loading preoperatively to reduce the stress of surgery during the immediate preoperative period [49]. Limited routine mechanical bowel preparation, use of multimodal analgesia and regional anesthesia to minimize narcotic administration, goal-directed restriction of balanced crystalloid intravenous fluids, early enteral feeding, early mobilization, and early removal of urinary catheters are specific components of the ERAS process.

The utilization of ERAS protocols is usually limited to the immediate pre- and postsurgery period whereas the PPSH has a larger conceptual framework that is focused on coordination and integration of care among providers for the duration of the entire episode of surgical care. This extends from the time that surgery is scheduled to 30 days post discharge [50]. The ERAS model of care may be considered a component of a PPSH process.

KEY POINTS: ENHANCED RECOVERY AFTER SURGERY

- ERAS and the PPSH are not the same
- ERAS protocols are focused on the immediate pre- and postoperative/postprocedural care
- The PPSH spans the entire continuum of the perioperative episode of care

Education and training

The specific skills required for anesthesiologists to be successful in the perioperative care model are evolving as perioperative medicine advances. Leadership and managerial skills as well as education in evidence-informed perioperative care expand the role that anesthesiologists assume outside of the operating room. Managing and directing the perioperative care of pediatric patients in partnership with surgical colleagues involves a new collaborative paradigm, and pediatric anesthesiologists are well trained and positioned to implement these changes [51]. Replacing traditional practices by integrating and reformatting existing systems will be the innovation that should result in increased access to perioperative services, value-added processes, and ultimately improved outcomes. Meeting the real needs and the true value of the pediatric PPSH requires an individual to coordinate and integrate each patient's care [2,4]. Given the vital need to restructure the perioperative experience and environment for pediatric patients and their families, the pediatric anesthesiologist should lead the implementation of the PPSH.

This new model provides an opportunity for residents and fellows to broaden their scope of care and take ownership of patients beyond the operating room and intensive care unit [52,53]. To advance this new model of care, consideration must be given to incorporating the competencies which are fundamental to the PPSH. There is a precedent for successful implementation of PSH training within the standard residency training programs in which traditional residency modules have been replaced with more PSH-specific training. For instance, in the first clinical year an introduction to the foundation in the PSH may be offered followed by the Clinical Anesthesia (CA)-1 year training in perioperative risk reduction and optimization in lieu of the standard preoperative clinic rotation. The postanesthesia care unit module is expanded to include recovery after surgery principles and pathways, and finally a design, implementation, and PSH management pathway elective is offered in the CA-3 year [53]. Should all anesthesiologists be trained in perioperative care outside of the operating room? Does this require lengthening the residency by an additional year? Should there be a specific fellowship in perioperative care? There is a major educational hurdle within anesthesiology to define the training of future generations of anesthesiologists as perioperative physicians.

The Accreditation Council for Graduate Medical Education (ACGME) approved subspecialty fellowship programs to provide rigorous training environments for the current generation of pediatric anesthesiologists [54]. In 2013 the American Board of Anesthesiology established the first certification examination in pediatric anesthesiology. These demographic and

oversight changes coupled with the ongoing restructuring of traditional models of healthcare delivery provide a unique opportunity for pediatric anesthesiologists to integrate their specific expertise and contribute to the care of the pediatric surgical patient [55,56]. The American Board of Pediatrics together with the American Board of Anesthesiology launched a combined training program in 2009 that enables physicians to fulfill training requirements for board certification in both specialties in 5 years. The goal of this innovative program is for newly trained physicians to develop careers focused on caring for children with complex medical and surgical conditions who require perioperative or periprocedural management. The educational experience provided by the complementary strengths of training in both pediatrics and anesthesiology should enable these physicians to become leaders in this expanding field.

KEY POINTS: EDUCATION AND TRAINING

- Managing perioperative care in collaboration with surgical colleagues represents a new paradigm
- Broaden the scope for anesthesiologists in training
- There is precedent for the successful implementation of PPSH inclusion in standard residency training

Payment models

Designed in the 1960s, the Medicare fee-for-service system created a healthcare payment model organized around healthcare providers rather than patients, rewarding the volume rather than the value of services, and focusing on sickness rather than preventative care. In order to define appropriate value-based payment models for children's healthcare, it is necessary first to define the value sought through the purchase of healthcare services for children. The experts believe society's goal for children is to maximize each child's opportunity to develop physically and emotionally such that he or she can productively contribute to society throughout his or her life, and a mix of process-of-care and outcomes should define the value of care for children including access to coordinated specialty care when indicated [40]. Although the dominant value-based payment models including supplemental payments, pay-for-performance, episode-based payments, and shared savings on total cost of care have been implemented within the context of pediatric practices across the US, pediatric practice lags behind in reimbursement reform.

The transition toward value-based care includes the movement toward alternative payment models (APMs). The APM is one of the few broadly supported ideas for moving healthcare forward. APMs such as accountable care organizations (ACOs), patient-centered medical homes and bundled payments, align reimbursement around the patient, focusing on coordinated, team-based care and improved outcomes. With increasing evidence and momentum building, APMs are one solution to the current cost and quality conundrum in healthcare. They hold the promise to alter the healthcare cost trajectory to create a sustainable, long-term future for government-supported and affordable private coverage. ACOs are not a payment method and the growth of ACOs in pediatric care has lagged behind adult models in part due to the uncertainty of the effectiveness of this model in pediatrics [57–59]. Each ACO is an arrangement among providers who are organized to receive bundled payments on behalf of participating providers [26,28]. There are specific areas where the PPSH model may contribute to payment enhancement. These include attention to cost management focusing on acute inpatient length of stay, post-acute care disposition, utilization cost, service line cost, physician preference items in supply chain, and reduction in variation analysis and strategies. Claims analysis and reconciliation, monthly reporting, dashboards, benchmarking, and monitoring to support process improvement are important analytics within the scope of the PPSH model. Gap assessment and redesign, quality improvement practices, collaborative sharing, care coordination and integration, and post-acute care partner designation all may positively influence reimbursement.

"Monetizing" the PSH refers to the process of valuing the coordination of services that are provided to patients during the perioperative episode of care and ensuring that each provider receives appropriate payment consistent with their contribution to the optimization of comprehensive surgical care and reduction of healthcare inefficiencies. The challenge is to show that the PPSH provides greater value to the institution than the cost of supporting the PPSH. Hospitals may pay PPSH participants based on achieving decreased overall costs of the perioperative episode of care. This may be achieved by decreasing hospital resources, standardization of implants and equipment, reducing laboratory and imaging studies, decreasing blood utilization, reducing intensive care utilization, and a reduction in the overall length of stay. Alternatively payors may directly compensate PSH providers based on a reduction in the use of hospital services resulting from earlier discharge or shifting care from inpatient to outpatient.

Once a PPSH is established within a specific institution and the services provided are defined, a method of payment must be designed. There are different options depending on the structure of each institution. Several potential models have been suggested, however the proportional split of professional fees must be determined prior to the delivery of care [60] (Box 15.4).

Box 15.4: Perioperative surgical home (PSH) payment models

- A fee for service payment for specific services provided or a discounted fee for service arrangement plus an opportunity to share in PSH-generated savings
- A percentage of bundled payments to the hospital (commercial or Medicaid)
- A portion of shared savings paid to the hospital as a result of the PSH
- Co-management agreements that define specific services provided by the PSH and compensation determined by tracking quality improvements
- Bonus payments for meeting quality and cost-saving metrics such as Hospital Quality Efficiency Programs (HQEP)
- Shadow bundles in accountable care organizations

CASE STUDY

Implementation of a pediatric perioperative surgical home care pathway for anterior cruciate ligament (ACL) repair at Boston Children's Hospital.

PPSH team

Anesthesiologist, surgeon champion, perioperative care coordination nurse, postanesthesia care unit (PACU) nurse, information technology group leader, executive sponsor, case manager.

Hypothesis

Anesthesia management varies across providers. The wide variability of anesthesia management can impact cost by impacting surgical end to transport out of OR (SET) time, PACU length of stay, patient outcomes, and readmissions.

Goals

- Reduce SET time and PACU length of stay.
- Reduce pain score variability by 20%.
- Maintain patient satisfaction.

Opportunity statement

- Anesthesia management that reliably produces shorter SET and PACU times while maintaining a positive recovery experience for patient and family.
- Present the identified anesthesia management as a departmental benchmark goal.
- Reduce the cost of the ACL repair episode of perioperative care.

PPSH population

ASA I and ASA II patients undergoing elective surgical repair of ACL.

Measurements/outcomes

- Surgical time: surgery start to surgery end
- SET time: surgical end to transport out of OR
- PACU length of stay: PACU admission to PACU discharge
- Cost of surgical episode of care
- PACU pain scores:
  - 0–3, low pain scores
  - 4–6, medium pain scores
  - >7, high pain scores.

Phase	Element of care	PPSH	Standard care
Before surgery	*Surgical Office* • ACL education • Postsurgical expectations • Discharge planning • Post-discharge follow-up planned • PT scheduled	*PPSH Team* Chart review and communication with subspecialists Phone call within 5 days prior to scheduled surgery Phone screen: • Medication reconciliation • NPO guidelines • Arrival time • Education of periprocedural plan • Identify postoperative caretaker • Getting ready for discharge on day of surgery Consider regional anesthesia adjunct Education sheets and teaching	Surgeon schedules case without communication with perioperative team
Preoperative	Patient education	Written education materials Standardized electronic order sets Initiation of multimodal pain regimen	Written education optional
	Standardized preoperative discharge planning	Patient and family education, including post-discharge caretaker and follow-up appointments	Lack of standardized discharge planning
Postoperative	Pain management Protocols for escalation of care	Oral medication and avoidance of opioids Decision tree for rapid escalation of care in case of medical deterioration or complications	Use of opioids
Discharge	*Surgical Teaching* Verbal and written education material post ACL repair	*PPSH Team* Verbal and written education material: • airway care • pain management with opioid sparing • diet • active crutch teaching

Introduction

Expertise in airway management in infants and young children is the cornerstone of pediatric anesthesia. This expertise consists of two major facets: a comprehensive knowledge and understanding of the developmental anatomy and physiology of the human upper airway from birth through adolescence, and the physical skills of airway management. This chapter will provide the basis upon which knowledge of pediatric airway management is gained. The chapter is divided into three major sections: (1) developmental anatomy and physiology of the upper airway; (2) procedures and techniques for management of the normal pediatric airway, and (3) specialized techniques with which to manage the child with an abnormal upper airway that presents challenges in ventilation or tracheal intubation.

The human upper airway is loosely defined as the air-conducting passages from the nose to the carina [1]. Anatomically, the upper airway of the developing fetus, infant, and child is a moving target. Its developmental course during fetal life is relatively less known compared with other organ systems, since much of this understanding is gained from descriptive animal and human postmortem studies. The structures of the upper airway continue to change their shape and properties until the latter part of the first decade of life. Furthermore, up to 3% of children may have congenital or acquired upper airway abnormalities [1].

From an evolutionary perspective, the human upper airway is relatively smaller than other related species, and is oriented in a more vertical position in the body. In humans, the facial bones and accompanying oral airway structures assume a more vertical position beneath the cranium (this mirrors the changes seen during human growth; see section "Developmental anatomy"). These changes were likely due to the acquisition of language for survival [2,3]. Diamond called this adaptation "The Great Leap Forward" and postulated that it occurred approximately 40,000 years ago [4].

Many other species are able to produce sounds that are analogous to vowels, but only humans are able to produce

Gregory's Pediatric Anesthesia, Sixth Edition. Edited by Dean B. Andropoulos and George A. Gregory.

consonants, the basis of the spoken language. The ability to form consonants, according to Shprintzen, is the result of the relatively smaller supralaryngeal tract that evolved in humans. This adaptation included the ability of humans to close off and separate the communication between the nasal or oral pharynx to facilitate production of consonants. The unique human property of having large adenoid tissue facilitates this separation. It is notable that the peak age of adenoidal growth (i.e. 3–5 years) is the same approximate age of the refinement of consonant sounds [3].

This anatomical adaptation necessarily confers a disadvantageous human property: the predisposition to upper airway collapse during sleep (i.e. obstructive sleep apnea syndrome, OSAS) or during artificially induced unconsciousness (i.e. sedation or general anesthesia). Other than brachycephalic dogs, such as the peculiar English bulldog [5], OSAS appears to occur only in humans.

Developmental anatomy

In embryological life, the upper airway develops within the structural framework of the development of the cranium and the most cephalad ends of the digestive and respiratory systems. The following description of the embryological development of the human is based on writings and descriptions from a number of references [6–10]. On the lateral surface of the 5-week-old, 4.0 mm embryo, one can observe five or six pairs of narrow masses called *branchial arches* (Fig. 16.1). Each branchial arch contains characteristic types of ectoderm and mesoderm, the primordial precursors of epithelial (e.g. skin) and mesothelial structures (e.g. muscle, bone), respectively. The areas between the arches are called *branchial clefts*. The tissue underlying the branchial clefts contains outpouchings of the foregut region, the *pharyngeal pouches*. These consist of endoderm and will develop into corresponding endothelial structures of the upper digestive and respiratory systems. The developing structures of each branchial arch receive motor or sensory innervation from an adjacent cranial nerve. Regardless of where the primordial muscle cell migrates, it will retain its original embryonic innervation.

The branchial arches

The first branchial arch will ultimately develop into the ramus of the mandible and the muscles of mastication. It also contributes to development of the middle ear bones and muscles between the ear and mandible, such as the tensor tympani, tensor veli palatini, and anterior belly of the digastric muscle. Motor and sensory innervation to the structures derived from the first arch is supplied by the trigeminal nerve.

The second branchial arch forms bony and muscular structures from the ear (proximally) to the hyoid bone (distally), including the muscles of facial expression that are innervated by the facial nerve (cranial nerve (CN) VII). In the developed human, the path of second branchial arch development can be traced from the styloid process, to the stylohyoid ligament, to the lesser cornu of the hyoid bone. Embryological abnormalities in the growth of the first and second branchial arches result in any one of a number of congenital airway syndromes involving the ear and jaw, such as Goldenhar syndrome.

The third branchial arch develops into the body and greater cornu of the hyoid bone and the stylopharyngeus muscle, which aids in elevating the pharynx during swallowing, and is innervated by the glossopharyngeal nerve (CN IX).

The fourth through sixth branchial arches contribute to the formation of the thyroid, cricoid, arytenoid, corniculate, and cuneiform laryngeal cartilages, as well as the muscles that form the pharynx, larynx, and upper half of the esophagus. These structures are innervated by the vagus (CN X) and accessory (CN XI) nerves. The earliest appearance of the future larynx is seen as a bud growing out from the ventral part of the foregut at approximately 4 weeks' gestation. The laryngeal and esophageal tracts are initially seen as one common tube that eventually separates into two adjacent functionally different conduits. By 16 weeks' gestation, the larynx contains all its definitive elements in their proper proportions.

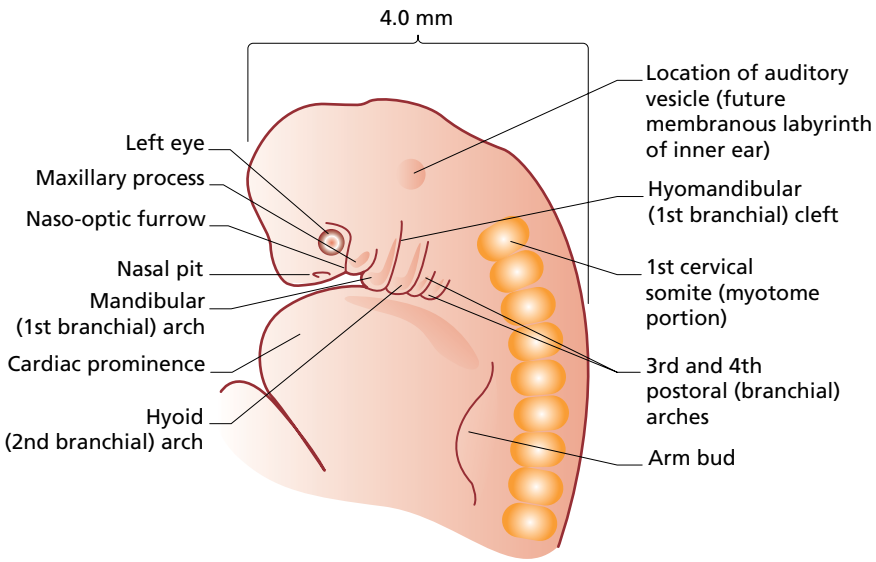

Figure 16.1 On the lateral surface of the 5-week-old, 4.0 mm embryo, one can observe five or six pairs of narrow masses called branchial arches.

During fetal and postnatal growth, the development of the size of the larynx closely parallels the size of the surrounding bony and cartilaginous structures [11].

The pharyngeal pouches

The pharyngeal pouches are outpouchings of the lateral wall of the foregut that develop into the pharyngeal structures. Each pouch, at its lateral-most aspect, contacts the ectodermal epithelium of a branchial cleft. The first branchial cleft becomes part of the external auditory canal, but the remaining branchial clefts are remodeled and do not correspond to recognizable structures in the mature human. Nevertheless, abnormal formation of this area can lead to cysts or more significant malformations.

The first pharyngeal pouch becomes incorporated into the future temporal bone and forms the epithelial lining of the middle ear and the tympanic membrane. Adjacent to the first pharyngeal pouch, the first branchial cleft develops into the external auditory canal.

The second pharyngeal pouch develops into the tonsil.

The superior portion of the third pharyngeal pouch differentiates into the inferior parathyroid and the inferior portion migrates caudally to become the thymus.

The fourth pharyngeal pouch forms the superior parathyroid gland; the area roughly corresponding to the fifth and sixth pharyngeal pouches is incorporated into the thyroid gland.

Anatomical structures of the upper airway and their relation to the practice of pediatric anesthesia

The approach to airway management of infants and young children is influenced by developmental differences in head and neck anatomy. These differences are modified by two major growth spurts during childhood, the first at the time of the acquisition of permanent dentition (i.e. age 7–10 years), and the second during puberty in the teenage years, both of which contribute to the vertical growth of the facial structures. Thus, it is no coincidence that these two general age ranges are the approximate points in life in which certain persons without obvious anatomical deformities will become difficult to intubate.

Skull

When compared to the older child, the infant's skull (especially the occipital region) is relatively larger, such that neck flexion may not be required to attain the classical "sniffing" position that optimizes visualization of the glottic structures during laryngoscopy. At birth, the neurocranium to face size ratio is 8:1, and declines to 6:1 at 2 years of age, 4:1 at 5 years of age, and approximately 2:1 by adulthood [12,13]. The growth of the lower facial bones is proportionately linear from ages 1 to 11 years [11].

The mandibular arch of the infant is U-shaped and becomes more V-shaped during childhood until adolescence when it is completely developed. The angle between the ramus and the body of the mandible is more obtuse in infants than in adults. This largely accounts for the relatively low incidence of difficult intubations in infants and young children compared with adults.

Nose

Overall, the most important difference in nasal anatomy between young children and adults is merely the smaller size. Small nasal passages are more likely to become obstructed with blood or secretions as a result of manipulations during general anesthesia. Young children are less likely to have occult nasal polyps or septal deviations when compared with adults [14]. The anatomical dimensions of the nasopharynx increase linearly between 1 and 11 years of age [11].

In the past, small infants were considered to be obligate nasal breathers and therefore predisposed to breathing difficulties during periods of nasal obstruction. However, this has largely been disproven [15], although infants with choanal atresia will often develop upper airway obstruction that results in varying degrees of hypoxemia [16].

Oral cavity

The infant tongue is relatively larger in proportion to the oral cavity when compared with the adult. Tongue volume increases linearly between ages 1 and 11 years [11]. Magnetic resonance imaging (MRI) studies of the upper airway during general anesthesia have demonstrated that, as in adults [17], upper airway obstruction occurs primarily at the levels of the soft palate and epiglottis, and not at the level of the tongue [18].

The 20 primary teeth are identified by a lettering system (Fig. 16.2A) They begin to erupt during the first year of life, and are shed at between 6 and 12 years of age. The 32 permanent teeth begin to appear at the same time as the primary teeth are shed and are identified by a numbering system (Fig. 16.2B).

Oropharynx

In newborns, the uvula and epiglottis are in close proximity, which makes possible the simultaneous acts of nasal breathing and oral ingestion of liquids. This anatomical relationship is maintained throughout most of the first year of life, but during the second year, the larynx begins to descend as it adapts to its greater role in phonation.

Although mechanisms have not been elucidated, the pharynx of premature newborns is susceptible to passive collapse, especially during apnea, but may also collapse as a result of cervical flexion or nasal obstruction [19]. These effects are exacerbated by the administration of general anesthesia or sedatives, which decrease pharyngeal muscle tone. Furthermore, pharyngeal collapse often occurs in premature infants during application of cricoid pressure.

Of interest, the upper airway of a normal infant is smaller in both inspiration and expiration at 6 weeks of age compared to the neonatal period. This relative narrowing may be caused by postnatal growth of adenoid tissue, or thickening of the mucous membrane lining in response to infection or second-hand smoke exposure. The linear dimensions of the soft palate and oropharynx increase linearly between 1 and 11 years of age [11,20].

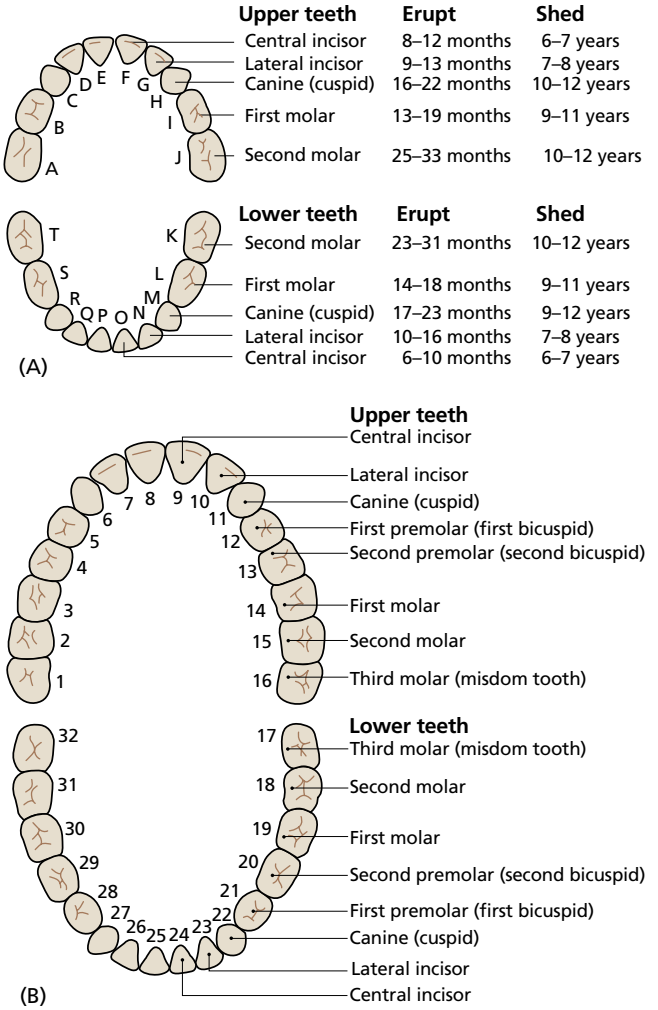

Figure 16.2 The picture is viewed as if the patient is facing the examiner with their mouth open. (A) The 20 primary teeth are lettered A through T, beginning with the right upper molar and ending at the right lower molar. (B) The 32 permanent adult teeth are identified by a numbering system that begins at the right upper third molar and ends at the right lower third molar. *Source:* Reproduced from The American Dental Association [421].

Adenoidal and tonsillar tissue are minimal at birth, and then grow rapidly between 4 and 7 years of age. The growth of airway lymphoid tissue parallels the growth of the facial and cervical bony structures [11]. Hypertrophied tonsil and adenoid tissue is likely the most common cause of upper airway obstruction after administration of general anesthesia in children in this age group.

The epiglottis of infants is relatively narrow and short, and angled into the lumen of the airway. The lower portion of the oropharynx at the level of the epiglottis is particularly compliant and prone to collapse during anesthetic- or sedative-induced upper airway obstruction [21]. Therefore, obstruction at the epiglottic level can be significantly lessened by placing the patient in the lateral position [21].

The effect of gender on oropharyngeal length has been studied, with particular reference to an association between relatively longer airway length and the predisposition to obstructive sleep apnea [22]. Prior to the onset of puberty, boys and girls have relatively similar oropharyngeal length but after the onset of puberty, the oropharyngeal lengths in boys are greater than that of girls, even after correcting for

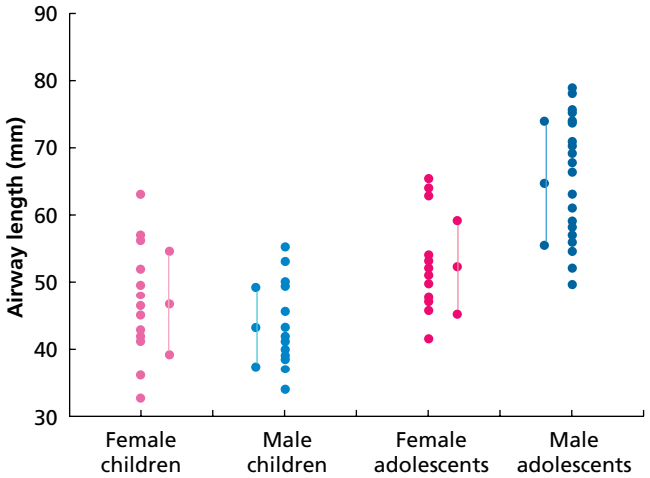

Figure 16.3 Prior to the onset of puberty, boys and girls have relatively similar oropharyngeal length but after the onset of puberty, the oropharyngeal lengths in boys are greater than those in girls, even after correcting for height and weight. *Source:* Reproduced from Ronen et al [22] with permission of the American Academy of Pediatrics.

height and weight (Fig. 16.3). The relatively longer upper airway length in males has been implicated as a possible etiological factor in the greater disposition in males toward OSAS [23]. Thus, postpubertal males may have a greater disposition toward upper airway collapse in response to administration of pharmacological agents that depress consciousness.

Larynx

During infancy, the relative position of the larynx is slightly higher in the neck than in older children and adults. Although its position relative to the cervical spine is complete by the age of 3 years (it descends from C2–C3 to C4–C5), it continues to descend relative to other facial structures such as the mandible [24]. The tip of the epiglottis proceeds in a gradual and linear descent from C2 to C3 from birth to 18 years of age [25]. This relative movement is unique to humans because of the shifting functionality from sucking and swallowing while breathing to the development of speech later in life. Early in life, a relatively high larynx facilitates simultaneous sucking and respiration due to the apposition of the epiglottis (as high as C1) and the soft palate. Additional differences in early life that protect against aspiration during feeding include relatively thicker aryepiglottic folds and larger arytenoids.

The chest wall of neonates and small infants is highly compliant and tends to collapse inward, thus reducing functional residual capacity (FRC) and promoting atelectasis. To preserve FRC, the adductor muscles of the larynx act as an expiratory "valve," and restrict exhalation in order to maintain positive end-expiratory pressure. This is referred to as "laryngeal braking" [26,27].

The higher position of the larynx during infancy influences airway management to the extent that the glottic opening is more easily visualized using a straight, rather than a curved laryngoscope, and in infants less than 1 year of age, elevation of the base of the skull is usually not necessary [28].

In children with pharmacologically induced neuromuscular blockade, the cricoid cartilage is the narrowest portion of the upper airway because of its inability to distend in a similar

manner as the vocal cords [29–31]. A tracheal tube that easily passes through the relatively compliant vocal cords may compress surface mucosa at the level of the cricoid cartilage and predispose to inflammation, edema, and subsequent scarring and stenosis [32–34]. Tracheal edema is more likely to increase airway resistance in smaller diameter airways since the resistance to flow through a tube is related to the fifth power of the radius of the tube (since this flow is largely turbulent). In non-intubated, sedated children without neuromuscular blockade, the adductor muscles of the vocal cords are active, and are the basis for the narrowest portion of the upper airway to occur at this level [35–37]. The relationship between the sizes of the structures along the upper airway remains relatively stable throughout growth and development [37]. Therefore, there appears to be no specific age during childhood at which the form or structure of the most appropriate tracheal tube (i.e. cuffed versus uncuffed) would require a change for the benefit of the child.

Some congenital conditions, notably trisomy 21, are associated with smaller than normal subglottic and tracheal diameters [38–42]. Therefore, appropriate tracheal tube sizes may be smaller than usual for age in these patients. Ultrasound examination of the subglottic region may be used to guide tracheal tube size selection [43].

Tracheal lengths (distance between glottis and carina) increase linearly during childhood [30,44]. A familiarity with these distances in infants will facilitate proper placement of the tracheal tube midway between the glottis and carina (Fig. 16.4). A shortened tracheal length (i.e. higher bifurcation) caused by a reduced number of tracheal cartilage rings is noted in certain conditions such as trisomy 21 [40] and myelomeningocele [39,45]. Therefore, in these patients, special attention is warranted to ensure proper tracheal tube position and avoidance of right bronchial intubation.

Developmental physiology of the upper airway

The human upper airway serves a concomitant function as a conduit for breathing and for the passage of food. This property, which is only found in higher evolved species, presents a unique problem, the basis of which is that the upper airway is integrally involved in the processes of breathing, speech, and eating, without the benefit of rigid cartilaginous support. In the conscious state, this requires rigorous neurological coordination between competing structures. Although relatively little is known about the development of neural control in the upper airway [1], it is this characteristic that renders the upper airway vulnerable to collapse during administration of sedatives or anesthetics.

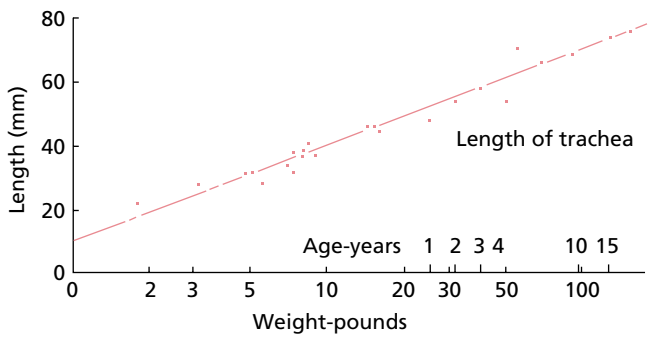

Figure 16.4 Distance between vocal cords and carina as a function of weight in pounds. *Source:* Reproduced from Butz [30] with permission of the American Academy of Pediatrics.

The pharyngeal and laryngeal muscles that normally contract to maintain upper airway patency are activated in parallel with the diaphragm. Activation of pharyngeal abductor muscles prevents upper airway collapse in response to the brief challenge of negative pressure created by diaphragmatic contraction. Contraction of pharyngeal adductor muscles maintains lung volume during the exhalation portion of a breath [46].

Development of airway protective mechanisms

The term "airway protective mechanisms" encompasses two separate but interrelated functions of the upper airway: (1) protection against aspiration of foreign material into the respiratory tree; and (2) protection against airway collapse during sleep or states of pharmacologically impaired consciousness.

The mechanisms that protect against aspiration of liquid or solid contents into the respiratory tree include a series of unconsciously controlled reflexes that include swallowing and cough (to transport substances away from the laryngeal inlet), and apnea and airway obstruction, which are attempts at prevention of substances from entering the respiratory tree [47]. Additional reflexes consist of laryngospasm and arousal [48]. Collectively, these have been termed the laryngeal chemoreflexes (LCR), and they mature throughout development [49]. The perinatal period represents a time of relatively high vulnerability to aspiration, as is clinically seen in the meconium aspiration syndrome, which occurs in nearly 2% of all livebirths [50].

In the newborn, introduction of water into the larynx results in a characteristic set of responses that include swallowing, apnea, bradycardia, and peripheral vasoconstriction with shunting to the central vascular bed. These adaptive responses are prominent in preterm infants and lessen with advanced gestational age [47,51–56]. The apneic reflexes have been implicated in the etiology of sudden infant death syndrome (SIDS) [57]. Administration of sedatives and anesthetic agents is associated with prolongation of the apneic reflex [58–60]. The apneic reflex is also prolonged (and bradycardia worsened) during baseline hypoxemia [61,62], anemia [63], and respiratory syncytial virus (RSV) infection [64,65]. Conversely, the apneic reflex is shortened by administration of central stimulants such as theophylline [59]. Soon after the newborn period, the apneic portion of the LCR response disappears [66]. Cough is more prominent, and continues for the remainder of life when foreign substances enter the laryngeal area.

The effects of anesthetics and sedatives on the efficacy and potency of airway protective reflexes are clinically important to establish the safety of pharmacological agents administered to non-tracheally intubated children. The body of knowledge concerning these effects is beginning to develop. At predefined depths of general anesthesia, propofol appears to be a more potent inhibitor of the laryngospasm reflex than sevoflurane [67], and fentanyl does not appear to reduce the propensity toward laryngospasm in sevoflurane-anesthetized children [68]. Data are also emerging on the effects of anesthetics on

upper airway patency. In adults, at similar depths of sedation or general anesthesia, propofol appears equal to isoflurane in promoting upper airway collapse [69,70], and both are more potent than equivalent levels of deep sedation attained with midazolam [71]. In children, the addition of 50% nitrous oxide promotes upper airway closure in those with enlarged tonsils who received oral midazolam [72], and halothane appears to preserve upper airway patency better than equipotent levels of sevoflurane [73].

KEY POINTS: DEVELOPMENTAL ANATOMY AND PHYSIOLOGY OF THE PEDIATRIC AIRWAY

- All six branchial arches and all four pharyngeal pouches contribute to formation of the airway
- The infant's occiput is relatively larger than the older child's, rendering neck flexion unnecessary to attain the sniffing position
- Primary teeth are shed between 6 and 12 years of age; attention to loose teeth is important in this age group
- Tonsil and adenoid tissue size is maximal between 4 and 7 years of age
- The larynx is at the C2–C3 level at birth, and descends with growth to the C4–C5 level at age 3 years
- With neuromuscular blockade, the cricoid cartilage is the narrowest portion of the pediatric airway; without neuromuscular blockade the vocal cords are the narrowest location

Management of the normal pediatric airway

Preoperative airway assessment

Preoperative airway assessment will identify nearly all children who, when anesthetized, are likely to develop difficult mask ventilation or difficult tracheal intubation. Information gained from the preoperative history and physical examination will determine the method of anesthetic induction and the approach for maintaining a patent upper airway following loss of consciousness. Similarly, risk factors for postoperative respiratory complications are identified at this time, allowing for appropriate preparation or delay of anesthesia and surgery when appropriate. Common airway assessment techniques used in adults have not been validated for use in infants and children; however, modifications of these methods may yield valuable information.

History

In almost all cases, a review of the child's previous anesthetic records as well as discussion with parents will reveal potential airway management problems. A history of previous uneventful anesthetics is encouraging, but changes in growth and development may affect airway anatomy. A reliable history of unobstructed breathing during sleep, especially while supine, often predicts the ability to mask ventilate without difficulty. Conversely, loud snoring and/or obstructive apnea are excellent predictors of upper airway obstruction following anesthetic- or sedative-induced unconsciousness.

During the preoperative interview, children and parents should be asked about the presence of loose deciduous teeth. Chipped or missing teeth should be documented. Very loose teeth should be electively removed after induction of general anesthesia to avoid accidental dislodgement (and pulmonary aspiration) during airway manipulations. A loose tooth is removed by grasping the tooth with a dry piece of gauze and pulling while rocking the tooth gently back and forth. Some bleeding is expected. Tooth removal is performed immediately following induction of anesthesia or after tracheal intubation, depending on the location of the tooth and risk of dislodgment during direct laryngoscopy. If elective tooth removal is contemplated, it should be discussed with parents and caregivers during the preoperative visit to avoid an unpleasant surprise when they are reunited with their child in the recovery room.

Children with non-permanent orthodontic hardware that may be dislodged during airway management should have such devices removed whenever possible. Occasionally, preoperative orthodontic consultation may be required.

Coexisting diseases and airway management

A number of coexisting diseases may influence airway management. For example, children with tumors of the head or neck may have distorted airway anatomy. Previous radiation therapy which results in scarring of the tongue and submandibular tissues is often associated with difficult tracheal intubation secondary to poor mandibular soft tissue compliance. Radiation therapy may also cause mucosal tissues to be friable and prone to bleeding.

If a child presents with an unfamiliar syndrome or diagnosis, the anesthesiologist should obtain a comprehensive understanding of the condition as it relates to airway management. The anesthetic implications of a number of common congenital syndromes and conditions are presented in Chapter 43.

The presence, type, and severity of pulmonary disease impact the advantages and disadvantages of different airway management techniques. For example, the child with limited pulmonary reserve may not tolerate anesthetic-induced hypoventilation and may require tracheal intubation and controlled ventilation for a procedure that would be performed with spontaneous ventilation and a natural airway in an otherwise healthy child. On the other hand, the child with highly reactive lower airways may benefit from a technique that is less stimulating to the airway.

In children with asthma, the severity, triggers, and current medication status should be assessed. Medical management should be optimized prior to surgery. This may include inhaled β-agonist therapy, inhaled corticosteroids, or a course of systemic corticosteroids, depending on the severity of disease and the procedure being performed. Adequate preoperative preparation of asthmatic children results in decreased intraoperative bronchospasm [74]. Uncontrolled asthma may warrant postponement of elective surgery. Some children may have persistent lower airway obstruction despite maximal medical management. In such cases, the anesthetic plan should include provisions for limiting triggers that exacerbate bronchoconstriction.

Bronchopulmonary dysplasia is a chronic lung disease associated with prematurity. Currently, most cases occur in

infants born at less than 30 weeks' gestational age and weighing less than 1200 g at birth [75]. Various factors contribute to the genesis of bronchopulmonary dysplasia, including mechanical ventilation-induced barotrauma and volutrauma, hyperoxia, infection, and genetic factors [75,76]. Although one study did not demonstrate an increased risk of postoperative respiratory complications [77], former preterm infants with pulmonary sequelae of prematurity may have a reduced tolerance of apnea and heightened airway reactivity, which can manifest as bronchospasm, oxyhemoglobin desaturation, or laryngospasm.

Children with significant pulmonary disease may benefit from preoperative consultation with a pulmonologist. Conditions meriting such consultation include cystic fibrosis, severe asthma, or pulmonary hypoplasia associated with congenital conditions such as congenital diaphragmatic hernia. Preoperative optimization of medical management and development of a postoperative care plan may decrease the incidence of postoperative complications.

Preoperative fasting and risk of aspiration

The adequacy of preoperative fasting and the risk of pulmonary aspiration of gastric contents should be assessed in every child. Current guidelines and recommendations for preoperative fasting in children are presented in Chapter 17. Children with high intestinal obstruction ideally should have gastric decompression prior to a rapid-sequence induction of general anesthesia. A history of gastroesophageal reflux disease warrants an assessment of its severity and response to therapy. Children with mild reflux disease or disease that has been effectively treated are candidates for inhaled induction of anesthesia. Children with esophageal motility disorders such as achalasia should be regarded as being at risk for pulmonary aspiration and managed accordingly.

Physical examination

Preoperative airway examination focuses on identification of physical features that suggest a difficult facemask ventilation or tracheal intubation. In adults, there are validated assessments that identify predictors of airway management difficulty [78–82]. Although seemingly useful (Fig. 16.5), similar validated assessments have not been published for infants and young children. Nonetheless, there are certain anatomical features that are consistently associated with airway difficulty in the pediatric population. These include limited mouth opening, limited neck mobility, maxillary hypoplasia, mandibular hypoplasia, and diseases associated with decreased compliance of the submandibular space. School-aged children and adolescents will cooperate with physical examination maneuvers to assess the airway, but in toddlers and infants, the airway exam is limited to an assessment of external physical features. In infants, neck mobility can be assessed by watching the infant track a colorful object, and mouth opening is assessed during crying.

Ultrasound examination has been used to examine the child's airway in an attempt to delineate the internal anatomical characteristics, predict optimal endotracheal tube size, and determine the presence of subglottic stenosis [83].

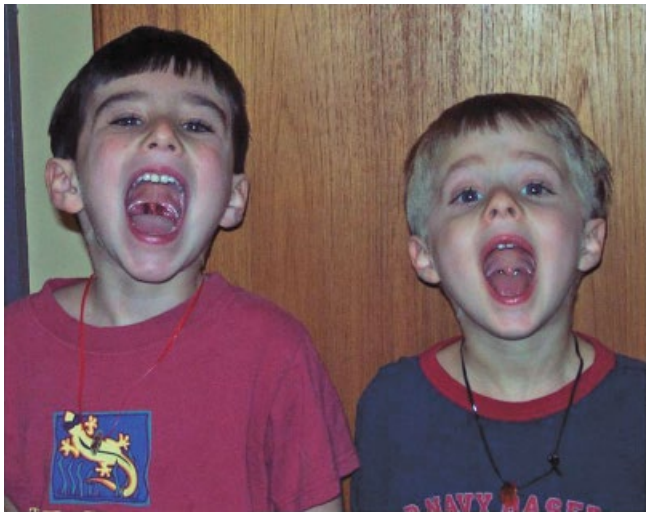

Figure 16.5 Although visualization of pharyngeal structures correlates with ease of intubation in adults, similar validation studies in pediatric patients have not been performed.

Routine airway management

Preoperative preparation of airway equipment

Airway-related equipment that should be prepared in the operating room prior to the arrival of the patient include the appropriate sized facemask, laryngoscope handle and blade, tracheal tube, oral airway, laryngeal mask airway, and working suction catheter. If use of a laryngeal mask is planned, it should be prepared with lubricant and ready for insertion.

A syringe of succinylcholine, 4–5 mg/kg, for intramuscular injection should be within reach in the event that laryngospasm or other type of upper airway obstruction occurs and immediate paralysis is required when intravenous access is absent. This dose should be calculated prior to the induction of general anesthesia.

Facemask ventilation

Proper positioning of the child during induction of general anesthesia is important in promoting upper airway patency and facilitating facemask ventilation and direct laryngoscopy. Because of the wide range of patient sizes encountered in pediatric practice, the adequacy of mask size and fit should be assessed prior to anesthetic induction. A properly fitting mask will cover the nose and mouth without covering the eyes or extending beyond the chin. A common mistake among trainees is to press the cephalad end of the mask onto the middle of the nose and unknowingly obstruct the airway. The cephalad end of the mask should be properly positioned on the bridge of the nose without pressing into the orbits. Introducing the mask to the child before it is connected to the anesthesia circuit provides a non-threatening opportunity for the child to acclimatize to it while giving the anesthesiologist an opportunity to assess fit.

Various types of pediatric facemasks are commercially available. While some have been designed to minimize dead space (attractive in the smallest patients), there are no data supporting the superiority of one mask type over another. Reusable black facemasks have largely been supplanted by transparent disposable facemasks. These disposable masks are advantageous in that the anesthesiologist can look through

them during ventilation and see the mist that accompanies airflow, assess the position of an oral or nasopharyngeal airway, or identify regurgitated fluid or vomitus. Application of a fruit- or candy-scented lip balm to the interior of the unscented mask may improve the child's acceptance.

During inhaled induction of general anesthesia, the facemask is initially applied gently to the face. The hand holding the mask should be held in such a way that the child's field of view is not obstructed. The other hand may be placed on the child's head and kept ready to hold the head still during the excitement stage of anesthetic induction. As consciousness is lost, the position of the hand holding the mask is adjusted so that the third and possibly the fourth and fifth fingers are over the bony mandible. Special care must be taken in smaller children not to exert pressure on the submandibular tissues, which can create upper airway obstruction by posterior displacement of the tongue. Following loss of consciousness, 5–10 cmH_2O of continuous positive airway pressure (CPAP) is applied by partial closure of the adjustable pressure limiting (APL) valve, and a head tilt or chin lift maneuver is performed with the left hand holding the mask while the right hand holds the breathing bag to assess breath-to-breath adequacy of air movement. Adequacy of ventilation is also continuously assessed by visual inspection of chest rise and breathing bag movement, auscultation with a precordial stethoscope, and the presence of a capnographic waveform.

Difficulty or inability to effectively perform manual ventilation through a facemask is uncommon in pediatric patients in the hands of experienced practitioners. Common causes for the inability to ventilate adequately through a facemask in children include enlarged tonsils or adenoids, and soft tissue (tongue, pharynx, etc.) obstruction in very small infants. A prospective, observational study found the incidence of difficult bag-mask ventilation in children up to 8 years of age to be 6.6%, using two or more of the following findings: application of CPAP of 5 cmH_2O, required use of an oral or nasal airway, need for two-person ventilation, oxygen desaturation <95%, or unanticipated need to increase inspired fraction of oxygen (FiO_2) [84].

Chin lift, jaw thrust, and continuous positive airway pressure

Simple maneuvers such as performing a chin lift or mandibular protrusion (jaw thrust) can restore upper airway patency and relieve obstruction by increasing pharyngeal diameter at several levels [85–89]. The combination of either of these two techniques with the application of approximately 10 cmH_2O of CPAP is the initial treatment of airway obstruction in the spontaneously breathing child [90]. These combined maneuvers (jaw thrust with CPAP or chin lift with CPAP) increase the diameter and patency of the upper airway and glottic opening [86]. While chin lift and jaw thrust have effects on tongue and epiglottis position, CPAP acts as a pneumatic splint to increase airway dimensions. Because jaw thrust combined with CPAP has not been shown to be superior to chin lift combined with CPAP, it has been suggested that chin lift with CPAP is preferable to a forceful jaw thrust, since this can result in postoperative discomfort [87]. In children with suspected cervical spine injuries, neck extension should be avoided; jaw thrust may be preferable in these cases.

Oral airway

After optimization of positioning, facemask application, and application of CPAP, the oral airway is usually the next intervention to restore patency of an obstructed upper airway in the anesthetized child. A variety of oral airways with subtle differences in design are commercially available for pediatric patients, with no literature supporting the superiority of one type or brand over another. However, those with hollow channels offer the advantage of being able to insert a suction catheter into the oropharynx with the oral airway inserted.

When inserting an oral airway, care must be taken to select the appropriate size. A properly sized airway should have its pharyngeal tip project just beyond the angle of the mandible when held next to the child's head with the opposite end at the mouth (Fig. 16.6). Insertion of an undersized airway can push the tongue posteriorly and worsen obstruction, while an oversized airway can impinge on the epiglottis or glottis and worsen obstruction or trigger coughing and laryngospasm.

Oral airways are generally reserved for use in anesthetized children and are poorly tolerated by awake or lightly anesthetized children as they can stimulate gagging, coughing, or laryngospasm. However, as a child emerges from anesthesia, it is best to leave an oral airway in place to prevent the child from biting on the tracheal tube and to maintain airway patency following extubation. Children will typically expel the device as they regain full consciousness.

Nasopharyngeal airway

A nasopharyngeal airway may be inserted to restore patency of the obstructed upper airway when the obstruction is suspected to be at the level of the upper pharynx or higher. Unlike an oral airway, a nasopharyngeal airway can be tolerated in the sedated or lightly anesthetized child and can be left in place postoperatively to maintain airway patency in selected circumstances such as following tonsillectomy for obstructive sleep apnea.

A disadvantage of nasopharyngeal airway insertion is occurrence of epistaxis. This can be minimized by using a soft airway and adequate lubrication. If time allows, topical administration of a vasoconstrictor to the nasal mucosa is helpful. Hypertrophic adenoid tissue can impede passage and may result in bleeding. The proper size nasopharyngeal

Figure 16.6 Sizing the oral airway, showing the pharyngeal tip projecting just beyond the angle of the mandible.

airway can be selected by holding it next to the face before insertion. With the flared external end at the position of the nasal opening, a properly sized airway will have the pharyngeal tip extending a finger breadth beyond the space between the angle of the mandible and the tragus (Fig. 16.7). A nasopharyngeal airway that is too short may not bypass upper airway obstruction, while one that is too long can impinge on the epiglottis and trigger coughing or laryngospasm.

Two-person, two-handed mask ventilation

When it is difficult to maintain a patent airway with the above techniques, having one provider apply the facemask using two hands and simultaneously perform a chin lift and jaw thrust while another provider delivers breaths with the breathing bag is more effective than a single-handed mask ventilation technique (Fig. 16.8). Patients requiring a two-person technique should be considered difficult to ventilate by facemask [91,92].

Figure 16.7 Sizing the nasopharyngeal airway, showing the pharyngeal tip projecting just beyond the space between the angle of the mandible and the tragus.

Figure 16.8 Two-handed mask technique.

Modified oral or nasal airway

The functionality of a standard oral or nasopharyngeal airway can be increased by inserting a 15 mm tracheal tube adaptor into the opening of the oral airway or the flared end of a nasopharyngeal airway (Fig. 16.9). The resulting modified airway can then be connected to the anesthesia circuit, and positive pressure can be delivered if the leaks around the airway are manually sealed. Positive pressure ventilation can be delivered by holding closed the mouth and opposite nasal passage [93]. This assembly with a nasopharyngeal airway is particularly useful in patients with limited mouth opening in whom oral airway or laryngeal mask insertion is not possible. The modified nasal airway is also a valuable adjunct to pediatric difficult airway management as a means to provide oxygen and inhaled anesthetic during oral intubation while maintaining spontaneous respiration [94]. Similarly, a cut tracheal tube can also be used for the same purposes [95], but because it is made of stiffer material it is more likely to cause trauma and bleeding during insertion.

Airway management with a facemask or natural airway

Maintenance of general anesthesia with a facemask is possible if a patent airway is easily achieved with or without an oral or nasal airway. Generally, use of a facemask is preferred for cases of shorter duration, and when the head of the operating room table is not turned away from the anesthesia machine. A natural airway that does not require the assistance of the anesthesiologist for patency is often used in conjunction with a nasal cannula for supplemental oxygen administration and the use of intravenous general anesthesia such as propofol. Special cannulae designed to monitor exhaled carbon dioxide are commercially available or a standard cannula can be modified for this purpose. This technique is commonly used during total intravenous anesthesia for radiological or gastrointestinal endoscopy procedures.

Figure 16.9 Oral and nasopharyngeal airways can be attached to a 15 mm tracheal tube adaptor to provide easy connection with an anesthesia machine circuit.

Laryngeal masks and supraglottic devices

The introduction of the laryngeal mask airway (laryngeal mask) into clinical practice marked the beginning of a new era of anesthesia care for adults [96] and children [97]. Since that time, the laryngeal mask has functioned as an alternative to the facemask and the tracheal tube, depending on the clinical situation. Of equal importance is its use as an airway rescue device in patients with life-threatening upper airway obstruction, or as an aid to difficult tracheal intubation.

The laryngeal mask consists of an airway tube with an elliptically shaped cuff at the distal end that is inflated after insertion. When properly positioned, its distal aperture lies opposite the laryngeal inlet while the tip of the cuff rests in the proximal esophagus. The inflated cuff creates a seal with the lateral walls of the hypopharynx, the esophageal inlet, and the tongue base.

The classic sniffing position is used for routine laryngeal mask insertion. The deflated or partially inflated laryngeal mask is held in the dominant hand like a pencil, with the tip of the index finger at the junction of the cuff and the airway tube on the side of the laryngeal aperture. The mouth is opened and the tip of the device is pressed cephalad along the hard palate and into the oropharynx until a resistance is felt as the tip engages the esophageal opening. Because of anatomical differences in children (e.g. large tongue, cephalad larynx, tonsillar hypertrophy), this technique may result in a lower success rate than in adults. Therefore, alternative approaches have been devised (i.e. lateral and rotational insertion techniques) and may be more successful in children [98–103]. These studies were performed using the classic laryngeal mask; therefore it is unknown whether these results can be extended to other commercially available laryngeal masks and supraglottic airways that may have more favorable insertion properties.

Airway management with the laryngeal mask is advantageous in a number of ways. Insertion of the device is simple and easily learned, and there is a high success rate with insertion even by inexperienced operators. Laryngeal mask insertion does not require muscle relaxation, can be performed at a lighter level of anesthesia as compared to tracheal intubation, and is associated with fewer hemodynamic changes when compared to tracheal intubation [104,105]. Use of a laryngeal mask is associated with less airway reflex activation than an endotracheal tube and has been shown to be associated with a nearly threefold reduction in the risk of perioperative respiratory adverse events (e.g. laryngospasm, bronchospasm, coughing, desaturation) in infants [106]. A meta-analysis of 19 studies comparing supraglottic airway devices to tracheal intubation in children found that during recovery from anesthesia the incidence of desaturation (odds ratio (OR) = 0.34 (0.19–0.62)), laryngospasm (OR = 0.34 (0.2–0.6)), cough (OR = 0.18 (0.11–0.27)), and breath holding (0.19 (0.05–0.68)) was lower when a laryngeal mask airway was used. Postoperative incidences of sore throat (OR = 0.87 (0.53–1.44)), bronchospasm (OR = 0.56 (0.25–1.25)), aspiration (1.33 (0.46–3.91)), and blood staining on the device (OR = 0.62 (0.21–1.82)) did not differ between laryngeal mask airway and tracheal intubation [107]. However, when compared to adults, optimal positioning of the laryngeal mask becomes progressively more difficult in direct relation to decreasing age of the child. Improper positioning of the laryngeal mask may lead to inadequate ventilation, airway trauma, mask dislodgement, and gastric insufflation. Fiberoptic assessment of laryngeal mask position is often useful to ascertain that the laryngeal mask is properly positioned. A jaw thrust maneuver while inserting the smaller sized laryngeal masks may facilitate optimal positioning by lifting the epiglottis off the posterior pharyngeal wall and allowing the laryngeal mask tip to slide into the upper esophageal sphincter without causing downfolding of the epiglottis. In a large dataset of pediatric patients, retrospective analysis demonstrated that laryngeal mask failure was associated with use during head and neck procedures, non-outpatient admission status, prolonged surgical duration, congenital or acquired airway abnormality, and patient transport [108,109]. The laryngeal mask may be difficult to place in conditions where mouth opening is limited, such as temporomandibular joint ankylosis. Thermally softening the laryngeal mask before placement may allow the mask to fit through the limited opening [110].

The laryngeal mask is not usually associated with mechanical trauma to the tracheal mucosa and vocal cords. This is particularly relevant in children undergoing multiple anesthetics over a relatively short time interval (e.g. daily radiation treatment). In one study the incidence of postoperative sore throat was equally as common compared with a tracheal tube [111]. The occurrence of postoperative sore throat in children appears to be correlated with laryngeal mask intracuff pressures above 40 cmH_2O [112]. The incidence of other less commonly reported complications from laryngeal mask use, such as lingual, hypoglossal, or recurrent laryngeal nerve injury [113–116], may also be decreased by routine monitoring of laryngeal mask cuff pressures.

In the years following the introduction of the originally designed laryngeal mask, a variety of different supraglottic devices have become available that have slightly different modifications. The ProSeal™ laryngeal mask (LMA North America) is similar to a classic laryngeal mask with the addition of a channel through which a gastric drainage tube can be passed. The ProSeal laryngeal mask is available in sizes appropriate for use in infants and children. Some practitioners avoid positive pressure ventilation with laryngeal mask use because of the possibility of gastric insufflation. Thus, the ProSeal may be preferred in patients who require positive pressure ventilation [117,118]. However, there is no evidence that any specific type or model of supraglottic airway (SGA) device is superior in clinical pediatric anesthesia practice. The choice of SGA is therefore left to practitioner preference.

The i-gel® SGA (Intersurgical, Liverpool, NY, USA) is another type of SGA that has been useful in pediatric anesthesia. It has a built-in bite block and contains a gastric access channel. An observational study in 50 children reported easy insertion and gastric access in all patients [119]. When compared to the Ambu® AuraOnce™ laryngeal mask (Ambu, Glen Burnie, MD, USA), the i-gel demonstrated higher leak pressures, longer insertion times, and a tendency to slide out of the oral cavity after insertion [120]. A larger comparative study (n = 170) in children demonstrated that the i-gel was equally as efficacious as the LMA® Supreme™ but the i-gel required relatively more manipulations [121]. A meta-analysis of nine prospective randomized controlled trials comparing the i-gel to other laryngeal masks found no differences in first

insertion success rates and ease of insertion when compared to the Proseal and classic laryngeal mask airways [122].

The air-Q intubating laryngeal airway (Cookgas LLC, Mercury Medical, Clearwater, FL, USA) is an SGA designed to facilitate tracheal intubation. It is unique because it easily accommodates a cuffed tracheal tube through the airway tube of its smaller sizes (<3) and has a custom stabilizer bar that allows its removal after tracheal intubation. Its efficacy as a conduit for tracheal intubation was assessed in an audit of 34 difficult intubations that found 97% tracheal intubations on the first attempt through the air-Q using fiberoptic bronchoscopy (n = 25), Shikani Optical Stylet (n = 7), or blindly (n = 2) [123]. However, blind insertion is not preferred and may result in severe airway trauma.

Like an oral airway, laryngeal masks and other SGAs are poorly tolerated in awake or lightly anesthetized patients (except infants with severe airway obstruction). Insertion at an inadequate plane of anesthesia can result in coughing, laryngospasm, gagging, and emesis. A number of studies have been conducted to determine optimal drug dosages to achieve adequate conditions for laryngeal mask insertion. Sevoflurane alone can be used to facilitate laryngeal mask insertion in children [124]: an effective concentration of 2.2 vol% provides satisfactory conditions in 95% of patients when 10 min are allowed to elapse for equilibration of brain and alveolar sevoflurane concentrations prior to insertion [104].

At approximately equipotent dose levels, propofol is a more potent suppressor of upper airway reflexes compared to thiopental [125] and is a superior induction agent for laryngeal mask insertion in terms of adverse respiratory events such as coughing or laryngospasm [126]. Propofol alone can be administered to facilitate laryngeal mask insertion. Doses exceeding 5 mg/kg are required to achieve satisfactory conditions in 90% of unpremedicated children [127]; however, such doses may result in undesirable hemodynamic effects and apnea. The combination of propofol with other drugs to facilitate laryngeal mask insertion is advantageous. For example, co-administration of lidocaine will result in less pain on injection of propofol [128–130] and may contribute to decreasing airway reflexes [131]. Opioids such as fentanyl [132], alfentanil [129], and remifentanil [133] may also aid in ease of laryngeal mask insertion when co-administered with propofol.

In adults, the laryngeal mask was originally designed for removal as the patient awakens [96]. In children, there has been controversy over whether it is better to remove the laryngeal mask under deep general anesthesia or after awakening. Some studies show a higher incidence of respiratory complications (coughing, laryngospasm, or oxyhemoglobin desaturation) when the laryngeal mask is removed when the child has largely regained consciousness [134,135], but others found a decreased incidence of such complications with awake removal [136,137], and some report no difference in complications based on removal technique [138,139]. One of the principal advantages of laryngeal mask removal under deep anesthesia is time efficiency – following laryngeal mask removal and assurance of a patent airway, the child can be transferred to the recovery room and allowed to emerge from anesthesia. If laryngeal mask removal under deep anesthesia is planned, the end-tidal sevoflurane concentration at which this can be safely performed in 95% of children without coughing, movement, laryngospasm or other airway complication is 2.2% [140,141].

Laryngeal mask insertion may be tolerated in conscious newborns with severe upper airway obstruction, as occurs with the Pierre Robin sequence, Treacher Collins syndrome, or Goldenhar syndrome [142–144]. This may facilitate management of the difficult airway by establishing a conduit through which fiberoptic intubation can be accomplished.

Pressure support ventilation decreases the work of breathing in spontaneously breathing children [145]. The advent of anesthesia machines with more sophisticated ventilators that can deliver pressure support ventilation has also made use of laryngeal masks more feasible as an alternative to tracheal intubation [146]. While work of breathing is improved with the application of CPAP [147], work of breathing is less and respiratory rate and end-tidal carbon dioxide are lower with pressure support ventilation compared to CPAP in children breathing with a laryngeal mask [148,149].

KEY POINTS: MANAGEMENT OF THE NORMAL PEDIATRIC AIRWAY

- Preoperative airway assessment includes a history of difficult airway management, assessment of dentition, and evaluation for craniofacial syndrome or anomaly
- Anatomical features consistently associated with difficult airway management include limited mouth opening and neck mobility, maxillary or mandibular hypoplasia, and decreased compliance of the submandibular space
- A properly fitting facemask covers the nose and mouth without covering the eyes or extending beyond the chin
- CPAP of 5–10 cmH_2O, chin lift, and jaw thrust by positioning fingers over the mandible (not subglottic soft tissue) are common maneuvers during routine airway management
- An oral airway of proper size can be placed if these maneuvers do not restore upper airway patency; placing an airway during light anesthesia can stimulate gagging, coughing, and laryngospasm
- Two-handed mask ventilation with jaw thrust, with a second person delivering manual breaths, is often useful for significant upper airway obstruction
- Supraglottic airway devices such as the laryngeal mask airway are very commonly used for shorter cases without airway anomalies or aspiration risk

Tracheal intubation

Indications for tracheal intubation are determined by the surgical procedure and the potential risk of aspiration of gastric contents. As a general rule, tracheal intubation is indicated for open cavity procedures of the abdomen or chest, intracranial procedures, and in cases where control of arterial PCO_2 is required. It is also indicated in cases where the anesthesiologist has limited access to the airway, such as procedures involving the head and neck or patients in the prone or lateral position.

Positioning for mask ventilation and tracheal intubation

In adults, the "sniffing position" (i.e. neck flexion and head extension) is classically described as the optimal head and neck position to facilitate direct laryngoscopy and tracheal intubation. The recommendation for this position is based on texts published between 1852 and 1944 [150]. However a number of more recent publications have suggested that the sniffing position in adults may offer no advantage over simple extension of the head for successful direct laryngoscopy [151–153]. In a study of the alignment of the oral, pharyngeal, and tracheal axes in children anesthetized for MRI scans of the head and neck, better alignment was achieved with simple extension of the head as compared to the sniffing position [154]. However, comparative trials examining the optimal position for laryngoscopy and intubation in children have not been carried out. The large occiput of an infant, when placed on a pillow, can flex the head and result in airway obstruction. Eliminating the pillow or placing a soft roll beneath the shoulders may improve upper airway patency.

Direct laryngoscopy

Direct laryngoscopy remains the most common method of tracheal intubation in children. Direct laryngoscopy using a straight Miller blade has traditionally been emphasized in infants and young children. This practice is largely based on anatomical studies [28] but comparative studies have not been performed [150,155,156]. The straight Miller blade may allow for greater control and displacement of the base of the tongue. The smaller size and lower profile of the straight blade may give the operator more room to pass the tracheal tube through the mouth and pharynx. When laryngoscopy is performed using a straight blade, the blade is advanced and used to directly lift the epiglottis to expose the larynx. The straight blade can also be directed into the vallecula and used to indirectly lift the epiglottis as is done with the standard curved blade. In Miller's 1946 original description of the infant version of the blade, it states "…the epiglottis is visualized and raised slightly to expose the cords or, if the operator desires, the tip of the blade may be placed in front of the epiglottis and raised sufficiently to visualize the cords after the method of Macintosh" [157]. While direct laryngoscopy with the Miller blade may be more difficult to learn [158], there is evidence in adults that a superior view of the larynx can be achieved compared to the Macintosh blade [158,159]. A comparison of laryngoscopic views between size 1 Miller and Macintosh laryngoscope blades in children age less than 2 years found similar views. The authors also noted that the view with the Miller blade lifting the epiglottis was similar to the view obtained when it was placed in the vallecula. The view with the Macintosh blade was improved when it was used to lift the tongue base when compared to lifting the epiglottis [160].

If visualization of the glottis is suboptimal during direct laryngoscopy, the laryngoscopist can improve it by external manipulation of the thyroid cartilage. This practice was described by Benumof and Cooper as optimal external laryngeal manipulation (OELM) [161]. The application of backward, upward, and rightward pressure on the thyroid cartilage (known as the BURP maneuver) is an example of a specific type of OELM that many laryngoscopists employ as a first-line attempt at achieving optimal glottic exposure [162]. In newborns and small infants, OELM can be performed using the fifth finger of the left hand (Fig. 16.10).

Figure 16.10 The glottis can be externally manipulated by using the fifth finger of the left hand that holds the laryngoscope.

Maintaining arterial hemoglobin saturation during laryngoscopy and tracheal intubation

The administration of high-flow oxygen via a nasal cannula (transnasal humidified rapid insufflation exchange or THRIVE) has been shown to be an effective technique for prolonging the time from apnea to oxyhemoglobin desaturation in adults [163]. This approach to achieving apneic oxygenation has been demonstrated to be effective in children under controlled conditions during apnea with jaw thrust to maintain airway patency [164]. Subsequent studies may demonstrate whether this technique is effective in preventing oxyhemoglobin desaturation during intubation attempts and airway management in children.

Hemodynamic response to laryngoscopy and tracheal intubation

Tracheal intubation in infants and children is an intensely stimulating procedure and can provoke tachycardia, hypertension, increased intracranial pressure, and bradycardia [165–169]. Tracheal intubation with flexible bronchoscopy does not result in a decreased pressor response compared to direct laryngoscopy [165]. Performance of intubation under deep anesthesia attenuates the pressor response to intubation; however, many of the agents used to achieve this can cause cardiovascular depression. The opiates fentanyl, remifentanil, and sufentanil have each been used for this purpose with success [170–172], while lidocaine does not appear to be effective [173].

Movement of the tracheal tube tip with neck movement

Flexion or extension of the neck results in predictable changes in location of the tracheal tube tip. In children, with both orotracheal and nasotracheal tubes, neck flexion results in caudal migration of the tube tip, while extension causes cephalad migration of the tube tip [174–176]. Therefore, bronchial

intubation or extubation may result with neck movement after securing the tracheal tube.

Tracheal intubation without neuromuscular blockade

With the introduction into clinical practice of sevoflurane, propofol, and remifentanil, there has been increased interest in achieving tracheal intubation without neuromuscular blockade. Successful intubation can be accomplished with sevoflurane alone [177], although other drugs are commonly co-administered. Intubating conditions can be improved when sevoflurane is combined with propofol [178,179], lidocaine [131], and remifentanil [180,181]. Topically administered lidocaine delivered to the larynx and trachea during laryngoscopy is commonly performed, however it has been associated with a greater likelihood of airway reflex activation, desaturation, and perioperative respiratory adverse events in observational studies [182,183]. If tracheal intubation without neuromuscular blockade is performed following intravenous induction with propofol, a systematic review identified remifentanil (4 μg/kg) as the only single-agent adjuvant to yield an acceptable incidence of excellent intubating conditions [184]. Dexmedetomidine (1 μg/kg) combined with remifentanil (2 μg/kg) following intravenous propofol induction (3 mg/kg) has also been demonstrated to be an effective technique [185].

"Awake" tracheal intubation

In select circumstances outside of the obstetric delivery room, tracheal intubation may be performed in unpremedicated newborn infants who might not tolerate the cardiovascular depressant effects of anesthetic or sedative drugs. However, infants and neonates do experience the pain and discomfort from laryngoscopy; its performance without sedative premedication or general anesthesia has untoward cardiovascular (and behavioral) effects and should be avoided whenever possible. Furthermore, the administration of anesthetic, sedative, and neuromuscular blocking drugs improves conditions for intubation and decreases the likelihood of airway trauma [186–189]. A consensus statement published by the International Evidence Based Group for Neonatal Pain states "tracheal intubation without the use of analgesia or sedation should be performed only for urgent resuscitations in the delivery room or for life-threatening situations associated with the unavailability of intravenous access" [190].

Nasotracheal intubation

Before the advent of muscle relaxants, nasotracheal intubation was the preferred route for tracheal intubation; the technique was perfected by pioneering anesthesiologists such as Dr Ivan Magill (now memorialized for the forceps used for this purpose that bear his name) [191]. Following the introduction of muscle relaxants into anesthesia practice, orotracheal intubation became the favored technique. In current anesthesia practice, nasotracheal intubation is required for certain procedures (e.g. Lefort I osteotomy), while it is preferable for other procedures but not essential (e.g. oral rehabilitation). In other situations, such as in infants in the prone position, many anesthesiologists prefer a nasotracheal tube because of the possibility that it is more stable and secure than an oral tube. For children undergoing cardiac surgery, a nasotracheal tube may leave more room in the mouth for transesophageal echocardiography probe insertion. Nasotracheal intubation may be more comfortable than orotracheal intubation if postoperative tracheal intubation is expected.

Nasotracheal intubation is more challenging to perform than orotracheal intubation. The most common complication is epistaxis, especially in children with adenoidal hypertrophy. Other less common complications include retropharyngeal perforation [192,193], sinusitis [194], bacteremia [195–197], turbinate avulsion [198,199], and necrosis of the skin of the alae nasae with excessive pressure from the endotracheal tube. Nasotracheal intubation is contraindicated in the setting of facial or skull fractures; intracranial tube placement has been reported following attempted nasotracheal intubation in this setting [200]. Oxymetazoline 0.05% can be applied to the nasal mucosa for vasoconstriction and to decrease the risk and severity of epistaxis. Cocaine (4–10%) and lidocaine with epinephrine have also been used for this purpose. Oxymetazoline is as effective as 10% cocaine and more effective than lidocaine with epinephrine for the prevention of epistaxis from nasotracheal intubation [201]. In a related study assessing vasoconstriction for endoscopic sinus surgery, oxymetazoline was preferable over both 0.25% phenylephrine and 4% cocaine [202]. To avoid triggering laryngospasm, topical vasoconstrictors should be sprayed after a deep plane of anesthesia has been reached or following administration of a neuromuscular blocking drug.

Topical vasoconstrictors used for nasal mucosal vasoconstriction are potent α-agonists that can be absorbed and exert systemic effects; these agents should be used judiciously. Life-threatening hypertension and pulmonary edema following the use of topical 0.5% phenylephrine has been described [202–204]. Severe hypertension and reflex bradycardia progressing to sinus arrest has also been reported following oxymetazoline administration [205,206].

The occurrence of nasal bleeding may also be reduced by softening the tracheal tube, which is achieved by soaking the tip in warm water or saline [207]. The use of a red rubber catheter to guide the tracheal tube through the nose into the pharynx is a more effective method to decrease epistaxis compared to softening the tube tip in warm water [208–210].

Once inserted through the nose, the tube should be advanced so that its tip lies in the pharynx. Direct laryngoscopy is then performed, and the tip of the tracheal tube located in the pharynx. Once laryngeal exposure is optimized, the tube is gently grasped and guided into the trachea using Magill forceps as the tube is advanced. Care must be taken not to damage the cuff of a cuffed tube with the forceps.

Occasionally, it is difficult to advance the nasotracheal tube into the trachea despite an excellent view of the glottic inlet. This may occur because the natural curvature of the nasotracheal tube directs the tip anteriorly as it is advanced rather than in a direction parallel to the long axis of the trachea. Techniques to overcome this problem include neck flexion, directing the tube posteriorly with the Magill forceps, rotating the tube so the narrowest part of the beveled tip is aligned parallel with the glottic opening, turning the head to the side,

Figure 16.11 Proper taping of the nasal RAE tracheal tube to avoid pressure on the skin of the nasal alae.

and rotation of the tube 180° as it is advanced to direct the natural curvature of the tube more posteriorly.

When securing a nasotracheal tube, it is important to tape the tube in a way that avoids excess pressure between the tube and the ala, as this can result in ischemia and subsequent ulceration (Fig. 16.11).

Tracheal tube selection

A variety of methods exist for determining the expected tracheal tube size in children, including formulas based on age, height–length ratio, ultrasound measurement [43], and qualitative methods such as comparison of tube size with the size of the fifth finger nail [211]. Although height is often used in the emergency department setting [212,213], age-based formulas are more commonly used by anesthesiologists. Similarly, although ultrasound measurement of the transverse diameter of the subglottic trachea accurately predicts proper tracheal tube size [214], the practicality of routinely performing ultrasound measurements to select tube size may limit the widespread application of this technique.

Uncuffed tube size is often determined by a modified Cole's formula: internal tube diameter (mm) = 4 + age/4 [211,215]. If a cuffed tube will be used, a one-size smaller diameter tube should be selected to account for the small increase in external diameter created by the deflated cuff: internal tube diameter (mm) = 3+ age/4 [215].

RAE tubes

Oral and nasal tracheal tubes with a preformed bend (RAE tubes, named from the initials of the inventors Ring, Adair, and Elwyn) may be desirable in surgical procedures involving the eyes, oral cavity, or face [216]. These tubes allow the anesthesia circuit to be directed away from the surgical field without kinking. The length of the preformed bend is fixed and varies with tube size. Sometimes the RAE tube that is the proper size for the child's tracheal diameter is too short or too long due to the fixed location of the bend. In cases where it is too long, a smaller size cuffed RAE can be used. In cases where it is too short, a standard straight tube may need to be substituted. For oral and nasal RAE tubes, a useful way of choosing the proper size based on length is to hold the tube next to the child's face and assess the location of the cuff or tube tip. For cuffed tubes, the cuff should lie at the level of the suprasternal notch; the tip of an uncuffed tube should lie at the level of the sternoclavicular junction.

Cuffed versus uncuffed tracheal tubes

Historically, uncuffed tracheal tubes were preferred in children up to the approximate age of 8–10 years. The lack of a cuff allowed for a greater internal diameter, which translated into lower resistance and decreased work of breathing during spontaneous ventilation, and greater ease of suctioning secretions. There was also concern that the use of cuffed tubes might be associated with a higher risk of subglottic injury. However, the use of modern tracheal tubes with high-volume, low-pressure cuffs has not been associated with an increased incidence of subglottic airway injury or an increased incidence of postextubation croup in anesthetized children [217].

In 1951, Eckenhoff published a seminal article describing the anatomy of the infant and pediatric larynx [29]. The widespread teaching based on this article was that the infant larynx is funnel shaped with the widest portion at the glottic inlet and the narrowest portion at the cricoid ring. This has been disproven in a purely static anatomical measurement model using MRI [35,37]; however, the cricoid ring remains *functionally* the narrowest portion of the airway because it is a complete ring and is non-distensible. These latter studies found the pediatric larynx to be slightly elliptical in cross-section, with a smaller transverse diameter and a larger anteroposterior diameter. Given this elliptical shape, an uncuffed tube of a size that effectively ablates an air leak would be expected to exert more pressure on the lateral walls of the larynx and trachea [218]. The cuff of a properly sized cuffed tracheal tube would conform to the shape of the trachea as it is inflated and pressure would be evenly distributed. The use of cuffed tubes in children is associated with a decreased incidence of postintubation stridor [219]. In addition to the anatomical factors described here, this may also be related to decreased need for repeat laryngoscopy and tube changes in cases where an uncuffed tube that is too small or too large is initially inserted.

Cuffed tracheal tubes provide a better seal to protect the trachea from macroaspiration, while simultaneously allowing for lower fresh gas flows (with associated economic advantages) and decreased operating room pollution. In cases such as tonsillectomy, use of a cuffed tube can limit escape of oxygen-enriched inspired gases and decrease the risk of intraoperative fires, although this does not obviate the importance of limiting inspired oxygen concentration in these cases. However, there is some evidence that the presence of a cuff may contribute to bronchoscopically proven airway injury [220].

In our clinical practice, uncuffed tracheal tubes are rarely used [221]. However, they remain useful in certain situations where maximizing the internal diameter of the tube is important. Because resistance to airflow is inversely proportional to the fourth power of the radius of the tube (or fifth power with turbulent flow), the ability to ventilate can be impaired by selecting a cuffed tube that is a size smaller than the appropriate uncuffed tube. This effect is most clinically significant with smaller tube sizes used in preterm and very low birthweight

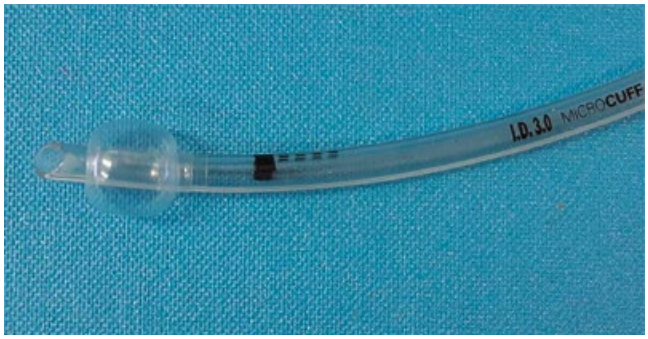

Figure 16.12 The Microcuff endotracheal tube. There is no Murphy eye, enabling location of the cuff more distally and allowing shorter cuff length. Note also the depth markings with the thick black line intended to be placed at the vocal cords. *Source:* Reproduced from Thomas et al [422] with permission of BMJ.

infants. Moreover, suctioning and pulmonary toilet are more difficult with the smallest tubes. An uncuffed tube is also advantageous when used as a bronchial blocker to achieve single lung ventilation. Because the bronchial blocker occupies a portion of the lumen, a larger lumen will help limit resultant increased resistance to airflow through the tube.

In 1994, a newly designed endotracheal tube called the Microcuff® was introduced for use in small pediatric patients (Halyard Health, Alpharetta, GA, USA) (Fig. 16.12). The Microcuff tube contains an ultrathin (10 μm) polyurethane-based inflatable cuff with a low-pressure high-volume profile to prevent tracheal mucosal trauma. In addition, the traditional Murphy eye was sacrificed to make room for the cuff to be located more distally than normal endotracheal tubes, situating it below the vulnerable subglottic area. Although numerous publications have demonstrated its usefulness [219,222], there is no proven advantage to its use over standard endotracheal tubes, and some anecdotal reports implicate the Microcuff in causing tracheal damage in neonates [223]. The absence of the Murphy eye may also have disadvantages. Rarely the distal end of the endotracheal tube can be obstructed with secretions or blood and the Murphy eye allows some ongoing ventilation; also, in the case of unrecognized right mainstem bronchus intubation, the Murphy eye may allow some ventilation of the left lung.

Determining proper endotracheal tube length

As in tracheal tube diameter selection, a variety of formulas have been created to predict the proper depth of orotracheal tube insertion. In infants and neonates, a commonly used rule of thumb is the "1,2,3,4–7,8,9,10 rule," where a 1 kg infant will have the tube taped at 7 cm at the maxillary alveolar ridge, a 2 kg infant taped at 8 cm, a 3 kg infant taped at 9 cm, and a 4 kg infant taped at 10 cm. In infants, when an uncuffed tracheal tube is used, it is common practice to advance the tube to achieve a deliberate right main bronchial intubation while auscultating the left chest. The centimeter depth at which breath sounds disappear (or become greatly decreased) is identified as the carina. The tube is then withdrawn midway between the carina and the vocal cords. Prior to performing this maneuver, it is useful to identify the centimeter marking relative to the gum or incisors following intubation and advancement of the cuff just beyond the vocal cords (or, with an uncuffed tube, 1–2 cm beyond the vocal cords). Knowing the centimeter marking with this depth of insertion as well as the depth of the carina gives the anesthesiologist an idea of how much cephalad or caudal tube displacement can safely occur. One study compared auscultation after deliberate main stem intubation to cuff palpation in the suprasternal notch and using the depth markings on the endotracheal tube. Auscultation after deliberate main stem intubation and cuff palpation resulted in a tube tip above the carina that was shorter and more predictable than placement of the tube using depth markings [224].

In older children, a good rule of thumb that is used to estimate the proper orotracheal tube depth in centimeters is to multiply the appropriate tube internal diameter (in millimeters) by 3. For nasotracheal intubation, multiplying the appropriate tube internal diameter by 4 is an effective method. When a cuffed tube is used, the "ballotte" technique can be used to place the cuff in its proper position at the level of the suprasternal notch. Identification of the depth of the tube relative to the maxillary alveolar ridge or maxillary incisors gives a more precise depth marking than identification relative to the lip.

A recent study suggested that the use of body surface area predicted proper tracheal tube length better than the use of age (in children older than 1 year of age) or weight (children less than 1 year of age) [225]. In recent years, the use of bedside point-of-care ultrasound has been described for confirmation of placement of the endotracheal tube in the trachea and to determine proper depth of insertion [83,226] (Figs 16.13, 16.14). This approach can be useful for additional confirmation of endotracheal tube placement in the case of difficult airway visualization.

Assessing tube size following endotracheal intubation

The appropriateness of the tracheal tube size selected must be verified in every child. A tube that is too large may exert excessive pressure on the tracheal mucosa, resulting in mucosal ischemia. In the short term, this can lead to mucosal edema and stridor following extubation, while in the long term it may contribute to the development of subglottic stenosis.

In some children, an oversized tube is identified by an inability to advance the tube into the trachea during the intubation attempt. The most common method to assess tube size after placement of the tube is the air leak test. After midtracheal positioning of the tube tip, the APL valve is closed and the circuit pressure is allowed to increase while a stethoscope is placed over the thyroid cartilage. The leak pressure occurs when air is heard escaping around the tube. The ideal leak pressure is between 15 and 25 cmH_2O. It is important to avoid a slow and prolonged leak test as this will have the hemodynamic consequences of a prolonged Valsalva maneuver. When a cuffed tube is used, the cuff inflation volume can be adjusted to achieve the desired leak pressure. For short cases, if the initial leak test is above 40 cmH_2O, some anesthesiologists will not exchange the tube for a smaller one in the interest of avoiding the trauma of repeated laryngoscopy. For longer cases, if the leak pressure is greater than 30–35 cmH_2O, exchange with a smaller tracheal tube may be preferred.

(B)

Figure 16.13 Ultrasound of the larynx. (A) Transverse image at the level of the upper larynx. The strap muscles are identified as hypoechoic (yellow), the thyroid cartilage (blue), and the echogenic false vocal cords (orange). (B) Sliding the probe minimally further caudally, the level of the true vocal cords is reached. The thyroid cartilage appears mildly echogenic (blue). The margin (the free edge) of the true cords appears hyperechoic (orange). The tiny area of echogenicity at the anterior margin represents the anterior commissure (red). The areas of echogenicity deep and lateral to the cords represent the arytenoid cartilages (yellow). *Source:* Reproduced from Stafrace et al [83] with permission of John Wiley and Sons.

(A)

(B)

Figure 16.14 Ultrasound of the trachea. (A) This structure comes into sight as the probe is oriented slowly inferiorly from the lower larynx. The thyroid gland surrounding the trachea is easily identified. The hypoechoic (=dark) anterior part of each tracheal ring (blue) is easily identified, but the walls of the trachea are not well identified on the transverse plane – ring down artifact from air is seen centrally. The esophagus is well seen posteromedial to the trachea on the left, often as a multilayered structure (green). The carotid arteries (red) are seen postero-lateral to the thyroid lobes. (B) As the probe is further oriented inferiorly, the thyroid gland is no longer visualized, but the remainder of the structures listed above remain clearly visible. The carotid vessels (red) are now seen to lie slightly more anteriorly and medially. Echogenic connective tissue now also fills in the space below the thyroid gland. The appearances of the trachea are unchanged. The multilayered structure of the esophagus (green) is easily appreciated. *Source:* Reproduced from Stafrace et al [83] with permission of John Wiley and Sons.

Rapid-sequence induction and intubation in pediatric patients

Rapid-sequence induction and intubation (RSII) is used to minimize the time from anesthetic-induced loss of consciousness and endotracheal intubation, to decrease the risk of pulmonary aspiration of gastric contents. RSII is often more challenging in pediatric patients when compared to adults because infants and small children have relatively higher oxygen consumption rates, reduced functional residual capacity (FRC), and elevated closing volumes, and thus will develop oxyhemoglobin desaturation more quickly during periods of apnea. Because of this propensity toward hypoxemia during RSII in children, and the lack of any feasible period of preoxygenation, many pediatric anesthesiologists perform a "modified" rapid-sequence induction [227]. In this modified technique, gentle facemask ventilation is performed using low inflation pressures (<10–15 cmH_2O) while cricoid pressure is applied until enough time has elapsed for complete neuromuscular blockade to be established. In support of this practice, appropriately applied cricoid pressure has been shown to be effective in preventing gastric inflation during gentle bag-mask ventilation in anesthetized infants and children [228,229]. In older children and adolescents who can cooperate with adequate preoxygenation, a classic RSII may be performed. If the initial attempt at intubation fails, gentle facemask ventilation through cricoid pressure should be performed. If ventilation is difficult with cricoid pressure despite the use of adjunctive devices (e.g. oral or nasopharyngeal airway, laryngeal mask) cricoid pressure should be lessened or released [230,231]. Regurgitation of gastric contents is more likely caused by performing laryngoscopy prior to the complete onset of neuromuscular blockade, rather than any other aspect of the induction technique.

Cricoid pressure is contraindicated in the presence of active vomiting, suspected laryngeal or tracheal injury, and unstable cervical spine injuries [230,232]. In children, cricoid pressure applied below the cricoid ring can result in significant distortion of the larynx and trachea and increase the difficulty of ventilation or intubation [233]. A report of the complications of RSII in a large children's hospital population revealed an incidence of difficult intubation of 1.7%; however it is unclear if these difficulties were related to presence of cricoid pressure [234]. The application of cricoid pressure can cause relaxation of the lower esophageal sphincter, paradoxically promoting the potential for regurgitation of gastric contents [235].

There is a lack of high-quality evidence supporting the efficacy of a "classic" RSII (induction followed by cricoid pressure and apnea) in children. Furthermore, in infants and young children, oxyhemoglobin desaturation will predictably occur with the duration of apnea required for the onset of complete neuromuscular blockade. These factors, together with the undesirable effects of cricoid pressure, have resulted in a "modified" RSII approach (gentle/low-pressure ventilation and ensuring complete neuromuscular blockade prior to laryngoscopy) being preferred to the "classic" RSII approach in pediatric anesthesia practice [236].

KEY POINTS: TRACHEAL INTUBATION

- Simple extension of the head, as opposed to "sniffing position"(neck flexion and head extension), may better align oral, pharyngeal, and tracheal axes in children
- Direct laryngoscopy with a straight (Miller) blade can be accomplished directly by lifting the epiglottis, or indirectly by placing the tip behind the epiglottis
- The curved (Macintosh) laryngoscope blade is best utilized by placing the tip behind the epiglottis into the vallecula
- Optimal external laryngeal manipulation using the BURP maneuver can often improve laryngeal visualization
- Tracheal intubation can be accomplished with neuromuscular blockade, or without blockade if deep anesthesia is achieved, often with propofol
- Nasotracheal intubation with Magill forceps and topical vasoconstriction is utilized for dental or craniofacial cases, some cardiac cases, and some cases in prone position
- Cuffed endotracheal tubes are preferred for use even in infants; exceptions may be premature or full-term neonates where larger internal diameter is important
- Assessment of proper depth of ETT placement can be achieved using formulae based on ETT diameter, depth markings on the tube during direct laryngoscopy, deliberate right mainstem intubation, or palpation of the cuff in the sternal notch
- An airleak at 15–25 cmH_2O with cuff deflated indicates an appropriate ETT size
- A "modified" rapid-sequence induction approach (gentle/low-pressure ventilation and ensuring complete neuromuscular blockade prior to laryngoscopy) is preferred to the "classic" approach (induction followed by cricoid pressure and apnea) anesthesia practice

Postoperative airway management

The first priority in the postoperative care of the child is ensuring a patent airway. Assessment should focus on residual effects of anesthetic agents, opioids, and sedatives in the context of the preoperative condition of the child, the course of intraoperative airway management, the surgical procedure, anticipated fluid shifts, and the expected postoperative course. During recovery, proper head and neck positioning promotes airway patency. In the supine position, a soft roll placed under the shoulders will extend the head and neck and help open the upper airway. Placing the child in the "recovery (lateral) position" increases upper airway size [21] and allows secretions to drain out of the mouth rather than backward into the pharynx. If airway obstruction fails to improve with positioning, and the child is semi-conscious, a soft nasopharyngeal airway can be inserted; if the child is still anesthetized, an oral airway may be preferred. If airway obstruction is incompletely relieved with a nasopharyngeal airway, a 15 mm tracheal tube adaptor can be placed into the external

flared end of a nasopharyngeal airway for the delivery of CPAP [93]. If one suspects that postoperative upper airway obstruction is caused by the residual effect of opioids, naloxone can be cautiously administered to test and treat this possibility. Incremental doses of 0.5–1 μg/kg can be carefully titrated to reverse respiratory depressant effects without reversal of analgesic effects. Children who fail these measures to restore airway patency may require tracheal reintubation.

Non-invasive respiratory support

In selected cases, non-invasive ventilatory support, such as CPAP or bi-level positive airway pressure (BiPAP) may be a useful option and can allow some patients to avoid tracheal intubation and mechanical ventilation in the postoperative period. Non-invasive support in older children is most often delivered by facemask or nasal mask, while nasal prongs are used in neonates and infants. Children and adolescents who use such devices preoperatively should receive respiratory support from these devices in the postoperative period. CPAP delivered by nasal prongs to neonates and infants is an effective way to improve respiratory function and prevent reintubation following extubation in the neonatal intensive care unit [237], as well as for treatment of apnea of prematurity [238,239].

Postoperative mechanical ventilation

If postoperative mechanical ventilation is required, a plan must be developed for transfer of the child's care from the operating room to the intensive care unit. Clear communication regarding the course of airway management should include discussion of the ease of facemask ventilation and direct laryngoscopy, tracheal tube size and insertion depth, current ventilator settings, and the reason for the need for postoperative mechanical ventilation. The child will need to be transitioned from general anesthesia to an appropriate sedation regimen. If airway management was difficult, a plan should be in place in the event of accidental extubation. Keeping an appropriately sized laryngeal mask at the bedside is essential in such cases. If an oral RAE tube was used, this should be changed to a standard tracheal tube as protrusion of the tongue can easily result in extubation, and pulmonary toilet is more difficult with RAE tubes.

KEY POINTS: POSTOPERATIVE AIRWAY MANAGEMENT

- After tracheal extubation, lateral positioning or an oral or nasal airway can improve airway patency in the anesthetized child
- Non-invasive respiratory support, such as nasal CPAP, bilevel positive airway pressure, or high-flow oxygen via nasal cannula, may be useful in selected patients
- If postoperative mechanical ventilation is necessary, a secure ETT, adequate postoperative sedation, clear communication to the ICU staff about airway management difficulties, and extubation plans are essential

Upper airway complications and management

Laryngospasm

Laryngospasm is a prolonged glottic closure maintained beyond the initiating stimulus and is a protective reflex that causes complete closure of the vocal cords to protect the trachea from aspiration of foreign material [240]. Prolonged laryngospasm can result in hypoxemia, bradycardia, postobstructive negative-pressure pulmonary edema, regurgitation and aspiration of gastric contents, and cardiac arrest. Laryngospasm is more common in children than adults; it has been estimated to occur at a frequency from 1 per 1000 anesthetics to 17 per 1000 anesthetics [241–243]. While one belief has been that hypoxemia itself will result in abolition of this reflex, data from the Pediatric Perioperative Cardiac Arrest Registry reveal that laryngospasm continues to be a cause of cardiac arrest in children [244].

The incidence of laryngospasm appears to be increased in children with a history of active or recent upper respiratory tract infection, especially within 2 weeks of anesthesia [245–249]. In addition to upper respiratory tract infection, a history of eczema, exercise-induced wheezing, nocturnal dry cough, and wheezing more than three times in the prior year have been observed to be strongly associated with bronchospasm, laryngospasm, and other perioperative adverse respiratory events. Likewise, having parents that smoke or a strong family history of asthma or atopy is associated with perioperative adverse airway events [249]. In a matched cohort study, the occurrence of perioperative adverse airway events was associated with a greater likelihood of hospital stay after surgery, longer hospitalization, and higher costs [250].

Anesthetic management choices also affect the risk for acute adverse airway events: intravenous induction (versus inhaled), inhaled maintenance (versus intravenous), and airway management with a laryngeal mask (versus endotracheal tube) are each associated with reduced likelihood of adverse airway events (laryngospasm, bronchospasm, desaturation, coughing) [106,249].

Initial treatment of laryngospasm consists of CPAP delivered by facemask with 100% oxygen. Deepening the anesthetic may relieve the obstruction and can be achieved with intravenous propofol, 1–3 mg/kg. If hypoxemia is occurring, the treatment of choice is immediate neuromuscular blockade with succinylcholine. In adults, low-dose succinylcholine (e.g. 0.1 mg/kg) is effective in treating laryngospasm [251]. However, larger doses may be preferred if reintubation is planned. When administering succinylcholine in children, some pediatric anesthesiologists prefer to co-administer an anticholinergic agent (i.e. atropine or glycopyrrolate) to prevent succinylcholine-induced bradycardia.

If laryngospasm develops prior to establishment of intravenous access, succinylcholine (4–5 mg/kg) may be administered via the intramuscular route [252]. Maximal twitch depression at the abductor pollicis following intramuscular injection of succinylcholine will develop in 3–4 min; however, clinical relief of airway obstruction occurs much sooner [253,254]. Succinylcholine-induced bradycardia is less likely with intramuscular administration [252,255]. Intralingual or submental administration of succinylcholine

has been recommended because of its rapid onset of action [256,257]; however, many avoid this route because of concerns about intraoral bleeding. Intramuscular administration of 4–5 mg/kg of succinylcholine may result in a phase II block, and more than 20 min may elapse before neuromuscular blockade resolves [252].

Additional treatments for laryngospasm, such as pressure in the "laryngospasm notch" [258], digital elevation of the tongue [259], nitroglycerine [260], and doxapram [261] have been proposed but their efficacy in children has not been evaluated.

Laryngospasm accompanied by a strong inspiratory effort and hypoxemia may lead to negative pressure pulmonary edema with or without pulmonary hemorrhage [262–265]. The treatment depends on the severity of symptoms and includes supplemental oxygen, furosemide, and positive pressure respiratory support.

Pulmonary aspiration of gastric contents

Pulmonary aspiration of gastric contents is a relatively uncommon event, although its incidence in children appears equal to or higher than that in adults [266–268]. The incidence in the pediatric population ranges from 1 in 2632 anesthetics [268] to 1 in 1000 anesthetics [266]. Death from anesthetic-related pulmonary aspiration is rare. Children with clinically apparent pulmonary aspiration who did not develop symptoms within 2 h were unlikely to develop subsequent respiratory complications [268].

Factors associated with increased risk of pulmonary aspiration include emergency surgery, presence of bowel obstruction or ileus, younger age, and ASA physical status 3 or 4 [266,268]. Obesity is not associated with an increased gastric fluid volume or increased risk of pulmonary aspiration [269].

Postintubation croup

Postintubation croup presents as inspiratory stridor, hoarseness, a "barky" cough, and in severe cases, intercostal retractions and respiratory distress. Postintubation croup is thought to result from airflow restriction due to tracheal edema from mechanical trauma or mucosal ischemia related to endotracheal intubation. The site of greatest restriction is at the level of the cricoid ring. The incidence in children was reported to be 1% in 1977 [270]; however, more recent data suggest a lower incidence [271]. Postintubation stridor may develop shortly following tracheal extubation or several hours later. Upper airway obstruction from other causes must be investigated before the diagnosis is made. Physical examination findings determine the need for treatment. Nasal flaring, subcostal or intercostal retractions, or other features indicative of increased work of breathing are indications for pharmacological therapy. Dexamethasone, 0.5 mg/kg up to 10 mg, may be effective, albeit not immediately. Nebulized racemic epinephrine may also be effective in the short term but should be reserved for severe cases. Because of the potential for rebound edema following racemic epinephrine, children should be observed for at least several hours to ensure that symptoms do not recur.

KEY POINTS: UPPER AIRWAY COMPLICATIONS AND MANAGEMENT

- Laryngospasm is treated first with positive pressure ventilation with jaw thrust; intramuscular succinylcholine or intravenous propofol or succinylcholine is used for significant airway obstruction
- Factors associated with pulmonary aspiration include emergency surgery, presence of bowel obstruction or ileus, younger age, and ASA physical status 3 or 4
- Significant postextubation croup is treated with nebulized racemic epinephrine and intravenous dexamethasone

Airway management for tracheostomy insertion

Infants and children who require chronic ventilatory therapy will likely benefit from insertion of a tracheostomy tube. Diagnoses associated with the need for tracheostomy include neuromuscular impairment, chronic lung disease, trauma, upper airway anomalies, congenital heart disease, and prematurity [272]. Infants who have had long-term tracheal intubation and mechanical ventilation may develop subglottic stenosis and require tracheostomy to provide long-term ventilatory support. The in-hospital mortality in pediatric patients who undergo tracheostomy during their hospitalization is as high as 8.5% [272]. Most of these children present to the operating room with a secured airway (tracheal tube). In these cases the ease of previous mask ventilation and tracheal intubation must be assessed preoperatively. Those children in whom direct laryngoscopy was difficult should have a plan developed in case accidental extubation occurs before tracheostomy completion. Such a plan might include leaving an airway exchange catheter in the trachea during completion of the tracheostomy and withdrawal of the tracheal tube to a position just above the tracheostomy incision, with the tip still between the vocal cords, that can be easily advanced for reintubation should this be required. These cases require close vigilance and communication with the surgeon throughout the procedure. The risk of a surgical fire can be reduced by minimizing the inspired oxygen concentration and avoiding the use of nitrous oxide. The choice of tracheostomy tube size and length depends on the indications for tracheostomy. Patients requiring chronic mechanical ventilation often benefit from low-pressure, high-volume cuffed tubes, often made with silicone or other soft material to minimize airway trauma. Patients with upper airway obstruction without significant lung disease often benefit from small uncuffed tracheostomy tubes, which are large enough to provide a patent airway yet permit sufficient air leak to allow vocalization. Consultation with the surgeon and pulmonologist is important to understand all the goals of the procedure and select the correct tracheostomy tube.

Certain children with upper airway congenital anomalies may not have an existing tracheal tube immediately prior to surgical tracheostomy. Airway management for tracheostomy may entail tracheal intubation with subsequent management

as described earlier. Alternatively, a laryngeal mask may be used as an anesthetic airway conduit during tracheostomy insertion.

A newly placed tracheostomy requires 7–10 days for the stoma to be well formed; prior to this period, if a tube change is needed, it should be performed by an otolaryngologist. After healing, tracheostomy tubes should be changed every 1–2 weeks to reduce the formation of granulation tissue or mucous plugs of the tube. A tracheostomy bypasses the humidification and warming function of the nose and upper airway; thus, an artificial humidification device is necessary. Heat and moisture exchangers (HMEs) are generally used to facilitate this function. They should be selected to minimize resistance to airflow, and minimize work of breathing [273].

Management of the child with a pre-existing tracheostomy

Tracheostomized children who present for general anesthesia and surgery require a different approach to airway management. During the preoperative visit, the anesthesiologist should determine the type, size, and presence of a cuff on the tracheostomy tube. Parents and caregivers should be asked about the frequency of suctioning, as well as the suction catheter size and the depth to which it is inserted. The presence or absence of a leak around the tracheostomy tube as well as the amount of ventilator support the child requires should also be determined during the preoperative assessment. These children should come with emergency replacement supplies for their tracheostomy, which should be kept with them throughout their perioperative course.

Inhaled anesthetic induction is the most common induction technique in these children. It is often necessary to connect a flexible "accordion" extension from the end of the anesthetic circuit to the tracheostomy tube to increase the limited clearance between the clavicles and mandible, especially in infants. In those with a significant leak around the tracheostomy tube, inhaled induction may be prolonged due to mixing of air inspired from the upper airway with gases inspired through the tracheostomy tube. Following the loss of consciousness, holding the mouth and nose closed or applying a sealed facemask will help decrease mixing and facilitate ventilation through the tracheostomy.

For short procedures, it is often unnecessary to change the tracheostomy tube. For intracavitary or long procedures, if there is a significant leak around the tracheostomy tube, a standard cuffed tracheal tube will enable effective positive pressure ventilation. This can be achieved by exchange of the existing tracheostomy tube with the same-sized cuffed tracheal tube. With an established tracheal stoma, this is easily accomplished; however, consultation with an otolaryngologist may be useful in selecting the most appropriate tube and for performing the exchange, if necessary. Another option is replacement of the tracheostomy tube with a wire-reinforced tube. This lower profile alternative can be useful in cases where a standard tracheostomy tube would encroach on the surgical field. This tube can be secured to the chest with tape or sutured in place in select circumstances. In cases where the tracheostomy site encroaches on the surgical field, the child's airway can be secured with an oral or nasal tracheal tube, and the tracheostomy site can be sealed with gauze and nonocclusive tape and dressing.

Tracheostomy tubes are available in a variety of sizes and lengths for pediatric use. They can be constructed from metal or plastic. Plastic tubes are most frequently used and are made from silicone or polyvinyl chloride. Some tracheostomy tubes are supplied with a tracheostomy disconnection wedge, which facilitates separation of connections to the tracheostomy. The internal and external diameters are usually marked on the flange of the tracheostomy tube. Several manufactured tubes have wire-reinforced designs allowing flexibility without kinking, and some have a long flexible proximal ends (e.g. FlexTend™), which place connections to the tube away from the child's neck, thus reducing the chance of tube obstruction in small patients.

Tracheostomy tubes are available in cuffed and uncuffed versions [274]. The cuff helps to protect the airway from secretions and facilitates positive pressure ventilation in children with poor lung compliance. Cuffed tracheostomy tubes have either a high-volume, low-pressure cuff, low-volume, high-pressure cuff, or a foam cuff, which is useful in patients with chronic aspiration. The Tight-To-Shaft tube (TTS™) has a low-volume, high-pressure cuff used for patients who need intermittent inflation such as during meals and at night. When deflated, the cuff assumes the profile of the tube and enables phonation and use of the upper airway. The cuff should be inflated with sterile water because it is gas permeable and will slowly deflate over time.

The Montgomery tube is a T-shaped silicone tube that has a short lumen projecting from its side at a 75° or 90° angle. It is typically used after tracheal reconstruction to stent the airway and can be left in place for months. The upper limb extends above the glottis and the short limb is brought out through the tracheostomy stoma.

KEY POINTS: AIRWAY MANAGEMENT FOR TRACHEOSTOMY

- Preoperative assessment of difficulty of standard tracheal intubation is important; leaving an airway exchange catheter or withdrawing the ETT to just above the tracheostomy but below the larynx may be necessary
- A tracheostomy tube is usually changed in 7–10 days by an otolaryngologist; provision for adequate sedation until that time is important
- Patients with an existing tracheostomy may need larger or cuffed tracheostomy, or standard ETT in the stoma or inserted translaryngeally, to mimize leak and allow airway access for longer surgeries

The difficult pediatric airway

There are two broad categories of pediatric patients with a "difficult" airway: those who are difficult to mask ventilate, and those who are difficult to tracheally intubate. Each category assumes that the attempts have been made by an experienced practitioner using standard methods of mask ventilation or direct laryngoscopy. Definitions for each of these categories

have been proposed but are inconsistent throughout the literature. Therefore, in this chapter we focus on airway management techniques once a practitioner is faced with the expected or unexpected situation of inability to adequately perform mask ventilation or tracheal intubation despite the use of standard equipment, as described previously in the section on management of normal pediatric airways.

There have been few systematic and validated studies that define predictors of difficult mask ventilation or tracheal intubation in the pediatric population. In adults, limited head extension, reduced mandibular space, and large tongue are predictive of difficult intubation [275]. These are also features in children with difficult intubations [276]. The mandibular space represents the area available to displace the tongue and soft tissue, which is required for an easy direct laryngoscopic view of the glottis. Reduction of this space by anatomical anomalies (e.g. micrognathia) limits the room available for soft tissue displacement by direct laryngoscopy. The mentum–hyoid distance provides an estimate of the mandibular space. In infants, the minimal mentum–hyoid distance for a "normal" airway in an infant should be 1.5 cm [276]. In one cohort study, difficult direct laryngoscopy in children was associated with age below 1 year, underweight patients, and ASA physical status 3 and 4 [277]. Another study of 511 children developed an equation to predict the probability of difficult laryngoscopy based on multivariate regression analysis of distances. The equation

$$Y = (0.015 \times L) + (0.007 \times T) - (0.015 \times E) + 0.179$$

(where L = lower lip border to mentum, T = ear tragus to the corner of the mouth, and E = ear lobe to corner of the mouth) predicts a greater probability of a difficult laryngoscopy if Y tends toward 1 and lower if it tends toward 0 [278].

The most information about characteristics of intubation attempts in children with difficult airways comes from the multicenter Pediatric Difficult Intubation (PeDI) registry [279]. This analysis contained over 1000 intubations in children with difficult airways and demonstrated that complications were associated with multiple intubation attempts, weight less than 10 kg, short thyromental distance, and three direct laryngoscopy attempts before the use of an indirect technique. This analysis, as well as two additional recently published studies, has indicated that the addition of supplemental oxygen during the intubation attempts will decrease the incidence of hypoxemia during intubation attempts [280–283].

Airway management in children with craniofacial anomalies

The diversity and complexity of craniofacial anomalies in children is vast; thus, an exhaustive review is not possible. Nevertheless, children with craniofacial anomalies can be defined according to the anatomical compartment that relates to the airway difficulty. Craniofacial dysmorphism may be defined as primary abnormalities of the maxilla, abnormalities of mandibular size, abnormalities of mandibular hinge and sliding function, and anatomical anomalies of the tongue and cervical spine. Classifying patients in this manner allows the selection of the most appropriate equipment for addressing the airway anomaly.

There is no device that represents a panacea for airway management; each device has unique strengths and weaknesses that need to be matched with the patient's condition and anatomical details. For example, a patient with limited mouth opening would be best managed with a flexible bronchoscope or optical/lighted stylet rather than a rigid video laryngoscope, whereas a patient with Pierre Robin sequence who presents with a potentially difficult mask ventilation may be best managed with a laryngeal mask followed by tracheal intubation through the mask, thus permitting ventilation during intubation. We use a simple acronym (AVAD: Anesthesia, Ventilation, Adjuncts, Devices) to guide the approach to airway management in these known difficult airway patients (Fig. 16.15). Thinking about the patient in terms of these components facilitates the formulation of a plan as well as a backup plan, and dictates the necessary equipment for the chosen

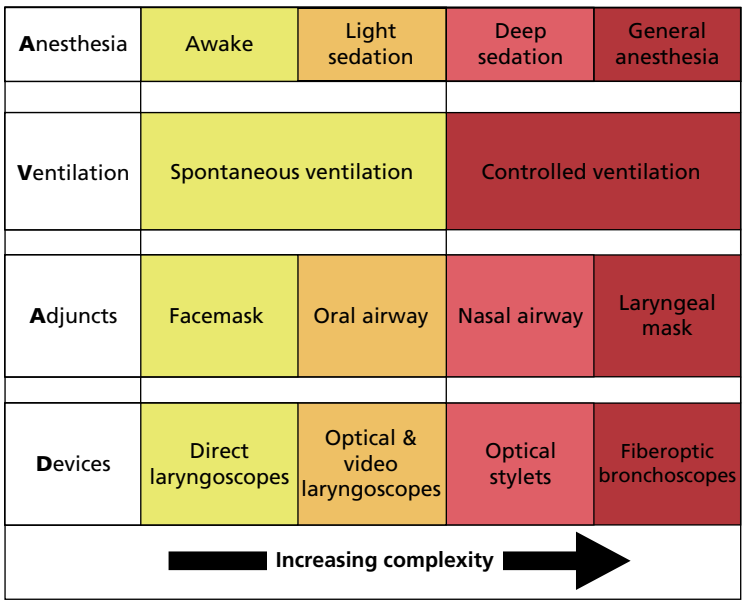

Figure 16.15 A simple acronym (AVAD: Anesthesia, Ventilation, Adjuncts, Devices) guides the approach to airway management in known difficult airway patients.

approach. The care provider should select an approach and device for each of the four components of the acronym. As an example, let us consider a neonate with Pierre Robin sequence. The Anesthesia plan may include deep sedation with a secondary plan for general anesthesia. The Ventilation plan may be spontaneous ventilation and the Adjunct a modified nasal airway, with a secondary plan of controlled ventilation using a laryngeal mask. The Device may be a video laryngoscope with the fiberoptic bronchoscope as a backup device. The chart ensures that all the critical aspects of the care plan are addressed, and horizontally represents increasing anesthetic and technical complexity. Nevertheless, practitioners should adopt a standard and consistent set of airway-related equipment and drugs for all anticipated difficult airway patients (Fig. 16.16). The most recent version of the American Society of Anesthesiologists Task Force on Management of the Difficult Airway was published in 2013 [284]. Although the general principles of difficult airway management are similar between adults and children, these guidelines did not specifically address management of pediatric patients.

When approaching the child with a known cause for a difficult airway, one of the first *a priori* decisions to be made is the anticipated level of consciousness during the airway management process. This largely depends on the anesthesiologist's confidence in their ability to avoid life-threatening hypoxemia in an anesthetized or sedated child using a facemask or a laryngeal mask.

"Awake" intubation

Tracheal intubation of an uncooperative child at a nearly conscious level is difficult and associated with complications [169,285]. Since the advent of the laryngeal mask, this approach has been largely abandoned for sedated or anesthetized techniques, with rare exceptions. For example, neonates with Pierre Robin sequence are expected to have difficulty with mask ventilation; therefore, awake insertion of a laryngeal mask and confirmation of adequate ventilation can precede induction of general anesthesia [142,144].

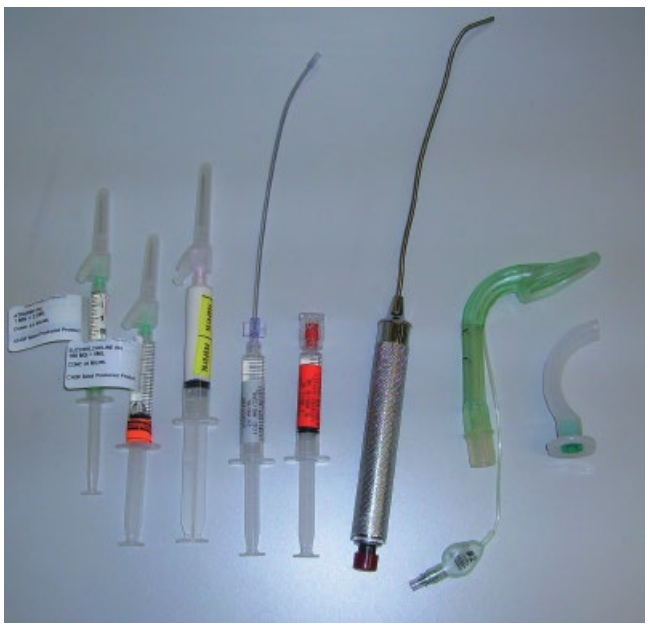

Figure 16.16 One example of a standard equipment and medication set-up for anticipated pediatric difficult airway. *From left to right*: atropine, succinylcholine, propofol, 2% lidocaine with mucosal atomizer attachment, vecuronium, lighted stylet, laryngeal mask, and oral airway.

Sedated intubation

Many children with anticipated difficult airways can be sedated to provide comfort and amnesia, yet retain spontaneous ventilation and upper airway patency during tracheal intubation attempts. A sedated technique is useful when there is the anticipation of life-threatening upper airway obstruction during induction of general anesthesia, such as may be seen in children with a large cystic hygroma [286]. Although light sedation has been described for intubation of infants using opioids, amnestic agents, and incremental doses of induction agents, most children will require deeper levels of sedation to ensure optimal intubating conditions. This can also be accomplished using dexmedetomidine, by itself or in combination with other agents [287]. Dexmedetomidine allows arousal with strong stimulation and maintenance of spontaneous ventilation, using a bolus dose of 1 μg/kg over 10 min followed by a continuous infusion of 0.7 μg/kg/h. Dexmedetomidine can be combined with incremental doses of ketamine (0.25 mg/kg) or midazolam (up to 0.1 mg/kg) to facilitate intubation without clinically significant respiratory depression [286,288]. Further studies are necessary to determine the optimal methods for preserving airway patency while minimizing reactivity during airway manipulations.

Intubation under general anesthesia

The majority of children with a known or expected difficult intubation can receive general anesthesia during the intubation process. Many pediatric anesthesiologists will require an indwelling intravenous catheter prior to administration of general anesthesia but this is practitioner dependent. Upper airway patency may be facilitated by insertion of an oral or nasal airway. A nasal airway may be attached to a 15 mm tracheal tube adapter, which allows connection to the anesthesia circuit for provision of anesthesia, oxygen, and CPAP during intubation attempts (see Fig. 16.9) [94].

Ventilation of the patient with a difficult airway

The ultimate goal of any airway management strategy is to maintain adequate oxygenation and avoid any level of life-threatening hypoxemia. It is critical that this overarching principle is not lost during attempts to secure the airway. Facemask ventilation represents the first step in maintaining oxygenation between intubation attempts. The optimal ventilation strategy for the management of the difficult pediatric airway remains unknown. Traditional teaching advocates the maintenance of spontaneous ventilation during airway management because of the fear of loss of the ability to ventilate with multiple traumatic attempts and to preserve the ability to quickly awaken the patient if necessary. In children, this concern is weighed against the possibility of coughing and other movements if the level of anesthetic is too light. There is no plausible research

that can examine this issue directly; much of the rationale for this strategy comes from case reports and clinical observations. Maintenance of spontaneous ventilation is advantageous because it facilitates oxygenation during airway manipulation [289], it provides clues to the glottic location by way of the bubbling of secretions that can be observed during fiberoptic intubation, and it provides the anesthesiologist with increased uninterrupted time to ventilate the child and accomplish the intubation. In addition, there may be greater upper airway patency and better visualization resulting from less soft tissue collapse when airway tone is preserved [290]. Although maintenance of spontaneous ventilation is preferred, some practitioners will attempt positive pressure ventilation and, if successful, will administer neuromuscular blockade to facilitate the intubation process. However, in adults, the addition of neuromuscular blockade in itself has been reported to change the anatomical characteristics of the upper airway and worsen ventilation or intubation conditions [291,292].

If paralytics are to be avoided, topical anesthesia should be applied to the glottic structures to minimize airway reactivity and should be performed when an adequate depth of anesthesia is confirmed. Lack of a physical response to a jaw thrust for 5 s usually indicates a satisfactory anesthetic depth for airway manipulation.

A total intravenous technique during intubation attempts will minimize operating room pollution from anesthetic gases. Various combinations of easily titratable intravenous agents (e.g. propofol, remifentanil) can be used for this purpose[293,294].

Much has been published recently on the value of oxygenation during indirect intubation attempts in an attempt to limit the number of episodes of oxyhemoglobin desaturation. Each episode of desaturation causes the intubation attempt to be halted, and additional intubation attempts are associated with increasing patient morbidity [279]. The use of pharyngeal or deep laryngeal oxygenation during orotracheal or nasotracheal intubation slows desaturation when compared to direct laryngoscopy without oxygen supplementation [281,283]. The use of nasopharyngeal oxygen has also been shown to limit desaturation during intubation attempts, and has been named "transnasal humidified rapid-insufflation ventilatory exchange (THRIVE)" [164]. We have suggested that oxygenation during indirect intubation attempts should become the standard of care in pediatric difficult airway management [280].

Impossible mask ventilation is unusual in the pediatric population. It is difficult to determine the true incidence because children suspected of impossible mask ventilation due to altered anatomy will undergo tracheal intubation using deep sedation and spontaneous ventilation. In an observational review of 22,000 adult anesthetics, the reported incidence of impossible mask ventilation was one in every 690 cases [295]. One-quarter of these patients were also difficult to intubate. Neck radiation was found to be the most significant predictor of impossible ventilation.

Indirect methods of tracheal intubation

There are many approaches to tracheal intubation in the child with a known or suspected difficult airway. In certain circumstances, it may be appropriate to attempt direct laryngoscopy if a reasonably long amount of time has passed since the previous intubation attempt and the anesthesiologist feels that the growth of the child has altered their airway anatomy in a favorable direction. If a direct method is deemed impossible, a variety of options exist for indirect tracheal intubation.

Fiberoptic bronchoscopy

The first article describing the use of flexible fiberoptic bronchoscopy in children appeared in 1978 [296], and despite many modifications in design it remains the "gold standard" for accomplishing tracheal intubation in the pediatric difficult airway [94,285,288,289,297–328]. Limitations of fiberoptic intubation in children include the significant time necessary for skill acquisition, the processing and preparation time of the equipment, the fragility of the bronchoscope, and the high purchase and repair costs. Despite these limitations the skill necessary to consistently perform a smooth fiberoptic intubation can be acquired during routine cases in children with normal airways. The introduction of 2.2 mm and 2.7 mm ultrathin bronchoscopes allowed fiberoptic intubation of neonates and small children with tracheal tubes as small as 2.5 mm [329,330]. These small bronchoscopes did not have a working suction channel, and so functionality was limited if the airway was occluded with secretions; however, modern versions are available with functional suction channels. Many larger bronchoscopes now incorporate a video chip-coupled device camera, which transmits the image from the tip of the scope to a screen and replaces the fiberoptic bundles that transmitted the image in older scopes. This provides a high-clarity image without the honeycombing typically seen with standard fiberoptic bronchoscopes.

Adult bronchoscopes can facilitate fiberoptic intubation in children. One method requires two providers. One places the bronchoscope at the glottic opening, while the other manipulates the tracheal tube independently into the trachea. This technique has the advantage over standard fiberoptic intubation of visualizing the passage of the tracheal tube through the vocal cords. A stylet in the tracheal tube will assist in directing the tube into the trachea. One case series describes use of this technique in small preterm neonates and it is a technique to consider when an ultrathin bronchoscope is not available or the clinicians lack the skill to use such a small scope [314]. A second technique involves the placement of a guidewire (e.g. 0.0035 in cardiac catheter guidewire; Mallinckrodt, St. Louis, MO) or tracheal tube exchanger into the trachea via the working channel of the bronchoscope. The bronchoscope is then removed and the tracheal tube advanced over the guidewire into the trachea [299,331–333].

In small children, the nasal route provides the most direct approach to the glottic opening with the flexible bronchoscope. This advantage has to be weighed against surgical considerations and the risk of nasal bleeding. Application of a vasoconstrictor such as oxymetazoline decreases this risk and visualizing the nasal passage prior to placing the tube may provide information as to the presence of polyps, adenoid tissue, or narrowing that may impede advancement of the tracheal tube. The other advantage of placing the scope first, before the endotracheal tube, is that a clear view of the airway anatomy and scope position can be maintained from the tip of the nares, through to the view of the carina, before the tube is advanced. The tracheal tube size should be matched closely to the fiberoptic bronchoscope size to reduce the incidence of

impingement of the tracheal tube on glottic structures. Rotation of the tracheal tube 90° counterclockwise will orient the Murphy eye anteriorly, and may enhance placement through the glottic opening [334,335].

During fiberoptic intubation, ventilation can be enhanced using the Frei endoscopy mask, which incorporates a perforated silicone membrane that allows passage of the bronchoscope [336]. Alternatively, one may use the "mask mouth technique," in which the facemask is applied only to the mouth and one naris is occluded while the bronchoscope is advanced through the opposite nasal passage [337].

The laryngeal mask can serve as a conduit for intubation and an adjunct for ventilation in children with difficult airways who do not tolerate brief periods of apnea. There are several manufactured designs and shapes but ideally the mask should provide full glottic exposure without encroachment of the epiglottis into the mask bowl. The ideal design will have a short and wide airway tube to facilitate removal of the device and allow passage of cuffed tracheal tubes, and will permit easy and effective ventilation through the device. Prior to using a laryngeal mask as a conduit for intubation it is critical to confirm that all components of the selected tracheal tube pass easily through the selected mask. Some masks will not accommodate the pilot balloon, particularly in smaller sizes [338,339].

To facilitate bronchoscopy through the laryngeal mask, a bronchoscope adaptor is placed on the 15 mm connector of the tracheal tube; the tracheal tube is then placed in the airway tube of the laryngeal mask and the cuff inflated. The anesthesia circuit is then attached to the tracheal tube and ventilation is established. An occlusive adhesive (e.g. Tegaderm™) can be applied to the bronchoscope adaptor to maintain a seal around the bronchoscope. Fiberoptic bronchoscopy is then carried out through the tracheal tube. When the trachea is entered, the tracheal tube cuff is deflated and the entire tube–bronchoscope adaptor unit is advanced into the trachea (Fig. 16.17) [340]. Removal of the laryngeal mask is challenging in children because the length of the tracheal tube is often similar to the length of the laryngeal mask tube. Techniques that may assist in laryngeal mask removal include using two tubes joined together to extend the working length, using a long pair of laryngeal forceps, or using a tube stabilizer or exchanger. Fiberoptic intubation through a supraglottic airway has been compared to videolaryngoscopy in a prospective multicenter study of patients with difficult intubation. Fiberoptic intubation via supraglottic airway and videolaryngoscopy had similar first-attempt success rates (67 of 114, 59% versus 404 of 786, 51%; OR 1.35; 95% confidence interval (CI) 0.91–2.00; p = 0.16); however, in subjects less than 1 year old, fiberoptic intubation via supraglottic airway was more successful on the first attempt than videolaryngoscopy (19 of 35, 54% versus 79 of 220, 36%; OR 2.12; 95% CI 1.04–4.31; p = 0.042). Complication rates were similar in the two groups (20% versus 13%; p = 0.096). The authors found that the incidence of hypoxemia was lower when continuous ventilation through the supraglottic airway was used throughout the intubation [341]. See Video clips 16.1–16.4.

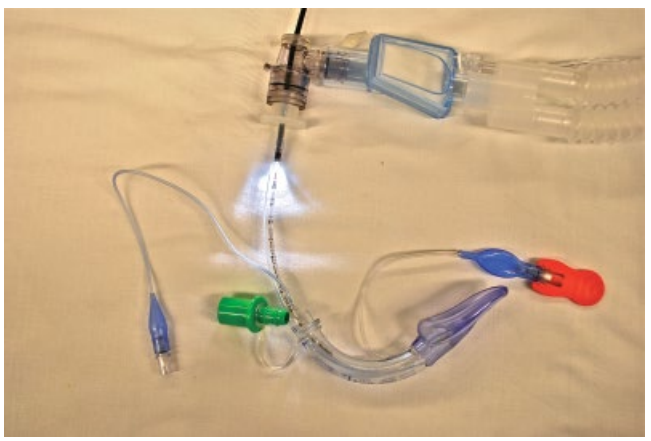

Figure 16.17 A bronchoscope adaptor is placed on the 15 mm connector of the tracheal tube, which is then placed in the airway tube of the laryngeal mask. This facilitates air exchange during bronchoscopic intubation.

Modified optical laryngoscopes

A variety of modified optical laryngoscopes have been developed to aid with direct visualization of the glottis in pediatric difficult airway patients. At the time of writing, there has not accumulated a sufficient body of knowledge with which to judge the comparative efficacy and complications of each of the devices. However, a number of case reports and case series have been published to date.

The Bullard laryngoscope (Circon ACMI, Stamford, CT) represents one of the earliest designs of an optical laryngoscope. It consists of a curved metal blade with an integrated fiberoptic light source attached to an eyepiece. It provides an indirect view of the glottic opening and requires minimal mouth opening (0.64 cm) for insertion. Like many optical laryngoscopes, visualization may be limited by secretions. In a series of 93 children aged 1 day to 10 years, intubation was successful in 90 patients (97%). Two failures were attributed to excess secretions [342].

The Airtraq® (King Systems, Noblesville, IN) is an intubating device that consists of a curved blade with two adjacent channels. It is designed to provide glottic exposure without alignment of the oral, pharyngeal, or laryngeal axes. One channel houses the optical system containing a series of prisms and lenses which end in a viewfinder (Fig. 16.18), while the second channel acts as a holder for the tracheal tube and a guide for advancing the tube into the trachea [343]. The infant Airtraq accepts tracheal tubes of internal diameter 2.5–3.5 mm, while the pediatric version accepts tubes of internal diameter 3.5–5.5 mm. The device is also available with the

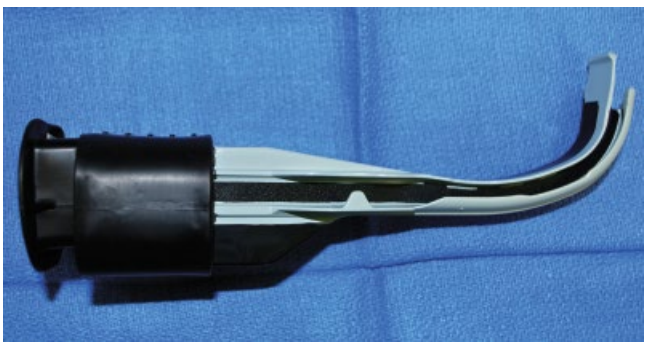

Figure 16.18 Pediatric Airtraq® intubating device.

posterior surface removed to facilitate nasal intubation. The Airtraq is inserted in the midline of the pharynx and the tip placed in the vallecula. The device is adjusted so that the glottis is located in the center of the viewfinder, after which the tracheal tube is advanced into the trachea. After confirmation of successful tracheal intubation, the tracheal tube is moved laterally away from the Airtraq, and the device slowly withdrawn. The Airtraq has been used successfully in patients with difficult direct laryngoscopy due to craniofacial anomalies such as Treacher Collins syndrome and Pierre Robin sequence [344]. In a series of 20 children managed with the Airtraq for elective surgery, one patient required the use of a malleable stylet to facilitate intubation because of difficulty aligning the glottis in the center of the view, and a second patient required two attempts to achieve successful intubation [345]. Other methods have been described to facilitate placement of the tracheal tube with an Airtraq® when there is difficulty aligning the glottis in the center of the image. These include the use of a gum elastic bougie, a flexible or malleable tracheal tube, and utilizing a fiberoptic bronchoscope while slightly withdrawing the Airtraq [346,347]. Like many indirect devices for tracheal intubation, the Airtraq may not be as useful for infants and neonates with difficult airways. Although it is possible to obtain an excellent view in this population, there is often difficulty with tracheal tube passage. This problem is also common with the non-channeled video and optical devices, and underscores the fact that the infant and neonatal airways are different from those of toddlers and older children [348]. The Airtraq improves the view in patients with difficult airways, and has the advantage of the preloaded tracheal tube which eliminates the maneuvers and injuries associated with non-channeled devices. However, its use may be limited to older children with ample mouth space in which to maneuver the device for an optimal glottic view and tube maneuverability.

The Truview EVO2 (Truphatek International, Netanya, Israel) is an indirect rigid laryngoscope with an angulated blade tip. The laryngoscope incorporates an optical lens that ends in an eyepiece that allows the operator to "see around the corner" and obtain an improved glottic view. It has an integrated oxygen port that allows oxygen administration during intubation. Tracheal intubation is achieved by placing the blade in the midline in the pharynx and following the curve of the tongue to the glottic opening. Once the glottis is visualized, the tracheal tube is advanced into the trachea. In a prospective comparison of intubation conditions between the Truview and the Miller laryngoscope in 60 neonates and infants, the Truview provided a statistically significant improvement in view with comparable intubation times [349]. In addition, since the Truview does not require neck extension for visualization and tracheal intubation, it can be used in patients with immobile cervical spines [350].

Video laryngoscopes

The miniaturization of video technology has fueled a revolution in laryngoscope design. There is a rapidly growing selection of video laryngoscopes available for pediatric use, such as the GlideScope®, the Storz® video laryngoscope, the McGrath Scope, and the Pentax Airway Scope. Video laryngoscopes can be categorized as angulated and non-angulated. Angulated video laryngoscopes provide improved views of the airway when compared to standard direct laryngoscopy but require a new skill to intubate the trachea indirectly. Non-angulated video laryngoscopes provide a magnified view which may not be adequate for an "anterior" airway, however inserting the breathing tube is usually not challenging. Sun et al performed a meta-analysis of 14 studies comparing video laryngoscopes to direct laryngoscopy in children. They showed that video laryngoscopy improved the glottic view in children with normal and difficult airways but took more time and failed more often. These results should be interpreted with caution since many of the studies included outdated early video laryngoscope designs such as the Bullard and GlideScope GVL 2, and the review did not distinguish between angulated and non-angulated devices [351]. A recent analysis of 1295 difficult intubations from the PeDI registry found that video laryngoscopy had a higher first-attempt success rate than direct laryngoscopy – 53% versus 4%; however, video laryngoscopy had lower success rates in patients who weighed less than 10 kg.

This section will focus on devices with specific pediatric designs.

GlideScope

The GlideScope (Verathon Medical, Bothell, WA) is a curved laryngoscope with an integrated miniature camera and a heated lens to minimize fogging during laryngoscopy. The device has evolved over the years from a bulky unit to a slim design (GlideScope Cobalt, Fig. 16.19). The Cobalt consists of a camera stick that is inserted into a disposable plastic sheath. A high-resolution image is displayed on a small portable video screen. The blade of the device is placed in the midline of the pharynx and the tip in the vallecula. A styletted tracheal tube is usually necessary, and although the manufacturer recommends a 50–60° degree angulation of the tube, others report higher success in placing the tube with a 90° hockey-stick configuration [352]. Passage of the tracheal tube should be observed on the video monitor to avoid injury to pharyngeal structures [353–359]. The Cobalt is available with a full complement of different-sized blades for use in premature neonates to adults. When compared with direct laryngoscopy in difficult airway patients, it has been shown to improve the glottic view without increasing the time to view [359–362]. In a study in infants, time to intubation was equivalent with the

Figure 16.19 GlideScope® Cobalt and disposable plastic blade.

Cobalt compared to direct laryngoscopy. In this study, the time to achieving an optimal view of the larynx was shorter with the Cobalt, however this was offset by a longer time for tracheal tube insertion [363].

There remains a population of patients in whom significant difficulty is encountered with tracheal tube placement despite an adequate glottic view with the GlideScope. Difficulties can arise from a number of factors including the limited ability to manipulate the tube within the smaller pediatric pharynx, the acute angulation of the tracheal tube causing impingement on the anterior commissure or anterior trachea, and difficulty locating the tube in the pharynx after inserting the blade [364]. Some practitioners advocate placing the tracheal tube and GlideScope simultaneously as a single unit or placing the tracheal tube in the pharynx under direct vision prior to placing the GlideScope. If the tracheal tube impinges on the anterior trachea or anterior commissure, the GlideScope should be withdrawn slightly to decrease the anterior displacement of the glottis allowing the axis of the tube and the trachea to become better aligned, and the tube rotated so that its concavity is oriented more posteriorly ("reverse loading," Fig. 16.20). The gum elastic bougie has also been utilized as a guide when using the GlideScope for tracheal intubation in children [365]. There will always be certain patients in whom the GlideScope and other video laryngoscopes will fail; thus, alternatives need to be readily available in difficult airway patients. See Video clip 16.5.

Storz video laryngoscope

The Storz video laryngoscope (SVL; C-MAC®; Karl Storz Company,Tuttingen, Germany) (Fig. 16.21) incorporates a camera into various standard blades. The Storz C-MAC video laryngoscope is a rigid blade that integrates fiberoptics and a lens into the light source of Miller- and Macintosh-type blades [366]. The blades connect to a device-specific camera that transmits the image to a video monitor. The use of the SVL is similar to other video laryngoscopes in that the blade is placed in the midline followed by insertion of the tracheal tube. Advancing the tracheal tube along the shaft of the blade rather than from the right side of the pharynx as in traditional laryngoscopy facilitates quick visualization on the video monitor and avoids injury to the palatoglossal structures. The SVL has been successfully employed in intubating patients with normal airways and has been reported to be more efficacious in pediatric difficult airway patients when compared to direct laryngoscopy [366–372]. Use of the SVL requires adequate mouth opening and practiced hand–eye coordination. The view through the SVL may be limited by fogging, which can be decreased by use of an anti-fog solution or prewarming the device.

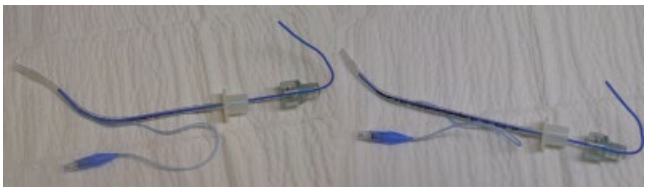

Figure 16.20 The tracheal tube on the left is "reverse loaded" by rotating the Murphy eye anteriorly on the stylet.

Optical stylets

The optical stylets were first introduced into clinical practice in the 1970s and remain useful adjuncts in the management of the adult and pediatric difficult airway. The optical stylet consists of a fiberoptic bundle within a rigid or malleable J-shaped stylet that ends in an eyepiece. These stylets can displace pharyngeal soft tissue because of their rigid form and are more easily maneuvered than flexible scopes. They often incorporate a port for insufflating oxygen and minimize secretions and fogging. However, we do not recommend oxygen insufflation even at low flow rates as pneumothorax and subcutaneous emphysema remain an ever-present risk in infants [373–375]. Optical stylets are simple to assemble and their use involves a short learning curve. Furthermore, they are inexpensive when compared to fiberoptic bronchoscopes and video or optical laryngoscopes. The optical stylet allows visualization of the tracheal tube as it passes through the vocal cords because the stylet is recessed within the tracheal tube during intubation; however, this view may be compromised by secretions or fogging.

Bonfils fiberscope

The Bonfils fiberscope and very similar Brambrink fiberscope (Karl Storz Company,Tuttingen, Germany) are rigid fiberoptic stylets with a J-shaped 45° anterior-angulated tip (Fig. 16.22). They provide a 90° angle of view and are available in all pediatric sizes. They are designed to be used via the retromolar approach. This approach brings the glottis into view rapidly and avoids negotiating the stylet around the bulk of the tongue. Once at the glottic opening, the preloaded tracheal tube is advanced through the vocal cords under direct vision. Some practitioners recommend the use of a rigid laryngoscope to create space for placement of the scope; however, some authors recommend against the use of this device in neonates [347,376–379]. The small optic aperture and significant 40-fold magnification render the visualization vulnerable to secretions [377]. In a simulated difficult pediatric airway, the Bonfils was easier to use and associated with better views of the larynx than direct laryngoscopy; however, intubation success rate and intubation times were similar [380]. In a comparative study in normal children, use of the Bonfils resulted in better laryngeal visualization than use of direct laryngoscopy or the GlideScope [381]. The Bonfils was

Figure 16.22 The Bonfils (two scopes on the left) and Brambrink (two scopes on the right) fiberscopes. See text for details. *Source:* Courtesy of Karl Storz Co.,Tuttlingen, Germany.

also successfully used in a 5-week-old infant with massive macroglossia and limited oral airway space due to multiple hemangiomata [382]. The Bonfils was compared to the fiberoptic bronchoscope in a small study of 26 children with known or suspected difficult intubation and found to be faster to use than the fiberoptic by two experienced investigators. The success rates were comparable and there were no differences in complications [383].

Shikani Optical Stylet

The Shikani Optical Stylet (SOS; Clarus Medical, Minneapolis, MN, USA) is a malleable, stainless steel, J-shaped stylet with an enclosed fiberoptic bundle [384] (Fig. 16.23). The pediatric SOS is 27 cm long and can accommodate tracheal tubes as small as 2.5 mm internal diameter. The SOS has been successfully used to intubate neonates and older children with a difficult airway. Extension of the head and application of jaw thrust facilitates elevation of the epiglottis off the posterior pharyngeal wall, which facilitates passage of the stylet [287,385–389]. The SOS is useful in patients who require maintenance of a neutral cervical spine during tracheal intubation [390]. As with the Bonfils, tracheal intubation can be accomplished efficiently and effectively with the assistance of the direct laryngoscope [391]. Use of the SOS is associated with minimal airway stimulation, permitting intubation in sedated children [144]. The SOS is lightweight, easily prepared and cleaned, and useful in managing the difficult airway in size ranges.

Lighted stylet

The lighted stylet allows tracheal intubation by observation of a transilluminated light in the neck. This often requires a darkened operating room to allow optimal visualization of the light. After the tracheal tube has been loaded onto the lighted stylet, it is inserted orally in the midline of the pharynx while performing jaw thrust, and the transilluminated light is located as a cone of light in the neck just above the suprasternal notch. It is critical that the light is located in the midline of the neck, as any deviation from the midline will direct the tube towards the esophagus. The centrally located light is then observed as the stylet is advanced caudally. Once the glottis is entered, the operator feels the stylet moving past the cords and observes an intensification of the light in the neck. Sometimes light is conducted down the trachea creating a characteristic "cone of light" effect. The tracheal tube is then advanced off the stylet and tracheal placement confirmed by the usual means. Resistance during the advancement of the stylet towards the glottis may suggest the device is off midline or the tip may be entrapped in the vallecula or on the aryepiglottic fold. This requires retraction of the device and reinsertion while improving jaw thrust to elevate the epiglottis off the posterior pharyngeal wall [392].

Lighted stylet-guided intubation utilizes tactile and visual cues to successfully place the tracheal tube. It is a low-cost technique that is easily learned and remains useful in cases where visualization of the glottis is difficult or impossible. It can be employed in awake patients with difficult airways and can be successfully utilized via the nasal route [393–399]. In a cohort of patients with normal airways, the lighted stylet was equally efficacious for tracheal intubation as the Airtraq [400].

In 1957, Sir Robert Macintosh was the first to describe the use of a lighted stylet to facilitate intubation [401]. Since the introduction of his 18 in illuminated tracheal tube introducer, there have been many stylet designs. The fiberoptic lighted intubation stylet (Anesthesia Medical Specialties, Santa Fe, CA) is available in pediatric sizes, accommodating tracheal tubes as small as 3.5 mm internal diameter. Lighted stylets for use with tube diameters less than 3.5 mm can be fashioned by inserting a single fiberoptic light pipe adjacent to an appropriately sized stylet for the selected tracheal tube. The light pipe is illuminated by a fiberoptic light source and in this manner a lightwand can be created for any sized patient (Fig. 16.24).

Digital intubation

Digital intubation is a rarely taught technique that should be learned by pediatric anesthesiologists [402]. It pre-dates direct laryngoscopy and may have been performed as early as the 1500s. It can be performed rapidly in patients who may be difficult to intubate by direct laryngoscopy or who may be in a position that does not allow easy access to the airway (e.g. extubation in the prone position). To perform a digital intubation, the anesthesiologist stands on the side of the patient facing the head of the operating room table. The gloved non-dominant index finger is placed along the surface of the tongue in the midline and is advanced to feel the epiglottis,

Figure 16.23 The Shikani Pediatric Optical Stylet. See text for details. *Source:* Courtesy of Clarus Medical, Minneapolis, MN.

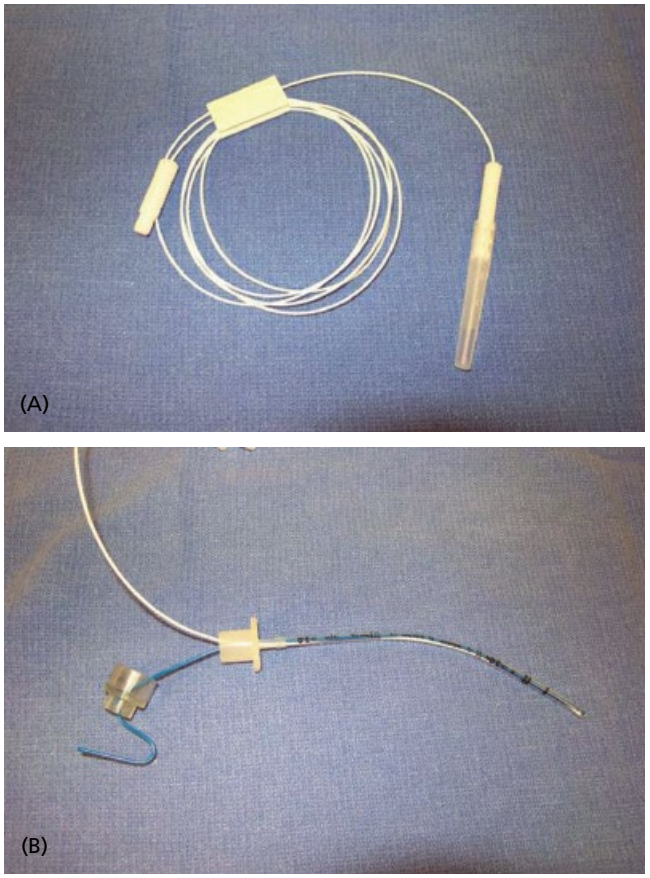

Figure 16.24 Lighted stylets for use with tube diameters less than 3.5 mm can be fashioned by inserting a single fiberoptic light pipe adjacent to an appropriately sized stylet for the selected tracheal tube. (A) Narrow gauge single fiberoptic light pipe. (B) Final assembly of fiberoptic light pipe, stylet, and endotracheal tube. See text for further explanation.

and then the finger is advanced further until the aryepiglottic folds are located. The dominant hand holds a styletted tracheal tube in a C-shaped configuration like a pencil and slides the tube alongside the non-dominant finger. The tip of the tracheal tube is directed through the glottis by the non-dominant finger and tracheal intubation is confirmed by the usual means. In a report of 39 digital intubations in 37 neonates, the mean time to intubation was 7 s. All the patients were successfully intubated; one patient required two attempts [403].

Extubation of the difficult airway

Extubation of the difficult airway can occasionally be more challenging than the intubation and requires careful planning and preparation to avoid complications. The operating room should be prepared in a similar fashion to the set-up for intubation and the device successfully utilized in securing the airway should be available in the operating room. In select cases, the use of an airway exchange catheter (Cook, Bloomington, IN) may be beneficial in the extubation of children with difficult airways. The Cook catheter is placed through the lumen of the tracheal tube into the trachea and is left in place after extubation. The catheter allows the administration of supplemental oxygen through a central hollow core. In a series of 20 pediatric difficult airway patients with an exchange catheter in place, five underwent successful reintubation over the catheter. No sedatives were required with the exchange catheter in place [404].

Surgical and invasive airway management

On extremely rare occasions, the anesthesiologist may encounter a dire "cannot ventilate, cannot intubate" situation associated with prolonged hypoxemia, which if left untreated, will likely result in patient mortality. Therefore, every pediatric anesthesiologist should have a reasonable approach to obtaining a surgical airway should this rare event occur. Cricothyroidotomy was first described in 1969 [405]. There are three methods of achieving oxygenation via the cricothyroid membrane: the small cannula (often an intravenous angiocatheter) approach, the commercially available large cannula approach using the Seldinger technique, and the open surgical technique in which a tracheostomy tube is inserted. The traditional techniques of choice for anesthesiologists and others not trained in open surgical tracheostomy are the needle cricothyroidotomy and Seldinger guided placement techniques. In an animal model of the infant airway, invasive airway access was difficult (60% overall success rate) and complications were common, including a 42% incidence of puncturing the posterior tracheal wall [406]; another animal model study had similar findings (67% success rate) but found that an emergency surgical tracheotomy could be performed within 4 min with a low rate of complications [407]. In small infants, identification of the cricothyroid membrane may be impossible, which is why some advocate for direct tracheal access using a scalpel. This skill can be practiced in a small animal model and requires very few steps.

Angiocatheter technique

The angiocatheter technique is probably the most plausible in pediatric patients requiring emergency surgical airway access. A needle cricothyroidotomy can be achieved using a 14-, 16- or 18-gauge angiocatheter that is placed through the cricothyroid membrane. While extending the cervical spine, the angiocatheter connected to a syringe of saline is introduced in the midline in the lower half of the cricothyroid membrane at a 45° angle in an inferior and posterior direction [408]. The syringe attached to the angiocatheter is gently aspirated during insertion, and return of air confirms tracheal entry. The catheter is then advanced off the needle into the trachea. A high-pressure oxygen source (such as a wall oxygen supply or jet ventilator) is needed to overcome the resistance of the catheter in order to deliver effective oxygenation (ventilation is not readily achieved). The oxygen source can be connected to the catheter by a 3 mL syringe with the plunger removed and attached to a 15 mm tracheal tube adapter. Barotrauma is a risk of ventilation through the angiocatheter, particularly in situations where exhalation is not possible because of upper airway obstruction. Structures at risk during the puncture are the superior thyroid artery along the lateral border of the membrane, the cricothyroid arteries, and the pyramidal lobe of the thyroid. The posterior tracheal wall could also be injured during the puncture attempt, thus confirmation of correct placement is critically important as insufflation of high-pressure gas outside the trachea can cause life-threatening tension pneumomediastinum

and tension pneumothorax. Even after correct placement, reassessment of positioning should occur frequently as children have little margin for error and a correctly placed catheter can become dislodged with minimal movement [409]. Oxygenation after accessing the trachea is particularly risky in neonates and infants: pneumothorax, barotrauma, hypotension due to air trapping, and increased intrathoracic pressures are known complications. One study compared rescue ventilation through an angiocatheter using the Enk oxygen flow modulator (Cook Medical, Bloomington, IN) to a jet ventilator in a rabbit model. The Enk flow modulator is a device for transtracheal ventilation consisting of a non-compliant tube with a distal Luer lock connector and openings for adjusting flow. Although it was a small study (9 rabbits), there were no differences in time to achieve adequate oxygenation between the two devices, and the authors concluded that both devices facilitated rescue ventilation through needle cricothyrotomy [410]. A potentially revolutionary device (Ventrain®; Ventinova, Eindhoven, The Netherlands) may transform ventilation after needle or surgical access in children. The basic concept and function of the device are very simple and address the major drawback of oxygenation through a small cannula, gas egress. Based on the Bernoulli principle, the Ventrain creates active expiration through small-bore cannulas by a jet-flow-generated suction. A small hole is occluded to enable ventilation, and release of the hole generates active expiration, reducing the risk of barotrauma [411].

The Ventrain has been used successfully in two infants with severe traumatic upper airway obstruction. Cook airway catheters were placed in the trachea and successful ventilation achieved using the Ventrain. The Ventrain may become a key ventilation tool in the severely obstructed child given its simplicity and novel function. Pediatric studies are needed to establish its efficacy and safety [412].

Large catheter Seldinger approach kits

Cricothyroidotomy kits based on the use of the Seldinger technique are now available for pediatric use. There are several manufactured kits that share common steps. A limited skin incision is made after identifying anatomical landmarks, a needle is inserted through the incision and cricothyroid membrane into the trachea, a guidewire is placed through the catheter, and the catheter is removed leaving the guidewire in place. A dilator airway catheter assembly is advanced over the wire into the trachea and the guidewire and dilator are removed [413]. Ideally, pediatric anesthesiologists should develop expertise with this approach using an animal model or a specially designed patient simulator. One commercially available kit, Quicktrach baby™ (VBM Medizintechnik GmbH, Sulz am Neckar, Germany) for infant emergency cricothyrotomy, was evaluated in 10 rabbits. The researchers found the Quicktrach baby to be a reliable technique with minor complications, and successful placement was possible in all attempts by the two anesthesiology trainees who used the device. This kit uses the cannula-over-needle technique and may be easier and quicker than other methods. The median time to place the device was 31 s with an interquartile range of 23–43 s. One rabbit had injury to the posterior tracheal wall mucosa and two animals had fractures of the cricoid cartilage. Although the device is designed primarily for cricothyrotomy it can also be directly placed in the trachea as a needle tracheotomy [414].

Intentional muscle relaxation for difficult airway management

In recent years, the traditional dogma of maintaining spontaneous ventilation and avoiding neuromuscular blockade for management of the difficult airway has been challenged. Case reports and case series in both adults and children indicate that mask ventilation may improve in the "cannot ventilate, cannot intubate" situation with muscle paralysis [415–417]. Functional airway obstruction, such as laryngospasm, opioid-induced muscle rigidity, and oropharyngeal obstruction with increased muscle tone, can be overcome with this strategy. In addition, if hypoxia with bradycardia has occurred, intravenous epinephrine can be administered to delay the onset of cardiac arrest while oxygenation is improving. Additional time is then available to intubate the trachea with specialized equipment, at times avoiding a surgical airway or significant hypoxia and cardiac arrest. Succinylcholine has been described in this scenario, but some authorities recommend non-depolarizing neuromuscular blocking agents. The recent availability of sugammadex, which in large doses can reverse even dense neuromuscular blockade with rocuronium or vecuronium, would appear to make this approach safer and more feasible [418]. Indeed, some difficult airway management algorithms in both adults and children now recommend considering muscle relaxation in the "cannot intubate, cannot ventilate" scenario before proceeding to a surgical airway [419,420].

Figure 16.25 presents algorithms for management of difficult mask ventilation, intubation, and "can't ventilate–can't intubate" scenarios for the pediatric patient, from the Difficult Airway Society [419].

KEY POINTS: THE DIFFICULT PEDIATRIC AIRWAY

- General anesthesia is utilized for the majority of pediatric patients with difficult airways; sedation with airway topicalization is less frequently used; awake intubation is reserved for emergency situations in small infants
- Preanesthetic IV access, maintaining spontaneous ventilation, and ensuring upper airway patency with CPAP, positioning, and an oral or nasal airway are important principles for the difficult airway
- Difficult mask ventilation with a difficult airway may be improved with neuromuscular blockade; availability of sugammadex is important for rapid reversal if necessary
- The fiberoptic bronchoscope can frequently be utilized for difficult intubation; oral or nasal routes or utilizing a laryngeal mask airway as a conduit are all effective techniques
- The pediatric videolaryngoscope has added significantly to effective management of the difficult airway and is now the first choice in many scenarios
- The need for surgical airway management is very rare; effective planning and immediate availability of a videolaryngoscope should avoid this scenario

Figure 16.25 (*Continued*)

CASE STUDY

A 2-month-old, male, former 31-week premature infant with Pierre Robin sequence presented for repair of bilateral large inguinal hernias, and open gastrostomy tube. Birthweight was 1600 g and it was evident after birth that the patient had significant micrognathia, with cleft palate. The patient had no other congenital anomalies, including no cardiac disease. He had moderate upper airway obstruction in the supine position without airway support. His airway had been maintained with nasal CPAP of 5–7 cmH_2O, with FiO_2 0.21–0.30 and flows of 1–2 L/min. In addition, he was nursed in the lateral or prone positions. He had no major apnea/desaturation events, had grown slowly with nasogastric tube feeds, – and now weighed 1950 g. The multidisciplinary team of neonatologists, otolaryngologists, pulmonologists, and craniofacial anomaly specialists was considering tracheostomy to maintain airway patency. However they were undecided at this point and wanted to address the hernias and a long-term feeding solution before attempting to wean the patient from CPAP and committing him to a tracheostomy. The patient's trachea had never been intubated, and he had not had previous surgery or imaging procedures. Medications were multivitamins and iron, and he had no drug allergies. On physical examination, the patient had obvious significant micrognathia, normal cervical range of motion, and very mild retractions with no obvious upper airway obstruction on nasal CPAP of 5 cmH_2O, FiO_2 0.21. There was a small 6 Fr nasogastric tube in the right naris. The lungs were clear to auscultation bilaterally, there was no cardiac murmur, and a 2 Fr percutaneously inserted central catheter (PICC) was present in the right arm. SpO_2 was 96%, chest radiograph revealed clear lung fields, normal heart size and configuration, and the PICC was present in the mid-superior vena cava. Preoperative laboratory studies included hemoglobin concentration of 10.1 g/dL, and a capillary blood gas of pH 7.36, $PaCO_2$ 44 mmHg, PaO_2 44 mmHg, and calculated base excess of +3 meq/L. After a discussion with the parents about the risks of difficult airway management and possible postoperative mechanical ventilation had occurred the day before, consent for anesthesia was obtained and the patient transported to the operating room (OR).

The following equipment had been assembled in the OR: standard Miller 0 and 1 laryngoscope blades; styletted uncuffed endotracheal tubes (ETT) of 2.5 and 3.0 mm sizes;

oral airways size 000, 00, and 0; disposable straight laryngeal mask airways (LMA) size 1 and 1.5; and the GlideScope Cobalt video laryngoscope with the small video baton and size 1 plastic laryngeal blade, and neonatal Magill forceps. Succinylcholine, 4 mg, and propofol, 6 mg, were drawn up in syringes. After discussion with the pediatric anesthesia fellow, it was decided to use the LMA as a conduit for fiberoptic intubation. A second attending anesthesiologist was present for induction of anesthesia and tracheal intubation, and the patient's otolaryngologist, who was operating with a series of short cases in the adjacent OR, was alerted the case was to start and available for emergency backup.

Standard monitors were placed, glycopyrrolate 0.02 mg was administered intravenously, the patient was preoxygenated with a facemask and FiO_2 1.0 for 3 min, and a #1 LMA, lubricated with 2% lidocaine gel, was inserted gently with the cuff deflated and the patient awake. He tolerated this well, the cuff was inflated with 3 mL air, and the airway was patent with audible crying. After gentle awake assisted ventilation demonstrated good chest excursion, inhalation induction with sevoflurane, 2% inspired, and 5 L/min oxygen flow, was begun. Inspired sevoflurane was increased slowly to 4%, the patient had a patent airway throughout and passed through Stage II of general anesthesia without incident and, with manually assisted ventilation and end-tidal (ET) sevoflurane of 3%, had SpO_2 99%, heart rate (HR) 135, and blood pressure (BP) 60/35. $ETCO_2$ was 24 mmHg. An extended 3.0 mm uncuffed ETT had been fashioned beforehand, made up of a standard 3.0 ETT with the connector removed and the upper half of a second ETT taped with a single layer of clear plastic tape with the connector removed. The extended ETT was loaded onto a 2.2 mm pediatric fiberoptic bronchoscope (FOB), pushed up to the proximal end of the scope. The video image was displayed on three large screens in the OR. The FOB was lubricated, had antifog solution applied to the tip, and was inserted into the end of the LMA with a standard FOB elbow adaptor, and advanced easily down the shaft of the LMA, with the second anesthesiologist gently assisting ventilation and stabilizing the LMA. When the aperture of the bowl of the LMA was reached, the glottis was in clear view, with the epiglottis stented up by the LMA. Slight vocal cord abduction was observed with inspiration. Propofol, 2 mg, was administered to deepen anesthesia and produce apnea, and the FOB was advanced carefully, always with the airway lumen in view, until the vocal cords had been passed, and the cartilaginous tracheal rings and pars membranosa were clearly in view. The scope was advanced further to just above the carina, to avoid carinal stimulation. Then, the ETT was advanced down the scope, through the LMA, and very gently through the glottic opening, rotated so that its beveled tip would be parallel to the vocal cord alignment. After passage of the ETT below the vocal cords, FOB position was checked and was still just above the carina. The FOB was withdrawn slowly, and the ETT tip could be seen in mid trachea. The ETT connector was placed on the end of the extended ETT, and manual ventilation produced excellent chest rise, equal bilateral breath sounds, and persistent $ETCO_2$ of 45–50 mmHg. SpO_2 had decreased to 91% but quickly recovered to 99% after 30 s of manual ventilation. HR was 120, BP slightly lower at 52/30, but with reduction in sevoflurane concentration to 2% and 10 mL lactated Ringer's solution bolus, returned within 2 min to 65/35. There was a leak around the ETT at 20 cmH_2O. While grasping the ETT in the back of the oropharynx with the Magill forceps, the LMA cuff was deflated, and the LMA removed gently over the extended ETT after the connector had been removed. The tape was removed from the extended ETT, producing a standard 3.0 ETT, the connector replaced, correct ETT placement and ventilation again verified, and the ETT secured in standard fashion. After the ETT was secured, a direct laryngoscopy was performed, and a Grade IV Cormack and Lehane view was evident, even with external laryngeal manipulation. All airway procedures were detailed in the electronic anesthesia record, and a patient alert for difficult airway clearly noted. A caudal anesthetic and rectal acetaminophen were used for intra- and postoperative analgesia. The case proceeded uneventfully, and it was decided to transport the patient back to the neonatal intensive care unit (NICU) with the endotracheal tube in place. Analgesia was provided with morphine, and the patient spent 48 h on mechanical ventilation, with good pain control. Extubation occurred in the NICU, with the patient awake, the anesthesiologist present at the bedside with LMA and fiberscope, and nasal CPAP ready to apply immediately after extubation. The patient was successfully extubated to nasal CPAP, spent another month in the NICU, and was weaned from CPAP, with improved upper airway obstruction and good somatic growth, and was discharged home with pulse oximetry and apnea monitoring, without tracheostomy, at age 3 months. The parents were well aware of the difficulty with tracheal intubation.

This case illustrates the principles outlined in this chapter, including thorough discussion and preparation for the difficult airway, assembling all airway equipment and drugs beforehand, choosing one primary method of intubation with at least one backup method available, having expert assistance immediately available, and planning for the difficult extubation. In addition, communication with other providers and parents, and documentation of airway procedures, are very important in the care of the patient with a difficult airway.

A meta-analysis of 19 studies comparing supraglottic airway devices to tracheal intubation in children found that during recovery from anesthesia the incidence of desaturation (OR = 0.34 (0.19–0.62)), laryngospasm (OR = 0.34 (0.2–0.6)), cough (OR = 0.18 (0.11–0.27)), and breath holding (0.19 (0.05–0.68)]) was lower when a laryngeal mask airway was used. Postoperative incidences of sore throat (OR = 0.87 (0.53–1.44)), bronchospasm (OR = 0.56 (0.25–1.25)), aspiration (1.33 (0.46–3.91)), and blood staining on the device (OR = 0.62 (0.21–1.82)) did not differ between laryngeal mask airway and tracheal intubation.

249 von Ungern-Sternberg BS, Boda K, Chambers NA, et al. Risk assessment for respiratory complications in paediatric anaesthesia: a prospective cohort study. Lancet 2010; 376: 773–83. An important prospective cohort study demonstrating that the incidence of laryngospasm is increased in children with active or recent upper respiratory tract infection, especially within 2 weeks of anesthesia. A history of eczema, exercise-induced wheezing, nocturnal dry cough, and wheezing more than three times in the prior year are strongly associated with bronchospasm, laryngospasm, and other perioperative adverse respiratory events. Having parents that smoke or a strong family history of asthma or atopy is associated with these perioperative adverse airway events.

277 Heinrich S, Birkholz T, Ihmsen H, et al. Incidence and predictors of difficult laryngoscopy in 11,219 pediatric anesthesia procedures. Paediatr Anaesth 2012; 22: 729–36. In this large cohort study, the overall incidence of difficult laryngoscopy (Cormack and Lehane (CML) grade III and IV) was 1.35%. In patients younger than 1 year, the incidence of CML III or IV was significantly higher than in the older patients (4.7% versus 0.7%). ASA physical status III and IV, a higher Mallampati score (III and IV) and a low BMI were all associated ($p < 0.05$) with difficult laryngoscopy. Patients undergoing oromaxillofacial surgery and cardiac surgery showed a significantly higher rate of CML III/IV findings.

CHAPTER 17

Induction of, Maintenance of, and Emergence from Anesthesia

Remek Kocz, James Armstrong, and Jerrold Lerman
Jacobs School of Medicine and Biomedical Sciences, John R. Oishei Children's Hospital, Buffalo, NY, USA

Evaluation of preoperative data and conditions

Preoperative evaluation including laboratory tests

The preoperative assessment of a child for general anesthesia requires a focused and systematic review of the history and all organ systems. The assessment should include details of the past medical history, current and recent medications, allergies, family history of anesthesia-related complications, nil per os (NPO) status, physical examination, and ancillary laboratory testing.

Before beginning a detailed medical history, a review of the child's vital signs, fasting status, and weight should be documented. Fasting guidelines before surgery can be found in the section "Nil per os." The child's weight should be assessed to determine whether the child's weight is normal or excessive (overweight or obese). An estimation of the child's ideal bodyweight may be calculated using the formulae in Box 17.1 [1,2].

The identity and legal status of the parent or guardian of all minors and cognitively challenged patients must be established preoperatively to ensure the consents for anesthesia and surgery are legal and the medical information is accurate. If the patient is >18 years of age, he/she may consent for anesthesia and surgery. If the child is female, <18 years, and either pregnant or has given birth in the past, in most jurisdictions she is deemed to be an emancipated minor and can consent to surgery. If the child is cognitively challenged, a health proxy (i.e. legal guardian) is required to consent for surgery, irrespective of the patient's age.

A family history of inheritable disorders or serious reactions that are potentially fatal under anesthesia should be sought. Specific mention should be made of malignant hyperthermia and muscle wasting diseases (e.g. Duchenne muscular dystrophy), both of which are discussed in the section "Medical conditions."

In reviewing the past medical history, the child's gestational age at birth is important, because infants who were born prematurely (i.e. <37 weeks' gestational age) and who are <60 weeks' postconceptional age may require overnight observation for perioperative apnea (see section "Ex-premature infants"). In addition, full-term neonates up to 4 weeks' postnatal age should not undergo general anesthesia as outpatients; they too should be admitted and monitored for at least 12 postoperative apnea-free hours.

A complete review of systems should be performed during the preoperative assessment including the cardiac, respiratory, central nervous system, gastrointestinal, genitourinary, endocrine and musculoskeletal systems.

Children with congenital heart disease should be questioned regarding: the nature and status of the heart defect; whether the defect resolved spontaneously or required surgery; if surgery was performed, the nature and date of the surgery; recent admissions or cardiology follow-up appointments related to the cardiac defect; and current cardiac medications. In most instances, a recent cardiology evaluation should be available in which a recent echocardiogram provides evidence of the heart function as well as the need for antibiotic prophylaxis for infective endocarditis. If the child's feeding, activity, color, or vital signs have changed substantially since the last cardiac evaluation, consideration should be given to delaying the surgery until a further cardiac evaluation is performed.

If a murmur is detected during the preoperative assessment, it is important to establish whether it is new or old and

Gregory's Pediatric Anesthesia, Sixth Edition. Edited by Dean B. Andropoulos and George A. Gregory.

Box 17.1: Ideal bodyweight in children [1,2]

- Infants 1–11 months: weight (kg) = (age (mon) + 9)/2
- Children 1–4 years: weight (kg) = 2 × (age (yr)+ 5)
- Children 5–14 years: weight (kg) = 4 × age (yr)

whether a cardiologist has evaluated it in the past. Assess the quality, duration, and location of the murmur, whether it radiates, and to where, and during which phase of the cardiac cycle it occurs. Evidence of heart failure should be ruled out before proceeding. If the murmur is possibly pathological in nature, if there are concomitant signs or symptoms of growth or activity delays, shortness of breath, cyanotic spells, syncope, or feeding problems, then a cardiology consult should be sought. Chapters 27 and 28 present additional information about congenital heart disease.

Illnesses that affect the respiratory system range from minor to major and life-threatening. Almost 30% of children present for surgery with an upper respiratory tract infection (URTI) that is most commonly self-limited. Apart from congenital anomalies that may present in the perinatal period (such as congenital diaphragmatic hernia or congenital lobar emphysema), it is important to question the parents about acquired infections such as recent croup or respiratory syncytial virus (RSV) and whether the child had been admitted to the hospital for any other respiratory problems. Children who present for tonsillectomy and adenoidectomy are diagnosed with either chronic infectious tonsillitis or obstructive sleep apnea (OSA). In the case of OSA, most children have a clinical diagnosis based on the otolaryngologist's assessment of the severity of the symptoms. There are no clinical metrics to confirm a diagnosis of OSA in children. The clinical presentation consists of non-specific signs and symptoms: their weight is normal or increased; they snore very loudly at night; they may have periodic nocturnal apneas and arouse without awakening during sleep; they are often fatigued in the morning despite having slept the entire night; and they may experience nocturnal enuresis, display signs of hyperactivity or inattention, and exhibit behavioral and learning difficulties at school. The definitive diagnosis can only be established by polysomnography, which evaluates the severity of the condition and guides subsequent treatment [3]. If a polysomnogram has been performed, it is important to be aware of the recorded saturation nadir during the sleep study. Children whose nadir is <85% show greater sensitivity to the respiratory depressant (apnea) effects of small doses of opioids [4]. In the absence of a polysomnogram, opioid sensitivity can be evaluated by observing the child's respiratory responses to small doses of opioids during general anesthesia. If apnea occurs in response to a small dose of opioids, no additional doses should be administered as these children are exquisitely sensitive to opioids. Additional opioid dosing only increases the risk of perioperative adverse airway events.

Gastroesophageal reflux (GER) is a normal physiological occurrence in the majority of infants that resolves in 95% of the population by 12 months [5]. Infant irritability and daily regurgitation are sometimes treated as symptoms of gastroesophageal reflux disease (GERD) with no improvement in symptoms. However, the prevalence of GER and GERD in children and adolescents has been estimated to be 4.1% and 7.6%, respectively [6]. Most children with documented GER undergo inhalation inductions, including anesthesia for procedures such as upper endoscopy, as this medical problem does not increase the risk for regurgitation and aspiration during anesthesia. Accordingly, we proceed with our usual anesthetic technique in children with GER.

Children with renal insufficiency or failure require a complete blood count, serum creatinine and blood urea nitrogen, and electrolyte concentrations preoperatively. If the child has renal failure, the type of dialysis and the timing of the last dialysis as well as the volume of fluid that was removed should be documented.

Children with Down syndrome present a number of significant challenges to the anesthesiologist. These children range in cognitive function from having very difficult behavioral problems to being high-functioning, very pleasant children. It is important to complete a cardiac history in these children, as congenital heart disease (e.g. ventricular septal defect and endocardial cushion defect) is common. These children have large tongues and narrow subglottic regions. Accordingly, tracheal tube sizes 0.5–1 mm internal diameter (ID) smaller than expected for their age should be immediately available. Much has been written about the instability of the cervical spine in Down syndrome, although reports of neurological sequelae associated with general anesthesia and surgery in these children are exceedingly rare [7]. Evidence of a pre-existing neurological complaint (the child favors one hand or foot over the other suddenly or has had a change in gait, complains of pain in the neck, is unable to turn the head to one side or the other, or complains of dizziness or fainting) should be noted and reason for concern regarding the stability of the cervical spine. In such cases, a neurological investigation should be sought before proceeding with anesthesia. Although the American Academy of Pediatrics recommends cervical spine imaging in all children with Down syndrome between 3 and 5 years of age, there is no evidence that these investigations are predictive of adverse neurological outcomes in the perioperative period. A survey of 171 pediatric anesthesiologists reported that only 18% obtain preoperative radiographs and/or consultations (in 9%) in asymptomatic children; the majority base their evaluation on the signs and symptoms present [8]. During anesthesia and tracheal intubation, we maintain the neck of children with Down syndrome in a neutral position at all times. Chapter 43 presents additional information about Down syndrome and other genetic conditions.

Children with diabetes mellitus present a number of challenges in the perioperative period [9]. Those with diet control or oral medications should have their morning blood glucose level checked. These children do not usually require additional care and can resume their diet and medications postoperatively. Insulin-dependent diabetics present a more complex management problem. A thorough history should detail their diabetes control, whether they experience hypo- or hyperglycemia, their typical HbA_{1c} level (with a goal of <7.5% in children and adolescents), the type and frequency of insulin and whether they use an insulin pump [10]. In many instances, the endocrinologist responsible for managing their diabetes provides a protocol to the patient and staff recommending appropriate management in the perioperative period [9]. Children who are prone to hypoglycemia should have a glucose

infusion during surgery with periodic measurement of the blood glucose concentrations during anesthesia. If the preoperative blood sugar is >250 mg/dL, a sliding scale of insulin should be started to reduce the blood glucose concentration. More commonly, a correction factor is applied to determine how much 1 unit of regular insulin will decrease the blood glucose concentration in the child. The factor is calculated as the ratio of 1500 and the total daily dose of insulin. For example, if the child takes 30 U of insulin per day, then 1 unit of regular insulin should decrease the blood glucose concentration by 1500/30 or 50 mg/dL. Children who use insulin pumps should also have a fasting glucose measured and their pump set to basal rate during surgery. If the pump is equipped with a continuous glucose monitoring system and alarms with high or low blood sugar concentrations during surgery, the blood glucose concentration should be determined to validate the alarm with an appropriate action being taken based on the result. Chapter 24 contains additional information about diabetes.

In adolescents, it is important to ascertain their use of tobacco and illicit drugs. This may not be possible until the child is separated from the parents. If there is any suspicion that illicit drugs such as cocaine, methamphetamines, opiates, or other cardio- or neurotoxins have been consumed recently, then a toxicology screen, an electrocardiogram, and a neurological examination should be obtained. Chapter 24 presents further information about the approach to the adolescent patient.

A list of medications, the frequency of their consumption, and when they were last taken should be compiled. Liquid medications may be taken on the morning of surgery. Children who take medication in the form of pills will often only take the medications if they are mixed with food. These medications, often antiepileptic drugs, should not be taken before surgery if they cannot be given without solid food. Medications such as β-blockers and α_2-agonists should be continued in the perioperative period, as suddenly stopping them may cause rebound. Angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARB) taken on the morning of surgery have been reported to cause profound hypotension in adults after induction of anesthesia [11,12]; although controversial, many recommend withholding these drugs on the day of surgery. Herbal medicines and supplements, more commonly ingested by adults, are taken by 6–10% of children in one survey, with Echinacea and arnica being the most commonly used herbals, but St John's wort, valerian, garlic, and gingko also widely used [13]. Valerian and kava may prolong the duration of anesthesia, and feverfew, garlic, ginger, and ginkgo increase the risk of perioperative bleeding. St. John's wort induces P-glycoprotein and CYP3A4 interactions, thereby decreasing the concentrations of critically important drugs, such as cyclosporin A. Furthermore, goldenseal inhibits CYP3A and 2D6, possibly prolonging the duration of ondansetron. Valerian and St John's wort should be tapered at least 1 week before scheduled anesthesia to minimize the risk of drug reactions [14–16].

Allergies present a very serious conundrum for anesthesiologists. Any reaction that a parent or child reports as abnormal should be listed as an allergy or sensitivity in the medical record. The reactions may be known side-effects of the drug (i.e. an erythematous skin rash after amoxicillin). Once listed as an allergy on a child's chart, it is often difficult to expunge the drug alert. Examples of allergic reactions that are not allergies that the authors have direct knowledge of include allergy to epinephrine because it causes headaches, a diaper rash from oral sulfonamide antibiotic, and a penicillin rash that occurred in the parent, not the child, but was listed on the child's chart. In fact, most allergies listed in the patients' charts have no immunological basis [17,18]. In a child, a flat skin rash produced by oral liquid antibiotic is often non-immunological in origin and warrants re-challenging the child with the antibiotic if the sentinel event occurred ≥5 years ago. Egg allergy is not a contraindication to propofol [19]; soy and peanut allergy are contraindications only to propofol manufactured with those additives, most commonly by European manufacturers. Latex is commonly cited as an allergy in children. Skin (and hand) latex reactions generally are non-immunological and do not proceed to systemic anaphylactic reactions. With the removal of latex from most medical products, children with spina bifida and congenital urological abnormalities are no longer exposed to latex products repeatedly and are far less likely to develop latex allergy [20]. Latex allergy is an acquired susceptibility after repeated exposures to latex; it is not congenitally acquired. The most important question to ask regarding latex susceptibility is whether the child develops any reaction when he/she touches a toy balloon to his/her lips or the dentist inserts a rubber dam in the mouth. If the lips or tongue swell, then the child is likely to be immunologically allergic to latex. A latex-free environment in the operating room will ensure safe conduct of these children. See Chapter 45 for further discussion of latex and other allergies.

Before every child is anesthetized, physical examination of the head and neck, chest, and heart must be performed. Physical examination of the head and neck includes evaluating the extent of mouth opening, the ability to extend the tongue and neck, the state of the dentition, and any detachable plates or oral appliances. All metal piercings and objects must be removed from the oropharynx to prevent aspiration, bodily injury if undergoing a magnetic resonance imaging (MRI) scan, or a skin burn if electrocautery is used in the vicinity (although bipolar cautery is safer than unipolar) [21]. Concerns over a piercing hole closing can be addressed by inserting sterile sleepers (non-metallic spacers), such as a large-diameter suture or epidural catheter, through the lumen for the duration of the procedure [22,23]. Tongue piercings may close quickly, within a few hours or less.

Auscultation of the heart and lungs should be performed and recorded on the preoperative record. Any abnormal findings should be recorded.

Routine laboratory testing such as complete blood count, chemistry panels, and urinalysis are not indicated for most elective surgical procedures involving children. However, in the event that the surgery may entail a large blood loss, a preoperative complete blood count along with type and screen or cross-match should be performed. In some children, it may be necessary to wait until they are anesthetized and intravenous access is established before sufficient blood can be obtained for the tests required.

The most recent recommendation by the American Society of Anesthesiologists (ASA) Task Force on Preanesthesia Evaluation states "the literature is insufficient to inform patients or physicians on whether anesthesia causes harmful

effects on early pregnancy. Pregnancy testing may be offered to female patients of childbearing age and for whom the result would alter the patient's management" [24]. We require a preoperative pregnancy test for all menarcheal females who require anesthesia at our institution. If the test is positive, we inform the child of the result and work towards a decision whether to proceed with surgery and anesthesia. If we proceed with anesthesia, the optimal anesthetic technique for the mother and fetus must be reached by consensus with the pregnant mother. Chapter 24 contains further discussion about pregnancy testing.

The clinical value of a chest radiograph in a child about to undergo surgery is typically less than an oxygen saturation reading. An oxygen saturation reading <95% is abnormal and may suggest deterioration of the child's pulmonary or cardiac status. In both instances, it warrants further investigation.

Specialized tests such as electrocardiography and echocardiography can be an invaluable clinical tool in a child with known congenital heart disease or myocardial dysfunction. These tests help to evaluate the cardiac anatomy, intracardiac shunting, ventricular function, right-sided heart pressures, valvular function, and the presence of pleural or pericardial effusions.

Radiological investigations such as computed tomography (CT) or MRI may be useful not only to the surgical team but also to anesthesia to evaluate the scope of the disease process such as that involving airway anatomy.

Once all of the relevant preoperative data have been compiled, an assessment of the "ASA physical status" of the child should be performed. This metric is an assessment of the child's pre-existing diseases, but it is not intended as a measure of perioperative risk (Table 17.1).

Medical conditions

Nil per os

All children scheduled for elective surgery should be fasted according to the ASA guidelines (Table 17.2) [25]. Note that there are no age-adjusted fasting intervals. Recently, a shift in philosophy in Sweden allows clear fluids until the time the child is "called" to the operating room, i.e. approximately 30 min since the last oral fluids, changing the fasting intervals to a 6–4–0 rule: 6 h for solids, 4 h for breast milk, and 0 for clear fluids. This has resulted in an incidence of aspiration of 3:10,000, consistent with the previously published data with more restrictive fasting guidelines [26]. Children who present with chewing gum must expectorate it before induction of anesthesia. Chewing gum increases both gastric fluid volume and gastric fluid pH, rendering the risk of pneumonitis should aspiration occur no different from those who do not chew. As a result, induction of anesthesia need not be delayed [27–29].

In emergency surgery, the bowels cease peristaltic action as soon as the injury occurs. The administration of opioids also impairs peristalsis. Hence, all foods present in the stomach at the time of the injury are likely to remain there until peristalsis resumes. The time until peristalsis resumes after an injury and/or opioid administration is unpredictable. The only time interval that correlates inversely with the risk of aspiration pneumonitis (i.e. gastric fluid pH <2.5 and volume >0.4 mL/kg) is the interval between the last oral intake and the injury [30]. Bowel sounds alone do not confirm that intestinal peristalsis and gastric emptying have resumed although, if gas is passed, one may conclude that peristalsis has resumed. We consider all children who undergo emergency surgery to be at risk for regurgitation and aspiration of gastric contents and take appropriate precautions including a rapid-sequence induction (RSI) and tracheal intubation to manage the airway.

Table 17.1 American Society of Anesthesiologists physical status classification system

Classification	Explanation
I	A normal healthy patient
II	A patient with mild systemic disease
III	A patient with severe systemic disease
IV	A patient with severe systemic disease that is a constant threat to life
V	A moribund patient who is not expected to survive the operation
VI	A declared brain-dead patient whose organs are being removed for donor purposes.

The addition of "E" denotes Emergency surgery: an emergency is defined as existing when delay in treatment of the patient would lead to a significant increase in the threat to life or body part.

Table 17.2 Fasting intervals before elective surgery

Clear fluids/jello	2 h
Breast milk	4 h
Infant formula/light solids	6 h
Heavy/fatty solids	8 h

Upper respiratory tract infection

Children who have had a recent URTI are at increased risk of perioperative respiratory adverse events after general anesthesia [31]. Ideally, they should not undergo elective anesthesia for 4–6 weeks after the infection to ensure residual pathological effects in the small airways have resolved. However, because many young children have frequent URTIs (6–7 episodes per year), most clinicians will proceed with anesthesia 2–4 weeks after the original infection. In children who present for elective surgery with a URTI, we recommend canceling the anesthetic if any one of the criteria in Box 17.2 is present [32], as each increases the risk of perioperative airway events. For infants <1 year of age, a URTI may herald RSV infection, posing a risk for serious morbidity and increased mortality particularly in preterm infants [33,34].

Children with clear rhinorrhea, whether due to a mild URTI or allergic rhinitis, should receive 1–2 drops of oxymetazoline (0.025%) or phenylephrine (0.125%) nose drops per nostril to reduce nasopharyngeal secretions during anesthesia. We prefer to manage these children with a facemask to reduce the risk of airway reflex responses, but if an airway must be used,

Box 17.2: Criteria for canceling elective surgery in a child with an upper respiratory tract infection (URTI)

1. Fever >38.5°C
2. Behavioral and eating changes
3. Mucopurulent secretions
4. Lower respiratory tract wheezing or rhonchi that do not clear with deep coughing

a supraglottic airway such as a laryngeal mask airway (LMA) is less likely to trigger airway reflex responses than a tracheal tube [35].

Asthma

Up to 20% of children have asthma or an asthmatic history, but significantly fewer present with severe asthma that may complicate anesthesia [36,37]. Children with a history of asthma should have their pulmonary condition optimized and be free of a recent exacerbation or hospitalization for asthma before proceeding with anesthesia [37,38]. The preoperative assessment should elicit the age of onset of asthma, number of and date of the most recent hospital admissions for asthma, current treatment (use of β_2-agonists or steroids by inhalation) and current state of the asthma. Most children have never stayed overnight in hospital for asthma; if they have, the asthma is severe and should be carefully assessed. If oral steroids have been recently prescribed for an acute exacerbation of asthma, careful preoperative examination of the chest must be performed to ensure that there is no lingering reactive airway component. Current evidence indicates that genetic and/or environmental interactions (β_2-adrenergic receptors) may predispose children to the presence and severity of asthma as well as to the individual's responses to β-agonist agents [39–41]. Pediatric anesthesiologists vary in their preoperative management of children with asthma [42]. On the morning of surgery, the child's lungs should be examined for wheezing. Preoperative bronchodilator therapy may be administered to children with mild to moderate asthma who are not wheezing as it reduces airway resistance during sevoflurane anesthesia and tracheal intubation by approximately 25% [43]. If wheezing is present, the child should be instructed to cough deeply to clear secretions present in the airways and bronchodilator therapy should then be administered. If the wheezing persists, the child should be referred to their pulmonologist for reassessment and further treatment, and the anesthetic should be deferred.

For children who present for emergency or urgent non-airway surgery and are wheezing, preoperative bronchodilator therapy should be administered. If tracheal intubation can be avoided, a facemask or LMA should be used. Equipment should be prepared to administer intraoperative bronchodilator therapy should the need arise (see section "Bronchospasm").

Ex-premature infants

Infants who were born premature (<37 weeks' gestational age) and are <60 weeks' postconceptional age (defined as the sum of the gestational and postnatal ages) require 12–24 h of postanesthesia apnea monitoring, irrespective of the nature of the surgery [44]. Some institutions use a younger age cut-off for apnea monitoring, i.e. 46 or 50 weeks' postconceptional age. Factors that increase the risk of perioperative apnea in ex-premature infants include age (<60 weeks' postconceptual age), anemia (Hb <12 g/dL), and a secondary diagnosis (e.g. intraventricular hemorrhage) [44,45]. Caffeine 10 mg/kg intravenously may be administered intraoperatively to reduce the frequency of perioperative apneas, but it cannot be relied upon to eliminate them completely. Once the infant has been apnea free for 12 h, he/she may be discharged home.

In contrast to general anesthesia, regional anesthesia does not appear to confer a similar risk of perioperative apnea and does not require perioperative monitoring unless the infant was also sedated or has multisystem disease or a history of perioperative apneas [46]. Spinal or caudal anesthesia should provide sufficient anesthesia to perform hernia surgery, the most common surgery in ex-premature infants [47]. If the infant is >44 weeks' postconceptional age, he/she may be discharged home from the postanesthesia care unit (PACU) following regional anesthesia alone. If the parents have an apnea monitor at home and have been trained to manage apnea, the child may be discharged home in the parents' care. See Chapter 23 for further discussion of the former premature infant.

Obesity

Obesity is an epidemic, and almost one-third of children worldwide are obese. Because growth in childhood is non-linear, obesity for a particular age of a child and sex is defined as >95th centile for body mass index (BMI; weight/height^2, kg/m^2) on growth curves. Obesity is a multifactorial disorder affecting cardiovascular, respiratory, renal, and endocrine systems and the liver. The severity of these disorders in children is usually relatively minor because the duration of the obesity in children has not been sufficient to adversely affect most organ systems. However, asthma and OSA are more common in obese children [48]. Moreover, nocturnal desaturation may upregulate the sensitivity to opioids (if the nadir of the nocturnal desaturation is <85% repeatedly) in children with OSA. It is important to have empathy for these children and recognize the child's psychological immaturity. These children are often emotionally unprepared for the stress of surgery and serious consideration should be given to preoperative anxiolysis for them.

Complications in the perioperative period occur more commonly in obese children compared with asthenic children, particularly airway and respiratory adverse events in terms of mask ventilation, laryngospasm, oxygen desaturation, and bronchospasm [49].

Before induction of anesthesia, the child should be positioned 45° head up to optimize preinduction oxygenation [50]. Airway management requires meticulous attention to maintaining a patent upper airway using a jaw thrust together with continuous positive airway pressure. Tracheal intubation is not difficult providing the occiput is elevated (double the usual displacement) such that in the profile view the tragus is above the level of the sternal notch [51]. During surgery, positive end-expiratory pressure should be applied to prevent atelectasis.

The greatest challenge in obese children is to determine the appropriate scalar for drug dosing. Total bodyweight is comprised of fat and fat-free masses. The fat mass is the depot in which lipophilic drugs are sequestered whereas the fat-free mass is the depot in which hydrophilic drugs are deposited. The fat-free mass is analogous to the lean body mass or the sum of the ideal body mass plus the mass that has accrued to support the physical and metabolic demands of the fat mass (i.e. excess weight in muscle, heart, liver, and other organs). Equations for the ideal bodyweight are shown in Box 17.1). The lean or adjusted body mass is the ideal bodyweight plus 0.3 or 0.4 of the difference between the total bodyweight and

Table 17.3 Tissue/blood partition coefficients for inhaled agents and nitrous oxide

Partition coefficients	Sevoflurane	Desflurane	Isoflurane	Enflurane	Halothane	Nitrous oxide
Blood:gas	0.65	0.42	1.46	1.9	2.4	0.46
Brain:blood	1.7	1.3	1.6	1.4	1.9	1.1
Muscle:blood	3.1	2.0	2.9	1.7	3.4	1.2
Fat:blood	47.5	27.2	44.9	36	51.1	2.3

ideal bodyweight. Loading doses depend on the volume of distribution of the drug; these have been reported in obese children [52,53]. The maintenance doses of anesthetics depend on the clearance of the drugs, and many of these have been reported [52,53].

Inhalation agents partition among the fat mass and the fat-free mass depending on their tissue solubilities and the duration of exposure: sevoflurane > isoflurane > desflurane > nitrous oxide (Table 17.3) [54]. Although sevoflurane is the preferred induction agent, desflurane and nitrous oxide are the preferred maintenance agents for surgery >2 h based on their fat solubilities (see Table 17.3). The latter two agents facilitate a rapid decrease in the context-sensitive half-life and therefore recovery from anesthesia [55]. See Chapter 10 for further discussion of pharmacology and Chapter 24 for further discussion of obesity.

Full stomach and rapid-sequence induction

The term "full stomach" refers to the possible presence of residual solid or liquid food in the stomach at induction of anesthesia and is usually associated with hypokinetic or akinetic intestinal peristalsis. In such cases, the child is at risk for regurgitation and possibly aspiration of residual gastric contents into the lungs during general anesthesia and sedation, a potentially fatal perioperative complication. The full stomach occurs most often during emergency surgery, but also in children with gastric dysmotility syndromes and diabetes. In most cases of emergency surgery, the time interval between ingestion of food and induction of general anesthesia is too brief to ensure complete evacuation of the gastric contents. The trauma, pain, and stress of the injury, coupled with the administration of opioids, lead to gastric and intestinal paresis and food remaining in the stomach for a prolonged period.

There are three important principles to remember in such cases. (1) There is no safe time interval after an injury that guarantees the stomach is empty of food. (2) There is no safe time interval after an injury that guarantees no risk of regurgitation of food present in the stomach. (3) All children (even those treated with prokinetic motility medications) are at risk for regurgitation and aspiration during induction of, maintenance of, and emergence from anesthesia.

The only variable that has been associated with an increased gastric fluid volume and decreased pH after a trauma is the time interval between the last ingested food and the occurrence of the trauma. The smaller the interval, the greater the risk that a large gastric volume and reduced pH are present [30].

To protect the airways in children who are at risk for regurgitation and aspiration during induction of anesthesia, rapid-sequence induction (RSI) was created to swiftly establish anesthesia and secure the airway expeditiously and safely. Although there is no evidence that RSI is the optimal strategy to prevent regurgitation, it seems sensible to induce anesthesia quickly and insert the tracheal tube into the larynx as quickly as possible. In order to perform RSI, one must prepare the appropriate equipment (see Box 17.3).

In most institutions, RSI is performed using intravenous anesthesia. The most common induction agent is propofol (2–4 mg/kg), although ketamine (1–2 mg/kg) and etomidate (0.2–0.3 mg/kg) may be used for hemodynamically unstable children. We recommend intravenous (IV) succinylcholine 2 mg/kg (preceded by atropine 0.02 mg/kg) for paralysis, although rocuronium 0.8–1 mg/kg has also been used. However, if the airway appears to be difficult or precarious, alternative strategies to secure the airway should be considered, including an inhalation anesthetic or topical local anesthetic and total intravenous anesthesia (TIVA). If an inhalation induction is performed, the child may need to be turned to the left lateral decubitus position emergently if regurgitation occurs. Topically anesthetizing the airway during TIVA while maintaining spontaneous respiration may be required.

There is much debate regarding the importance and relevance of cricoid pressure, a key element in RSI [56]. Currently, there is no evidence to support or refute the use of cricoid pressure during RSI. However, there are some concerns regarding the application of cricoid pressure in infants and children. In young children, the cricoid ring and trachea are

Box 17.3: Rapid-sequence induction for children

Pre-induction

- Laryngoscope handle/blades sized for age
- Age-appropriate tracheal tubes with a stylet
- Active Yankauer suction
- Induction agents and muscle relaxants in weight-appropriate doses
- Preoxygenation through a tight-fitting mask and breathing circuit (as tolerated)
- Optimal positioning of the head and neck
- Suction and removal of an existing nasogastric tube

Induction

- Rapid intravenous induction of anesthesia using predetermined drug doses
- Cricoid pressure, if utilized, should be age appropriate and not compress or distort the airway
- Maintenance of a tight facemask seal (100% O_2) without assisted ventilation (except for infants)
- Once fasciculations are visible after succinylcholine or suppression of the twitch response after a non-depolarizing relaxant, laryngoscopy and tracheal intubation are performed rapidly
- A predetermined size tracheal tube is then inserted
- If a cuffed tracheal tube is used, the cuff is inflated before the lungs are auscultated. Cuff pressure is adjusted once auscultation is performed

mobile and deformable. In fact, a force of only 10 Newtons can compress the lumen of the airway by 50% in young children, one-third the force recommended for cricoid pressure in adults [57]. Cricoid pressure may also increase the difficulty of tracheal intubation by distorting the anatomy or compressing the cricoid ring. Very few assistants are trained properly in the location of the cricoid ring and in the magnitude of the force required to occlude the esophagus [58,59]. It remains our view that cricoid pressure is not required for RSI to be a rapid and safe technique to secure the airway in children.

Malignant hyperthermia

Preparation of the anesthetic machine for an elective case of malignant hyperthermia (MH) begins with scheduling the child as the first case of the day since the concentration of inhaled anesthetics in the operating room is at its nadir if the room is unused overnight [60]. The vaporizers should be removed from the machine, the anesthetic breathing circuit and carbon dioxide canister replaced with new equipment, and the anesthetic workstation purged of all residual inhalation anesthetic by flushing the machine with a fresh gas flow of ≥10 L/min (air/oxygen mixture) while the ventilator is operating. Although the threshold vapor concentration above which MH reactions occur is unknown, older studies aimed to reduce the inhaled agent concentration in the machine to ≤10 ppm whereas the Malignant Hyperthermia Association of the United States (MHAUS) currently recommends limiting the concentration of triggering anesthetic to <5 ppm; neither concentration is measurable without sophisticated detectors. The times required to purge all anesthetic workstations to these trace concentrations of inhalational anesthetics vary 15-fold, from 10–15 min for the Datex-Ohmeda Excel workstation to 140 min for the Drager Fabius CE (Table 17.4) [60]. To reduce the flush times of the latter to <10 min, one may replace the integrated breathing circuit with autoclaved circuit components or insert a charcoal absorbent filter into the inspiratory (and expiratory in the case of a full-blown MH reaction) limb of the breathing circuit [61].

Table 17.4 Time to wash out inhalational anesthetics to less than 10 ppm

Anesthetic workstation	Time (min)
Datex-Ohmeda-GE	
Modulus 1	5–15
Excel 210	7
AS/3 c	30
Aestiva (sevoflurane)	22
Aisys (sevoflurane)	25
Avance	39
Other	
Narkomed (Dräger)	20
Dräger Primus	39–70
Dräger Fabius GS	104
Dräger Zeus	35–85
Kion (Siemens)	>25
Perseus (Dräger)	15
Felix AInOC (Taema, Air Liquide)	135
Flow-i b (Maquet)	46
Leon (Heinen + Löwenstein GmBH)	106

Once the breathing circuit has been flushed, a trigger-free anesthetic regimen including propofol, opioids, non-depolarizing muscle relaxants, nitrous oxide, benzodiazepines, and regional anesthesia may be used [60]. In addition to the basic monitors, end-tidal CO_2 (the earliest sign of an evolving MH reaction) and temperature should be monitored. IV dantrolene (Revonto, Louisville, KY) should be available in sufficient quantity to treat, should a reaction occur (2.5 mg/kg IV based on total bodyweight stops most reactions, but doses as great as 10 mg/kg or greater may be necessary). This preparation is lyophilized dantrolene, 20 mg/ampoule containing 3 g mannitol and an adjusted pH 9.8. The elimination half-life of intravenous dantrolene is 10 h; recrudescence may occur after 6 h when the blood concentration of dantrolene is below the 3 μg/mL threshold [62]. Redosing the dantrolene at half the original dose at 6 h will prevent recrudescence. Ryanodex (Eagle Pharmaceuticals, Woodcliff Lake, NJ) is a new rapidly soluble formulation of dantrolene that includes 250 mg of dantrolene with only 125 mg mannitol and requires only 5 mL water for dissolution [60]. There is no role for prophylactic preoperative dantrolene in children with MH. Children who are MH susceptible may undergo ambulatory surgery provided they are observed for signs of MH for about 2 h postoperatively and given instructions to call the anesthesiologist on call for a fever that does not respond to acetaminophen or signs of MH for 24–48 h after discharge. Chapter 45 contains additional information about MH.

Myopathies [63,64]

The muscular dystrophies, Duchenne (DMD), Becker (BMD), and Emery–Dreifuss (EDMD), are X-linked degenerative muscle dystrophies that demonstrate progressive weakness first in the skeletal muscles and later the cardiac muscles at varying rates. The pathogenesis of the dystrophies is the absence of dystrophin (<3% of normal) in skeletal muscle. As a result, administration of an inhalation anesthetic (halothane >> sevoflurane) with or without succinylcholine destabilizes the muscle membrane causing rhabdomyolysis, hyperkalemia, and myoglobinuria [65]. DMD, which occurs in 1:3500 of the population, affects skeletal muscles in young males (<8 years of age) [63]. As these children reach adolescence, the skeletal muscle wasting wanes and the predominant effect is a progressive cardiomyopathy. BMD is a milder form of muscular dystrophy, with a later onset (second decade) and a much less frequent occurrence of 1:50,000. Cardiac involvement in BMD consists of dilated cardiomyopathy in one-third of those affected, as well as hypertrophic cardiomyopathy and arrhythmias [66]. In the case of EDMD, this rare defect stems from mutation in genes that encode for emerin and the lamins A and C in skeletal muscle membrane [63]. The inheritance pattern, X-linked or autosomal dominant, leads to the slow progression of contractures, muscle wasting and weakness, and cardiac conduction defects (from sinus bradycardia to complete heart block leading to syncope) or a generalized cardiomyopathy. Hence, preoperative echocardiogram and electrocardiogram are warranted before anesthetizing these adolescents.

The interaction between anesthetics and mitochondrial myopathies is far less clear [67]. Those infants who develop lactic acidosis in association with their mitochondrial myopathy should receive normal saline (with glucose as needed) for their IV solution rather than lactated Ringer's solution.

Although MH is associated with only two muscle disorders, the King–Denborough and central core diseases, rhabdomyolysis as a distinct entity can theoretically occur in children with mitochondrial myopathies who receive an inhalation anesthetic. Hence, it is reasonable to purge the anesthetic workstation of inhalational agents and avoid triggers. Even though many children with mitochondrial myopathies have received inhalation anesthesia without complications, it seems reasonable to consider alternative anesthetics (e.g. TIVA) when possible. See Chapters 33 and 43 for further discussion of myopathies.

Sickle cell disease

Sickle cell disease (SCD) or sickle cell anemia occurs primarily in children of Sub-Saharan descent, with a frequency in North America of 1:5000. Characterized by an autosomal recessive inheritance pattern, this defect is a single nucleotide polymorphism of glutamate for valine on chromosome 11 that results in the replacement of Hb AA with Hb SS in every red blood cell. Homozygous individuals have the full-blown disease, SCD, whereas heterozygous individuals have an asymptomatic version, known as sickle cell trait (SCT). In children with SCD, 100% of the cells are at risk for sickling; these children have chronic low hemoglobin concentrations (6–8 g/dL), may have acute vaso-occlusive crises, and may receive multiple red blood cell transfusions. The vaso-occlusive crises involve a number of organs including bone, chest, and brain, arise almost randomly, occur in some children more than others, are unrelated to the presence of hypoxia, hypovolemia, or hypothermia, and may be fatal [68]. Evidence now suggests that those with SCD who develop vaso-occlusive crises have markers of a systemic inflammatory response to the disease which upregulates endogenous factors, including an adhesive factor, which traps sickle red cells in arterioles and precipitates occlusive crises [69]. Whether the traditional factors of hypoxia, hypovolemia, and hypothermia exacerbate the initial process or compound the inflammatory process has not been clearly established.

Sickle cell may also present in a heterozygote form, Hb AS, known as sickle trait. Children with Hb AS have normal hemoglobin concentrations; they are unlikely to sickle or present complications during most anesthesia and surgery, providing extreme conditions such as hypothermia or cardiopulmonary bypass are not employed. Two additional hemoglobinopathies, Hb SC and Hb SD, occur less frequently in the population than Hb SS; the hemoglobin concentrations in these children are also normal, but they are as likely to sickle as those with Hb SS.

SICKLEDEX® (Streck Inc., La Vista, NE, USA) is a screening test that determines the presence of sickle hemoglobin in blood without, however, differentiating between SCD and SCT. It can be performed rapidly, inexpensively, and reliably in infants >6 months of age. In infants <6 months of age, however, the presence of Hb F interferes with the SICKLEDEX test, rendering the results non-confirmatory. In fact, infants <6 months of age rarely sickle because of the presence of Hb F. The definitive diagnostic test for the type of sickle hemoglobin is hemoglobin electrophoresis or high-performance liquid chromatography. These tests identify the specific normal and abnormal hemoglobins present in blood in infants and children of any age.

To attenuate the risk of a perioperative sickle crisis during elective surgery in children with SCD, some hematologists recommend transfusing packed red cells to increase the total hemoglobin of 10 g/dL [70]. This practice was shown to reduce the frequency of acute vaso-occlusive crises in children with SCD. Others disagree with both the practice of prophylactic blood transfusions as well as the indications for transfusions in children undergoing minor surgery. The disadvantages of frequent transfusions in children who are at risk for sickle crises include sensitizing the recipient to minor antibodies (i.e. Kell and Duffy), iron overload, and transfusion reactions. For surgeries and conditions in which the risk of sickling is great, exchange transfusion is advisable to reduce the percent of cells that are capable of sickling. It is important to consult your local hematologist regarding the institutional management of children with SCD before the day of surgery to avoid surgical delays. See Chapters 12 and 24 for further discussion of sickle cell disease.

Anterior mediastinal mass

Children with an anterior mediastinal mass (AMM) present a life-threatening risk for anesthesia when they present for a tissue (lymph node) biopsy, CT scan for diagnosis, or indwelling central line for chemotherapy [71]. These tumors grow (in some cases, very rapidly) in a small and confined space, the anterior mediastinum. In this space, growing tumors can compress vulnerable mediastinal structures, specifically the tracheobronchial tree and/or right side of the heart (superior vena cava, right atrium, or pulmonary artery). Four tissues can be found in AMMs in children: lymphomas, teratomas, thymomas, and ectopic thyroid masses. The most rapidly growing tumor in the anterior mediastinum is the lymphoblastic lymphoma, a non-Hodgkin lymphoma with a doubling time of only 12–24 h. These children may present with minor findings (e.g. night sweats) that rapidly progress over 1–2 days to life-threatening symptoms (e.g. orthopnea, superior vena cava syndrome). In children, investigating the effects of the tumor on the mediastinal structures as well as acquiring tissue for the cell type usually requires general anesthesia. The decision to proceed with local or general anesthesia depends on the age and level of cooperation of the child, the extent of mediastinal organ compromise, and the accessibility of the node or tumor for biopsy. All radiological and preoperative data should be reviewed by a multidisciplinary team that involves the surgeon, anesthesiologist, and oncologist before embarking on the surgery.

In children who can tolerate local anesthesia and sedation, the decision to proceed with the surgery is clear. However, for children who cannot tolerate local anesthesia with sedation and who have tumors that severely compromise the airway and/or pulmonary artery, steroids or radiation should be considered for 12–24 h to shrink the tumor (usually a lymphoblastic lymphoma). The risks associated with prediagnosis treatment include tissue necrosis that may render diagnosis of the tumor cell type difficult and the development of tumor lysis syndrome. As a result, many oncologists are reluctant to treat these children with steroids or radiation, even for brief periods, before establishing the diagnosis. Determining the tumor cell type is critical to ensuring the most appropriate treatment regimen and minimizing complications.

Box 17.4: Cardiac indications for infective endocarditis prophylaxis

1. Prosthetic cardiac valve
2. Previous infective endocarditis
3. Cardiac transplantation children who develop a valvulopathy
   Congenital heart disease (CHD):
   i. Unrepaired cyanotic heart disease (including palliative procedures)
   ii. Repaired CHD with prosthetic material or device during the first 6 months after procedure
   iii. Repaired CHD with residual leak at or adjacent to prosthetic patch or device

For most children who require radiological investigation, tumor biopsy, or chemotherapy access, general anesthesia with spontaneous respiration is ideal. If the child cannot lie flat, preparations must be made to induce anesthesia and intubate the trachea with the child in the left lateral decubitus position. We recommend that the trachea is intubated at induction of anesthesia to secure the airway should the child have to be turned prone to maintain cardiorespiratory homeostasis. We also caution against using muscle relaxants to facilitate tracheal intubation in order to maintain spontaneous respiration and keep the tumor from pressing on the heart. It is important to recognize that the capnogram may be the key to establishing whether pulmonary circulation (and cardiac output) is present; sudden compression of the pulmonary artery will either reduce the end-tidal CO_2 level of the expiratory plateau or abolish it altogether before systemic manifestations are present. See Chapter 26 for further discussion of AMM.

Infective endocarditis prophylaxis

In 2007, the American Heart Association extensively revised the indications for infective endocarditis (IE) prophylaxis [72]. The new recommendations were crafted for dental procedures and adopted by the dental societies. Prophylaxis is no longer recommended for IE in children undergoing routine gastrointestinal, urological, and genitourinary surgeries although many specialists in these areas continue to request endocarditis prophylaxis. Also, there must be a cardiac, as well as a procedural indication for IE prophylaxis. Accordingly, it is incumbent upon the anesthesiologist to communicate with the specific specialist to determine whether endocarditis prophylaxis should be administered.

For dental procedures, Box 17.4 presents the only cardiac indications for IE prophylaxis. The antibiotic regimen for endocarditis prophylaxis has not significantly changed since it was previously published [72,73].

KEY POINTS: EVALUATION OF PREOPERATIVE DATA

- There is no substitute for a thorough, detailed history, and physical examination during preoperative evaluation
- Children should not be subjected to prolonged preanesthetic fasting; clear liquids can be ingested until 2 h before induction in most patients
- Preoperative testing is guided by the patient's underlying conditions and surgical procedure, and is not automatically done if not needed
- Upper respiratory infections, asthma, prematurity, and obesity are commonly encountered and deserve special attention and anesthetic planning

Preparation of operating room, equipment, and monitors

Anesthetic workstation

A thorough machine check must be completed before commencing the anesthetic. Modern anesthetic machines provide complete start-up checks that, for the most part, are entirely automated. These will be machine specific, must be performed unless there is insufficient time due to a pending emergency, and are not discussed any further. Refer to the operations manual for the specific machine to conduct the machine check.

As part of the anesthetic workstation preoperative evaluation, the emergency tank pressures must be checked. An emergency oxygen cylinder is required on all machines should the line oxygen supply fail. Because oxygen is a gas in pressurized cylinders, the pressure in the tank decreases linearly as the tank empties. The volume (in liters) of oxygen that is present in the emergency E cylinder is the product of the number of liters of oxygen in a full cylinder (680 L) and the ratio of the pressure within the tank to 2200 psi (the pressure of a full cylinder of oxygen). The number of minutes of oxygen remaining in the E cylinder for a given oxygen flow rate (Q) (with the ventilator turned off) is:

$$\text{Time}\,(\text{min}) = \frac{\text{Tank pressure}\,(\text{psi}) \times 0.28}{\text{Q}\left(\frac{\text{L}}{\text{min}}\right)}$$

A source of air should also be available in order to deliver less than 30% oxygen for infants at risk for oxygen toxicity and for those with congenital heart disease in whom excess oxygen may cause excess pulmonary blood flow (i.e. hypoplastic left heart syndrome). This is usually provided by a wall source, although an emergency air cylinder should be available. Supplementary nitrous oxide cylinders are not essential to maintain anesthesia should the wall source fail. Moreover, they can be a source of operating room pollution and costly to replace. Nitrous oxide in E cylinders contains both liquid and gaseous nitrous oxide at 745 psi. The pressure within the cylinder remains constant until all of the liquid nitrous oxide has evaporated. Up to that point, the content of nitrous oxide cylinders can only be determined by their weight. When the pressure gauge on the cylinder begins to decrease, the cylinder is nearing empty and must be replaced quickly.

Anesthetic equipment

To ensure that the anesthetizing location is properly and completely prepared, it is useful to refer to a checklist as shown in Box 17.5, the SALTED mnemonic.

Box 17.5: SALTED mnemonic

S	Suction, stylet and solution (IV fluids Ringer's lactate or normal saline)
A	Airways oral and nasal – different sizes
L	Laryngoscope – Miller blades from sizes 0–3; MAC 2 or 3
T	Tubes – tracheal tubes of appropriate sizes, tape
E	Equipment – anesthesia machine with breathing circuit, McGill forceps, facemasks, back-up self-inflating AMBU bag, fluid warmer, venous cannulation kit, and standard monitors
D	Drugs (anesthesia and resuscitation drugs)

Airway

Appropriately sized equipment should be available for each child. A range of sizes of facemasks, oral airways, laryngoscope blades, tracheal tubes, and LMAs should be present. We prefer cushioned clear facemasks that fit the contour of the faces of all children and permit the rapid identification of either fluid or solid material within the mask. The importance of oral airways in establishing a patent upper airway in children has been supplanted in our practice with the jaw thrust maneuver (see section "Laryngospasm"). We advocate the use of a Miller or Wisconsin straight blade for tracheal intubation in infants and children although when used properly, these blades are as effective for laryngoscopy as the Macintosh blade in this age group [74]. A range of sizes of laryngoscope blades should be available in every anesthetizing location. We advise against placing a roll under the shoulder of neonates and infants during laryngoscopy unless the laryngoscopist is seated; the shoulder roll raises the larynx, which is already anterior and cephalad in the neonate compared with older children, making it more difficult to align the axes while the laryngoscopist is standing. In neonates with limited oxygen reserve or when an awake intubation is being performed, a straight blade fitted with a source of oxygen at the tip may prevent desaturation during laryngoscopy [75].

The classic laryngeal mask airway (cLMAs–LMA® Classic™ Airway, Teleflex® Medical Europe, Westmeath, Ireland) was introduced to replace the facemask in adults and has subsequently proven to be a versatile and useful airway device in children as well [76]. To fit pediatric airways, the dimensions of the adult cLMA were scaled down in size, although the mask was otherwise unmodified. The cLMA has proven to be effective in circumstances other than elective anesthesia, such as neonatal resuscitation and fiberoptic intubation. A range of sizes of the cLMA should be available (Table 17.5).

Although effective, the cLMA does not "protect" the airway from regurgitation and laryngospasm. Since the tone of the gastroesophageal sphincter is reduced in children compared with adults, children may be at greater risk for regurgitation in the presence of a full stomach or positive pressure ventilation. Hence, it is best to avoid LMAs in these clinical situations. Modifications of the cLMA to include a vent for regurgitant gas or liquid from the esophagus as in the LMA®-ProSeal™ (Teleflex® Medical Europe, Westmeath, Ireland) supraglottic airway may better protect the airway against aspiration. A recent meta-analysis of a range of supraglottic devices concluded that in children the LMA-Proseal airway may be the preferred airway as it has the greatest leak pressure and smallest risk of difficulty seating [77].

Table 17.5 Airway equipment

Laryngoscope blade size		
Age (years)	**Miller blade size**	
0–0.5 years	Miller 0	
0.5–2 or 3 years	Miller 1	
2–4 years	Miller 1.5	
3–8 years	Miller 2	
Classic LMA size		
Weight (kg)	**LMA size**	**Max. ETT size**
0–5 kg	#1	3.5 mm ID
5–10 kg	1½	4.0
10–20 kg	2	4.5
20–30 kg	2½	5.0
30–50 kg	3	6.0

ETT, endotracheal tube; ID, internal diameter; LMA, laryngeal mask airway.

Complications of the cLMA in children include gastric inflation, aspiration, airway obstruction, and laryngospasm. The frequency of complications with the cLMA in infants may be greater than that in older children; caution should be exercised when using LMAs in children <2 years [78]. Fiberoptic studies have demonstrated that the epiglottis folds down into the bowl of the cLMA in an otherwise properly functioning device, although the relevance of this finding remains unclear.

A range of diameters of tracheal tubes should always be available for the child's age as well as tubes 0.5 mm ID smaller and larger. The appropriate size of uncuffed tracheal tube is based on the ID of the tube. Guidelines for tracheal tube sizes in infants and children are: infant's weight <1500 g, 2.5 mm ID; 1500 g to full-term gestation, 3.0 mm ID; neonate to 6 months of postnatal age, 3.5 mm ID; and 0.5–1.5 years, 4.0 mm ID. The uncuffed tube size for children ≥2 years may be estimated using the formula: age (in years)/4 + 4 (or 4.5) mm ID. For cuffed tubes popularized by the high-compliance, low-volume Microcuff® (Halyard Health, Alpharetta, GA, USA) tubes, the tube size (mm ID) for children <2 years is estimated as age (in years)/4 + 3 and for children >2 years, age/4 +3.5.

The length of a tube from the lips to mid-trachea in infants <1000 g in weight is 6 cm, 1000–2500 g is 7–9 cm, in neonates 10 cm, and in infants and children, 10 + age (years) cm.

In the past, uncuffed tracheal tubes were the mainstay for securing the airway in children <8 years of age. The circular shape of the tracheal tube was similar to the shape of the lumen formed by the cricoid ring, allowing a good seal to form without the need for a cuff. Cuffs were avoided in children out of the concern that the loosely adherent pseudostratified columnar epithelium within the cricoid ring would swell and further encroach on this narrowest portion of the upper airway, resulting in stridor, upper airway resistance, and respiratory failure. Because airflow within the upper airway is turbulent, a 50% reduction in the radius of the airway would increase the resistance to airflow by the fifth power of the radius or 32-fold. This increase in resistance would rapidly lead to respiratory distress, fatigue, and ultimately respiratory failure in young infants and children, particularly if they

were also septic. To preclude this potentially serious airway problem in the perioperative period, in addition to avoiding cuffed tubes, we carefully selected the tracheal tube in children which either passed through the cricoid ring without resistance or did so with an audible leak at a peak inspiratory pressure of ~20 cmH_2O. If an audible leak were present at a peak airway pressure ≤10 cmH_2O, the tracheal tube would be changed to one with an ID 0.5 mm greater, otherwise ventilation may prove to be inadequate during the surgery. Before proceeding, the peak inspiratory pressure at which a leak was audible would be retested. This process would be repeated until a satisfactory sized tube was present.

Recently, the shift from uncuffed to cuffed tracheal tubes in children has been in no small part facilitated by the introduction of the soft, high-compliance cuffed Microcuff tube [79]. These tubes have no Murphy eye. Their polyurethane cuff is positioned very close to the tip of the tube, with a cylindrically shaped rather than spherically shaped cuff as in low-compliance cuffed tubes, mimicking the shape of the larynx. The Microcuff tubes confer several additional advantages over the traditional uncuffed tubes, including decreased contamination of the operating room with anesthetic gases, reduced number of laryngoscopies and reintubations, and more consistent tidal volumes (as chest wall and abdominal compliance change during surgery) [80]. Overall, these factors substantially reduce the number of manipulations of the airway in children, the operating room costs, and operating room pollution. However, several relatively small sized studies reported a similar incidence of complications in children with high-compliance cuffed and uncuffed tubes [81,82]. A recent Cochrane review concluded that the results of published studies were of low quality and failed to prove either tube type was superior to the other [83].

A functioning wall suction with suction tubing (that is long enough to reach the operating room table) and a plastic Yankauer suction tip is mandatory. Yankauer suction must be used carefully to avoid trauma to oropharyngeal tissues. To achieve this in young children who have not received their molar teeth, the Yankauer should be inserted between the cheek and the teeth and passed behind the premolars to reach the hypopharynx. With this approach, the child cannot damage their central incisors if they bite down on the suction while it is in the mouth. In addition, the suction should sweep the hypopharynx to avoid applying prolonged negative pressure to tissues (such as the uvula) that may lead to edema and bleeding. We prefer to use a Yankauer suction rather than a suction catheter in the operating room because the former is capable of suctioning large volumes of blood, thick secretions, and/or vomitus expeditiously should the need arise, and the latter is often difficult to pass into the hypopharynx.

The optimal ventilation strategy for infants and children during surgery has been the subject of much interest [84]. For many years, volume-controlled pressure-limited ventilators were the standard for ventilating the lungs of infants and children during surgery. However, these ventilators could not compensate for either the circuit compliance or the variable leak around the tracheal tube. There was additional concern regarding the shape of the pressure tracing during inspiration and the risk of delivering high pressures. Pressure-controlled ventilation has been used successfully in the neonatal intensive care unit (NICU) for many years, in part because it limited the peak pressure and avoided barotrauma with its constant inspiratory pressure pattern. It also provided a more even distribution of inspiratory gas in the lungs, thus reducing ventilation/perfusion (V/Q) mismatch. Despite the clear advantages of the pressure-controlled ventilation strategy, many anesthesia ventilators were simply unable to ensure reliable tidal volumes as they failed to compensate for decreases in the compliance of the abdomen and chest as a result of external pressure by the surgeons, their instruments, or peritoneal insufflation of the abdomen or chest during laparoscopy. A new generation of anesthetic machines offers markedly improved ventilators and ventilation strategies that are hybrids of the best aspects of both volume- and pressure-regulated ventilation. These new ventilators may prove to be ideal for infants as small as preterm and term neonates. The hybrid pressure-regulated volume-controlled mode in which a fixed tidal volume, which accounts for the compressible volume of the breathing circuit, is used during controlled ventilation and a pressure support mode, is used once spontaneous respiration commences. With all ventilators that are used in small neonates, it is essential to avoid barotrauma by presetting weight-appropriate respiratory parameters before commencing ventilation.

Emergency drugs

Emergency drugs should always be available before inducing anesthesia. Syringes of weight-appropriate doses of atropine and succinylcholine should be immediately available with a small gauge (23 or 25 G) needle to facilitate intramuscular or sublingual injection in an emergency. A syringe of propofol (1–2 mg/kg) should also be available to facilitate tracheal intubation or LMA insertion, as well as to break laryngospasm and increase the depth of anesthesia quickly [85]. Vasopressors and inotropic drugs are not routinely prepared for healthy children undergoing elective surgery, but may be prepared for children with congenital heart disease or those who are unstable hemodynamically.

Monitors

The ASA and similar authorities all over the world mandate basic monitoring for all anesthetics (Box 17.6). Monitoring children during anesthesia must include the standard five parameters: electrocardiogram, blood pressure, oxygen saturation, capnogram, and temperature, as well as any additional monitors specific for the child's medical or anesthetic condition, such as a depth of anesthesia monitor. Many infants and preschool age children do not accept the application of monitors while they are awake. Although induction of anesthesia is usually well tolerated and safe in expert hands, we recommend that every effort should be made to apply at least a pulse oximeter before anesthesia is induced. The remainder of the monitors should be applied as soon as the child loses consciousness.

Electrocardiogram

A standard three- or five-lead continuous electrocardiogram should be used in every anesthetic to detect arrhythmias (bradycardia) and peaked T waves or ST segment changes (hyperkalemia or local anesthetic). The most common rhythm disturbance in healthy children is bradycardia; ventricular

Box 17.6: Basic mandatory monitoring for anesthesia and other monitors

- Temperature
- Secondary optional monitors
  - anesthetic depth monitoring
  - cerebral oxygenation monitoring
  - invasive monitors

Box 17.7: Causes of bradycardia

1. Hypoxia
2. Vagal reflex response (e.g. prolonged laryngoscopy, traction on the extraocular muscles)
3. Medication (e.g. succinylcholine)
4. Congenital heart defect, cardiac conduction defect, heart failure, and cardiomyopathy
5. Raised intracranial pressure
6. Electrolyte imbalance (hyperkalemia, hypocalcemia)
7. Massive air embolism
8. Tension pneumothorax

arrhythmias are exceedingly uncommon. The most common causes of bradycardia in children are hypoxia and vagal reflex responses but bradycardia may transiently occur during induction of anesthesia with sevoflurane (Box 17.7). The most common causes of ventricular arrhythmias in children are hyperkalemia and intravascular injection of an amide local anesthetic.

Blood pressure

Blood pressure is usually measured non-invasively using an automated oscillometric technique every 3–5 min during elective surgery. The cuff width should cover approximately two-thirds the length of the humerus. In children, systolic pressure is used as a measure of the volume status and, second, cardiac function. Diastolic pressure is not as closely regarded as peripheral vascular resistance is low in infants and children. Invasive pressures are usually reserved for surgeries that may be prolonged, those associated with large blood loss or congenital heart disease, or for sick children who require inotropic support or repeated blood gas measurements.

Pulse oximetry

Pulse oximetry displays the hemoglobin oxygen saturation by measuring the transmittance of two wavelengths of red light, 660 and 940 nm, through the blood in arterioles, and in most critical care settings changes pitch as the saturation decreases. The probe is commonly affixed to a digit, but may also be applied to the earlobe, the hypothenar eminence, or lateral aspect of the foot in infants. Finally, most oximeters include motion-artifact compensation software to display the oxygen saturation continuously, even if the child is moving, as is often the case during induction or emergence from anesthesia. Pulse oximetry measures accurate saturations between values of 70% and 100%. Most nail polishes do not interfere with the accuracy of oximeter readings, although we prefer that the oximeter be applied to an unpainted surface. Pulse oximeters may fail to detect a pulse in the presence of a low cardiac output, low blood pressure, hypothermia, or vasculopathy. It should be noted that carbon monoxide is neither sensed nor measured by current standard pulse oximeters (Masimo Rainbow SET™, Masimo Corp., Irvine, CA, USA, is one example of a device that can measure carboxyhemoglobin). The importance of oximetry cannot be overstated, with the incidence of desaturation reported to increase with decreasing age [86]. However, this review expressed the view that caution should be exercised when extracting desaturation rates from automated record-keeping systems as up to 35% of recorded hypoxemic events were due to factors other than hypoxemia.

Capnography

Infrared analysis of the end-tidal carbon dioxide tension in the breathing circuit has been used to estimate the partial pressure of carbon dioxide in blood. Two distinct techniques have been used to display the end-tidal carbon dioxide tension: sidestream capnography, which continuously aspirates gas from the breathing circuit and analyzes the carbon dioxide tension in a remote sensor; and mainstream capnography, which analyzes the carbon dioxide tension directly within the breathing circuit. The accuracy of sidestream capnometry improved dramatically when circle system breathing circuits replaced T-piece circuits, by reducing the dilution of expiratory gas. Sidestream capnometry measured at the elbow of the circle breathing circuit is accurate even in infants as young as neonates (with small tidal volumes) without cyanotic heart disease. Alternatively, mainstream capnography may be used, although this technique is unpopular, particularly in infants and neonates, because they increase the deadspace in the circuit and the bulky and heavy sensors may kink small pediatric tracheal tubes. A range of light, small-deadspace, mainstream capnography sensors, marketed as cap-ONE (Nihon Kohden, Surrey, UK), can be utilized with facemasks and tracheal tubes, with applications both in pediatric and adult settings [87]. Recent studies have pointed towards a high degree of accuracy. Capnography may also be accurately monitored at the elbow of a circle circuit while the child breathes through a facemask, and through baffled nasal prongs during sedation.

Temperature

With induction of anesthesia, children redistribute heat from the core to the periphery via peripheral vasodilatation. Heat loss from the body occurs by four routes in the following proportions in children: 39% by radiation, 34% by convection, 24% by evaporation, and 3% by conduction [88]. To preclude substantial heat loss, the following strategies should be utilized.

As soon as the case is scheduled or the operating room is vacated by the previous patient, the operating room temperature is increased to ~28°C, which may take up to 1 h to achieve. Increasing the temperature within the operating room increases both the temperature of the walls and ceiling as well as the air within the room, thereby attenuating both radiation and convective heat losses [88]. Forced air warmers are the

single most effective strategy to minimize heat loss for any surgery of 1 h duration or greater [89]. Although it is comforting to prewarm the air mattress before the child enters the operating room, commencing the forced air warmer before the child is anesthetized does not alter their temperature at the end of surgery, however it may predispose to airborne contamination of the operating room, resulting in the possibility of a surgical site infection [90]. Until further evidence is forthcoming, we recommend that forced air warmers be switched on after the skin is prepped and draped for surgery.

Supplemental warming devices such as warming blankets, overhead heat lamps, and fluid warmers should also be available for infants to maintain normothermia should the need arise.

The temperature of all children who receive anesthesia or sedation should be monitored continuously during surgery and in the PACU. Core temperature is ideally measured in the mid-esophagus, immediately retrocardiac. The optimal location of the probe can be confirmed when using a combination esophageal stethoscope and thermistor, by inserting the stethoscope until the heart sounds are maximal. Alternative sites to measure core temperature include the rectal, nasopharyngeal, and axillary sites, although each measurement site has its limitations. Rectal temperature probes may yield inaccurate temperatures if the probe exits the rectum or is immersed in stool. The nasopharyngeal site may underestimate the core temperature if it is cooled by gas passing through the ventilation circuit. Axillary temperature may underestimate core temperature because of IV fluid infusing through the ipsilateral arm, because the probe is not positioned against the axillary blood vessels, or because the probe is adjacent to the forced air warmer.

Anesthetic depth monitoring

Reports of awareness in up to 1% of children undergoing elective surgery surprised many experienced pediatric anesthesiologists [91,92]. Although most consider the frequency of awareness in children to be much less than this, children rarely self-declare their awareness, so it is conceivable that our experience underestimates the true incidence.

Analysis of these reports of awareness in children suggests that many of the episodes could be attributed to institutional anesthetic practices that expose children to low concentrations of anesthesia during periods of intense stimulation. In some cases, these occurred during the transport of children from the induction room to the operating room [91] or when the anesthesiologists deliberately decreased the anesthetic concentrations immediately after loss of eyelash reflex to reduce the theoretical risk of seizures [92]. These practices contrast to most of our practices where the anesthetic concentrations of sevoflurane are neither interrupted nor dramatically decreased until an adequate depth of anesthesia is achieved. We believe that the frequency of awareness during pediatric anesthesia is far less than that recently reported, that most instances are explicable by local institutional practices, and that these reports do not justify routine depth of anesthesia monitoring in children.

The Bispectral Index (BIS™, Medtronic Corp., Minneapolis, MN, USA) is the most widely studied anesthetic depth monitor in children in North America, although other monitors such as the Cerebral State Index (Cerebral State Monitor, Danmeter A/S, Odense, Denmark) and Spectral Entropy monitor (E-Entropy™ Monitor, GE Healthcare Finland, Helsinki, Finland) are approved for clinical use. The BIS measures anesthetic depth continuously over a scale from 0 to 100, with readings between 40 and 60 considered adequate for general anesthesia. The BIS monitor requires 30–60 s to display an index value. The probability that recall will occur is significantly increased if the BIS is >60 for more than 30 s. A number of factors may influence the BIS readings. First, the BIS measurements vary with the anesthetic administered [93]. For example, at equipotent concentrations, the BIS measurements during halothane anesthesia are 50% greater than those during sevoflurane anesthesia. In part, the difference may be explained by the very different electroencephalography (EEG) patterns of the two anesthetics: the EEG pattern associated with sevoflurane anesthesia displays more slow waves and fewer fast rhythms activity than halothane. Although the BIS measurements correlate generally with the sevoflurane concentration, the accuracy of the measurement is poor. BIS readings during nitrous oxide and ketamine anesthesia do not reliably estimate the depth of anesthesia and may overestimate the BIS reading for a given depth of anesthesia. Second, young age affects the BIS readings [94–96]: readings in children <5 years of age are less reliable than those in children >5 years of age. The most likely explanation for this effect relates to the maturation of the EEG from birth to school-age children. Third, the depth of anesthesia measurement is substantially affected by the extent of muscle relaxation. Recovery of the twitch response increases the BIS readings while paralysis decreases the BIS. This effect complicates interpretation of the BIS reading. In patients who are not paralyzed, the electromyography (EMG) component contributed by spontaneous respiration may erroneously increase the BIS reading. Fourth, position may affect the BIS reading. Placing the patient in the Trendelenburg position (30° head down) increases the BIS by 20% [97].

There are few indications for the routine use of the BIS monitor in children except for those who cannot tolerate general anesthesia because of hemodynamic instability, those in whom nitrous oxide is not used, and those anesthetized with TIVA. Chapter 19 presents further discussion of monitoring.

KEY POINTS: PREPARATION OF OPERATING ROOM, EQUIPMENT, AND MONITORS

- Although modern anesthesia machines have sophisticated electronic machine checks, the anesthesiologist is responsible for checking the breathing circuit for leaks, that suction is available, and that emergency oxygen and ventilation sources are present
- Atropine, succinylcholine, and propofol should be readily available and drawn up for every case for airway emergencies; resuscitation drugs should be available in close proximity but only prepared for high-risk patients
- Electrocardiography (ECG), non-invasive blood pressure, pulse oximetry, and temperature are mandatory for every pediatric anesthesia case; invasive monitors are used for high-risk cases; anesthetic depth monitoring is of very limited use in children

Methods for inducing anesthesia

Anxiolysis

Anxiolysis is defined as the use of sedative drugs or behavioral techniques to reduce anxiety in a child. Several strategies may be used to achieve preoperative anxiolysis, but in some children multiple techniques may need to be used concurrently. These may be used to facilitate a smooth separation from parents before entering the operating room and/or a smooth induction of anesthesia.

There are many reasons why a child may be anxious preoperatively: fear of separation (1–6 years of age) or a phobia (e.g. fear of a facemask), which occurs in 2.8–8% of children; a rational fear about their pending surgery (e.g. fear of waking up during the surgery or mutilation – usually occurring in adolescents); an underlying anxiety disorder, which occurs in 15–20% of children; and unsatisfactory experiences during previous anesthetics [98,99].

Children may have varying levels of difficulty expressing their anxiety based on age, language skills, cognitive capabilities, and emotional understanding. In such instances, a compassionate anesthesiologist who addresses the child and his/her fears and questions is certainly reassuring but somewhat less effective than anxiolytic medications.

Preoperative anxiolytics confer a number of disadvantages including possible respiratory or cardiovascular depression, and the need for personnel to monitor the child. The anesthesiologist must be familiar with the possible routes of administration of the premedication, which itself may inject some anxiety (e.g. intranasal midazolam), and the time to peak effect. A panoply of strategies may be used to achieve anxiolysis in children before induction of anesthesia. These are summarized as follows.

Parental presence at induction of anesthesia

Both children and parents may find the process of inducing general anesthesia to be stressful. Parents may truly believe that parental presence at induction of anesthesia (PPIA) will calm their child. However, there is now a substantial body of evidence that refutes this belief: PPIA had no significant overall effect on parental anxiety or parental satisfaction, failed to enhance cooperation during induction or shorten the time taken for induction, and did not reduce the frequency of emergence delirium (ED) or negative behavior up to 6 months after discharge [100–102].

Despite these findings, PPIA is routinely practiced and encouraged at many institutions. Some parents believe that it is their civil right to be present for a procedure that involves their child (by this logic the parent should also be allowed to remain for the entire surgery) [103]. Nonetheless, we believe that there are instances when PPIA may be very helpful, as in cognitively impaired children whose parent can calm and direct them, children with cancer, and with multiple surgeries. Cognitively impaired children may require oral or intramuscular sedation in order to garner a level of cooperation to facilitate induction of anesthesia (see section "Pharmacological sedation"). Such patients frequently require repeated anesthetics and are frightened of the entire hospital environment. We have found it helpful to discuss previous anesthetic experiences with the parent or caregivers, and take their perspective into account when formulating a plan for anesthetic induction. A poorly executed plan may create recurring maladaptive behavior upon return visits.

If PPIA is planned for selected children, a plan for managing the children and their parents should be in place before commencing the program. First, since separation anxiety does not occur before age 8 months, the children for whom PPIA should be considered should be 1–6 years old and slightly older. Second, we recommend that parents attend a training session about how their child may react and appear during induction of anesthesia so they are comfortable before the actual event occurs. The parent should be educated in advance that their child might cry, resist the anesthesia mask, and experience noisy breathing or involuntary movements during induction of anesthesia and that these are all normal responses. Some parents may become very emotional when they see their child become anesthetized, and the training session should defuse the responses around these events. Third, if a parent expresses an unwillingness to accompany their child to the operating room, they should not be forced to do so. Finally, everyone on the operating room team must understand his/her role in this event and someone must be designated to escort the parent from the operating room at the appropriate time or when the anesthesiologist deems it appropriate. The parent must be informed that at any time the anesthesiologist may ask them to leave the operating room and they must comply. We believe that PPIA is not a right but a privilege; only after the anesthesiologist has determined that it is in the best interest of the child for the parent to be present should a parent be permitted to accompany their child to the operating room.

Distraction techniques

A variety of education and distraction techniques have been investigated to reduce preoperative anxiety in children coming for surgery. Preoperative coloring books, stories, videos, and websites have been developed for children of all ages to educate them about the appearance of the operating room, the equipment that will be used, and how children are anesthetized. Whether these videos reduce either parental or child anxiety is unclear [101]. Operating room tours (usually on weekends, where a staff member dresses the family and children in operating room attire and they visit an operating room and play with anesthesia facemasks) are most informative, although they may not be effective anxiolytics [104]. On the morning of surgery, child-life providers may orient those children who may be at risk for emotional instability and separation anxiety, marking the inside of a facemask with flavored lip balm or scented oils and applying the mask to their faces. The anesthesiologist should conduct his/her preoperative visit by focusing directly on the child to discuss the facemask and the lip balm or oil scent that they chose and then later engage the parents.

Distraction techniques including video games, video glasses, earphones, portable internet devices, smart phones, play dough, table-based games, magic, clowns and clown doctors, and music all reduce preoperative anxiety to varying extents [101,105–109]. The children of parents who received acupuncture before their child's surgery were less anxious and more cooperative at induction of anesthesia, an indication of the important role of the parent's anxiety in the child's behavior.

To complement the above strategies, the circulating nurses and/or anesthesiologist should be skilled and trained to facilitate smooth and rapid separation of the child from the parents and then distract the child by pointing out wall designs, pictures, and other features as they travel to the operating room. Once the child enters the operating room, the anesthesiologist should establish rapport by telling a story, engaging them in conversation about a recent birthday, holiday, or vacation, or singing as they prepare for induction of anesthesia.

Pharmacological sedation

Some children require premedication to facilitate a smooth separation from their parents. Several medications and routes of administration have been investigated with oral midazolam, the most widely used premedication in North America and elsewhere.

Oral premedication

The benzodiazepine midazolam has received widespread acceptance as a premedication for children that is very reliable with few complications. Midazolam has been administered via the oral, intravenous, nasal, rectal, and intramuscular routes, with the most common route being the oral route. Midazolam may depress respiration when it is administered by any route, although apnea is infrequent in the absence of other medications, even in the presence of obstructive sleep apnea [110]. Apnea has been observed during inhalation induction with sevoflurane.

The oral formulation of midazolam in North America is a cherry-flavored syrup in a concentration of 2 mg/mL. It can be injected into the (lateral gutters of the) mouths of toddlers using a needleless syringe or ingested from a cup in older children. This formulation usually leaves a bitter aftertaste (after the oral or nasal route), which may prompt some children to expectorate it. To prevent this, we encourage the child to drink the midazolam in one gulp and reward them with up to 15 mL of water. A new European formulation of oral midazolam (ADV6209) that contains midazolam along with γ-cyclodextrins, sucralose, and orange aroma, is currently under investigation as an improved formulation (lack of bitter aftertaste) of oral midazolam in a dose of 0.25 mg/kg [111]. This formulation was well accepted and provided good sedation; confirmation of these data is pending.

The oral form has a limited (15%) bioavailability, hence large doses of midazolam are required for sedation. A fixed dosing regimen for all ages increases the failure rates in younger children [112]. We recommend the following dosing regimen with age: 1.0 mg/kg for children 1– 3 years of age, 0.75 mg/kg for children 4–6 years of age, 0.5 mg/kg for those 7–9 years of age, and 0.3 mg/kg for children age 10 and over (up to 15 mg) [113]. With these larger doses of midazolam, children are adequately premedicated in a timely manner, within 10–15 min in younger children, although in older children the peak effect may not be achieved until 30 min. Emergence from anesthesia is not usually delayed by oral midazolam, except possibly after very brief surgery [114].

There are few contraindications to oral midazolam; fewer than 3% of children with obstructive sleep apnea experienced transient hemoglobin desaturation [110].

Oral ketamine (5–6 mg/kg) has been successfully used in children, although it offers few advantages over midazolam and may cause more postoperative vomiting [115]. Postoperative hallucinations and nightmares have not been reported after oral ketamine. Some have combined oral midazolam (0.5 mg/kg) and ketamine (3 mg/kg), yielding better sedation than with the individual agents [115].

Oral clonidine, an α_2 agonist, confers several benefits as a premedication including decreased emergence agitation, decreased postoperative pain, and decreased postoperative nausea and vomiting (PONV). Clonidine provides better sedation at the time of induction, equivalent times to extubation and PACU discharge, a lack of respiratory depression, and mild sedation in the PACU compared with oral midazolam. However, the onset of sedation after oral clonidine (2–4 μg/kg) is at least 40 min, much slower than that of oral midazolam. Dexmedetomidine, another α_2 agonist, has also been widely used for preoperative sedation of children. As with clonidine, the oral route has a slow onset, and bradycardia and hypotension may occur [116]. Although these α_2 agonists are effective for premedication, their slow onset of sedation, the frequency of bradycardia, and the fact that sedation persists beyond the duration of most anesthetics limit their use in this regard. When compared with dexmedetomidine (4 μg/kg) and clonidine (4 μg/kg), oral midazolam (0.5 mg/kg) was a more effective premedication and without the side-effects of the α_2 agonists listed above [117].

Intranasal premedication

Most premedications have also been administered by the intranasal (IN) route. IN midazolam (preservative-free 0.2–0.3 mg/kg as a 0.5 mL volume) has good bioavailability, however it leaves a bitter aftertaste that most children report as unpleasant and that persists for quite a while after the anesthetic [118]. In a comparison of two premedications administered by the parents and evaluated by both the parents and an observer, oral midazolam (0.5 mg/kg) was more easily administered and accepted with better parental separation at 30 min after premedication than IN midazolam (0.2 mg/kg) [119]. IN sufentanil 2-4 μg/kg has also been an effective premedication, although it is rarely used in children. In the original studies, it caused chest wall rigidity necessitating succinylcholine administration [120]. IN dexmedetomidine (1 μg/kg) is also well tolerated in children, but its onset of action is slower than with IN midazolam (0.2 mg/kg) [121,122]. IN dexmedetomidine yielded smoother separation from the parents but only modestly better acceptance of the facemask at induction of anesthesia [123]. Additionally, IN dexmedetomidine decreased postoperative agitation and shivering as well as providing more effective postoperative analgesia. Currently, IN dexmedetomidine is not approved by the Food and Drug Administration (FDA) in the USA for use in children.

Intramuscular premedication

Many cognitively impaired patients refuse IN or oral premedications. Intramuscular (IM) ketamine may be very useful in the uncooperative patient before establishing IV access or applying an anesthesia mask. The typical child that presents in this manner is a large, autistic teenager who refuses to ingest or accept any premedication. If the child will not transfer to the operating room under any conditions (including parental guidance), the remaining choices are to either cancel the surgery or premedicate the child with an IM injection.

Unless contraindicated, it is the authors' practice to administer 3–5 mg/kg ketamine IM mixed with 0.02 mg/kg atropine (maximum 0.5 mg atropine). The onset of action is typically within 5 min and the duration of action is 20–30 min. Atropine appears to be superior to glycopyrrolate in preventing hypersalivation after administration of ketamine [124]. In anticipation of the injection, the parent or caregiver along with the child should be seated on a stretcher and IM ketamine is administered into either a bare deltoid region of an arm or through the clothing in the same region [125,126]. The optimal location for IM injection of ketamine is unknown, however one can be guided by consensus recommendations for IM administration of vaccines from the Centers for Disease Control and Prevention (CDC) [127]. In patients over 3 years of age, the deltoid muscle is preferred, although the vastus lateralis muscle (anterolateral thigh) may also be used. A needle length must be selected that is sufficient to penetrate the overlying skin and adipose tissue. The needle length will vary with both the age and size of the patient. Familiarity with anatomical landmarks is essential to prevent injury to neurovascular structures when performing an IM injection. Once ketamine is administered, it may take up to 5 min for the child to become sedated. In most instances, this premedication will be metabolized before the end of anesthesia.

Induction techniques

Induction of anesthesia is defined as the transition from the awake to the anesthetized state. In North America, general anesthesia in children is most commonly induced by inhalation of potent anesthetic gases, although alternate routes including the IV, IM and rectal routes may also be used in certain circumstances. The choice of the technique depends on several factors including the child's age, level of cooperation, clinical condition, and preoperative status. For some techniques such as an IV induction or a single-breath induction, a qualified assistant should be present.

Inhalation induction

All infants and children, including those who are crying and upset, can undergo a smooth inhalation induction given the proper atmosphere and attitude by the staff. On many occasions we have engaged upset children in the operating room in a warm and reassuring manner and successfully induced anesthesia by mask without tears. It is our belief that holding children down and forcing a mask on their face (derisively known as "brutane") has no place in pediatric anesthesia and may psychologically scar the child for life. When presented with a fearful or emotional child preoperatively, we first address the child's (and their parents') fears, providing an age-appropriate explanation of the process, and use preoperative anxiolytic strategies and/or sedation as appropriate. If fearfulness and resistance persist at induction of anesthesia, another set of strategies is used. In short, the optimal preoperative process is one that is tailored to the needs of the child and parents, with the overriding goal of patient safety taking precedence.

Preschool-age children often present the greatest challenges at induction of anesthesia. Distraction techniques and premedication are key strategies that should be used to minimize anxiety and distress during separation from parents and induction of anesthesia in this age group. We have designed our induction strategy to empower children during the induction and maximize their participation. Upon arrival in the operating room, we apply as many monitors as the child permits. The child chooses his/her favorite of two or three choices of scented lip balm and then colors the inside of the mask with it or, if the child is too young (<3 years of age), we apply it to the facemask. With the child seated on the operating table and his/her back to our chest (or on our lap if the patient has a diaper), we bring the facemask slowly and gently to the nose and mouth, while 70% nitrous oxide in oxygen is flowing in the breathing circuit at 5–7 L/min total fresh gas flow. We often challenge the child to try to "blow up the balloon" (reservoir bag) by breathing as deeply as possible. We employ a 1 L reservoir bag in the pediatric breathing circuit to reduce the time to wash-in anesthetic into the circuit. It is critically important to ensure the adjustable pressure limiting (APL) valve is wide open so the child does not feel he/she cannot exhale as a tight mask fit is applied. During this time, we distract the child by singing a song, or telling a joke or a story until the end-tidal and inspired nitrous oxide concentrations equilibrate or the child ceases to respond to verbal stimulation. At this time, children are sufficiently sedated that they will not recall any unpleasant anesthetic odor. Accordingly, we then dial in 8% sevoflurane in a single move and, once the end-tidal sevoflurane equilibrates, we reduce the total fresh gas flow to 2–3 L/min. As soon as the child loses consciousness (and their neck becomes too supple to hold their head), we place them supine while they continue to breathe 8% sevoflurane in 70% nitrous oxide. The remaining monitors are then applied. During this early period of the induction, we maintain near complete silence in the operating room and the surgeons are prohibited from stimulating or manipulating the child. If the child becomes apneic during this period (particularly after a premedication), we gently assist ventilation. To reduce the risk of awareness, the concentrations of sevoflurane and nitrous oxide are maintained until IV access is established. Once IV access is established, we administer an IV dose of propofol (1–2 mg/kg) and discontinue the nitrous oxide to facilitate laryngeal mask insertion or tracheal intubation [128]. Anesthesia is continued with 8% sevoflurane in 100% oxygen until we have verified that the airway device has been placed successfully. If apnea occurs after the airway is secured, the inspired concentration of sevoflurane may be decreased by 25–35% or more, until spontaneous ventilation resumes. If nitrous oxide is not contraindicated, it may be reintroduced at this time, together with an appropriate concentration of anesthetic vapor. Only after the airway is secured may the surgeon begin to examine the child.

Another strategy to achieve a deep level of anesthesia with sevoflurane is to slowly increase the inspired concentration of sevoflurane in a stepwise manner (2% per min). Although this approach achieves the same outcome, it has several disadvantages including a prolonged induction time and an exaggerated excitement phase.

Another distraction strategy is known as troposmia. Troposmia is a distorted perception of an odor that, in this case, can be attributed to the presence of inhalation anesthetics. The anesthesiologist asks the child his/her favorite flavor after applying a standard (i.e. strawberry) lip balm to the facemask. The child is then told that as he/she is anesthetized, the

anesthetic will magically change the strawberry flavor to the child's favorite flavor. In one study, 80% of the children confirmed that they smelled their favorite flavor when they breathed the anesthetic gas [129].

The child with mask phobia poses a very real challenge for those attempting to induce anesthesia by inhalation [130]. Besides refusing a mask, these frightened children often steadfastly refuse needles (and therefore an IV induction), leaving clinicians few options for inducing anesthesia. Several different solutions have been devised to address this problem ranging from removing the mask from the breathing circuit to forcing the facemask on a child's face, which we do not condone. We believe that induction of anesthesia with the former strategy is the preferred approach, whereas induction with the latter approach is potentially traumatic and psychologically harmful and cannot be recommended.

There are many reasons why children may be fearful of facemasks including the unappealing odor of 8% sevoflurane administered at the outset, lack of premedication for a child who became traumatized at a previous induction, a partly closed APL valve, which may prevent the child from completely exhaling during the induction, and claustrophobia. Irrespective of the reason, we believe that if the mask is the focal point of the fear, it should be eliminated from the induction. To induce anesthesia without a facemask, we interlace our fingers, with the elbow of the breathing circuit positioned between our fingers, delivering 70% nitrous oxide in oxygen (Fig. 17.1). We cup our hands under the child's chin (since nitrous oxide is heavier than air) and gradually bring them closer and closer until they cover the child's mouth. Although this approach may increase operating room pollution, we believe it is the optimal approach to manage the child with mask phobia. Once the hands are tight over the mouth, we dial 8% sevoflurane into the fresh gas flow. When the child is adequately anesthetized, we attach the facemask to the breathing circuit and continue the anesthetic. When interviewing these children during the recovery period, the children are thrilled that they avoided the "feared" mask.

Another approach to deliver anesthesia by mask if the anesthesiologist wishes to include sevoflurane from the outset (i.e. without premedication or nitrous oxide first) is to rotate the facemask 90° and use the balloon of the cuff to occlude the nares as anesthesia is induced. In this way, the child cannot smell the sevoflurane and anesthesia is smoothly induced.

Children who are older (usually >6 years of age) and understand how to hold their breath can perform a single-breath induction of anesthesia [131,132]. In order to perform a single-breath induction, the anesthesia circuit must be first primed with 8% sevoflurane (with or without 70% nitrous oxide) by compressing the reservoir bag three to four times with a large gas flow. A 2 L reservoir bag is preferred to provide a sufficient reservoir in the event the child takes a particularly large or additional breath. Before taking a single breath through the breathing circuit, the child practices vital capacity breathing, inhaling through the mouth and exhaling to residual volume (instructing the child to exhale until there is no air left in their lungs) through the mouth. Once the child has mastered the breathing maneuvers, the child exhales to residual volume at which point the facemask is applied tightly to the face. The child is instructed to take a single vital capacity breath through their mouth and to hold it for as long as possible. While the child is holding his/her breath, the anesthesiologist counts aloud slowly. Published data suggest that children lose their eyelash reflex within 1 min, whereas in our experience, the child loses consciousness before our count reaches 20 (s). At that point, the head and neck are supported and the child is slowly reclined to the supine position.

Intravenous induction

Most children do not want an IV induction because they fear the pain associated with establishing IV access. Three factors increase children's responses to IV insertion even in the presence of topical local anesthesia: age (≤1 year), activity level, and the endothelin receptor A TT genotype polymorphism [133]. If a child requires an IV induction, such as one with a full stomach, there are several options available to anesthetize the skin: topical anesthetic creams, vapo-coolants, or skin infiltration with local anesthetic. Several creams are available including: EMLA® (eutectic mixture of 2.5% lidocaine and 2.5% prilocaine; AstraZeneca LP, Wilmington, DE, USA), which requires 45–60 min to establish topical anesthesia; Ametop® (4% tetracaine gel; Smith & Nephew, Mississauga,

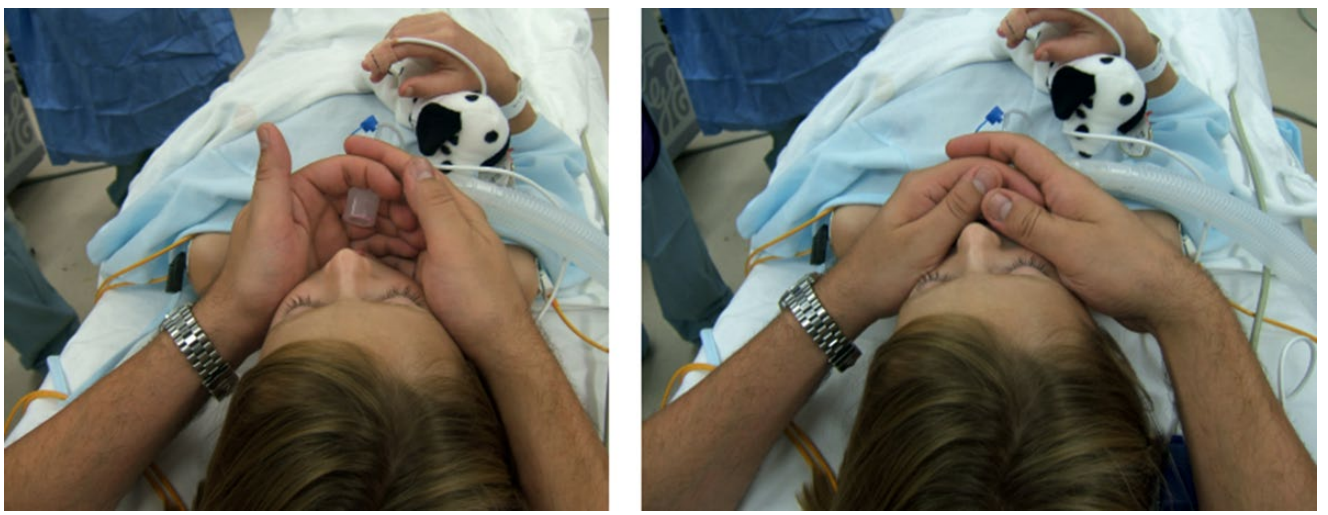

Figure 17.1 Inhalational induction without using a facemask.

ON, Canada), which requires 30 min to establish anesthesia and does not blanch the skin or cause venoconstriction; LMX4® (liposomal 4% lidocaine; Eloquest Healthcare, Ferndale, MI, USA); and Synera® patch (eutectic mixture of 70 mg lidocaine and 70 mg tetracaine; Galen Ltd., Craigavon, UK), which also requires 30 min for topical anesthesia [134]. We commonly offer older children the option of breathing 50% nitrous oxide before establishing IV access in the operating room while anesthetizing the skin. To successfully anesthetize the skin, a small intradermal wheal of 1% or 2% plain lidocaine is made directly over the target vein with a 27 g or 30 g needle and then a small amount of local anesthetic is deposited in the underlying subcutaneous tissue. Larger-gauge needles and large-volume injections are associated with much more pain. Vapo-coolants (e.g. ethyl chloride) have also been widely used to reduce the pain of injection, and do not cause venoconstriction. A recent Cochrane Review concluded that vapo-coolants reduce pain moderately during IV cannulation in both adults and children [135]. Some studies have found that ethyl chloride does not reduce the pain from IV cannulation. In these instances, it may be that ethyl chloride has not been applied correctly: it should be sprayed for 4–10 s after the tourniquet is applied and IV cannulation should follow immediately, since the analgesic effect lasts only 60 s [136]. A new device (J Tip™; National Medical Products, Irvine, CA, USA) for anesthetizing the skin before IV cannulation employs a needleless subcutaneous jet injection of lidocaine. It has not been widely adopted or extensively studied. Transillumination and near-infrared light devices (e.g. Accuvein®, Accuvein Inc., Huntington, NY, USA; VeinViewer®, Christie Medical Holdings Inc., Memphis, TN, USA) have been advocated as aids for finding peripheral veins in children, however they have not proven to reliably increase the first-pass success rate of IV cannulation [137].

Currently, the only induction agents available for use in the US are propofol, ketamine, and etomidate. Since 2011, sodium thiopental has been unavailable in the US, although it remains available in other countries.

Propofol (2,6diisopropylphenol) (1–3 mg/kg IV bolus) is the most widely available induction agent. It is available as Diprivan® (Fresenius Kabi USA, Lake Zurich, IL, USA) in a 1% solution that includes intralipid (long-chain triglycerides from soy oil), EDTA (ethylenediaminetetraacetic acid), egg lecithin, and pH adjustment. Since propofol is a phenol derivative, it is painful when injected into the small peripheral veins in children. Numerous strategies have been investigated to attenuate or prevent the pain of injection, with two techniques appearing superior to the rest at ameliorating the pain at injection: pretreatment with 70% nitrous oxide in oxygen by inhalation or a modified Bier block using 0.5–1 mg/kg 1% lidocaine injected into the vein that is occluded for 45–60 s [138].

Propofol is a very safe induction agent for children. When propofol was originally released, it was contraindicated in children with egg allergy. Egg lecithin is derived from egg yolk, a product to which children are not known to be allergic [19]. A second concern relates to children with soy allergy who may develop anaphylaxis to propofol. This theoretical concern has not been reported in the literature, in part because all soy proteins are removed in the manufacturing process of propofol, according to Fresenius Kabi, USA, the manufacturer. However, non-North American manufacturers caution against the use of propofol in children with soy and peanut allergy as children with soy allergy share epitopes with peanuts and develop peanut allergy [139]. Fortunately, >80% of children who claim to have peanut allergy are actually hypersensitive to peanuts, not immunologically allergic [140]. If children with peanut allergy have not been tested immunologically, the clinician may either avoid propofol or administer a small aliquot of propofol to assess their allergic sensitivity to propofol.

Ketamine (1–2 mg/kg) may be used for induction of anesthesia, although the associated concern of rare postoperative nightmares has relegated it to a second-tier anesthetic, given for specific indications such as sepsis or cyanotic heart disease. In children with tetralogy of Fallot, ketamine has divergent effects: it increases pulmonary blood flow in the presence of mild cyanosis but decreases the flow in those with moderate to severe cyanosis [141].

Although etomidate is not approved for use in children in North America, it has been used off-label. Its primary indication is for patients in septic shock. In adults, etomidate (0.3 mg/kg) suppresses adrenal function when administered as a bolus for rapid-sequence induction or a continuous infusion [142]. A single dose of IV etomidate in children during elective surgery suppresses cortisol levels for 24 h without affecting outcomes [143]. Pharmacokinetic data suggest that infants >6 months and young children may require larger doses of etomidate than older children [144]. Etomidate may cause myoclonic jerking and pain upon IV injection. The latter may be addressed by IV lidocaine pretreatment.

Sodium thiopental (5–6 mg/kg in healthy non-premedicated children, 3–4 mg/kg in neonates) has been used for almost half a century as an IV induction agent but in the past two decades has been supplanted by propofol. The induction dose should be reduced in premedicated children and debilitated patients. Thiopental induces anesthesia very rapidly, and its effect is terminated equally rapidly, primarily by redistribution. Only 10% of thiopental is metabolized per hour, which delays emergence, particularly if repeat doses are administered. Hence, this anesthetic is not suitable to be given by continuous IV infusion

Intramuscular induction

Intramuscular inductions are infrequently used in children because they are painful and induce anesthesia slowly. The only anesthetic currently used for IM injections is ketamine, in a dose of 3–5 mg/kg. This induction technique is usually reserved for cognitively impaired and combative adolescent children. The onset of sedation is approximately 3–5 min, with a duration of approximately 30–45 min.

Rarely, children who require their airways secured emergently present without IV access. In such cases, any one of several approaches may be undertaken. IV access may be established before induction of anesthesia, after induction of anesthesia with an inhalation agent, or after IM injection of ketamine (3–5 mg/kg), atropine (0.02 mg/kg), and succinylcholine (4 mg/kg).

Rectal induction

Rectal induction was a popular strategy for induction of anesthesia in young children (<5 years of age) in the past, particularly for those unwilling to take oral premedication or who

were very frightened. Several regimens have been used for rectal induction: methohexital 15–25 mg/kg, midazolam 1.0 mg/kg, ketamine 5 mg/kg, or thiopental 30–40 mg/kg [145–147]. Rectal inductions suffer from several issues including poor bioavailability of the induction agent (due to unpredictable rectal venous absorption or evacuation of the drug from the rectum), risk of laryngospasm (with methohexital), and possible delayed recovery from anesthesia. Currently, rectal inductions are rarely employed. Most prefer to involve the parents to manage the child's behavior at induction of anesthesia rather than administer a rectal premedication.

KEY POINTS: METHODS FOR INDUCING ANESTHESIA

- Parental presence has limited ability to reduce anxiety; oral midazolam and distraction techniques are more successful
- Inhalation induction with nitrous oxide and sevoflurane is by far the most common technique; a "maskless" induction or single-breath induction can be accomplished in appropriate settings
- IV induction, normally with propofol, can be accomplished after IV placement with a variety of topical anesthetics, with minimal upset to the child
- IM induction with ketamine is reserved for uncooperative developmentally delayed children, or patients with congenital heart disease with poor IV access who might not tolerate an inhaled induction

Problems during induction of anesthesia

Desaturation

The SpO_2 of healthy, awake children breathing room air should be >95%. A similar saturation should be maintained after induction of anesthesia and airway instrumentation, particularly with a FiO_2 ≥33%. However, in some children, the SpO_2 decreases to <94% in the early anesthesia period and does not increase substantively despite an increase in the FiO_2. In the presence of a normal capnogram, the most common diagnosis is an endobronchial intubation, followed by asthma, mucous plug, and atelectasis. Once air entry in the left chest is confirmed, the lungs are clear to auscultation, and the tracheal tube is devoid of purulent secretions, the next most probable diagnosis is segmental atelectasis. Atelectasis develops with induction of anesthesia. This, combined with reduced tidal volumes and respiratory effort, decreases lung volumes and chest compliance. The result is that most of the pulmonary circulation perfuses the basal segments of the lungs whereas most of the ventilation preferentially inflates the upper lung segments. This V/Q mismatch is relatively unaffected by an increase in FiO_2 from 30% to 100% because of the sigmoidal shape of the oxyhemoglobin dissociation curve. Thus increasing the FiO_2 is ineffective; to restore the saturation to >94%, the atelectatic alveoli must be recruited [148]. This is achieved by manually inflating the lungs to 20–30 cmH_2O pressure for 20–30 s (known as an alveolar recruitment maneuver). This maneuver should be applied cautiously to the child with an unstable circulation. Alveolar recruitment shifts the ventilation up the pressure–volume curve where right-to-left shunting is minimal. The effectiveness of alveolar recruitment is independent of the FiO_2. Once the recruitment is completed, spontaneous respiration may resume with a physiological positive end-expiratory pressure (~5–10 cmH_2O). An underappreciated cause of atelectasis is gastric distension caused by assisted ventilation using excessively large peak pressures in small children. To decompress the stomach, a soft 8–14 F catheter should be passed into the stomach and attached to low suction.

Bronchospasm

Bronchospasm occurs infrequently during induction of anesthesia with sevoflurane and halothane [149] but is more common during inductions with isoflurane and desflurane [150] and after tracheal intubation in children, particularly in those with irritable airways such as severe asthma. Bronchospasm is defined as a sudden constriction of the walls of the airways. Wheezing on the other hand, which literally means "hissing," is whistling (high- or low-pitched) noises in the airways. To keep these two terms distinct, remember the expression: "all that wheezes is not bronchospasm." Bronchospasm occurs more commonly in children with asthma, pulmonary infections, and anaphylaxis. Wheezing can occur at multiple levels in the airway including the larynx (e.g. stridor) and intrinsic to the airway (e.g. asthma) or extrinsic to the airway (e.g. pneumothorax).

The factors that predispose to bronchospasm during anesthesia include a recent upper respiratory tract infection, asthma, foreign body in the airway (e.g. peanut or tracheal tube), first- and second-hand smoking and GER [151]. Preoperatively, the chest should be auscultated for breath sounds. If new-onset wheezing is detected, elective surgery should be canceled and the child referred to the pediatrician or pulmonologist for investigation. The reason for canceling elective surgery is that wheezing is a sign of unstable pulmonary disease that increases the perioperative risks after general anesthesia. If the surgery is urgent/emergent, bronchodilator therapy should be instituted preoperatively, airway management should be aimed at avoiding a tracheal tube, and equipment prepared to provide intraoperative bronchodilator therapy. If the child wheezes chronically despite maximum pulmonary therapy and no acute exacerbation is present, a dose of bronchodilator should be administered preoperatively and, if possible, a tracheal tube avoided.

If bronchospasm occurs after tracheal intubation, the cause should be diagnosed and treated. First, rule out an endobronchial intubation by auscultating the lungs bilaterally and verifying the depth of the tracheal tube from the lips. Second, suction the tracheal tube to remove any mucous plugs that may be present in the airways. Although passing a suction catheter down the tracheal tube does not rule out the presence of mucus or a defective cuff on the tube, it reduces the probability that one is present. If the bronchospasm is not resolved with either of these maneuvers, a dose of albuterol should be administered via the tracheal tube. To deliver an albuterol aerosol, a metered dose inhaler (MDI) adaptor (RTC 24-VP; Instrumentation Industries, Bethel Park, PA, USA) is attached

between the tracheal tube and the anesthesia breathing circuit. Alternatively, a non-MDI albuterol canister may be inserted into the barrel of a 30 mL syringe in the inverted position (after removing the syringe plunger) and the plunger reinserted on top of the canister to activate the puffer into the elbow of the breathing circuit. When activated at the elbow of the breathing circuit, 3–12% of the aerosolized albuterol reaches the tip of the tracheal tube, depending on the ID of the tracheal tube (from 3 to 6 mm ID) [152]. Hence five to ten activations may be required in order to deliver sufficient albuterol to affect the bronchial tone. If these maneuvers fail and bronchospasm continues, 1–2 μg/kg epinephrine may be administered IV. If bronchospasm persists despite these treatments, then an extrinsic cause for the bronchospasm should be sought, diagnosed, and treated.

Laryngospasm

Laryngospasm is an infrequent but potentially life-threatening emergency that occurs during induction or emergence from anesthesia. The frequency of laryngospasm in children varies dramatically among studies, the study populations, and predisposing factors from 0.4% to 10% [153–156]. Factors that increase the risk of laryngospasm in children are shown in Box 17.8 [156,157].

Laryngospasm is defined as reflex closure of the false and true vocal cords, although the precise pathogenesis of this reflex remains unclear. Complete laryngospasm is defined as closure of the false vocal cords and apposition of the laryngeal surface of the epiglottis and inter-arytenoids resulting in the complete cessation of air movement and noisy breathing, lack of movement of the reservoir bag, and an absent capnogram. In contrast, incomplete (or partial) laryngospasm is defined as apposition of the vocal cords leaving a small gap that permits a persistent inspiratory stridor and limited movement of the reservoir bag with progressively increasing respiratory effort. Some assert that incomplete laryngospasm is not laryngospasm at all, but for treatment purposes this is a moot point.

Laryngospasm begins as faint inspiratory stridor during induction of or emergence from anesthesia associated with cues that suggest upper airway obstruction. These visual cues of airway obstruction include suprasternal and supraclavicular indrawing as inspiratory effort increases, increased diaphragmatic excursions, and flailing of the lower ribs.

Box 17.8: Factors that increase the frequency of laryngospasm

- Young age (infants and young children)
- History of reactive airways disease
- Recent URTI (<2 wk)
- Exposure to second-hand smoke
- Airway anomalies
- Airway surgery
- Airway devices (tracheal tubes, possibly LMA)
- Stimulating the glottis during a light plane of anesthesia
- Secretions in the oropharynx (e.g. blood, excess saliva, gastric juice)
- Inhaled anesthesia (versus intravenous anesthesia)
- Inexperienced anesthesiologist

LMA, laryngeal mask airway; URTI, upper respiratory tract infection.

As greater inspiratory effort is expended, the stridor increases in intensity and volume, and the chest wall movement resembles that of a "rocking horse." As the laryngospasm progresses, air movement through the almost closed glottis ceases and the inspiratory effort becomes completely silent. This is an ominous sign. If progression of the laryngospasm is not stopped, the limited reserve of oxygen in the lungs will be exhausted and desaturation will ensue. This will be followed immediately by a decrease in heart rate, and can result in cardiac arrest. This downward spiral must be interrupted as follows.

The management of laryngospasm requires a multifaceted and immediate response as depicted in Figure 17.2 [154]. As soon as the diagnosis is suspected, a tight-fitting facemask should be applied to the child's face, 100% oxygen delivered with positive end-expiratory pressure (to a maximum of ~15–20 cmH_2O to limit gastric inflation). If the triggering event is blood, secretions. or foreign material in the airway, these should be removed to eliminate the source of glottic stimulation. As soon as the offending agent (if one is present) has been removed, a jaw thrust maneuver should be applied. The jaw thrust maneuver requires familiarity with the anatomy of the retromandibular notch, an area subtended by the condylar process of the ascending ramus of the mandible anteriorly, the mastoid process posteriorly, and the external auditory canal superiorly [158]. Digital pressure applied (initially bilaterally) to the most cephalad point on the posterior edge of the condylar process of the ascending ramus of the mandible should be directed toward the frontal hairline. Pressure on the edge of the condylar process should be applied for 3–5 s at a time and then released, all the while sealing the facemask tight against the child's face. By applying and releasing pressure on the condylar processes, the repeated painful stimuli may result in sufficient pain to cause the child to cry. If the child cries, the vocal cords must open and this would terminate the laryngospasm. In addition to delivering 100% oxygen and positive end-expiratory pressure to the upper airway, this maneuver confers the additional benefit of pain and the "flight and fright" response, which stimulates the child and results in an increase in respiratory effort and vocalization, possibly breaking the laryngospasm. Remember that laryngospasm is unlikely to develop or persist if the vocal cords are moving and the child is vocalizing or crying. If positive pressure ventilation, 100% oxygen, and the jaw thrust maneuver fail to break the laryngospasm, further intervention should be administered immediately before desaturation and bradycardia develop. Appropriate treatment at this stage includes IV atropine (0.02 mg/kg) and IV propofol (<1 mg/kg) [159,160]. If the laryngospasm breaks, ventilation should be assisted with 100% oxygen and an inhalation anesthetic. However, if the laryngospasm does not abate and the heart rate and oxygen saturation continue their downward course, succinylcholine (1–2 mg/kg IV or 4–5 mg/kg IM) should be administered and the trachea intubated.

An interesting report suggests that gentle chest compressions effectively break laryngospasm in children [161]. To add chest compressions to the management of laryngospasm, one requires a pair of free hands to perform the compressions rather than abandoning any or all of the maneuvers described previously. It is uncommon that a

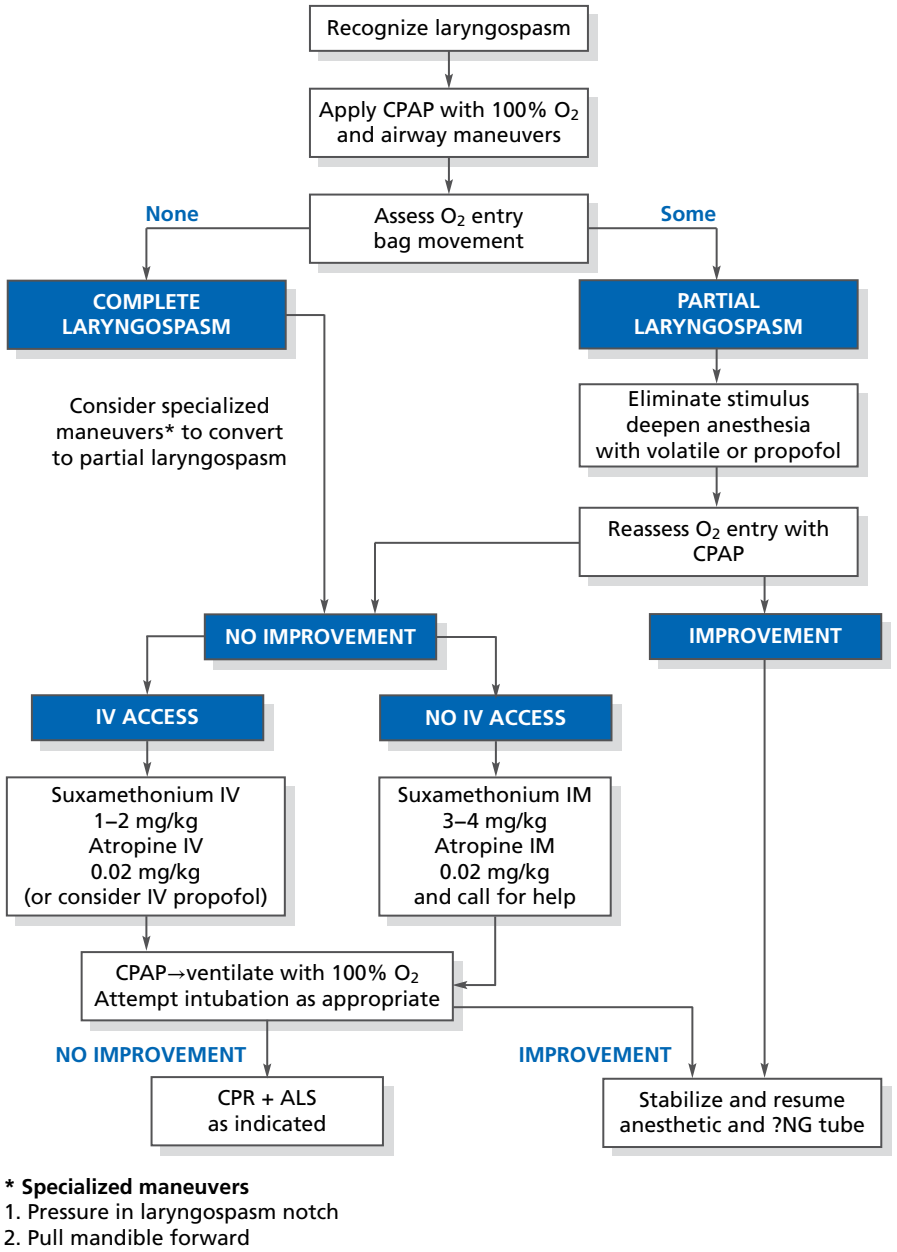

Figure 17.2 Algorithm to diagnose and manage laryngospasm in children. *Source*: Reproduced from Hampson-Evans et al [154] with permission of John Wiley and Sons. ALS, advanced life support; CPAP, continuous positive airway pressure; CPR, cardiopulmonary resuscitation; IM, intramuscular; IV, intravenous; NG, nasogastric.

free pair of hands would be readily available to provide chest compressions, but it may be worthy of consideration. The risks associated with performing chest compressions include sternal or rib fractures, which must be explained to the parents if they occur. It is our opinion that the current evidence is insufficient to recommend the routine use of chest compressions to relieve laryngospasm in children. Chest compressions are indicated for severe bradycardia (<60 beats/min (bpm) with poor perfusion, and poor or non-existent pulse).

A number of authors have used either topical or intravenous lidocaine to prevent laryngospasm on emergence from anesthesia in children. A recent systematic review of the subject concluded that 1–2 mg/kg IV lidocaine or topical lidocaine administered within 5 min of extubation was effective in preventing laryngospasm in children [162,163].

Bradycardia

Bradycardia is a slowing of the heart rate below age-defined limits. The threshold for infants (<1 year of age) is 100 bpm, for young children 1–5 years of age, 80 bpm, and for older children >5 years, 60 bpm. Since cardiac output in infants and children depends to a large extent on the heart rate, a slow heart rate means a reduced cardiac output. If the heart rate falls below these limits, corrective action should be taken to restore the heart rate while cardiopulmonary resuscitation begins.

Although hypoxia is the foremost cause of bradycardia in children, drugs are also well-known causes. Since sevoflurane replaced halothane, the frequency of bradycardia during inhalation anesthesia has diminished dramatically [149]. Succinylcholine remains a cause of bradycardia in children even after a single dose, although it is no longer recommended for elective tracheal intubation in children. Recently, the

frequency of bradycardia during the first 6 min of sevoflurane anesthesia in children with Down syndrome was found using an electronic database to be five-fold greater than in matched control children [164]. This may occur even with a structurally normal heart. Intervention (atropine or isoproterenol) may be required in children because cardiac output is dependent upon heart rate.

The causes of bradycardia in healthy children are listed in Box 17.7. In order to stop the progressive slowing of the heart rate, the underlying cause of the bradycardia should be treated (e.g. oxygenate the hypoxic child) and atropine 0.02 mg/kg IV administered. Atropine is only effective when electrical activity is present within the heart and the etiology of the bradycardia is vagal in origin. If asystole occurs, the definitive treatment is epinephrine (10 μg/kg); atropine is not indicated. Secondary treatment may include isoproterenol. Further details of cardiopulmonary resuscitation are presented in Chapter 13.

Hypotension

The incidence of hypotension during induction of anesthesia in children is small. In minimum alveolar concentration (MAC) studies, we defined hypotension as a >30% decrease in systolic blood pressure from baseline. At 1 MAC, systolic blood pressure in both neonates and infants 1–6 months of age anesthetized with halothane [165], and all children as old as adolescents anesthetized with sevoflurane or desflurane, was maintained, that is, within the defined limits (<30% decrease from baseline) [166,167]. The decreases in systolic and mean blood pressures in healthy children at >1 MAC sevoflurane and halothane were neither remarkable nor in need of intervention [131,168]. The combination of induction of anesthesia with 8% sevoflurane and an intravenous bolus of propofol (1–2 mg/kg) is a popular technique for securing the airway in an unparalyzed child without causing either bradycardia or hypotension [128].

In addition to the effects of induction agents, direct and indirect factors may lead to hypotension during induction of anesthesia in children. Direct causes include prolonged preoperative fasting, bleeding, chronic vomiting, and anaphylaxis. Indirect causes of hypovolemia include impending brainstem herniation, septic shock, cardiac tamponade, tension pneumothorax, major vascular compression (pulmonary arterial compression from an anterior mediastinal mass) and, rarely, hypothyroidism.

The treatment of hypotension must first address the underlying cause, by restoring euvolemia rather than administering pressors. Balanced salt solutions such as lactated Ringer's solution should be administered in bolus doses of 10–20 mL/kg, repeating as necessary, while the inspired concentration of inhaled anesthetic is decreased.

KEY POINTS: PROBLEMS DURING INDUCTION OF ANESTHESIA

- Desaturation during induction can be caused by airway obstruction, laryngospasm, bronchospasm, endobronchial intubation, or atelectasis as the main causes; prompt diagnosis and treatment are essential
- Bradycardia is less common now that halothane has been replaced by sevoflurane, but can still be caused by hypoxemia, high-dose sevoflurane, succinylcholine, vagal reflex, and others. It is more common in Down syndrome patients
- If hypotension is defined as >30% decrease from baseline, the incidence of hypotension is low, and even 8% sevoflurane plus propofol bolus 1–2 mg/kg for intubation is usually very well tolerated in healthy children

Maintenance of anesthesia

Methods

The most widely used prescription to maintain anesthesia in infants and children is inhalation anesthetics. Over the past 150 years, the molecular structure of inhalation anesthetics has been refined to the point that today these anesthetics are effective, reliable, easy to deliver, offer favorable qualities, and are safe. One key advantage that distinguishes inhalation anesthetics from IV agents is that we can continuously measure the end-tidal concentration of the former. This measurement provides invaluable knowledge regarding the accuracy of our delivery system and the patient's responses to the anesthetic. Currently, the three inhalation anesthetics, isoflurane, sevoflurane, and desflurane, are used to maintain anesthesia. Although a discussion of the pharmacology of inhaled anesthetics is beyond the scope of this chapter (see Chapter 10 for a more extensive discussion), several key principles can be summarized. All three anesthetics preserve cardiorespiratory homeostasis in healthy children. The only caveat relates to the use of desflurane in severe asthmatics and children exposed to second-hand smoke, who may experience more adverse respiratory events related to changes in pulmonary resistance during and after administration of desflurane [169]. In addition, if desflurane is used to maintain anesthesia with an LMA, perioperative adverse respiratory events are more common [170,171].

The speed of emergence after isoflurane and sevoflurane anesthesia is similar when the anesthetic concentration is tapered during maintenance, although the speed of emergence after desflurane will be more rapid than after both isoflurane and sevoflurane, particularly if (1) it was the sole anesthetic during the maintenance period, and (2) it was supplemented with short-acting opioids or non-opioid analgesics and if the surgery was prolonged [172]. Alternately, if large doses of opioids were used for analgesia, it is possible that the sedative effects of the opioids may delay emergence and result in similar emergence times with all anesthetics.

Nitrous oxide is the oldest anesthetic still in use and is commonly used during maintenance of anesthesia in children. Although it has several disadvantages, we believe none warrant its withdrawal from practice. Nitrous oxide is contraindicated in several clinical scenarios (including bowel obstruction, middle ear surgery, spinal surgery with motor evoked potential, and cardiopulmonary bypass), but has provided a background of anesthesia, sedation, and analgesia during painful procedures for decades. Omission of nitrous oxide increases the risk of awareness [173]. However, its effect on PONV remains debated: in a very large study in adults, the contribution to PONV was minimal [174], and in children its contribution to PONV increased with time, with a substantial effect

evident after 3 h of administration [175]. Side-effects from nitrous oxide include those mentioned previously as well as depression of methionine synthetase and atmospheric pollution. The environmental concern regarding nitrous oxide relates to its effects on global warming and depletion of the ozone layer. With an estimated life in the troposphere of 110 years [176], nitrous oxide is not environmentally green, although it is estimated that <5% of the nitrous oxide released in the atmosphere originates from medicinal use. Methods to reduce the medical footprint on the troposphere include combining desflurane with nitrous oxide, reducing the use of desflurane, using sevoflurane or isoflurane with an oxygen/air fresh gas flow, and improved carbon dioxide absorbents [177].

TIVA has generated much interest as the primary anesthetic for children with malignant hyperthermia, for those undergoing spinal surgery with motor evoked potential monitoring, and for those with a history of severe PONV. The primary general anesthetics for use in TIVA are propofol and ketamine. Propofol has antinausea properties that have been exploited in children with histories of PONV. Side-effects from propofol include pain on injection and propofol infusion syndrome (PRIS). Pain on injection of propofol may be obviated by pretreatment with 70% nitrous oxide or by applying a modified Bier block for 30–45 s with IV lidocaine (0.5–0.75 mg/kg) [138]. However, its major liability remains PRIS, which in some jurisdictions has resulted in it being proscribed for use as a sedative in children [169]. To date, propofol has caused PRIS in children sedated with propofol infusion rates >5 mg/kg/h for ≥48 h [178]. Between 1989 and 2004, more than 33 cases of PRIS were reported in children, as evidenced by an evolving lactic acidosis (for no apparent clinical reason) during propofol sedation/anesthesia that either reverted to a normal pH once the propofol infusion was discontinued or resulted in sudden death [179–181]. Currently, continuous propofol infusions are used in North America for sedation for medical and surgical procedures in children, but not in intensive care units where sedation for several days may be required. Sequential blood gas determinations would be prudent in all children who are sedated with propofol for prolonged periods. If an inexplicable lactic acidosis develops during propofol infusion, the infusion should be discontinued and appropriate resuscitation measures instituted.

Propofol infusion rates for anesthesia in infants and children to prevent movement during MRI or surgery range from 200 to 300 μg/kg/min (12–15 mg/kg/h) [182,183]. In the case of surgery, supplemental medications including opioids, muscle relaxants, and sedatives may be required. We have also noted that younger infants as well as those who are cognitively challenged require much greater infusion rates to prevent movement during MRI than older children without cognitive impairment. A word of caution when preparing propofol infusions for infants <1 year of age: the clearance of propofol is lowest in neonates and increases from neonates to infants 1 year of age, after which clearance remains unchanged into adulthood [184]. Thus, after the initial loading dose of propofol, the reduced clearance in young infants may require a reduced infusion rate to facilitate a rapid recovery.

To account for the differing pharmacokinetics of propofol (and other medications) over time and in children with differing physiology, target controlled infusions have been developed [185]. These infusion pumps incorporate software that automatically adjusts the infusion rate to the child's characteristics and to the desired blood concentration of propofol in that age group. To date, these infusion pumps have been modestly successful but are not widely available and are not expected for use in humans in North America in the near future.

Supplemental analgesics have also been used during either inhalation or IV anesthesia to prevent physiological responses and movement to pain. Remifentanil (with a zero context-sensitive half-life) 0.05–0.1 μg/kg/min may be administered as an infusion, whereas other opioids (fentanyl and morphine) are administered in IV boluses. Fentanyl (1–2 μg/kg) or morphine (0.05–0.1 mg/kg) may be administered IV with the dose adjusted up or down depending on the child's exposure to opioids, the severity of the pain, and concomitant analgesics.

Age versus minimum alveolar concentration

The MAC is defined as the minimum alveolar or end-tidal concentration of inhalation anesthetic at which 50% of the subjects move in response to a noxious stimulus, usually a skin incision in humans. In children, the MAC values for most inhalation anesthetics increase with decreasing age, reaching a peak during infancy. For example, the MAC of halothane and isoflurane increases with increasing gestational age and through early infancy, reaching its zenith in infants 1–6 months of age. It then decreases with increasing age (Fig. 17.3) [186]. The MAC for desflurane also increases during infancy but reaches its zenith in infants 6–12 months of age and then decreases with increasing age [167]. In the case of sevoflurane, the pattern of MAC and age differs substantially from that of the other inhalation anesthetics; the MAC of sevoflurane is constant, 3.2%, in neonates and infants 1–6 months of age and then decreases abruptly to 2.5% in infants from 6 months up to adolescence [166]. The neurobiological reason why MAC changes with age in childhood and why the relationships differ among the inhalation anesthetics has eluded researchers, although several theories have been proposed including

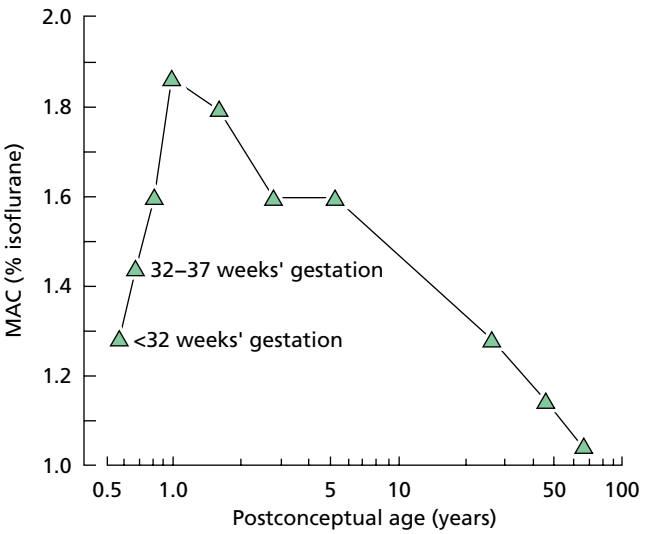

Figure 17.3 Age and the minimum alveolar concentration (MAC) of isoflurane from premature infants to adults. Reproduced from LeDez and Lerman [186] with permission of Wolters Kluwer.

differences in central nervous system (CNS) development and neurohumoral factors.

The concept of MAC includes the notion that the contributions of all concurrently administered inhaled anesthetics are additive towards the total MAC. Thus, 60% nitrous oxide with 1% isoflurane is equivalent to 0.6 + 1.0 or 1.6 MAC of inhalation anesthesia. This notion applies to isoflurane and halothane in children as well as to all the inhalation anesthetics in adults. However, when the MAC values of sevoflurane and desflurane in children were determined in combination with nitrous oxide, the MAC contribution of 60% nitrous oxide was only 20%, two-thirds less than the effect of nitrous oxide in the presence of isoflurane and halothane [166,187]. The reason for this substantially diminished effect of nitrous oxide with these two relatively insoluble anesthetics has not been explained.

A number of factors influence the MAC of inhalation anesthetics. Approximately 90% of adults who are homozygous or heterozygous for the melanocortin-1 receptor gene (i.e. redheads) require 20% more anesthesia than those without this mutation [188].

Children with cerebral palsy and severe mental retardation require 25% less halothane than healthy children [189]. Other variables that must be taken into consideration when determining MAC levels in children include chronic anticonvulsant therapy.

In addition to the traditional nociceptive stimulus of skin incision, the MAC responses to other stimuli including tracheal intubation and extubation, LMA insertion and extubation, tracheal intubation/skin incision ratio, and wakefulness have been reported in children [190]. The tracheal intubation to skin incision ratio in children is ~1.33 for halothane and sevoflurane. MAC awake for sevoflurane in children 2–5 years of age, ~0.66%, is almost 50% greater than in children 5–12 years, 0.44% [191].

Fluid management

General principles

Intravenous fluid sets should be prepared before the child arrives in the operating room. For infants and children, a 500 mL bag of lactated Ringer's solution with a buretrol is appropriate, although for neonates and preterm infants, a 250 mL bag and/or an infusion pump is preferable. For children >8 years of age, the IV infusion set may be prepared with a macro- or micro-drip without a buretrol and either a 500 or 1000 mL bag of balanced salt solution. All pediatric IV sets should include a manual controller, a one-way valve (to prevent medications from passing retrograde up the IV tubing), and needleless ports and/or three-way stopcocks for medication administration.

For neonates and preterm infants from the NICU, we continue the clear maintenance infusion from the NICU, i.e. 10% glucose and supplemental calcium. The infusion rate should remain unchanged during surgery since unexpected intraoperative hypoglycemia may occur if the hyperglycemic infusion rate is suddenly reduced. If sequential blood glucose concentrations are measured during surgery, it is possible to titrate the NICU infusion to maintain normoglycemia. Intralipid infusions are best discontinued before transfer to the operating room to reduce the risk of contaminating the Intralipid and central venous access line with repeated line accessing.

Most IV fluids administered to healthy children during elective surgery now consist of a non-glucose isotonic salt solution, commonly lactated Ringer's solution in North America. These solutions replaced glucose-containing hypotonic solution after reports of seizures, aspiration, and brain damage. Worldwide, the shift to isotonic solutions for intraoperative fluid maintenance in children has occurred more slowly [192]. Lactated Ringer's solution is slightly hypotonic (280 mOsm/L) and contains small concentrations of potassium as well as lactate. Normal saline (0.9% NaCl) is isotonic (308 mOsm/L) and contains no ionic moieties, but has a pH of 5.0. It is not routinely used as the primary maintenance solution since large volumes may lead to a hyperchloremic metabolic acidosis (non-anion gap type). We advocate glucose-containing solutions, such as 1% or 2.5% glucose in lactated Ringer's solution as a maintenance solution for full-term neonates and infants <6 months of age, and for young children who are cachectic, chronically malnourished, tolerate fasting poorly (maple syrup urine disease), and suffer from debilitating disease who may be at risk for hypoglycemia [193,194]. These solutions should avoid both hyperglycemia and hyponatremia intraoperatively. Although the incidence of hyponatremia has been dramatically reduced with the shift in practice to isotonic salt solutions, there may be reason to monitor serum electrolytes in specific surgeries [195].

Children with specific medical conditions should have tailored IV solutions. For children in renal failure or renal insufficiency, normal saline has been the preferred balanced salt solution because it contains no potassium, however there is some evidence that the non-anion gap acidosis that may occur may cause inadvertent hyperkalemia [196]. Thus lactated Ringer's solution may be the preferred solution. Children with a mitochondrial myopathy who developed lactic acidosis during infancy should be fasted for brief periods preoperatively and receive only normal saline with glucose supplementation as needed.

Infants and young children (<2 years of age) who may be hypovolemic should be assessed preoperatively for the magnitude of their fluid deficit: mild, moderate, or severe [197]. The signs of mild dehydration (5% bodyweight loss or approximately 50 mL/kg deficit) include poor skin turgor and dry mouth. The signs of moderate fluid dehydration (10% of bodyweight loss or 100 mL/kg deficit) include sunken fontanel, tachycardia, and oliguria, in addition to the signs of mild dehydration. The signs of severe fluid dehydration (15% of bodyweight loss or 150 mL/kg deficit) include sunken eyeballs, hypotension, and anuria, in addition to the signs of moderate dehydration.

Correction of the hypovolemia requires a staged infusion of fluids. Approximately 50% of the deficit should be replaced in the first hour, 25% in the second, and 25% in the third. A balanced salt solution should be used to restore euvolemia. Chapter 11 presents an extensive discussion of fluid therapy.

Elective surgery

For minor, elective surgery, the traditional calculation for the hourly fluid infusion rate has been based on replacing the triad of fluid deficit during fasting, on-going maintenance, and blood and third space losses. In children, the calculation was predicated on the 4–2–1 mL/kg/h where 4 mL/kg is for the first 10 kg, 2 mL/kg is for the second 10 kg, and 1 mL/kg is

for the third 10 kg and any additional bodyweight thereafter, as popularized by Holliday and Segar [198]. The initial blood loss may be replaced with balanced salt solution at a rate of 3 mL of solution for every 1 mL of blood loss. For third space losses, the replacement volume is based on the severity of the losses: 1–2 mL/kg/h for minor surgery, 2–5 mL/kg/h for moderate surgery, and 6–10 mL/kg/h for major surgery and large third space losses.

In a reappraisal of their 1957 fluid recommendations for children in the perioperative period, Holliday et al reviewed a series of reports of hyponatremia in children (>6 months of age) who had received hypotonic glucose-containing solution and evaluated the risks of using a balanced salt solution for maintenance fluids [199]. They determined that their original formula could lead not only to hyponatremia if excessive volumes were rapidly infused in young children, but that it could lead to water and sodium overload in some children if the formula was used with a balanced salt solution. This was of particular concern in the postoperative period because pain and certain medications may lead to inappropriate antidiuretic hormone secretion and an excess infusion of balanced salt solution might place some children at risk of congestive heart failure. They concluded that their previous 4–2–1 fluid formula that was used with hypotonic glucose-containing solutions should be replaced with a 2–1–0.5 formula with isotonic fluid in the postoperative period. They recommended a two-pronged approach: intraoperative rehydration with 10 mL/kg/h with balanced salt solutions in all children (for 2–4 h), and a postoperative maintenance rate of balanced salt solutions using half their original formula or 2–1–0.5 mL/kg [199].

Although most pediatric surgeons are careful to minimize bleeding during surgery, it is important to remain vigilant throughout the procedure to monitor blood loss. For those procedures that result in significant tissue trauma or blood loss, the provider must ensure appropriate size IV access to transfuse blood and blood products as needed and a measure of volume status/replacement. Packed cells cannot be rapidly infused through either 24-gauge IV catheters or peripherally inserted central catheters (PICC). The smallest intravenous cannula through which blood can be rapidly infused is a 22-gauge catheter. Every effort should be expended to insert the largest IV catheter that the child's size can accommodate. Initial blood loss is replaced with a balanced salt solution in a ratio of 3 mL of salt solution for every mL of blood loss. This replacement, together with the maintenance requirement, should be logged on the anesthetic record. As the combined volume of balanced salt solution approaches 75–100 mL/kg, it is important to consider the possibility of dilutional thrombocytopenia and dilution of coagulation factors; coagulation indices should be measured at this time.

The threshold for triggering packed cell transfusions in children has also undergone a renaissance in the past decade, with evidence that the outcome and complications after a conservative transfusion trigger (i.e. 7 g/dL) were similar to those with a liberal transfusion trigger (9 g/dL [200,201]. The estimated blood volume in a child decreases with increasing age from 95–100 mL/kg in premature infants to 70 mL/kg in adults 202]. Note that obese children have an estimated 10% reduced blood volume compared with similar aged children [193]. To estimate the allowable blood loss during surgery, one may use the following equation [202]:

$$\text{Maximum allowable blood loss (MABL)} = (\text{starting Hct} - \text{target Hct}) / (\text{starting Hct}) \times \text{estimated blood volume}$$

For example, if target Hct for a patient with starting Hct of 35% is 20%,15/35 = 0.43; if an 18-month-old patient weighs 10 kg and has a blood volume of 750 mL, 0.43 × 750 = 323 mL is the MABL.

Some use a modified version of the MABL calculation, replacing the "starting Hct" in the denominator with the "average Hct" to increase the allowable blood loss before transfusion. Irrespective of which equation is used to estimate the allowable blood loss, the actual Hct should be determined before blood transfusion is initiated to ensure that the actual Hct warrants initiating blood. When initiating a blood transfusion to a child, two formulae provide rough estimates of the amount of blood required to increase the hemoglobin concentration 1 g/dL: 4 mL/kg packed cells and 6 mL/kg whole blood. Chapter 12 presents additional information about blood transfusion.

Postoperative nausea and vomiting

The incidence of PONV in children depends on a number of factors that relate to the patient (motion sickness history, age), the anesthetic (inhaled anesthetics, nitrous oxide, opioids, preoperative fluid administration, postoperative fluid ingestion), and the surgery (inguinal/orchidopexy, tonsillectomy and adenoidectomy, strabismus, and middle ear surgery). The importance of each of these factors has been the subject of intense investigation.

Children should be fasted preoperatively for brief periods and not forced to drink oral fluids postoperatively until they request them [203]. Intraoperatively, the child should be adequately hydrated with IV fluids [204] and provided with regional anesthesia and non-steroidal anti-inflammatory agents instead of opioids where possible. If the child is scheduled for emetogenic surgery and has a history of PONV, the optimal anesthetic regimen may include propofol oxygen/air and two antiemetics, although evidence is conflicting regarding the beneficial roles of substituting propofol for inhalation agents and air for nitrous oxide [174,205]. In a recent systematic review, TIVA was as effective as a single antiemetic in preventing PONV after strabismus surgery in children, although the frequency of bradycardia was greater after IV anesthesia [206]. The role of nitrous oxide is not "all or none", but rather depends on the duration of exposure [207].

The optimal prophylactic antiemetic strategy to administer to children during anesthesia is dexamethasone and a 5-HT3 receptor antagonist such as ondansetron [208]. A dose of dexamethasone between 0.0625 and 1 mg/kg (maximum 24 mg) has been shown to be equally effective, although we limit our maximum dose to 10 mg [209]. One report suggested that dexamethasone is associated with an increased incidence of postoperative tonsil bleeding [210], although the preponderance of evidence refutes this association [211–213]. The dose of ondansetron that we recommend for prophylaxis in children is 0.05–0.15 mg/kg.

KEY POINTS: MAINTENANCE OF ANESTHESIA

- Sevoflurane is by far the most common approach to maintenance of anesthesia; TIVA techniques using propofol and opioid infusions are also frequently used
- Isotonic non-glucose solutions, i.e. lactated Ringer's, are now the mainstay of fluid therapy, decreasing the risk of hyponatremia and hyperglycemia
- Transfusion triggers are now more restrictive; for infants and children without significant cardiopulmonary issues, 7 g/dL is usually accepted
- To prevent postoperative nausea and vomiting, two antiemetics, commonly a 5-HT3 receptor antagonist and dexamethasone, are usually quite effective

Emergence and recovery from anesthesia

As surgery concludes, the inspired concentration of inhalation anesthetics or infusion rates of IV drugs are tapered and discontinued. Recovery after inhalation anesthetics follows the order desflurane < sevoflurane < isoflurane < halothane. The degree of paralysis should be assessed and neuromuscular blockade antagonized as required. Before extubation, the child's respiratory effort and motor strength are assessed. Equipment should be available to manage the airway (facemask, 100% oxygen) as well as complications from the extubation (suction).

The primary focus of the entire anesthesia team during emergence is to assess the child's airway, their ability to breathe, and their ability to protect the airway should bleeding or vomiting occur once the airway is extubated. It is our practice to extubate the airway, whether from a tracheal tube or LMA, when the child has fully recovered airway reflexes and is awake. There are very few surgical or medical indications to remove the airway during deep levels of anesthesia, and little evidence that this practice results in better outcomes. Contraindications to deep extubation may include a difficult airway, morbid obesity, severe OSA, and diseases with severely limited pulmonary reserve (e.g. cystic fibrosis). The greatest concern regarding deep extubations is that a child who is deeply anesthetized and transported with an unsecured airway relies totally on extremely high-quality nursing in PACU to monitor the airway until the child is awake. The evidence regarding the frequency of adverse airway events after deep tracheal extubation or awake is mixed [214,215]. In most instances, the anesthesiologist returns to the operating room after transferring the child's airway and care to the PACU nurses. In some institutions, the nurses are trained and qualified to manage the airway in an anesthetized child, although an anesthesiologist should be available to manage airway issues should they occur.

In our experience, children who have an LMA are at increased risk for developing progressive airway obstruction several minutes after they emerge from anesthesia and the device is removed. Accordingly, we remove all LMAs in the operating room before transferring the child to PACU. Recent evidence concluded that safe conditions are optimized when the LMA is removed during a deep plane of anesthesia with the child in the lateral decubitus position [216]. In the case of desflurane, we reported a substantially greater frequency of adverse airway reflex responses when the LMA was removed during a deep level of anesthesia than when it was removed awake or compared with isoflurane [170]. We recommend that all LMAs be removed when the child is awake, especially if desflurane has been administered.
