The timing of tracheal extubation is critical for minimizing the risk of adverse airway events during emergence. The optimal time for extubation requires that the child has emerged from anesthesia to the extent that he/she can support their own airway. Recognizing the optimal time for extubation requires an appreciation of the three phases of emergence from inhalation anesthesia in children: early, middle, and late. Each of these phases may last for up to several minutes depending on the anesthetics administered and the age of the child. During the early phase of emergence, the child first coughs intermittently, gags, struggles, and moves non-purposefully. This phase passes relatively quickly as the child enters the middle or quiescent phase. During this phase, the child may appear to be deeply anesthetized, apneic, or "agitated," during which time he/she breathholds, strains, and/or desaturates, the last necessitating assisted ventilation of the lungs to maintain an SpO_2 to >95%. As the child resumes quiet, spontaneous respiration, he/she enters the late or third phase of emergence, which is characterized by purposeful movement, flexing the hips, coughing, and gagging on the tracheal tube, all of which increase in intensity until the child grimaces and opens their eyes spontaneously. Removing the tracheal tube during either the early or middle phase increases the risk of triggering an adverse airway event (e.g. laryngospasm). It is only during the third phase of emergence that adverse airway reflex responses are least likely to be triggered if the tracheal tube is removed. We teach our residents that if you think the time is right to remove the tracheal tube, don't! Leave the tube *in situ* for another minute (or two) until the child is definitely in the late or third phase of emergence. It is at this time that the tracheal tube may be removed with the lowest risk of adverse airway events.

While children emerge from anesthesia, the practitioner can follow one of two strategies: either no-touch or stimulation. With the former technique, the child breathes 100% oxygen undisturbed and unstimulated while the third phase of emergence is awaited. When the end-tidal anesthetic concentration decreases to a level consistent with wakefulness (e.g. sevoflurane concentration <0.6%, depending on adjuvant agents) [191], the eyes will open spontaneously, he/she will reach for the airway, gag, and grimace indicating it is time to remove the airway. Some advocate the "no touch" technique with the child in the lateral decubitus position to reduce the risk of laryngospasm [217]. With the latter technique, the initial recovery is the same as with the no-touch technique, however the transition through the second and third phases is speeded by applying digital pressure (in the direction of the front hairline) to the posterior ramus of the coronoid process, the most cephalad portion of the ascending ramus of the mandible, for 3–5 s [158] when the end-tidal anesthetic concentration of isoflurane is <0.25% or sevoflurane is <0.6%. The child reacts to this stimulus by arousing, gagging on the tracheal tube, moving purposefully, and opening the eyes. Both strategies generate similar outcomes with safe and protected airways.

Box 17.9: Causes of delayed emergence from anesthesia

- Residual drug effects: inhalational anesthetics, opioids, propofol
- Non-anesthesia medications: recreational drug use (cocaine, crack), herbal medicines (valerian, St John's wort)
- Depressed neuromuscular junction: residual neuromuscular blockade or pseudocholinesterase deficiency
- Hypothermia
- Hypo- or hyperglycemia
- Electrolyte imbalance: hyper- or hyponatremia
- Acid–base disturbance
- Hypercapnia
- Cerebrovascular accident/hypoxia: check pupil size and responsiveness to light bilaterally, presence of a gag reflex, symmetrical limb reflexes

In the vast majority of children, emergence progresses smoothly as described previously, with increasing arousal culminating in the child gagging and rejecting the presence of the tracheal tube. However, in rare instances, this sequence of events fails to progress at all, or if it progresses it is not smooth. Children who fail to emerge from anesthesia must be assessed for a variety of potential problems (Box 17.9). The most common cause of delayed emergence is a relative drug overdose as in failure to taper or reduce the dose of inhalation or IV anesthetic. However, rare but potentially catastrophic events such as unexpected hypoglycemia or an intracranial bleed (dilated pupil) may complicate the anesthesia and surgery and lead to prolonged coma. Laboratory tests may be required to diagnose the cause of the coma. Definitive treatment should be administered once the diagnosis is confirmed.

Complications during recovery

The incidence of complications in PACU is 5–10% [218,219]. Of these, 77% are attributable to vomiting and 22% to respiratory issues. The remaining 1% or less are attributable to cardiac issues. The age distribution of the complications is important: vomiting is more than twice as frequent in children >8 years of age than in younger children, whereas respiratory complications occurred twice as frequently in infants <1 year of age than in older children.

Postoperative nausea and vomiting

The frequency of PONV in PACU has decreased dramatically since the introduction of prophylactic antiemetics for most children who are anesthetized. Routine use of two antiemetics, dexamethasone and ondansetron, reduces the perioperative incidence of vomiting by up to 80% or greater [196]. Most children who vomit, vomit after ingesting their first fluids (in the stepdown PACU), in the car, or at home. Hence, we allow children to drink oral fluids after surgery only when they request to drink [203]. If the child continues to vomit, there are few effective interventions to stop the vomiting. Oral fluids should be withheld for a period and ondansetron may be given again, either IV or sublingually. It is important to appreciate that the child may be a rapid metabolizer (CYP 2D6 polymorphism) or have a rapid transporter P-glycoprotein polymorphism, resulting in a poor antiemetic effect [220,221]. Since we do not test for polymorphisms, it is reasonable to administer a second dose of ondansetron if the previous dose was given 2 or more hours before. Alternately, a dose of metoclopramide may be administered IV (at 150 μg/kg). It should be noted that droperidol (prolonged QT syndrome) and promethazine (respiratory depression in patients <2 years of age) both have US FDA boxed warnings (contraindications) for PONV treatment in children.

Emergence delirium

The introduction of sevoflurane into pediatric anesthesia caused a recrudescence in the frequency of emergence delirium (ED) after anesthesia. ED and pain are two conditions that fall under the umbrella term, emergence agitation. ED has been recognized as a sequela of anesthesia for several decades, increasing in frequency every time a new, less soluble inhalation anesthetic was introduced. ED has been characterized as follows: the incidence peaks in children (of both sexes) 2–6 years of age; it is more common after some anesthetics (sevoflurane ~ desflurane ~ isoflurane >> TIVA); it lasts 10–15 min and is terminated either spontaneously or after a single IV dose of propofol, midazolam, clonidine, dexmedetomidine, ketamine, or opioids [222–225].

The challenge in diagnosing ED in children in the PACU after surgery is differentiating it from pain [226]. To that end, ED was assessed in children undergoing MRI with either sevoflurane or halothane [227]. In the absence of any source of pain after the MRI, the frequency of ED after sevoflurane was five-fold greater than that after halothane.

A host of studies continued to report ED after a variety of surgeries, with and without adequate analgesia, and using non-validated delirium scales. This led to much confusion regarding the nature, cause, and treatment of ED. In order to clarify much of the confusion, the pediatric anesthesia emergence delirium (PAED) score was developed and validated as an objective measure of ED where a score >10 was indicative of the presence of ED, although some have suggested that a score >12 may be more specific [228,229].

Laryngospasm, postoperative stridor, and negative pressure pulmonary edema

Laryngospasm, postoperative stridor, and negative pressure pulmonary edema occur not only at induction of anesthesia but also at or after emergence from anesthesia. Factors that increase the risk of laryngospasm include removing the tracheal tube from the larynx prematurely, the presence of blood, secretions, or foreign material within the pharynx, secondhand smoke, and a recent history of upper respiratory tract infection (see Box 17.8). For a full discussion of laryngospasm please refer to the section "Problems during induction of anesthesia."

Postextubation stridor may also occur upon tracheal extubation. Stridor occurs because the epithelium within the cricoid ring swells after the tube is removed, thus reducing the cross-sectional diameter of the airway. Because airflow in the upper airway is turbulent, the resistance to airflow increases as the fifth power of the radius decreases. That is, if the radius of the airway within the cricoid ring decreases by 50%, the resistance to airflow increases 32-fold. In the infant with increased oxygen requirements and metabolic rate, residual opioids, muscle weakness, and anesthesia may further compromise the

ability to maintain an increased work of breathing in the presence of stridor, and that could hasten fatigue and respiratory failure. Children with Down syndrome have a greater risk of postextubation stridor [230]. The treatment for stridor includes humidified oxygen, IV dexamethasone (1 mg/kg IV), and nebulized racemic epinephrine (0.5 mL epinephrine in 2 mL saline). Rarely is it necessary to reintubate the airway for persistent and severe stridor in PACU. If hypoxemia or respiratory failure occurs, the trachea should be reintubated with a smaller size tube than the original one. An audible leak should be present after intubation to avoid further irritating the epithelium. If racemic epinephrine treatment is repeated more than twice, the child should be observed for rebound edema in either the PACU or a monitored unit.

Negative pressure pulmonary edema, or postextubation pulmonary edema, is an infrequent complication, usually occurring immediately or within several minutes after tracheal extubation in healthy, muscular adolescents and young adults, although it has been reported in infants [231–234]. Once the trachea is extubated, the child appears somnolent and unresponsive as the airway appears increasingly obstructed. A cascade of events then occurs with lightning speed beginning with upper airway obstruction and laryngospasm that ranges from very mild to severe. Contemporaneously, the oxygen saturation decreases, almost out of proportion to the severity of the airway obstruction. Despite ventilation by mask with 100% oxygen, tracheal reintubation is usually required to restore the saturation to normal values. Reintubation may be achieved using a muscle relaxant, propofol, or both. Upon reintubation, pink frothy pulmonary edema fluid is suctioned from the tracheal tube. Positive pressure ventilation with sufficient oxygen to restore the oxygen saturation to >94% and positive end-expiratory pressure should be maintained until oxygen, positive end-expiratory pressure, and ventilation are no longer needed to maintain the oxygen saturation. There is usually no need for additional measures to treat the pulmonary edema other than tracheal intubation. Sedation may be required for 12–24 h or more until the pulmonary edema resolves and/or the trachea can be extubated.

The mechanism of the pulmonary edema post extubation is believed to begin with extremely negative intrathoracic pressures generated against a closed glottis (i.e. laryngospasm) (known as the Muller maneuver) that augments transvascular filtration of hypoproteinemic fluid into the interstitium with a secondary surge in venous return [235]. These mechanisms combine to produce pulmonary edema.

Oxygen desaturation

Failure to maintain an adequate oxygenation saturation in the recovery room is a common problem. Unrecognized hypoxia may lead to a deterioration in the child's clinical status with bradycardia and cardiac arrest occurring suddenly. Continuous monitoring of the child's oxygen saturation is essential in the PACU to ensure an early warning indication of this complication. The minimum acceptable oxygen saturation in PACU is ≥94%. Administration of oxygen by facemask may be required to maintain the oxygen saturation, particularly if residual anesthesia or opioids are present, a craniofacial or muscular abnormality is present, or if the child is obese or fluid overloaded. In healthy children, desaturation is generally indicative of hypoventilation and/or airway obstruction. However, oxygen administration may mask the signs of hypoventilation, delaying airway intervention [236]. Because ventilation is not monitored in children without artificial airways en route to and in the PACU, we rely on clinical signs to diagnose and treat airway obstruction and hypoventilation.

Children should be weaned from oxygen dependency (assuming they did not require supplemental oxygen preoperatively) before they are discharged to the floor or the step-down unit. Some children remove the facemasks themselves when they awaken from anesthesia; if their oxygen saturation is maintained while breathing room air, then no additional oxygen treatment is required. If the child requires supplemental oxygen by facemask, it should be weaned to nasal prongs and then removed to room air while the saturation is monitored. If the child cannot maintain their oxygen saturation after attempts to wean them from the oxygen, further investigation (such as a chest radiograph) may be required to rule out organic causes such as aspiration, pneumonia, or pneumothorax. Chapter 18 presents additional information about PACU management.

KEY POINTS: EMERGENCE AND RECOVERY FROM ANESTHESIA

- Delayed emergence has a number of causes including residual anesthetics, opioids, neuromuscular blockers, hypoxia, hypothermia, or CNS injury; investigation must occur immediately and effective treatment be instituted
- Awake extubation of the trachea is recommended, unless very experienced PACU nursing and anesthesiologist response are available to respond to airway emergencies
- Emergence agitation is common in children 2–6 years of age and after inhalation anesthesia; treatment with opioids, propofol, midazolam, or dexmedetomidine can be effective; the Pediatric Anesthesia Emergence Delirium scale can be used to diagnose emergence delirium, but may be confused with pain
- Laryngospasm can result in postobstructive pulmonary edema if severe, and must be addressed immediately with positive pressure ventilation, mandible thrust, and, if necessary, propofol or succinylcholine

Transport to the postanesthesia care unit and intensive care unit

Transferring children from the operating room to either the postanesthesia care unit (PACU) or the intensive care unit (ICU) carries inherent risks that must be anticipated and assessed continuously.

Before being transported to PACU, the child must have a stable airway, be able to maintain adequate oxygenation and ventilation, have stable heart rate and blood pressure measurements, and have adequate pain control. An expert who remains vigilant throughout the transport and who is trained to manage potential postoperative problems should accompany the child.

During transport to PACU, most children breathe spontaneously, without requiring an oral airway in place. The optimal position to transfer a child, particularly after airway surgery, is the lateral decubitus position, known as the "recovery position." In this position, the upper leg is flexed at the hip, and the upper knee is resting on the bed in front of the lower leg. The child's upper hand should be placed under the lower cheek. This position facilitates drainage of secretions, blood, or vomitus out of the mouth rather than onto the larynx, and the tongue falls to the lower cheek or out of the mouth rather than posteriorly onto the larynx. The lateral position combined with airway maneuvers improves airway patency [237]. In addition, this position permits direct intervention in the airway should the need arise.

Supplemental oxygen may be administered by nasal prongs or facemask during transport, although if the child is monitored with pulse oximetry during this time, desaturation may not occur even in the presence of profound hypoventilation. Some advocate pulling up the chin to feel air movement on their palms during transport. We do not encourage maneuvers that close the child's mouth because this often obstructs the airway. Instead, we recommend extending the child's neck with the base of the hand (thenar and hypothenar eminences) applied to the forehead, and holding the fingertips over the mouth/nose to sense expiration.

Others transport the child to PACU in the supine position. This position undermines all of the advantages outlined for the decubitus position and facilitates posterior displacement of the tongue that may obstruct the airway [237]. Opioids have been shown to depress the hypoglossus motor nuclei centrally, which will relax the genioglossus muscle [238]. If the child is positioned supine, relaxation of the genioglossus muscle may cause the tongue to obstruct the laryngeal inlet. When opioids are administered along with inhalation anesthetics, the motor tone of the genioglossus muscle decreases, allowing it to fall back and obstruct the airway. Thus, children who receive opioids along with inhalation anesthetics should be transported in the lateral decubitus position to reduce the risk of airway obstruction during recovery.

Children who have recovered from anesthesia and who have normal heart and lungs generally do not desaturate when breathing room air, unless their airways become obstructed. Administering oxygen en route to PACU came into vogue about 25 years ago, at about the same time as portable pulse oximetry was introduced for transport. Studies at that time demonstrated that children desaturate en route to the PACU. However, in most instances, the desaturation resulted from airway obstruction, not from desaturation during tidal respiration. Rather than administering oxygen during transport, the child should be positioned in the recovery position with the neck extended by the anesthesiologist's thenar and hypothenar eminences and observed carefully for evidence of upper airway obstruction. In this position, the anesthesiologist's fingertips are positioned over the child's mouth and nose to sense the warm air of expiration. If a facemask is used to deliver oxygen, the observation of moisture on the mask is the only means to detect respiration unless portable capnometry is also employed.

If the patient is scheduled for transport to the ICU, additional planning is required before transfer. The medical and nursing staff in the ICU must be given a verbal summary of the child's condition as it relates to anesthetic/drug infusions, cardiorespiratory status, and ventilation requirements in order to prepare the appropriate equipment. The decision to transport the child with or without a tracheal tube should be made in conjunction with the intensive care team with a view to the child's longer-term management. Depending on the reason for admission to ICU, the child should be transferred with appropriate monitoring, emergency drugs, and equipment to maintain cardiorespiratory stability including equipment to re-establish the airway should it be lost during transport. Specifically, propofol, succinylcholine, and atropine should be immediately available (and inotropes depending on the child's needs) as well as a bag, facemask, second tracheal tube, and a functioning laryngoscope.

In the case of neonates, particularly preterm infants, the distance between the operating room and the NICU is usually substantial and over several floors. Given the precarious nature of the neonate's airway and the need for adequate analgesia, it seems prudent to transfer these small infants with their airways secured with a tracheal tube; once in the NICU, a dialogue should take place between the anesthesiologist and the neonatologist regarding the timing of tracheal extubation.

CASE STUDY

A 3-year-old child with loud snoring, brief periods of apnea during sleep, fatigue upon arousal in the morning, and attention deficit disorder presented to the otolaryngology service for possible ambulatory tonsillectomy. The child was small for his age, 13 kg in weight, and otherwise healthy. The review of systems was unremarkable. He had an uneventful bilateral tympanostomy as an infant under general anesthesia. The child had no history of allergies to medications and was receiving no medications. There was no family history of anesthesia-related complications or muscle diseases, although both parents had type II diabetes.

The child was fasted for surgery. To smooth the separation from his parents, 10 mg oral midazolam was administered in a medicine cup and followed with a swallow of water. The nurse accompanied the child to the operating room where he was monitored.

The child chose a flavor from three possible choices and used the lip balm to color the inside of the clear facemask. The mask was then gently applied to his face while 70% nitrous oxide in oxygen flowed. When the child stopped responding to conversation, 8% sevoflurane was added to the fresh gas. After intravenous access was established, a dose of propofol (1.5 mg/kg) was administered and the trachea intubated with an uncuffed RAE tube. After the gag was inserted into the mouth, the child began to breathe spontaneously with a gas mixture of 70% nitrous oxide in

1% isoflurane. Dexamethasone (2 mg) and ondansetron (1 mg) were administered intravenously. Without a polysomnogram, it was unclear whether this child desaturated at night and was hypersensitive to opioids. Accordingly, his opioid sensitivity was evaluated by administering 20 μg/kg morphine. After a single dose intravenously, the child stopped breathing, the oxygen saturation was 94%, and his heart rate decreased from 125 to 96 bpm. A second dose of morphine was administered for a total of 40 μg/kg. At the conclusion of the anesthetic, the child continued to breathe spontaneously but made no effort to reject the tracheal tube.

When the end-tidal isoflurane concentration had decreased to 0.2% and the child had not aroused, concern was expressed. The doses of the propofol and opioids were rechecked to verify that an accidental overdose had not occurred. The ampoules for the dexamethasone and ondansetron were similarly rechecked. A venous blood gas was sent for blood gases, electrolytes, and glucose concentration. All of the laboratory results were within normal limits.

At this time, the child's vital signs were within normal limits. Help was summoned and a differential diagnosis of possible causes was explored. The parents were asked again about recent prescription or non-prescription (including herbal) medications that the child may have taken, but there were none.

No obvious cause for the failure to emerge from anesthesia was forthcoming until one of the anesthesiologists removed the tape from the child's eyes. Lifting the eyelid revealed a shocking finding. The child's left pupil was fixed and dilated, unresponsive to light.

The child remained intubated and was taken for an emergency CT scan which showed an intraventricular bleed, hydrocephalus, and a midline shift. Neurosurgery were consulted and they scheduled the child for a ventriculoperitoneal shunt. Cerebral angiogram later demonstrated an arteriovenous malformation that was successfully coiled by an interventional radiologist. The child made a slow but steady recovery after this completely unexpected and unpredictable neurological catastrophe.

CHAPTER 18
Postanesthesia Care Unit Management

Warwick Ames and Allison Kinder Ross
Duke University Medical Center, Durham, NC, USA

Introduction

The importance of the postoperative care unit in the safe, successful management of a child who has undergone anesthesia cannot be overstated. Centralization of care by a group of specially trained nurses who are expert in interpreting and responding to the events following anesthesia is key. This phase is beset with potential pitfalls and complications that require rapid assessment and treatment. Not only are there the basic needs that exist of a patient awakening from anesthesia, but in children there are additional unique aspects of postanesthesia care. Particularly in infants, perioperative anesthetic morbidity is higher than in other age groups, which further underscores the importance of the dedicated pediatric postanesthesia care unit (PACU) [1]. The Pediatric Perioperative Cardiac Arrest (POCA) registry supports the importance of proper management in the postoperative period [2]. The increased incidence of adverse events mandates care and consideration in the design and staffing of a pediatric PACU in addition to the essential appropriate postoperative management of potential issues and complications.

Essentials of the postanesthesia care unit

Design

When determining the design of a recovery area, the ideal location of any PACU is directly contiguous to the operating rooms to minimize transfer time and distance. There should be no elevator transport between the operating room and PACU if possible, although clearly many offsite procedure locations (such as magnetic resonance imaging (MRI) or interventional radiology) render this impractical [3].

The floor plan or design of a pediatric PACU need not differ from any other PACU environment. The entry from the OR and exit following recovery need to be different to avoid congestion [3]. Typically a PACU will have an open plan to permit optimum visibility, although this may not be ideal for all recovering children (Fig. 18.1). Not only can the audible distress of another patient be disruptive, but chatter and discourse of the medical staff have been noted as an unwanted feature of postoperative recovery [4]. The importance of lowering environmental stresses such as excessive noise is now being recognized in modern designs [4]. The presence of curtains between each bed space allows some visible privacy, but does nothing to change the noise pollution. Separate rooms would allow for a better sound barrier, but they may be undesirable as they do not allow for vigilant monitoring by a nurse who is covering several patients. Lines of sight are critical. Separate rooms may also be more difficult to navigate in an emergent scenario (Fig. 18.2). A possible compromise is to have rooms with sliding glass dividers and curtains between them that allow flexibility between rooms but the ability to separate the rooms as needed. With any plan, separate isolation rooms are needed, either for barrier purposes or reverse isolation. The number of beds required in the PACU should reflect the surgical volume, with a ratio of 1.5–2 beds to each operating room according to current perioperative environment design models [3].

Finally, there are many general features that are required by the Joint Commission on Accreditation of Healthcare Organizations, for example at least two fire exits, ample handwashing facilities, and separate clean and dirty storage areas, to name but a few. The average temperature in a pediatric PACU should be around 24°C (75° F), relative humidity between 40% and 60%, and in general there should be a slight positive pressure in the unit. Air changes should occur at a minimum rate of six per hour.

Equipment

The equipment in the pediatric PACU needs to have the ability to recover patients of all sizes. The American Academy of Pediatrics and the American Society of Anesthesiologists have

Gregory's Pediatric Anesthesia, Sixth Edition. Edited by Dean B. Andropoulos and George A. Gregory.

Figure 18.1 A modern pediatric PACU with open design, immediate adjacency to operating rooms, parents present, ample staffing with experienced pediatric PACU nurses, and prompt availability of anesthesia providers to respond to emergencies.

Figure 18.2 An alternative pediatric PACU providing more privacy and less noise pollution.

proposed guidelines for the pediatric perioperative anesthesia environment [5]. The essential components were identified to promote the safety and well-being of infants and children by reducing the risk for adverse events. In particular, all pediatric anesthesia equipment and drugs that are required in the operating room should be available for patients in the PACU. It is the authors' recommendation that a replica, fully stocked, mobile anesthesia cart be conveniently located in the PACU. Equally all bed slots should be identical, to facilitate safe delivery of care.

Every child admitted to the PACU must have his or her vital signs monitored, which mandates monitoring equipment that is appropriate for all ages and sizes. Suction apparatus and oxygen delivery, via a flow meter to allow titration of inspired oxygen as required, must be available at each bedside. Equipment for intravenous fluid administration must allow for microadjustments of volume delivery. Particularly

Figure 18.3 A standard emergency cart centrally located within the PACU with age-specific airway supplies and defibrillator on top.

in the smallest children, placing the intravenous fluids on a pump to deliver set volumes on arrival to the PACU is advisable. Due to the increased risk of heat loss in children in the operating room, devices for the maintenance of normothermia must be available and utilized.

The pediatric PACU should also have a focal, easily accessed location for the placement of portable emergency equipment. To prepare for the unexpected, a resuscitation or "code" cart with equipment appropriate for pediatric patients of all ages, including pediatric defibrillator paddles, must be immediately available. Specialized equipment for management of the difficult pediatric airway by a variety of techniques for airway control, intubation, and ventilation, including emergency cricothyrotomy, is desirable. A dedicated airway bag that contains packets of age/weight-specific airway supplies should be a part of the resuscitation cart apparatus (Fig. 18.3). To simplify procedure in the event of an emergency, written pediatric doses for resuscitation drugs, and potentially pediatric advanced life support (PALS) algorithms, should be visible or immediately available. All emergency equipment must be frequently checked and regularly maintained with a checklist system.

Staffing

Staffing of the pediatric PACU is an important component for the success of the environment. For most patients, recovery from anesthesia is uneventful, but it is also a time

when catastrophic events can occur. Pediatric-trained medical and nursing staff are required to be vigilant, caring, and knowledgeable. In 2016 the American Society of Anesthesiologists published updated recommendations specifically for a pediatric PACU [6]. This task force recommended that in order to apply specific expertise in the provision of pediatric anesthesia services, an anesthesiologist or other physician trained and experienced in pediatric perioperative care, including the management of postoperative complications and pediatric cardiopulmonary resuscitation, must be immediately available to evaluate and treat any child in distress.

The intensity of nursing care is typically greater in a pediatric PACU than on the pediatric ward with assignments based on acuity. The requirements of PACU nursing will be institution dependent. Prior pediatric experience and PALS training would clearly be advantageous and is recommended. Mock emergencies and codes, possibly to include scenarios using simulation, should be routinely performed with anesthesia and nursing staff so that the care is seamless in a true emergency. Although not stated by the task force, nursing staff should be pediatric trained and, ideally, have a background in pediatric intensive care. This would suggest confidence in the care of the unconscious child, ability to recognize a child in distress, ability to recognize a lost airway, and having expertise in the safe administration of potent analgesics. To recognize the subspecialty expertise, the pediatric PACU nurses are to be engaged as part of the perioperative team and be members of pediatric perioperative team meetings that include surgeons, anesthesiologists, and nursing staff. This builds a cohesive group for the good of the pediatric perioperative environment.

At our hospital, we have a twice daily debriefing between the PACU nursing staff and the on-call pediatric anesthesiologist. Issues such as staffing levels and resources (e.g. available intensive care beds), patient numbers, level of acuity, and post-PACU plans are discussed to prepare collectively for the work ahead.

Transport

Any hospital patient transport presents a period of significant risk of morbidity and mortality [7,8]. The transport of a child from the operating room to the PACU should not be considered routine. Apnea, loss of a patent airway, vomiting, and emergence agitation are just a few of the potential problems encountered during transfer. To be prepared for these events, it is advisable for the anesthesia provider to have resuscitation drugs and airway equipment that are individualized for the patient or surgery that was performed. Children should be transferred in on a bed or crib with guardrails. The lateral recovery position is often used because it facilitates a patent airway with gravity opening the airway and draining oral secretions and blood (Fig. 18.4). Oxygen must always be available along with a suitable delivery device such as nasal cannulae, facemask, or anesthesia circuit with mask. The use of a monitoring device such as pulse oximetry depends on the status of the patient and distance to the recovery area.

Figure 18.4 Lateral recovery position with airway open to encourage forward drainage of secretions. (Bed rail left down only for purpose of photo.)

KEY POINTS: DESIGN, EQUIPMENT, STAFFING, AND TRANSPORT

- Design of a pediatric PACU is similar to that for adults, but considerations for privacy and noise reduction have become evident in recent designs
- A pediatric PACU needs to have a full range of pediatric anesthesia equipment and drugs for children of all sizes, and an easily accessed location for emergency equipment
- Expertise in pediatric PACU nursing, and availability of an anesthesiologist, as well as formal training in pediatric resuscitation, is important for recovery of pediatric patients
- Transport to the PACU is a high-risk period, and continuous monitoring, either of clinical signs or pulse oximetry, and rapid availability of oxygen and positive pressure ventilation are important

Handover and assessment

The universal criteria by which patients are deemed suitable for the pediatric PACU are variable and depend on many factors including staffing and acuity. Some patients are easily considered candidates for PACU, including healthy outpatients for minor procedures, and others are clearly not suitable, such as the potentially hemodynamically unstable patient with cardiac disease. Other cases fall into a gray area that requires thoughtful consideration of the ultimate location for recovery. Skills and comfort level of the individual PACU and relationship with the floor or intensive care units may affect the decision of disposition post surgery. For example, following a repair of cleft palate, some centers will recover a patient in the PACU while other centers will prefer direct admission to the step-down or intensive care unit. Similarly, some PACUs may be comfortable with an intubated patient and the subsequent extubation procedure, while others may not [9,10]. Programs to increase efficiency in high-turnover otolaryngology operating rooms have been described in which tonsillectomy patients are transferred to the PACU intubated, and the trachea is extubated by a PACU nurse when the

patient is fully awake [11]. An anesthesiologist is immediately available for emergencies, and this approach has been reported to decrease operating room turnover time by 17 min, while not increasing PACU time or the incidence of airway complications. Important to the success and safety of such programs are appropriate patient selection, a well-defined protocol with thorough training, and adequate PACU nursing staffing. It is important, therefore, when determining admission parameters, that there be a clear understanding by the surgical and anesthesia personnel what location is suitable for the recovery of the individual child.

After the decision is made to admit to the PACU, it is important that there be good communication to the PACU from the operating room. Advance communication from the operating room at the very least should include a phone call as the case nears completion. The call alerts the PACU to the new admission and should include details regarding the age, weight, and stability of the patient, any intraoperative complications that would affect postoperative care, and any special needs. This initial call allows the nurses to target care, prepare medication, and reorganize staff assignments as necessary. Once the patient arrives, the admitting staff should perform an initial assessment prior to the handover from the anesthesia staff. This assessment must quickly determine airway patency, oxygen saturation, heart rate and rhythm, temperature, and blood pressure. If all is well, it is then possible to proceed to the medical handover.

With regard to the communication between the anesthesia provider and PACU nurse, and in every aspect of medicine, the handover of patient care is critical. Patient safety is vulnerable, especially when crossing professional boundaries. Not only is there a great gap between documented patient information and information transferred during handover but there is often misunderstanding that can occur simply due to differences in culture, training, norms, attitudes, perspectives, goals, expectations, status, gender, and socio-economic status [12]. Indeed, communication breakdowns are a leading cause of medical errors. In 2006, a Joint Commission of Hospital Accreditation (JCAHO) analysis found that 70% of sentinel events were caused by communication breakdowns, half of those occurring during handovers [13]. To address the problem, the Joint Commission instituted a National Patient Safety Goal in 2006, calling on hospitals to implement a standardized approach to patient handovers.

In order to improve the handover, it is important to recognize the process, a novel example of which was described at Great Ormond Street Children's Hospital in London [14]. The handover of patient and information from the operating room to the cardiac intensive care unit was reviewed by motor racing teams that likened the handover to a racing pitstop. Their recommendations and involvement resulted in standardized handovers, thereby eliminating variation, and resulting in clear and concise instructions to ensure that even if team personnel changes, all members are absolutely clear about their responsibilities. Communication was noted to be a critical factor in success. The same principles must be applied to the handover of a patient from the operating room to the PACU.

It has been advocated that training be instituted using interactive simulation-based sessions of standardized patients, clinicians, and manikin simulators with facilitated video debriefing to stimulate thought and reinforce positive behavior. Also the introduction of mnemonics is useful to ensure timely, accurate, and complete information about a patient's care plan, treatment, current condition, and any recent or anticipated changes. Examples of these techniques include the "Five P's" (patient name, problem list, plan of care, purpose of plan, precautions), as well as "I-SBARQ" and "I PASS the BATON," which are shown in Tables 18.1 and 18.2 [15]. The hope is that the use of any of these measures will facilitate a consistent process, thereby improving patient safety.

Table 18.1 I-SBARQ communication tool.

I	Introduction	• Identify yourself and the patient
S	Situation	• Patient age • Gender • Preop diagnosis • Procedure • Mental status preprocedure • Patient stable/unstable
B	Background	• Pertinent medical history • Allergies • Sensory impairment • Family location • Religion/culture • Interpreter required • Valuables deposition • Meds given • Blood given – units available • Skin integrity • Musculoskeletal restrictions • Tubes/drains/catheters • Dressings/cast/splints • Counts correct • Other – lab/path pending
A	Assessment	• Vitals • Isolation required • Skin • Risk factors • Issues I am concerned about
R	Recommendation/ request	• Specific care required immediately or soon • Priority areas • pain control • IV pump • family communication
Q	Questions	

Table 18.2 I PASS the BATON communication tool

I	Introduction	Introduce yourself
P	Patient	Name: identifiers, age, sex, location
A	Assessment	"The problem": procedure, etc.
S	Situation	Current status/circumstances, uncertainty, recent changes
S	Safety concerns	Critical lab values/reports; threats, pitfalls, and alerts
B	Background	Comorbidities, previous episodes, current meds, family
A	Actions	What are the actions to be taken and brief rationale
T	Timing	Level of urgency, explicit timing, prioritization of actions
O	Ownership	Who is responsible (person/team) including patient/family?
N	Next	What happens next? Anticipated changes? Contingencies?

Monitoring and patient safety

The American Society of Anesthesiologists has published Standards for Postanesthesia Care, most recently updated in 2014 [16]. These standards are minimum requirements, and specify only that, "The patient shall be observed and monitored by methods appropriate to the patient's medical condition. Particular attention should be given to monitoring oxygenation, ventilation, circulation, level of consciousness, and temperature. During recovery from all anesthetics, a quantitative method of assessing oxygenation, such as pulse oximetry, shall be employed in the initial phase of recovery." Pulse oximetry is certainly used universally in pediatric anesthesia during the early phases of recovery, but electrocardiographic (ECG) monitoring is not always used, with heart rate taken from the pulse oximeter or manual counting. An advantage of ECG monitoring is the ability to have a monitor of circulation when the pulse oximeter does not function due to patient movement or poor perfusion. Additional benefits are the ability to diagnose non-sinus rhythms and to measure respiratory rate using impedance plethysmography. In addition, although the utility of capnography via a nasal cannula in non-intubated patients undergoing procedural sedation is well established, newer data suggest it may also be useful in some patient populations in the PACU. Hypoventilation can be masked initially with supplemental oxygen, whereas capnography increases the detection of apnea both earlier and more consistently. This type of monitoring in pediatric patients, prone to apnea, could be more prevalent in the future [17,18].

Detailed nursing standards for postanesthesia care have also been published and are regularly updated [19]. Although the exact details of monitoring and assessment will be governed by regulatory agencies and local institutional policies and procedures, in general, a pediatric patient recovering from general anesthesia should have 1:1 nursing care for the initial recovery period, along with frequent vital signs, i.e. every 5–15 min during the early recovery phases.

Regardless of the policies and guidelines in place, there is no substitute for well-trained PACU nurses with expertise and experience in pediatric anesthesia who can recognize problems, institute treatment, and call for help from their anesthesia and nursing colleagues. The anesthesiologist also must be mindful of the setting, i.e. a busy children's hospital PACU with multiple anesthesiologists and nurses available to address patient problems, versus a freestanding surgical center with one or two operating rooms, PACU nurses with limited pediatric experience, and no readily available anesthesia providers for PACU problems because all are caring for patients in the operating rooms. The setting often determines the preferred treatment strategy, i.e. deep versus awake tracheal extubation, or the type or age of patient treated.

Parental presence

As previously stated, the primary goal of the pediatric PACU is to provide a safe environment for patients to return to their preanesthetic state. However, there is evidence that children may suffer negative behavioral changes following hospitalization for surgical procedures [20]. Although it is difficult to predict which child will do poorly, cohort studies have revealed that particular individual, familial, and procedural variables were able to identify the children at greatest risk of significant negative behavior change [21]. In particular, a factor that predicted negative behavior was increased parental anxiety. Other factors included younger age, overnight admission, lower birth order, and, surprisingly, having a discussion with the anesthetist preoperatively [21].

It would seem intuitive that separation from a parent may compound the child's stress due to hospitalization and procedures. For this reason, many parents request to be present as their child recovers from anesthesia [22,23]. The policy of allowing parents into the PACU, however, is uniquely institutional and varies both culturally and nationally. It is not universally adopted, in part because there is little evidence that having a parent present during recovery from anesthesia results in a positive outcome and, as previously mentioned, parental anxiety may be counterproductive. However, in a randomized prospective study from Canada, a benefit in healthy children undergoing outpatient surgery to parental presence in the PACU was a decrease in negative behavior change at 2 weeks postoperatively [24]. There was no difference in the acute distress (measured by "crying episodes") in the PACU between the group with a parent present versus the group where no parent was present. Despite these findings, parents may be successful with non-pharmacological measures to relieve pain and distress. These non-pharmacological methods, involving imagery, relaxation, breathing techniques, and massage, may make pain more tolerable and give children a sense of control without the administration of drugs [25]. A qualitative interview study of children and parents following tonsillectomy noted that children have their own coping strategies in mind. These included: (1) distraction such as watching TV, thinking of something else, talking, and reading; (2) relaxing, eating ice cream; and (3) simply having someone present [26].

The debate as to the value and appropriateness of parents in the PACU will continue. Most anesthesiologists have an anecdotal experience that colors their perspective on the matter. However the emergence from anesthesia is obviously a potentially stressful time for the child. The sensation of pain, nausea and vomiting, and waking in a strange and foreign environment are all contributors to this stress. The idealized benefit of a familiar and recognized caregiver is compelling although the actual evidence for such an advantage is poor. There are a significant number of studies on the effects of parental presence in the preoperative period and during induction of anesthesia, but the inclusion of the presence of parents in the postoperative period and the PACU environment remains in need of additional study.

KEY POINTS: HANDOVER/ASSESSMENT, MONITORING/PATIENT SAFETY, AND PARENTAL PRESENCE

- After initial assessment, a standardized handover process detailing important information is crucially important for PACU care
- More intensive PACU nursing staffing, i.e. often 1:1, is necessary during the early recovery phases. Pulse oximetry at a minimum is employed, with or without ECG, and blood pressure/temperature are also measured
- Parental presence in the PACU is practiced in many institutions and may reduce stress for many patients and families

Discharge criteria

Discharge criteria have been created to permit an objective evaluation of children leaving the recovery unit. The criteria will depend upon the patient age, surgery performed, and the subsequent destination (home versus floor versus intensive care). The two commonly used and cited scores in the literature are the modified Aldrete score for inpatient care [27] and the postanesthetic discharge scoring systems (PADSS) for patients being discharged home [28]. Both scores use a selection of physiological variables to form an objective measure for discharge eligibility (Tables 18.3 and 18.4). Whether the anesthesiologist must personally reassess the patient before discharge, or rely on a protocol with a physician order to discharge the patient when criteria are met, is governed by both regulatory agencies and local institutional policy and procedures.

The key components of scores like these include the following parameters: hemodynamic stability, respiratory sufficiency, neurological baseline, ability to maintain and protect the airway, absence of excessive bleeding, normothermia, minimal pain (patients should be observed for at least 30 min after the last dose of opioid), ability to ambulate if appropriate, and absence of excessive vomiting. The ability to drink clear liquids prior to discharge is not a discharge criterion, and forced ingestion of liquids is actually associated with a higher incidence of postoperative nausea and vomiting (PONV) [29].

Patient age is also a critical factor. Although actively debated, it is suggested that preterm infants should reach a minimum number of weeks postconceptual age (PCA) to be considered for outpatient surgery due to risks of postoperative apnea. Most institutions use conservative criteria close to 50 weeks' PCA or a very conservative 60 weeks, however 44 weeks can generally be considered the absolute minimum PCA for outpatient surgery based on when the true risk of apnea is considerable. Even in those infants who reach the minimum age criteria for discharge, an extended recovery time with observation during feeding and sleeping may be warranted [30]. Risk factors associated with apnea of prematurity are anemia, PCA, and gestational age. A separate entity known as apnea of infancy can occur in term infants but, because of its rarity, term infants are not subject to the same postoperative monitored care unless other factors warrant it [31]. It is recommended that term infants on the other hand should be a minimum of 4 weeks of age to be eligible for same-day discharge. Although the risk of apnea in a full-term infant is extremely low, case reports suggest that it is not zero [32–34].

In addition to overall discharge criteria from anesthesia, there are also procedure-specific issues that may affect the time to discharge. For example, a child who receives a spinal anesthetic should show signs of resolution of both sensory and motor blockade prior to discharge. Children undergoing adenotonsillectomy typically would stay in PACU for 2 h and show an ability to take fluids. In a study to determine the factors that may delay discharge in children undergoing tonsillectomies, it was found that PONV and oxygen desaturation were the two major factors contributing to prolonged length

Table 18.3 Modified Aldrete score. Nine or more points are required for recovery to be confirmed

Category	Score = 2	Score = 1	Score = 0
Respiration	Breathes, coughs freely	Dyspnea, shallow or limited breathing	Apnea
O_2 saturation	SpO_2 >92% in room air	Supplemental O_2 to maintain SpO_2 >92%	SpO_2 <92% with oxygen
Circulation	BP within 20 mmHg of preop	BP within 20–50 mmHg of preop	BP within 50 mmHg of preop
Consciousness	Awake and orientated	Wakes with stimulation	Non-responsive
Movement: voluntarily or on command	Four extremities	Two extremities	No extremities

Table 18.4 Post Anesthetic Discharge Scoring System (PADSS) discharge criteria table. At least nine points are required to be eligible for discharge

Category	Description of status	PADSS score
Vital signs	Within 20% range of preop	2
	Within 20–40% range of preop	1
	>40% range of preop	0
Ambulation	Steady gait/no dizziness	2
	Ambulates with assistance	1
	Not ambulating/dizziness	0
Nausea and vomiting	Minimal, treated with oral meds	2
	Moderate, treated with parenteral meds	1
	Continues after repeated treatments	0
Pain	Acceptable to patient	2
	Pain somewhat acceptable	1
	Pain not acceptable to patient	0
Surgical bleeding	Minimal: no dressing changes required	2
	Moderate bleeding: dressing change	1
	Severe bleeding: intervention required	0

of stay (LOS) [35]. The authors noted that the overall risk of prolonged LOS decreased with increasing age. Interestingly, LOS was not affected by the presence of an upper respiratory tract infection (URTI), leading the authors to suggest that patients with a URTI could be eligible for outpatient surgery.

Finally, handover of care for inpatients being discharged from the PACU to the floor or ICU needs to be as rigorous as with arrival. Full handover should include not only the intraoperative report but also the medications given and any PACU issues or special instructions. Prior to the final handover of the child to the accepting team, it should be confirmed that the intravenous infusions are placed on mechanized infusion pumps rather than free-flowing drips, a final examination of wound sites should be done, and an appropriate escort (nurse or doctor) who can give an accurate report to the accepting team needs to accompany the child for transport.

KEY POINTS: DISCHARGE CRITERIA

- The modified Aldrete score rates respiration, oxygen saturation, blood pressure, level of consciousness, and movement
- The Post Anesthetic Discharge Scoring System for outpatients rates vital signs, ambulation, nausea/vomiting, pain, and surgical bleeding for discharge home
- Age of the child and specific criteria for discharge according to the surgical procedure are important considerations

Potential postanesthesia problems and complications

Respiratory

Children are more likely to have airway-related problems than cardiovascular problems in the immediate postoperative period. Next to episodes of nausea and vomiting, the most frequent complications in the PACU are those that require airway support [36]. Maintenance of the airway following general anesthesia and sedation presents challenges due to the negative factors that occur during the perioperative period. Not only are the children still under the sedative influences of the anesthesia, but there are also risks of inadequate reversal of neuromuscular blockade, as well as diffusion hypoxia and the consequences of additional analgesic medications being administered in the PACU that can result in additional altered respiratory drive. The normal anatomy of a neonate or infant can render the airway vulnerable, and when side-effects of surgery are added, particularly surgery involving the airway, it is clear that a specialist's care and attention to detail may be required.

Although tracheal extubation occurs in the operating room in the vast majority of pediatric anesthesia programs and cases, the benefits and risks of extubation while deeply anesthetized versus "awake" continue to be debated [37]. A recent observational cohort study of 880 children 1–18 years of age undergoing tonsillectomy demonstrated no difference in airway complications between those whose trachea was extubated while deeply anesthetized (n = 577) versus those extubated awake (n = 303), with both groups experiencing a rate of about 18%, which included all minor and major complications [38].

The patient whose trachea has been extubated while deeply anesthetized will often be at increased risk of airway obstruction from airway muscle laxity, or emerging from anesthesia with increased risk for laryngospasm, during the early period after admission to PACU, and so extra vigilance is required in this situation. In a minority of pediatric anesthesia programs, the patient is taken to the PACU with the endotracheal tube in place, in order to increase operating room efficiency. The trachea is extubated on the physician's order by protocol so that the PACU nurse can perform the extubation when criteria are met [10].

Hypoxemia is not uncommon in the pediatric patient who is recovering from anesthesia and surgery. In addition to mechanical issues that involve the airway, there are other intrinsic pulmonary events that lead to hypoxemia. The combination of a higher oxygen consumption in the presence of a relatively reduced functional residual capacity and higher closing capacity puts the younger child at greater risk of oxygen desaturation. For all these reasons, postoperative patients should receive supplemental oxygen either by mask or by blow-by devices, and children are no exception. Children can be reluctant to accept any device to provide oxygen, but *purposeful* removal of the mask or blow-by device is often a good sign that it is no longer required. As oxygen is being delivered, the basics of airway support must still continue to be employed including ensuring the airway is patent, there are clear breath sounds on auscultation with good chest excursion, no signs of respiratory distress (stridor, nasal flaring), no wheezing, and a normal respiratory pattern devoid of apneic episodes. A child may be best managed by placing him or her in the lateral recovery position and employing jaw thrust and mouth opening when airway obstruction is evident. Compared to the supine position, the lateral position will increase total airway volume by 45% in children who have been sedated for MRI, with the greatest change seen in the region between the epiglottis and vocal cords [39]. One must remember that neonates are mostly obligate nasal breathers, and the occlusion of the nares with assorted tubing or with improper mask placement can lead to a compromised airway.

Residual neuromuscular blockade

Residual neuromuscular blockade has significant clinical implications for the patient in the PACU. These implications are due to changes in pharyngeal function with increased risk of aspiration, airway muscle weakness that can lead to obstruction, and attenuation of the hypoxic ventilatory response. In adults, there is evidence that up to 40% of patients exhibit a train of four ratio of <0.9 in the recovery area [40,41]. Although evidence would suggest that children have a more complete response to neuromuscular reversal and respond to lower doses of neostigmine significantly better than adults, the complications that can result from incomplete reversal can be devastating in a very young child [42,43]. When a child is admitted to the recovery area and exhibits the typical signs of incomplete reversal such as weakness, or floppiness with the "fish out of water" appearance, neuromuscular blockade must be considered a cause and treated promptly before

respiratory decompensation ensues. Administering additional neuromuscular blocking reversal is not necessarily the treatment of choice and should only be used if the maximum dose of neostigmine (0.07 mg/kg) has not already been administered as that dose should not be exceeded. Larger doses of neostigmine will lead to further muscular weakness and possible cholinergic crisis. Instead, care should be supportive, including reintubation if respiratory compromise is significant.

Residual neuromuscular blockade may become less of an issue with the advent of sugammadex, a novel agent that encapsulates rocuronium or vecuronium providing rapid and complete recovery even from profound neuromuscular blockade. At the time of writing, it has not received approval from the US Food and Drug Administration (FDA) in children but its successful anecdotal use is well reported [44]. Sugammadex as a rescue medication in the pediatric PACU seems intuitive.

Postextubation stridor or croup

One complication that is typically not seen until the PACU course is postextubation stridor (also known as postintubation croup). Forty years ago the incidence of postextubation croup after anesthesia was reported at 1.6–6% [45]. Although these data are old, there is little evidence that the incidence has changed despite trends toward the use of cuffed endotracheal tubes. An editorial on the subject outlined the changes that have occurred over the last several decades based on published literature, and how these changes have supported the use of cuffed endotracheal tubes in children [46]. It remains unclear what the overall outcome will be with changes in practice, and whether eventually there will be a significant difference in the incidence of stridor in the PACU based on preference of endotracheal tube. Postextubation stridor often may not need immediate treatment beyond humidified oxygen. However, if there are any signs of respiratory distress, nebulized racemic epinephrine (0.5 mL of 2.25% solution in 3 mL normal saline for children over 6 months of age, 0.25 mL if less than 6 months) provides a rapid response. The mechanism of action of racemic epinephrine is through its stimulation of α receptors resulting in vasoconstriction and secondary reduction in mucosal and submucosal edema. Due to the rebound effect of racemic epinephrine that may occur up until 2 h after administration, the child must remain in the PACU or in a monitored setting until this risk is no longer present, as readministration may be necessary. Although it may take at least an hour to see results, a single dose of dexamethasone (0.15–0.6 mg/kg) can be administered for reduction of airway edema, and the duration significantly outlasts racemic epinephrine with a half-life of over 30 h [47–49]. Despite the long half-life, dexamethasone dosing should be repeated every 6–12 h until resolution. In cases of significant respiratory distress, the child should be admitted to a monitored setting where heliox (60–80% helium:20–40% oxygen mixture) can be delivered [50]. Although heliox has no anti-inflammatory or bronchodilatory properties, its low density allows improved oxygen delivery and carbon dioxide elimination. In extreme cases, reintubation with an endotracheal tube at least 0.5–1 mm smaller than the original tube may be needed.

Laryngospasm

Laryngospasm, an event typically associated with intraoperative care, remains a potential complication in the PACU. Neonates and infants are at greatest risk, with the relative risk decreasing by 11% for each yearly increase in age [51]. Laryngospasm may occur due to irritation of the vocal cords, commonly from either saliva or blood, or simply from the child still being at risk while emerging from anesthesia with Stage II being exhibited. Laryngospasm is the forceful closure of the vocal cords, resulting in total obstruction of the airway, and if untreated can be catastrophic. The first step must be the administration of oxygen by positive pressure mask with jaw thrust. In addition to simple jaw thrust, pressure applied to the "laryngospasm notch," located behind the lobule of the pinna of each ear, is anecdotally effective [52]. If the patient exhibits full airway obstruction without evidence of air movement, or if significant desaturations or bradycardia occur, succinylcholine is to be administered (or another rapid-acting muscle relaxant if succinylcholine is contraindicated). When laryngospasm occurs in the PACU, intubation is typically not necessary, and all that is needed for relaxation of the vocal cords is a small dose of intravenous succinylcholine (0.1–0.5 mg/kg). Small doses of propofol have also been reported for the treatment of laryngospasm in children [53]. The child will require bag/mask ventilation until good spontaneous respirations are restored. Atropine should be available in the event that either the succinylcholine or episode of hypoxia during the laryngospasm causes bradycardia.

Apnea

Although apnea may occur for many reasons in the PACU, apnea in the ex-premature infant requires careful consideration during the preoperative work-up to guarantee that the appropriate postoperative destination is secured. With increasing survival of prematurely born infants, an increasing number of these patients appear on the operating schedule and so require care in the PACU. Typically, if the child is still in the intensive care nursery, then postoperative care will continue on the neonatal intensive care unit. However, if the child is on the ward or is an outpatient, individual consideration for the unique pathophysiology of a premature infant must be given to determine the postoperative disposition and level of monitoring. Apnea is defined as cessation of airflow for more than 20 s, or the cessation of breathing for less than 20 s if it is accompanied by bradycardia or oxygen (O_2) desaturation [54]. The frequency is inversely related to gestational age and the actual cause of apnea of prematurity is unknown, although it is likely multifactorial [55]. Depression or immaturity of the respiratory central generator located in the brainstem is most likely, in addition to vulnerability to inhibitory influences such as hypoxia and temperature changes [56].

Beyond considerations that exist for infants with apnea of prematurity, the presence of obstructive sleep apnea (OSA) in any child presents a significant risk in the postoperative period and is responsible for considerable morbidity with a complication rate of up to 27% [57]. In fact, in 60% of children with severe OSA, nursing intervention in the postoperative period was required to treat complications that included desaturation to SpO_2 <90% [58]. The children also demonstrated signs of increased work of breathing and/or new radiographic findings of pulmonary

edema, effusion, infiltrate, pneumothorax, or pneumomediastinum. Because of the potential complications that exist in this population, the American Society of Anesthesiologists in 2006 published practice guidelines for perioperative management that suggested that children with a history of OSA having adenotonsillectomy should be admitted for overnight stay if they are less than 3 years of age or if they have contributing medical conditions such as obesity [59]. If an otherwise well child greater than 3 years of age has mild to moderate OSA with an apnea–hypopnea index <10, same-day discharge may be considered. If the decision is made to discharge the child the same day as the procedure, it is best if the case is performed earlier in the day and the child discharged after a minimum PACU stay of 2 h [60].

Due to the chronic hypoxemia exhibited by children with OSA and its effects on respiratory drive, it is important to be cautious when ordering pain medication postoperatively. Children with a history of OSA have a higher incidence of apnea after administration of a typical 0.5 μg/kg dose of fentanyl when compared to children without OSA [61]. As a reference, children with sleep apnea who demonstrated an oxygen saturation <85% on polysomnography required only half the morphine dose to have the same analgesic effect as a child who did not have the same degree of desaturation [62].

When an infant or child is showing signs of OSA in the PACU, immediate maneuvers to stimulate the patient and open the airway are to be performed. These maneuvers include repositioning with a shoulder roll or to lateral position, performance of jaw thrust or insertion of a nasal or oral airway, and occasionally the administration of positive pressure by mask. If these measures are unsuccessful, the child may require intubation until he or she is fully recovered and able to maintain their own airway. In addition, the child who requires nasal continuous positive airway pressure (nCPAP) or bi-level positive airway pressure (BiPAP) by mask at home during sleep may benefit from its application in the PACU.

Pulmonary edema

Pulmonary edema is rarely seen in children, but must be considered as a cause in the postoperative differential diagnosis of hypoxemia with desaturations in the PACU [63]. Causes of pulmonary edema may be related simply to the delivery of a large volume of fluid or blood products in the operating room with or without significant fluid shifts, or to negative pressure (NPPE). The clinical presentation is the same between these, but history will help delineate the cause. A history of forceful respirations against a closed airway such as laryngospasm, biting on the endotracheal tube, or even long-standing history of upper airway obstruction from enlarged tonsils or epiglottis that has now been relieved with surgery, can lead to NPPE. The pathogenesis of NPPE from negative intrathoracic pressure causes decreased pulmonary capillary perivascular pressure, favoring hydrostatic transudation of fluid into the interstitial tissue. Although normal pleural inspiratory pressures are -2 to -5 cmH_2O, negative pressures from -50 to -100 cmH_2O are possible, particularly in young muscular males. After the obstruction is relieved, there is a sudden increase in venous return and a redistribution of blood volume from peripheral to central circulation with a resulting increase in pulmonary hydrostatic pressure that is compounded by capillary leak [64]. In any of these scenarios, if significant pulmonary edema is present, the child will exhibit lower pulse oximetry readings, tachycardia, and tachypnea. Rales will be heard on chest auscultation and occasionally the child may exhibit pink frothy sputum. If the child is otherwise stable and saturations are kept within normal range with supplemental oxygen, this is all that may be required. However, depending on the degree of pulmonary edema and respiratory distress, intubation with delivery of positive end-expiratory pressure (PEEP) may be necessary along with diuresis (furosemide 0.1 mg/kg with a maximum of 5 mg) to assist with the shift of fluid out of the lungs. In the case of negative pressure pulmonary edema, the use of PEEP is supported, but whether the delivery of diuretics is of benefit remains unclear [65].

Pulmonary aspiration

The risk of pulmonary aspiration in the perioperative period in children is low at approximately 0.1%, but it is not negligible and is at least two times higher than the risk in adults [66]. Particularly after airway surgery, the increased amount of secretions and blood puts a child at risk for aspirating these fluids during recovery from the sedative effects of anesthesia or pain medications. If aspiration is suspected, examination of the lungs and a chest radiograph may help determine the diagnosis if significant rhonchi or coarse breath sounds are heard unilaterally, particularly on the right side. Treatment is supportive as sequelae are typically mild, although incidence and severity may correlate with the underlying medical condition of the child [66]. Pharmacological intervention with steroids or antibiotics for presumed aspiration is unwarranted.

Pneumothorax

Another cause of hypoxemia in the PACU is pneumothorax. Many surgical procedures such as central line placement, ventriculoperitoneal shunts, and any thoracic procedure put the child at risk for intraoperative pneumothorax that may not exhibit until the postoperative period. A thorough examination and chest radiograph will help determine the diagnosis. In the event that the pneumothorax is significant and causing respiratory compromise, a chest tube will need to be inserted and the child sent to the appropriate postoperative setting. Lesser degrees of pneumothorax may be treated with 100% oxygen by non-rebreathing facemask to hasten resolution by displacing nitrogen and allowing for faster resorption of the pneumothorax.

KEY POINTS: RESPIRATORY COMPLICATIONS

- Hypoxemia must be rapidly investigated and treated; supplemental oxygen by blow-by device or facemask is important in early recovery for prevention
- Postextubation stridor or croup is treated with humidified oxygen if mild; if it is severe, dexamethasone, racemic epinephrine, and longer PACU observation or admission are indicated
- Laryngospasm is treated with positive pressure and jaw thrust; if it does not resolve quickly, low-dose succinylcholine, or propofol, is indicated
- Apnea in former premature infants up to 50–60 weeks' postconceptional age requires vigilance, often a longer PACU stay, and inpatient admission for monitoring in patients with significant risk factors

Cardiovascular

Although respiratory complications far outweigh hemodynamic issues in the typical recovering pediatric patient, children can decompensate rapidly and cardiovascular depression is a late and ominous sign. In an analysis of the American Heart Association Get With The Guidelines–Resuscitation registry, a higher mortality was noted following cardiac/hemodynamic causes of cardiopulmonary arrest. Non-survival was also associated with older age, weekends, non-pediatric environments, and at night [67].

Hypotension

Hypotension in the PACU, particularly in the presence of tachycardia, narrow pulse pressure, poor capillary refill (>3 s), and low urine output (<0.5 mL/kg/h), is typically the result of hypovolemia. Depending on the nature of the procedure, the cause of the hypovolemia needs to be quickly determined in order to decide whether to administer fluid or blood products. Attention to any blood accumulation in surgical drains allows for a rapid assessment. Isotonic crystalloid fluid boluses (normal saline, lactated Ringer's solution, or Plasmalyte®) should be administered in 5–10 mL/kg increments depending on the degree of hypotension and ongoing losses with critical assessment of changes in blood pressure and heart rate in response to the fluid challenge. If there is any question as to the nature of the hypotension, blood should be drawn to check for acid–base status and base deficit as well as hemoglobin and/or hematocrit. If replacing blood loss, 10–15 mL/kg of packed red blood cells will raise the hemoglobin by 2–3 g/dL if no ongoing blood loss is occurring.

Other causes of hypotension that would be extremely uncommon in the PACU would be anaphylaxis from either latex exposure or delivery of postoperative drug, early signs of perioperative sepsis, or mechanical reasons such as pneumothorax or pericardial tamponade. Sympathetic block from central neuraxial anesthesia typically does not exist in a child below the age of 5 years due to lack of significant peripheral vasodilation or venous pooling, and rarely would cause hypotension in a child older than 5 years with the typical low concentrations of local anesthetic that are used for postoperative infusions.

Hypertension

The presentation of hypertension in the postoperative period is typically the consequence of pain and is therefore usually associated with tachycardia and other outward signs of discomfort. If pain is suspected, appropriate treatment is necessary to alleviate the physiological responses in a rapid, safe manner. If not due to pain, the most common cause of hypertension may actually be the result of inaccurate readings due to a small blood pressure cuff, so this cause must be ruled out early. Hypertension is rarely due to volume overload but some children are more susceptible than others to excessive intraoperative volume resuscitation, so the possibility does exist. Hypertension may also be the result of emergence agitation or bladder distension; in patients with renal failure, rebound hypertension can occur because they have not taken their regular antihypertensive agent due to nil per os (NPO) status issues. In a child with moderate to severe hypertension in the PACU that is not attributable to pain, treatment may consist of intravenous agents such as hydralazine (0.25–0.5 mg/kg), labetalol (0.2 mg/kg), nitroprusside infusion (1–10 μg/kg/min), or nicardipine infusion (0.5–5 μg/kg/min). Clevidipine is a short-acting, intravenous calcium channel blocker that has been studied for the treatment of hypertension during the emergence from anesthesia in children. Its use in the PACU has not been reported [68]. Close hemodynamic monitoring needs to occur if any of these agents is being delivered.

Tachycardia

Tachycardia is very non-specific in the PACU. As previously mentioned, when accompanied by hypotension, the combination suggests hypovolemia that needs to be promptly managed. Tachycardia and hypertension together suggest pain, anxiety, or both. Tachycardia can also be secondary to administered drugs in the operating room such as atropine or glycopyrrolate; when no other factors are present, these causes should be considered and no further treatment is necessary. Rarely tachycardia may be due to an underlying conduction abnormality, particularly in a child with a history of cardiac disease, and these children will require a cardiology consult and/or admission to the ward to determine the significance. If an arrhythmia, i.e. supraventricular tachycardia, is suspected, it is crucial to record the abnormal rhythm, either by printout or electronically with as many leads as possible, and to record a standard 12-lead ECG, so that the consultant physicians will have adequate information.

Bradycardia

Bradycardia is often a more ominous sign than tachycardia and is often consequent to hypoxia. Indeed, the heart rate of a preterm infant will begin to fall within 30 s of onset of apnea [69]. Therefore attention should be directed toward airway management and ensuring adequate oxygenation in the face of sudden, unexpected bradycardia. Having corrected hypoxia as a cause of bradycardia, other causes such as increased intracranial pressure or simple vagal response to airway maneuvers can be entertained. If bradycardia persists and is accompanied by low cardiac output or hypotension, atropine (0.02 mg/kg) should be administered. If this is unsuccessful and the patient remains in a low-output state, resuscitation efforts should then proceed with intravenous epinephrine and standard CPR per PALS protocol.

Other than tachy- or bradyarrhythmias, arrhythmias are extremely rare in the PACU. With the reduction in the use of arrhythmogenic inhalational agents such as halothane, nodal or junctional arrhythmias are less frequent, although these may be seen when higher doses of dexmedetomidine have been administered. However, a greater number of patients with congenital heart disease are surviving and requiring surgeries unrelated to the heart. These patients may have underlying defects in their conduction pathways that may become obvious in the PACU. A rhythm strip should be run in any child who has an unexpected change in heart rate to help determine any cardiac etiologies, and a cardiologist should be consulted prior to discharge from the PACU if concern remains about significant cardiac pathology as a cause of the arrhythmia. Additionally, any hemodynamically significant arrhythmia requires basic resuscitation protocol.

KEY POINTS: CARDIOVASCULAR COMPLICATIONS

- Children can decompensate rapidly, and resuscitation training and practice is important for the rare serious PACU emergency
- Hypotension is uncommon and hypovolemia is the most common cause
- Hypertension from pain and emergence agitation is common
- Tachycardia is often non-specific and results from pain, agitation, hyperthermia, and medications
- Bradycardia can be drug induced (dexmedetomidine, neostigmine) or more rarely an ominous sign of hypoxemia or cardiovascular depression that must be emergently addressed

Hypothermia and hyperthermia

Hypothermia is defined as a core temperature of less than 36°C [70]. It is well documented that children lose heat more readily than adults, and anesthesia can further disrupt the patient's ability to thermoregulate [71]. Neonates and infants are at particular risk of developing hypothermia even during transport from the operating room to the PACU. A working group established by the American Society of Anesthesiologists (ASA)/Physician Consortium for Performance Improvement noted that anesthetic-induced impairment of thermoregulatory control is the primary cause of perioperative hypothermia [72]. Even mild hypothermia (1–2°C below normal) has been associated in randomized trials with a number of adverse consequences including increased susceptibility to infection, impaired coagulation and increased transfusion requirements, cardiovascular stress and cardiac complications, and postanesthetic shivering and thermal discomfort [73]. In addition, neonates are at risk of apnea and bradycardia when hypothermic. Beyond the physiological issues, hypothermia also has an impact on efficiency of a PACU and is associated with an increased length of stay, which has logistical and financial implications for a successful surgical unit [73].

It is therefore not surprising that perioperative temperature management is one of the five quality incentives established by the ASA as Pay-for-Performance and Anesthesiology Quality Incentive [72]. The goal is to have measured at least one body temperature that is equal to or greater than 36°C (96.8°F) within the 30 min immediately before, or the 30 min immediately after anesthesia end time, with some exceptions.

Temperature is to be measured as part of the initial assessment upon a child's arrival in the PACU. Measurements from different sites may not correlate particularly well because of compensatory mechanisms such as vasoconstriction that can change the relationship between the central and peripheral temperature. Core temperature must be estimated from peripheral sites and taken rectally, axillary, orally, or via tympanic membrane. All of these sites have issues related to reliability, accuracy, and flaws in measurement technique. Axillary temperatures in neonates and infants do correlate well with rectal temperature and thus remain the preferred method in many PACUs [74,75].

Acknowledging the importance of avoiding hypothermia has led to the practice of prewarming patients in the operating room [76,77]. When this has not occurred and the patient arrives hypothermic to the PACU, a number of measures are often employed. Simple and standard measures such as fluid warmers, warm blankets, and infrared heat lamps are first line but may not be completely effective in treating hypothermia [78]. Only active warming devices such as convection or forced-air warming devices have consistently been proven effective at treating hypothermia and are therefore recommended by the ASA for these circumstances [79].

Hyperthermia in the PACU is a very different entity. The typical cause of hyperthermia would be aggressive warming in the operating room. Although extremely rare, one must still have a high index of suspicion for a late presentation of malignant hyperthermia (MH) in a hyperthermic child, particularly if any other associated signs are present such as muscle rigidity, hyperventilation, and tachycardia. Aggressive diagnosis and treatment should then ensue if a true case is suspected.

A more common concern would be how to recover the patient who may be MH susceptible but who has received a non-triggering anesthetic. Despite the seriousness of an episode of MH, it is reasonable for a patient who is at risk for MH to be admitted to the PACU and still be able to be discharged the same day as the procedure when they have not been exposed to potent inhaled anesthetics or succinylcholine [80]. In fact, there is no advantage to keeping a patient who is MH susceptible in the PACU for a prolonged period of time if there are no other complicating factors [81]. Based on a review of over 250 MH susceptible patients, and per the Malignant Hyperthermia Association of the United States (MHAUS) website, a 1 h stay in the primary PACU with an additional 1–1.5 h in a step-down PACU, if indicated, is recommended [82].

KEY POINTS: HYPOTHERMIA AND HYPERTHERMIA

- Infants and young children are at significant risk for hypothermia in the PACU
- Even mild hypothermia (below 36°C) can have adverse consequences such as delayed emergence, apnea, and longer PACU stay
- Active warming measures such as a forced-air warming system are necessary for significant PACU hypothermia
- Hyperthermia is normally the result of aggressive operating room warming, but the remote possibility of malignant hyperthermia should be considered in some patients

Emergence agitation or delirium

It is not uncommon for children to emerge from anesthesia disoriented and frightened, resulting in negative behavior of restlessness, anxiety, and inconsolability. As part of the assessment of this behavior, careful consideration of an organic cause must be made. For example, hypoxemia, hypercarbia, hypotension, hypoglycemia, raised intracranial pressure, or untreated pain should all be ruled out. Only after this has

occurred can the phenomenon of emergence delirium (ED), also referred to as emergence agitation (EA), be considered.

In the modern era of the pediatric PACU, the issue of ED has become a popular topic of discussion. For example, a well-referenced analysis of perioperative morbidity published in 2004 failed to include ED as an adverse event as it seemingly was not considered a major issue at that time [1]. Defined as "a disturbance in a child's awareness of and attention to his/her environment with disorientation and perceptual alterations including hypersensitivity to stimuli and hyperactive motor behavior in the immediate post anesthesia period," ED can be stressful for the child, parents, and caretakers [83].

There is a range of behavioral responses following anesthesia, from crying uncontrollably after emergence for more than 3 min (mild), to uncontrollable behavior requiring physical restraint for more than 3 min (major) [83]. With such a range of presentation, it is difficult to describe the precise incidence of ED as it may be as high as 80% depending on how it is defined. The spectrum of clinical presentation has therefore led to the creation of behavioral scales such as the Pediatric Anesthesia Emergence Delirium (PAED) scale (Table 18.5). When tested in 50 children for validity, the PAED scale revealed consistency and reliability [84].

The issue of EA/ED was not truly evident until the practice of using sevoflurane instead of halothane started. The suspicion that sevoflurane resulted in more frequent episodes of ED was reviewed in a meta-analysis that confirmed sevoflurane was associated with a consistently higher incidence of agitation when compared to halothane [85]. In fact, ED is associated with both of the newer inhalational agents, desflurane and sevoflurane [85,86]. Because desflurane and sevoflurane have a greater incidence of ED compared to isoflurane or halothane, this results in the conundrum of the supposed benefit of shorter-acting agents in promoting a quicker recovery and shorter discharge times possibly being negated by the increased incidence of ED from a rapid emergence. This concern was demonstrated to be valid in a study comparing recovery and discharge criteria between halothane and sevoflurane in children undergoing myringotomy tube placement. EA was significantly higher in the sevoflurane group versus the halothane group (57% versus 27%, respectively), and discharge times were similarly prolonged with the sevoflurane group [87].

It is easy to assume then that the speed of wakefulness is directly proportional to the likelihood of ED occurring. A recent study demonstrated that the odds of ED fell by 7% for every minute the child remained asleep following general anesthesia [88]. However, it is simply not the fact that rapid emergence is responsible for ED. Delaying emergence by gradually decreasing the inhaled agent has no effect on the incidence of ED [89], and comparative anesthetics that offer quick emergence such as propofol still demonstrate that inhaled agents are associated with a greater incidence of ED [90]. This was shown in a randomized crossover study in which propofol was noted to have a zero prevalence of ED compared to sevoflurane as a maintenance agent [91]. The propofol group did have a longer recovery stay, but parental satisfaction was higher in the propofol group than in the sevoflurane group.

In order to prevent EA/ED, it is important to know the factors that predict its occurrence. First, ED may be associated with the type of surgery. An increased incidence is found after otorhinolaryngological and ophthalmological surgeries, at 26% and 28% respectively, when compared to other types of procedures [92]. In addition, there are patient factors that predict postoperative ED, such as age <5 years, increased preoperative anxiety, and a temperament that is more emotional, more impulsive, less social, and less adaptable [20]. Clearly these factors cannot necessarily be controlled preoperatively. There are also anesthesia factors, over and above what agent is used to induce and maintain anesthesia. For example, the smoothness of the induction is a predictor of emergence. Weldon et al studied 80 children <6 years of age receiving either sevoflurane or halothane [93]. All the children were premedicated with midazolam and received caudal regional anesthesia after their inhaled induction so that postoperative pain would not be a factor in their EA. Although the study was designed to compare the inhaled agents, and showed that children who received sevoflurane had a significantly higher incidence of EA than halothane at arrival to PACU (26% versus 6%), it also showed that the incidence of EA was higher in the children who had increased anxiety preoperatively per the Yale Preoperative Anxiety Scale [20,94]. In addition to an increased incidence of agitation on admission and more episodes of severe agitation, these same children also had a greater incidence of difficult mask inductions.

Early thoughts as to the cause of EA/ED included the presence of pain. Although pain may be a contributing factor to an unsatisfactory emergence period, it has not been shown to be the cause of ED. In fact, ED has been shown to have a similar incidence after non-painful procedures such as MRI [87]. In children who have undergone sevoflurane anesthesia without surgical intervention, a small dose of fentanyl (1 μg/kg) 10 min prior to emergence reduced EA from 56% to 12% with no increase in time to discharge [94]. Studies using caudal block in order to take the pain issue out of the equation of postoperative ED have shown inconsistent results as to the effectiveness of regional anesthesia in addition to sevoflurane for avoidance of EA [95].

In addition to avoiding the agents that are commonly associated with ED, such as sevoflurane and desflurane, other

Table 18.5 Pediatric Anesthesia Emergence Delirium (PAED) scale

Child makes eye contact	Not at all	Just a little	Quite a bit	Very much	Extremely
Child's actions are purposeful	Not at all	Just a little	Quite a bit	Very much	Extremely
Child is aware of surroundings	Not at all	Just a little	Quite a bit	Very much	Extremely
Child is restless	Extremely	Very much	Quite a bit	Just a little	Not at all
Child is inconsolable	Extremely	Very much	Quite a bit	Just a little	Not at all

agents have been studied to determine if using them prophylactically will reduce the incidence of ED. In a meta-analysis, midazolam and 5-hydroxytryptamine-3 receptor (5-HT3) inhibitors such as ondansetron were not found to have a protective effect against ED. Adjuncts to inhalational anesthesia such as ketamine, gabapentin, and fentanyl have been shown to be effective [96]. Transition to propofol towards the conclusion of a sevoflurane anesthetic reduces the incidence of ED and improves quality of emergence [97]. In a survey of practice amongst Canadian anesthesiologists, propofol was the most commonly used adjunct to both prevent and manage ED [98]. In the same study, α_2-adrenoceptor agonists were seldom used despite the increasing evidence of their efficacy.

The α_2-adrenoceptor agonists are an emerging group of drugs used in the management of postoperative agitation. Clonidine causes sedation, analgesia, and reduction in sympathetic tone and can be administered via many routes. An intravenous dose of 2 μg/kg after anesthetic induction has been demonstrated to significantly reduce the incidence and severity of EA in boys undergoing circumcision with penile blocks under sevoflurane anesthesia [99]. This efficacy in the management of ED with clonidine has not been consistent at a dose of 1.5 μg/kg when compared to the more efficacious tropisetron [100]. Dexmedetomidine, another α_2 agonist, has both prophylactic and treatment potential for ED. When dexmedetomidine was used as a single bolus dose immediately after inhalation induction, the incidence of EA in children who received sevoflurane with caudal block was significantly lower in a dose-dependent manner. The incidence of agitation in the group who did not receive dexmedetomidine was 37%, whereas the group receiving 0.15 μg/kg had an incidence of EA of 17%, and a group who received 0.3 μg/kg had an incidence of 10% with no differences in time to discharge. Alternatively, infusion of dexmedetomidine at a rate of 0.2 μg/kg/h after induction and continuing 15 min into PACU is effective in reducing the incidence of ED [101,102]. The incidence of EA in the children who received dexmedetomidine infusion was 26% compared to 60.8% in the sevoflurane group with no differences in time to extubation or discharge from PACU.

In addition to the expected preventative measures and agents, melatonin, a hormone secreted by the pineal gland, when administered preoperatively has been demonstrated to be efficacious in the management of ED in a dose-dependent manner of up to 0.4 mg/kg (maximum 20 mg) when compared to midazolam [103]. Although doses of melatonin at 0.05 mg/kg and 0.2 mg/kg decreased ED, a dose of 0.4 mg/kg was the most efficacious and reduced the incidence of ED to 5.4%.

Beyond pharmacological intervention, parental presence has been evaluated in terms of its effect on ED. Although there was no measurable improvement in the incidence or duration of ED, the parents themselves had greater satisfaction with being present during the recovery phase [104].

EA continues to be addressed, and additional work needs to be done to determine not only how to prevent its occurrence, but also to improve the process by which it is diagnosed and treated when it does occur. A recently published algorithm for reducing the risk of ED in pediatric patients is shown in Figure 18.5 [97]. These goals are necessary in order to make an otherwise uneventful perioperative course more pleasant for the child, family, and providers.

KEY POINTS: EMERGENCE AGITATION OR DELIRIUM

- Emergence agitation is brief and self-limited; emergence delirium is longer-lasting and associated with lack of eye contact and purposeful movement, lack of awareness of surroundings, restlessness, and inconsolability
- Emergence delirium is associated with sevoflurane, young children (1–5 years), ear, nose, and throat (ENT) or eye surgery, and anxious patient/parent temperament
- Propofol, opioids, dexmedetomidine, and regional anesthesia with less sevoflurane are effective strategies

Seizures and myoclonus

Postoperative seizures are an uncommon event in the PACU but can be indicative of a more serious underlying problem. Regardless of the etiology of the seizure, supportive measures should be immediate and include the delivery of oxygen with airway maintenance and special efforts to avoid self-harm in the child. Depending on the severity and duration of the seizure, oxygen may be delivered by facemask or positive pressure ventilation, or require endotracheal intubation. A physician should be in attendance and determine the need for immediate pharmacological intervention, also depending on the severity or duration of the epileptic activity.

Postoperative seizures have numerous causes with significant consequences. Hypoxemia may be rapidly ruled in or out and treated as necessary with appropriate oxygenation and ventilation. If this is clearly not the cause, stat laboratories to rule out hypoglycemia and other electrolyte disturbances such as hyponatremia and hypocalcemia must be sent, then rapidly interpreted and treated. A rare but potentially fatal cause of postoperative seizures is local anesthetic toxicity and the seizures may actually be a prelude to cardiovascular collapse. A thorough history of local anesthetic delivery should be assessed, including last dose and total dosing, if there is any suspicion of local anesthetic toxicity. If this is determined to be the cause, in addition to supportive measures, intravenous lipid emulsion should be delivered if cardiovascular arrest ensues [105]. PACU providers should be made aware of this possibility and be informed as to the location and delivery of lipid emulsion. See Chapters 10 and 20 for further discussion of this problem.

Beyond seizure activity, myoclonus may be observed in the PACU. Myoclonus is defined as the involuntary contraction of a muscle or muscle group and is caused by a variety of factors including some anesthetic agents such as etomidate, or occurs as a prodrome to seizure activity. After other causes of myoclonus are ruled out, the possibility of central anticholinergic syndrome (CAS) should be entertained. CAS is secondary to the central antagonism of muscarinic cholinergic receptors and may be caused by medications that cross the blood–brain barrier such as atropine or scopolamine [106]. The symptoms vary from agitation to actual coma, with myoclonus as a presenting sign. Slow delivery of physostigmine (10–30 μg/kg with a maximum of 3 mg) is the treatment of choice.

Pain

Pain management does not begin in the PACU, but needs to be a consideration for the entire perioperative period, and is the responsibility of every anesthesiologist. In the PACU, the recognition of postoperative pain becomes the duty of a recovery nurse as intraoperative analgesic medications wear off and the pain becomes more intense as the patient recovers. Although a complete discussion of pain is beyond the scope of this chapter and is presented elsewhere in this book (see Chapter 37), in the PACU environment it is important to consider how to assess the pain, what analgesics are appropriate, and what potential pitfalls and complications exist.

The assessment of pain in children remains a challenge, in part because of the diversity of age range. No single assessment tool or score can possibly be applied equally to the newborn and the adolescent. Although of little benefit to children who are pre- and non-verbal, developmentally delayed, or cognitively impaired, self-reporting is probably the most important single reliable indicator of pain. Children as young as 3 years of age can reliably score their own pain [107], provided that they are trained to use the chosen score prior to surgery. There are many validated pain intensity scales including visual analogs, faces scales, and numeric ratings, which are presented elsewhere. The Oucher score utilizes photographs of a child's face exhibiting varying expressions of pain intensity alongside a numerical rating scale and allows the young child to self-report. Different ethnic versions are available and it has been validated in the 3- to 12-year-old age group, specifically in the PACU setting [108] (Fig. 18.6).

In those children unable to provide a self-report (age 3 years or less, or developmentally delayed), behavioral observational scales assist the caregiver in determining a level or degree of pain. The Children's Hospital of Eastern Ontario Pain Scale (CHEOPS) [109], the face, leg, activity, cry, consolability scale (FLACC) [110] (Table 18.6), and the Preverbal, Early Verbal Pediatric Pain Scale (PEVPPS) [111] are all valuable tools but limited in that behavior varies significantly between individuals. These scales are not perfect as a paucity of abnormal behavior does not mean an absence of pain, and negative behavior does not necessarily indicate pain.

Finally, physiological signs such as tachycardia, tachypnea, and hypertension can be used as indicators of pain but are the least sensitive and least specific markers [112]. Particularly in a child, these physiological signs can be present due to other stresses including anxiety or fearfulness, and need to be combined with other evidence that suggests pain as a cause. With all the different types of scales available, each institution needs to determine the ones that work best for their environment for the different age groups and keep them consistent for reliability across providers.

In the clinical setting, proving the existence of pain through a validated pain score is less important than actually understanding the potential degree of pain with knowledge of the surgery and actively managing symptoms and signs of distress. The PACU nursing staff have many pain management strategies available to them, both

Figure 18.6 OUCHER pediatric pain scale for children ages 3–12 years. (A) African American version; (B) Hispanic version. *Source*: Reproduced from Beyer and Knott [108] with permission of Elsevier.

pharmacological and non-pharmacological, to ease pain and distress postoperatively [113]. Multimodal approaches are often the most effective and take advantage of non-opioid and opioid agents as well as other measures for comprehensive pain management.

Non-opioid pharmacological agents offer pain relief without some of the unfavorable side-effects such as nausea and vomiting and respiratory depression, and are therefore useful adjuncts to the postoperative pain management plan. Simple analgesics that require oral administration such as *acetaminophen* require patient cooperation and the absence of nausea and vomiting. The mode of action of acetaminophen is predominantly central by modulating dynorphin release through inhibition of cyclo-oxygenase (COX) [114], and the current understanding is that it is highly selective for COX-2 [115]. Oral dosing is 10–15 mg/kg. Intravenous acetaminophen has become a drug of choice as an adjunct to pain management in the perioperative setting [116]. A dose of 10–15 mg/kg IV every 6–8 h, with a maximum daily dose of no more than 60 mg/kg in children less than 12 years, or 3000 mg in adult-sized patients, is effective. It is crucially important to account for and report to the PACU nursing staff all acetaminophen dosing in the operating room so that maximum dose limits are not exceeded.

Other non-opioid agents such as the non-steroidal anti-inflammatory drugs (NSAIDs) can be delivered orally or intravenously. *Ibuprofen* at 10 mg/kg is given orally every 6 h, and can be alternated with acetaminophen throughout the postoperative period. Another NSAID option is intravenous *ketorolac* at 0.2–0.5 mg/kg every 6 h with a single maximum dose of 15 mg and a maximum daily dosage of 90 mg [117]. Little difference in efficacy has been noted between the NSAIDs, and the mode of action is again by COX inhibition similar to acetaminophen, but predominantly peripherally in this case [118]. NSAIDs are invaluable in the successful management of pain and have been demonstrated to have a significant opioid-sparing effect of up to 46% [119,120]. Although NSAIDs are widely used, caution should be exercised in children due to potential side-effects. Their use in neonates and infants is not currently indicated because of the risk to the developing kidneys. Their use in children also remains controversial due to the risk of bleeding from platelet dysfunction as well as the question of bone healing after certain orthopedic procedures [121,122]. *Aspirin* and other salicylates can cause Reye syndrome in children and are therefore rarely recommended in this population of patients except for

Table 18.6 The face, legs, activity, cry, consolability (FLACC) scale [110]

Categories	Scoring		
	0	1	2
Face	No particular expression or smile	Occasional grimace or frown, withdrawn, disinterested	Frequent to constant quivering chin, clenched jaw
Legs	Normal position or relaxed	Uneasy, restless, tense	Kicking, or legs drawn up
Activity	Lying quietly, normal position, moves easily	Squirming, shifting back and forth, tense	Arched, rigid or jerking
Cry	No cry (awake or asleep)	Moans or whimpers; occasional complaint	Crying steadily, screams or sobs, frequent complaints
Consolability	Content, relaxed	Reassured by occasional touching, hugging or being talked to, distractable	Difficult to console or comfort

Each of the five categories – (F) face, (L) legs, (A) activity, (C) cry, (C) consolability – is scored from 0 to 2, which results in a total score between zero and ten. *Source:* Reproduced from Willis et al [110] with permission from Jannetti Publications.

specific indications that do not include postoperative pain management [123].

Opioids continue to represent the mainstay of analgesia in the PACU. The popularity of these drugs stems from their efficacy, speed of onset, and titratability. When non-opioid agents are ineffective by themselves for pain management, the addition of an opioid analgesic is required. Often fentanyl is the opioid intravenous analgesic of choice for the initial PACU period and for outpatients. Intravenous *fentanyl* 0.5–1.0 μg/kg every 3–5 min or *morphine* 0.05–0.1 mg/kg every 10–15 min have been extensively used and studied, but caution needs to be exercised as these medications have significant adverse potential, especially in children. In particular, neonates are prone to ventilatory depression, having immature and poorly-developed responses to airway obstruction, hypercapnia, and hypoxemia [124]. Hydromorphone at 10 μg/kg every 10–15 min may also be used in the PACU setting for severe pain.

Although typically administered intravenously, opioids have good bioavailability by other routes. For example, fentanyl can be given intranasally at 2 μg/kg without an increase in vomiting, hypoxemia, or increased discharge times [125]. Short procedures such as myringotomy, when an intravenous line is not inserted, are ideally suited to this route of administration.

Opioids can also be administered through infusion devices, and patient-controlled analgesia (PCA) can be used for children typically 6 years and older [126]. Background or basal infusions should be used with caution and will require ongoing monitoring not only in the PACU but on the ward [127]. If a child is to receive PCA, it is advantageous to have this mode of analgesia started in the PACU with instructions so that it is fine-tuned and the child's pain is well under control prior to discharge to the ward.

For children who are going home from the recovery room, providing them with an oral dose of their prescribed medication prior to discharge will help the transition process from hospital to home. This allows the family additional time to get prescriptions filled and provides for a more comfortable ride home for the child. Before giving an oral medication, however, it needs to be clear that the child is alert enough to take the medication, able to secure their own airway easily, and be free of nausea or vomiting prior to discharge. In addition, any oral medication that is made of a combination of the opioid with either acetaminophen or ibuprofen must be started only after the appropriate time interval has passed to keep those agents on an every 4 or every 6 h schedule.

Non-pharmacological analgesic remedies may include physical contact through cuddling, stroking, massage, holding, and rocking. In addition, newborn infants can often be comforted with concentrated sugar water (24% dextrose 0.1–0.2 mL instilled intraorally or applied to a pacifier), perhaps due to the sucrose's release of endogenous opioids [128]. Older children may require more sophisticated methods using cognitive interventions along the lines of distraction, guided imagery, and simple delivery of information. In addition, behavioral interventions such as biofeedback, positive reinforcement, and relaxation exercises with controlled breathing can be used to help alleviate pain in the postoperative period.

KEY POINTS: PAIN MANAGEMENT IN THE PACU

- Assessment of pain in young children is challenging, but the FLACC scale for children less than 3 years, and Oucher scale for 3 years and older, are validated
- Hypertension and tachycardia are non-specific but often are signs of pain
- Non-opioid approaches such as intravenous acetaminophen or ketorolac, regional anesthesia, and sucrose for young infants can be effective
- Intravenous opioids including fentanyl and morphine are effective; adequate time is needed before repeat doses to allow the drugs to work
- Non-pharmacological means such as holding, swaddling, parental presence, rocking, feeding clear liquids, and limiting environmental stimulation are often effective

Postoperative nausea and vomiting

Postoperative nausea and vomiting (PONV) is a major cause of patient dissatisfaction in adults following anesthesia and surgery. Children have an even higher incidence of postoperative vomiting (POV) than adults [129], and nausea, which is difficult to diagnose in younger patients, is most likely underreported. Effective management is important not simply for the humanitarian aspect but because LOS in the PACU is largely determined by PONV. Each episode of vomiting can result in a 28 min delay in children after adenotonsillectomy [29] and result in being a major cause of unanticipated admission after outpatient surgery [121].

In 2014, the Consensus Guidelines for the Management of PONV were developed as an evidence-based tool for clinicians [130]. The guidelines focused on identifying patients at risk, what the risk factors for PONV/POV are, recommendations for prophylaxis, and the most effective treatment regimens. Prophylactic management of pediatric POV typically requires drug intervention that may be costly or associated with unwanted side-effects [131]. It is therefore ideal to target those children at particular risk of POV. Risk factors for children are similar to those for adults with a few differences. POV is rare under the age of 2 years but increases with age until puberty, after which it decreases. A study in children under 14 years of age noted a sharp increase in PONV at age 3 years with a 0.2–0.8% increase per year [132]. There appears to be no gender difference in preadolescent patients, and a history of PONV or motion sickness in a child's parent or sibling may be a risk factor. Certain surgical procedures are associated with a higher incidence of POV in children such as adenotonsillectomy, orchidopexy, penile surgery, hernia repair, and especially strabismus repair [133].

The revised PONV consensus guidelines included a simplified risk score to determine the degree of POV risk in children. The degree of risk is based on the number of the following risk factors that are present: (1) duration of surgery ≥30 min; (2) age ≥3 years; (3) strabismus surgery; and (4) history of POV or PONV among relatives. Risk of POV is elevated as the number of risk factors increases, with one risk factor

representing a 10% risk and four risk factors representing a 70% risk for POV [132]. Of interest, this risk assessment analysis does not include tonsillectomy (with or without adenoidectomy) as a dominant risk factor for POV, when it is described by many as a significant cause of morbidity [134].

Having determined the children who represent a risk of POV, the next step is to address factors for reducing baseline risks such as promoting the use of propofol for either total intravenous anesthesia (TIVA) or subhypnotic low-dose infusions [135]. Although not yet validated in pediatrics, in adults the avoidance of inhalation agents and nitrous oxide and the use of straight regional techniques is recommended in those patients with a high risk for PONV. This is rarely applicable to children, but a multimodal approach to pain management aimed at reducing opiate need is vital [136]. The assertion that NSAID use in tonsillectomy/adenoidectomy procedures leads to increased postoperative bleeding has been debunked in a Cochrane Database systemic review [137]. Therefore the use of NSAIDs after such procedures should be encouraged to reduce opiate need. Finally, adequate intraoperative hydration has been shown to reduce the frequency of PONV [138], although insisting that children drink prior to discharge may actually increase the incidence.

Prophylactic drug therapies can either be monotherapy or a combination of medications. The prophylactic antiemetics recommended for pediatric patients include the 5-HT3 antagonists ondansetron, dolasetron, granisetron, tropisetron, and ramosetron. Since the publication of the first guidelines, ondansetron (0.05–0.1 mg/kg up to 4 mg) has been approved for use in children as young as 1 month of age, and granisetron (40 μg/kg) and tropisetron (0.1 mg/kg) were added as therapeutic options. Ramosetron reduced the incidence of PONV to 9% in children undergoing strabismus surgery but has yet to be listed as a therapeutic option in children [139]. Because the 5-HT3 antagonists as a group have greater efficacy in the prevention of vomiting than nausea, these drugs are the first-line choice for prophylaxis in children. Newer data on pharmacokinetics of ondansetron suggest reduced clearance in children under 6 months of age. This is due in part to the immaturity of the cytochrome P450 enzymes and has led to recommendations that children younger than 4 months of age should be monitored more closely after ondansetron [140]. 5-HT3 antagonists do elongate the QT interval and caution should be exercised in using high doses, to avoid induction of cardiac dysrhythmias.

Other therapies to prevent POV include dexamethasone (0.15 mg/kg), droperidol (0.05–0.075 mg/kg up to 1.25 mg), dimenhydrinate (0.5 mg/kg), and perphenazine (0.07 mg/kg). The revised guidelines specify a revised upper limit for the dose range of dexamethasone, reduced from 8 mg to 5 mg to address concerns over unwanted side-effects such as hypoglycemia, delayed wound healing, and wound infection [141]. Dexamethasone is also associated with tumor lysis syndrome, a condition in which the destruction of tumor cell leads to a potentially catastrophic metabolic derangement. The use of dexamethasone may mask the indices used to direct oncology management and so its use must be discussed prior to administration in a newly diagnosed cancer patient. That being said, dexamethasone is a highly effective antiemetic, with timing of drug administration a key factor in successful prophylaxis. For example, dexamethasone should be administered early in the anesthetic [141] while ondansetron has been shown to be more effective when given preoperatively [142].

The 2014 consensus guidelines recommend that children who are at moderate or high risk for POV should receive combination therapy with two or three prophylactic drugs from different classes. This differs from the recommendations for adults, where combination therapy should be reserved for "high risk" patients only. The combinations recommended in the revised consensus guidelines for children are ondansetron (0.05 mg/kg) with dexamethasone (0.015 mg/kg), ondansetron (0.1 mg/kg) with droperidol (0.015 mg/kg), or tropisetron (0.1 mg/kg) with dexamethasone (0.5 mg/kg). All of these combinations require intraoperative administration, and the particular drugs, doses, and timing need to be conveyed during handover so that any breakthrough PONV/POV may be managed with that knowledge available.

The recommendations for treatment of PONV/POV when it occurs in the PACU, or when prophylaxis fails, include the use of an antiemetic chosen from a different therapeutic class than the agents used for prophylaxis. Droperidol can be used for pediatric patients who have failed all other therapies and are being admitted to the hospital, although the potential for extrapyramidal side-effects exists. The FDA issued a "black box" warning on droperidol in 2001 for its association with QT prolongation. In the doses prescribed in the US, the risk of cardiac effects from droperidol is no higher than with other available antiemetics, but this possibility may still significantly reduce the willingness of physicians to prescribe it [143]. Promethazine also has a black box warning for children less than 2 years of age due to reports of respiratory depression and death when used with opioids in the perioperative period.

Aprepitant, a neurokinin-1 receptor antagonist, has recently been approved for the management of chemotherapy-induced nausea and vomiting in children over the age of 12 years. Its use is widely reported in adults for prophylactic management of PONV although there are no data as yet in children.

Non-pharmacological therapies have undergone some investigation in pediatrics. Aromatherapy, whilst effective in adults, has been studied in children with no significant clinical benefit [144]. Acupuncture has been successfully used for POV prophylaxis in children undergoing strabismus repair, dental surgery, and tonsillectomy [145], but others have found use of this technique in children to be inconclusive [134].

With the options available and the fact that the incidence of POV is undoubtedly higher in children than in adults, a

KEY POINTS: POSTOPERATIVE NAUSEA AND VOMITING

- Risk factors for PONV in children include: age 3 years to puberty; surgery >30 min; strabismus, ENT, hernia, or orchidopexy surgery; and family history of PONV
- Propofol, regional anesthesia, use of NSAIDs, and reduction of opioid dose are effective prevention strategies for PONV
- Prophylactic antiemetics including 5-HT3 antagonists (ondansetron) and dexamethasone reduce the incidence of PONV in children
- Droperidol and promethazine (under age 2 years) have FDA black box warnings and should be avoided unless there are no other effective treatments

greater need for a better understanding and age-appropriate management of POV in children is necessary to reduce this unwanted side-effect in the perioperative period.

Medication errors

Medication errors in the PACU are a frequent occurrence, possibly as high as 5% of all orders, and have significant potential to cause harm [146]. Medication errors may occur at any point from prescription to administration and are the result of breakdowns in communication, calculation errors, decimal point errors, the use of a leading/trailing zero, and/or knowledge deficit on the part of the health professional.

Children are at increased risk because almost all medications are prescribed on a weight basis and therefore require a calculation step. In fact, error rates for children have been found to be inversely related to the weight of the patient, with the greatest errors occurring in the smallest children [147]. Analgesic medications in particular are commonly involved in medication errors because of widespread use, split dosing, and weight-based dosing regimen.

Although medication errors in children may occur at any time and for any of the previously stated reasons, most errors occur at the ordering stage and are often simply the result of poor handwriting [147,148]. For this reason, electronic prescribing systems in the PACU are becoming increasingly frequent and offer the clinician and the patient the promise of safer prescribing. The American Academy of Pediatrics has recognized that, within the hospital, computerized physician order entry (CPOE) can prevent medication errors, and this is gaining increasing support in the literature [149,150]. Particularly in children, this safeguard may be an additional layer that will prevent potentially catastrophic events in the postoperative period.

Urinary retention

Urinary retention is often difficult to assess in the pediatric patient due to a child's inability to communicate the issue clearly, and it therefore may be underdiagnosed. In the adult population, urinary retention has an approximately 16% incidence and is associated with the amount of intraoperative intravenous fluid delivery and bladder volume on admission to the PACU as well as advancing age [151]. This would suggest that straight catheterization or bladder emptying prior to emergence in the operating room should occur in patients who have received a considerable amount of intravenous fluid in the operating room without a urinary catheter present. There is no association of urinary retention in the PACU with such factors as gender, urinary symptoms, type of surgery or anesthesia, or intraoperative administration of anticholinergics or morphine. Postoperative urinary retention is not a significant factor after caudal anesthesia when compared to ilioinguinal/iliohypogastric block, and does not delay recovery [152]. However, Metzelder et al demonstrated that children who underwent distal hypospadias repair and receive penile block were significantly less likely to exhibit postoperative urinary retention when compared to a group who received caudal anesthesia (5/33 versus 15/27, respectively) [153].

Urinary retention, often forgotten as a possibility in children in the PACU, should be considered in any child who has otherwise unexplained tachycardia or signs of discomfort that cannot be attributed to the procedure.

Conclusion

The pediatric PACU environment requires careful planning and ongoing maintenance in order to provide a safe, efficient environment for the recovering pediatric patient. Despite the widespread knowledge of basic principles of postanesthetic recovery and the publication of general national standards, as this chapter indicates, specific practices are dictated by institutional experience and preference. Basic tasks such as recognizing and managing potential perioperative complications are made more complex by the nuances of taking care of pediatric patients of all ages and understanding the differences across these ages while also incorporating the parents into the experience.

CASE STUDY

The nursing staff in the pediatric PACU are notified by telephone from the operating room that a 4-year-old male has just undergone a tonsillectomy and adenoidectomy and is ready for transfer to the PACU. The operating room nurse, using a checklist to ensure that all of the important information is conveyed, gives the patient name, age, and weight, identifies the surgeon responsible, and gives a brief description of the operation. She also confirms with the anesthesia provider that there are no additional concerns or issues to be conveyed at the time of initial report. A pediatric-trained PACU nurse then prepares for the admission by establishing that the allocated bed space directly adjacent to her other patient is clean, that the monitoring is complete and working, and that there is an Ambu® bag and functioning suction.

The patient arrives in the PACU escorted by the anesthesia team and surgical resident. The patient is in the left lateral recovery position and has an oxygen mask applied that is connected to a full tank. On arrival, a rapid assessment is made by the PACU nurse and reveals a sleeping child with pink lips and patent airway. Monitors are placed and show an oxygen saturation of 100%, pulse (P) of 100, and blood pressure (BP) of 100/60. Temperature is 37°C.

Using I-SBARQ method, the nurse anesthetist introduces herself and the patient's identity is confirmed by name band with the PACU nurse. The remainder of the handover is as follows:

The patient is a 4-year-old male weighing 20 kg with a history only significant for obstructive sleep apnea who underwent adenotonsillectomy and is currently stable. He has no known drug allergies and receives no current medications. The family are in the surgical waiting room and have spoken to the surgeon. The patient has undergone general anesthesia,

with an inhalational induction of anesthesia, intravenous line placement, and the insertion of a 4.5 cuffed RAE endotracheal tube. He received fentanyl 20 μg and no muscle relaxants. For antiemetic prophylaxis he was given dexamethasone 2 mg and ondansetron 2 mg, as well as IV acetaminophen 300 mg. Fluid given was 400 mL of lactated Ringer's solution. The surgery had taken longer than anticipated due to excessive intraoperative bleeding. A deep extubation of the trachea was performed at the end of the case to avoid coughing and rebleeding. There were no drains and no labs were pending. Vital signs remained stable throughout the case with the exception of tachycardia that persisted throughout at a rate of 100–130 beats per minute. The patient's risk factors are his sleep apnea and risk of postoperative obstruction and the issue that the nurse anesthetist conveys she is concerned about is the risk of bleeding in the PACU in addition to the sleep apnea.

The nurse anesthetist has no additional specific care requirements to report, but the anesthesiologist has written postoperative orders including pain medication at a reduced dose, due to the apnea history. The IV is to be put on a pump and the family informed of the patient's arrival to PACU.

Within 10 min after arrival in the PACU, the child wakes up crying and coughing. His parents are invited into the PACU to help pacify him and aid in the assessment of anxiety versus pain. The parents are immediately concerned over the amount of blood in the saliva and ask the PACU nurse if this is normal. The PACU nurse reassesses the patient and notes that there are indeed copious blood-filled secretions from the airway which require suctioning. The vital signs are measured and noted to be as follows: SpO_2 98%, P 140, and BP 90/60. The anesthesiologist is called with a brief report of the concerns and he comes immediately to the bedside to assess.

At this time the patient vomits what appears to be a large volume of blood. The anesthesiologist immediately determines the possibility of an ongoing tonsillar bleed and so instructs the PACU nurse to administer 10 mL/kg bolus fluid and to arrange for blood products to be delivered. The child is kept in head-down position to the side and vital signs are frequently measured. The anesthesiologist communicates his concerns to the surgeon in the operating room with an updated assessment of the current situation, and a rapid plan of action is established.

During this time, other members of the PACU team bring the centrally located emergency cart with airway equipment to the bedside, along with emergency drugs for the induction of anesthesia. A second fluid bolus of 10 mL/kg is administered and a stat hemoglobin level sent for analysis, prompting the procurement of blood from the blood bank. The child is no longer vomiting and vital signs improve after the second delivery of volume, as noted by an increased BP and reduced heart rate. Resuscitation is deemed adequate and the patient is electively transported back to the operating room for re-exploration of the tonsillar bleed. The parents remain in the PACU during this time and are informed of the events as they occur. The child underwent a successful cauterization of the tonsillar bleed and made an uneventful recovery.

This case illustrates several basic points:

1. Proper handover and communication in the PACU environment are essential. The Joint Commission has made the process of handover a key element of their assessment of a medical center or unit and evidence shows that good communication reduces the incidence of adverse events.
2. The PACU is an environment of constant vigilance and attention to detail. Regular patient assessment and attention to changes in condition require rapid management. Fully functioning monitoring with frequent measurements is imperative.
3. There must be a central core of emergency equipment supply and drugs, and all team members should be familiar with what is present and available in the PACU. The ability of the PACU team to recognize the potential need for emergent airway care or volume resuscitation requires appropriate equipment and supplies that are readily available.
4. Even without issues such as pain, severe nausea and vomiting, or emergence agitation, the PACU is an environment in which a seemingly stable patient can become unstable and all team members need to act swiftly and appropriately.

CHAPTER 19
Monitoring and Vascular Access

Dean B. Andropoulos[1,2]

[1] Texas Children's Hospital, Houston, TX, USA

[2] Department of Anesthesiology, Baylor College of Medicine, Houston, TX, USA

Introduction

Vascular access, and monitoring of circulation, respiration, the central nervous system, and other end organs, is a central task for the pediatric anesthesiologist. The vast majority of cases will require simple peripheral venous access, and standard non-invasive monitors. Extensive surgery or significant underlying disease may necessitate invasive cardiovascular monitoring, and procedures where the brain is at risk may require central nervous system monitoring. This chapter will address peripheral venous access, and then invasive vascular access and monitoring, followed by monitoring of respiration, temperature, renal monitoring, monitoring of neuromuscular blockade, and central nervous system monitoring. Finally, point-of-care ultrasound will be reviewed.

Venous access

Peripheral veins

Any visible peripheral vein, and many that are not visible, may be utilized for peripheral venous access. One strategy in pediatric patients is to cannulate a small superficial vein on the hand or foot with a small catheter (24 or 22 gauge) before induction, or during inhalation induction of anesthesia, to facilitate the early administration of intravenous agents and provide expeditious airway management. Later, with the airway secure and with an immobile patient, larger-bore peripheral venous access can be achieved. Simple surgeries without blood loss require smaller catheters, but if significant fluid or blood administration is anticipated, larger catheter sizes should be utilized. Recommended sizes for major surgery are 22 or 24 ga 1″ catheters for infants newborn through 6 months, 22 ga 1″ or 20 ga 1.25″ catheters for 6 months to 3 years, 20–22 ga or 18 ga 1.5″ for 3–12 years, and 16 or 14 ga 2″ catheters for teenage or adult patients. Resistance to fluid flow predicted by Poiseuille's law is proportional to the length of the catheter and the viscosity of the fluid, and inversely proportional to the fourth power of the catheter radius. When rapidly infusing the more viscous colloids or packed red blood cells, it is important to use a large-bore, short catheter in a large peripheral vein.

The saphenous vein at the ankle is large and in a constant anatomical position in patients of all ages. It can usually be cannulated even if it cannot be seen or palpated. A recommended technique is to apply a tourniquet below the knee, prepare the site antiseptically, and extend the ankle at the medial malleolus with one hand while puncturing the skin at a shallow angle of 10–30° with an angiocatheter 0.5–1 cm

Gregory's Pediatric Anesthesia, Sixth Edition. Edited by Dean B. Andropoulos and George A. Gregory.

anterior and 1 cm inferior to the medial malleolus. Advance the catheter slowly in the groove between the malleolus and the tibialis tendon until blood return through the needle is established. Advance the needle and catheter together several millimeters, then advance the catheter over the needle into the vein with the index finger of the same hand that made the skin puncture, while maintaining extension of the ankle so that the saphenous vein is tethered straight in its course, to minimize the possibility of puncturing the posterior wall due to kinking of the vein. If the vein can be entered but the catheter will not advance its full length into the vein, a small flexible guidewire of 0.015″ or 0.018″ may be used to assist in cannulation of the saphenous or any other peripheral vein [1]. Other large peripheral veins may be found in infants and children on the dorsum of the hand, at the wrist superficial to the radial head, as branches of the cephalic or brachial venous system in the antecubital fossa, or on the dorsolateral aspect of the foot. The latter site is especially prominent in many newborns.

The external jugular vein is often visible in infants and children undergoing anesthesia and surgery. This site can be used in cases of difficult access. A recommended technique is to choose the larger external jugular vein, place a small rolled towel under the shoulders and place the patient in 30° Trendelenburg position, prepare the site antiseptically, and have an assistant compress the vein gently with pressure just above the clavicle to further distend it. Rotation of the head 45–90° away from the side of cannulation, and slight extension of the neck and traction of the skin over the vein with one hand will tether the vein into a straighter course to facilitate successful cannulation. The vein is punctured high in its visible course with an angiocatheter attached to a syringe filled with heparinized saline, and with the needle bent upwards 10–20° to facilitate the very flat, superficial angle of incidence necessary to cannulate the vein without puncturing its back wall. With constant, gentle aspiration of the syringe, the vein is entered and catheter advanced into the vein. Short peripheral catheters of the same size as recommended above should be used. A catheter advanced too far into the venous plexus beneath the clavicle will often exhibit resistance to the free, gravity driven, flow of fluid, and traction or withdrawal of the catheter a few millimeters may be necessary. External jugular catheters are often difficult to secure to the skin on the neck, and suturing them in place is recommended. This will enhance stability postoperatively as the patient begins moving. One advantage of using the external jugular vein for a peripheral venous catheter is that it is easily accessible under the surgical drapes, and can be frequently monitored for extravasation or kinking of the catheter, which is more common with this site than with the other commonly used peripheral veins.

Umbilical vein

The umbilical vein in the fetus is a conduit to carry oxygenated and detoxified blood from the placenta, through the abdominal wall, the liver, and patent ductus venosus to the inferior vena cava (IVC) and the right atrium [2] (Fig. 19.1). This vessel can usually be cannulated at the umbilical stump for the first 3–5 days of postnatal life. Passage into the IVC

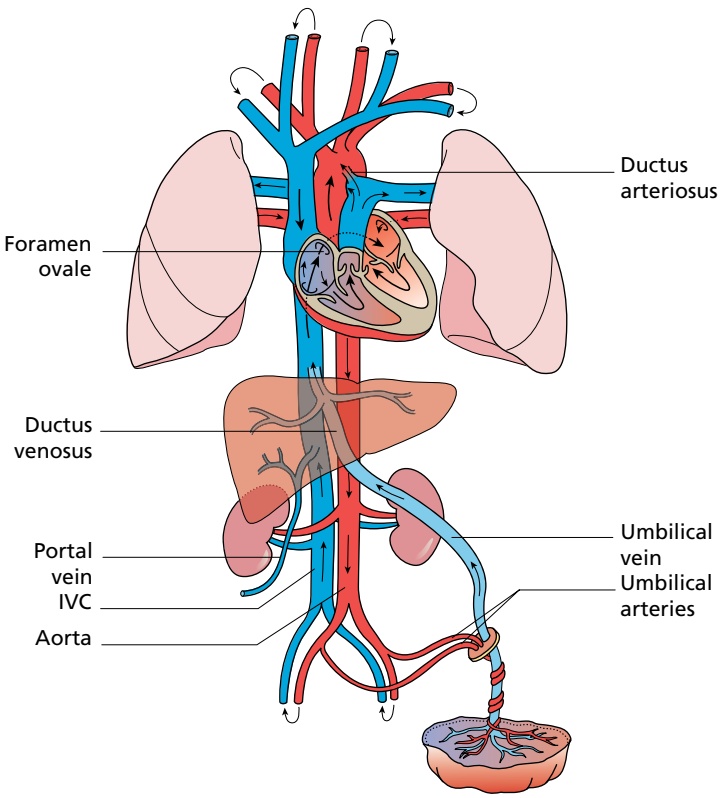

Figure 19.1 The fetal circulation. A catheter placed in the umbilical vein should have its tip through the ductus venosus into the inferior vena cava (IVC) at or near its junction with the right atrium. The tip of an umbilical artery catheter should lie at the level of the third lumbar vertebral body, between the origin of the renal arteries and the bifurcation of the aorta. *Source*: Reproduced from Parellada and Guest [2] with permission of William and Wilking (CCC) Wolters Kluwer Health.

depends on the patency of the ductus venosus, which often exists for the first few days, just as the ductus arteriosus. Sterile technique without a guidewire is used to pass the catheter blindly a premeasured distance. If no resistance to passage is met and free blood return is achieved, the catheter tip is usually in the high IVC or right atrium, and functions as a central venous catheter. Catheter tip position must be determined by radiography as soon as possible to determine if it is through the ductus venosus into the IVC or the right atrium. Often, the ductus venosus is not patent, and the catheter tip passes into branches of the hepatic veins and is visible in the liver radiographically. In this location the catheter must not be used except for emergencies. Central venous pressure monitoring is inaccurate in this position, and portal vein thrombosis, liver and intestinal necrosis can occur with the infusion of hyperosmolar or vasoactive drugs such as sodium bicarbonate and dopamine. An alternative site for central access must be chosen.

KEY POINTS: PERIPHERAL AND UMBILICAL VENOUS ACCESS

- The saphenous vein at the ankle often provides reliable large peripheral vein access in infants and small children
- The external jugular vein can be used as an emergency peripheral intravenous access site
- The umbilical vein can be used for a catheter that passes through the ductus venosus into the IVC for the first 3–5 days of postnatal life

Percutaneous central venous access

Percutaneous central venous access can be utilized for several indications:

- difficult peripheral venous access or need for prolonged vascular access
- need to monitor central venous pressure, i.e. large fluid shifts or blood loss, or cardiovascular surgery
- need for vasoactive infusions [3].

Precise indications will vary according to the practitioner. A double-lumen central catheter of the smallest acceptable size is recommended for percutaneous central venous catheter placement. For all sites, either audio Doppler or two-dimensional ultrasound can be used to facilitate insertion. The larger distal lumen is used for central venous pressure monitoring and drug injection, and the smaller proximal lumen for vasoactive and other infusions. The smallest available double-lumen catheter is currently 4 Fr in size. Superior vena cava (SVC) catheters should be used with caution or not at all in patients weighing less than 4 kg because of the increased risk of thrombosis (see section "Complications of vascular access"). Recommended sizes and lengths are shown in Table 19.1.

Sterile technique using preprocedure scrubbing, cap, mask, gloves, gown, and wide draping leads to a "cleaner" insertion technique with fewer infectious complications [4]. In cardiac patients, the left side SVC lines should generally be avoided. The risk of erosion/perforation is greater, and 5–15% of patients with congenital cardiac disease have a persistent left SVC, which most often drains either to the coronary sinus or left atrium, neither of which is a desirable location for a catheter tip. So, if left-sided line placement is contemplated, ascertain by echo/cath report the presence of the left SVC. If this is not known in a patient with congenital heart disease, choose an alternative site, i.e. femoral vein.

Table 19.1 Recommended central venous catheter sizes and lengths according to weight

Patient weight	IJ/subclavian vein	Femoral vein
<10 kg	4 Fr, 2 lumen, 8 cm	4 Fr, 2 lumen, 12 cm
10–30 kg	4 Fr, 2 lumen, 12 cm	4 Fr, 2 lumen, 12–15 cm
30–50 kg	5 Fr, 2 lumen, 12–15 cm	5 Fr, 2 lumen, 15 cm
50–70 kg	7 Fr, 2 lumen, 15 cm	7 Fr, 2 lumen, 20 cm
>70 kg	8 Fr, 2 lumen, 16 cm	8 Fr, 2 lumen, 20 cm

IJ, internal jugular.

The following general discussion of the Seldinger technique in pediatric patients can be applied to all percutaneous vascular access sites, either venous or arterial. The Seldinger technique is used for all percutaneous central venous cannulations. A central line insertion and maintenance "bundle" will reduce infection rates and should be followed, including a checklist to ensure all steps are followed [5] (Box 19.1). After wide sterile skin preparation with iodine or chlorhexidine-based solution, wide draping is carried out, preferably with a clear, fluid-impermeable adhesive aperture drape so that the underlying anatomy is clearly visible. Slow, controlled, careful needle manipulation, especially in small infants, must be emphasized. The slight movement in or out of only 1 mm or less may be enough to prevent passage of the guidewire. It is very important to have the guidewire prepared to insert and immediately accessible when the vein is entered, so the anesthesiologist does not have to look away from the puncture site to reach for the wire on a distant tray, often resulting in enough movement of the needle to prevent successful guidewire passage. After the desired vein is entered, the needle position is fixed by stabilizing it against the patient's body with the heel of the nondominant hand, and the guidewire is carefully advanced into the right atrium. The resistance to wire passage should be minimal. Experienced operators learn to recognize the "feel" of a guidewire passing successfully. If any resistance is encountered, the wire must be carefully withdrawn and another approach made if the needle is still in the vessel, ascertained by free aspiration of blood. Forcing a guidewire in the face of resistance can lead to significant complications. The electrocardiogram should be carefully observed as the guidewire is slowly advanced. Premature atrial contractions (PAC) are usually observed as the first guidewire-induced dysrhythmia, signifying atrial location. If no PAC are observed, the operator should suspect that the guidewire is not in the atrium. If ventricular extrasystoles are the first observed dysrhythmia, especially if they are multifocal in nature, the wire is very likely in an artery, and the left ventricle has been entered retrograde. After guidewire passage, a very small skin incision with a #11 scalpel is made. Finally, careful dilation and catheter passage follows. The dilators in the prepackaged central venous catheter kits are often one size larger than the catheter, i.e. 5 Fr

Box 19.1: Central line catheter care bundles

Insertion bundle

- Wash hands before the procedure
- For all children aged ≥2 months, use chlorhexidine gluconate to scrub the insertion site for 30 s for all areas except the groin, which should be scrubbed for 2 min. Scrubbing should be followed by 30–60 s of air drying
- No iodine skin prep or ointment is used at the insertion site
- Use a sterilized prepackaged tray with catheter that contains all necessary equipment and supplies, including full sterile barriers
- Create an insertion checklist, which empowers staff to stop a non-emergent procedure if it does not follow sterile insertion practices
- Use only polyurethane or Teflon catheters[a]
- Conduct insertion training for all care providers, including sides and video

Maintenance bundle

- Assess daily whether catheter is needed
- Catheter-site care
  - No iodine ointment
  - Use a chlorhexidine gluconate scrub to sites for dressing changes (30-s scrub, 30-s air-dry)
  - Change gauze dressings every 2 days unless they are soiled, dampened, or loosened[a]
  - Change clear dressings every 7 days unless they are soiled, dampened, or loosened[a]
  - Use a prepackaged dressing-change kit or supply area
- Catheter hub, cap, and tubing care
  - Replace administration sets, including add-on devices, no more frequently than every 72 h unless they are soiled or suspected to be infected
  - Replace tubing that is used to administer blood, blood products, or lipids within 24 h of initiating infusion[a]
  - Change caps no more often than 72 h (or according to manufacturer recommendations); however, caps should be replaced when the administration set is changed[a]
  - The prepackaged cap-change kit, or supply area elements to be designated by the local institution

[a] These procedures are according to the Centers for Disease Control and Prevention (CDC) recommendations.

dilator for 4 Fr catheter. This may be undesirable for small infants, and either passage of the catheter without dilation, or use of a dilator the same size as the catheter is preferable to make the smallest possible hole in the vein to minimize bleeding and trauma to the vessel wall, both of which may lead to an increased incidence of thrombosis or vascular insufficiency. Meticulous attention must be paid to blood loss in small infants during catheterization procedures, with direct compression of bleeding puncture sites using the heel of the non-dominant hand while threading dilators, catheters, etc. Use of an assistant may be necessary in difficult catheterizations. After passage of the catheter to the desired depth, it is secured with sutures and a dressing. If more than 1 cm of catheter is outside the patient, additional suturing or catheter-holding devices are necessary,

Internal jugular vein

The right internal jugular (IJ) vein is the most common site chosen for central venous access in pediatric cardiac surgery, and is often an excellent choice for other major surgery. It is large, and runs in close proximity superficial to the carotid artery along most of its length. The primary advantage of using the internal jugular vein is that it provides a direct route to the right atrium, and thus a high rate of optimal catheter positioning if the vessel can be cannulated. Various studies report only a 0–2% incidence of catheter tip outside the thorax, in contrast to 5–10% for the subclavian route [6,7]. The primary disadvantage comes from difficulty in cannulation in small infants, who have large heads and short necks, and thus it is difficult to obtain the shallow angle of approach necessary to access the vessel. Also some series report a 10–15% incidence of carotid artery puncture in infants and ultrasound studies of neck vessel anatomy reveal the partial or complete overlap of the internal jugular vein anterior to the carotid artery [7]. This site is also not comfortable for some awake infants, and tip migration may be significant with turning the head or flexion/extension of the neck [8]. All insertion techniques involve placing a small roll under the shoulders, using steep Trendelenburg position, and rotating the head no more than 45° to the left. Greater rotation will produce more overlap of the internal jugular vein and carotid artery, and increase the risk of carotid puncture [9]. Recent studies have demonstrated that liver compression and simulated Valsalva maneuver increase the diameter of the internal jugular vein, possibly increasing the success rate of cannulation [10].

There are numerous approaches to the internal jugular vein, some of which are described here (Fig. 19.2).

- Muscular "triangle" method: puncture at the top of the junction where the sternal and clavicular heads of the sternomastoid muscle meet, lateral to the carotid impulse, directing the needle at the ipsilateral nipple. These landmarks are often not well defined in infants.
- Puncture exactly halfway along a line between the mastoid process and the sternal notch, just lateral to the carotid impulse.
- Use the cricoid ring as a landmark, and puncture just lateral to the carotid impulse.
- Jugular notch technique: puncture just lateral to the carotid impulse, just above the jugular notch on the medial clavicle – a low approach.

An ultrasound technique should be used to identify clearly the course of the vessel and detect any significant overlap with the carotid artery. There is no need to use a finder needle for small catheters where the access needle is 20 ga or smaller. Surface landmarks are often inaccurate for estimating the correct depth of insertion for SVC lines, i.e. locating the tip midway between the sternal notch and nipple. See section "Ascertainment of correct position of central venous catheters" for method to ascertain the correct placement for all sites. See Video clip 19.1.

Subclavian vein

The subclavian vein is positioned immediately behind the medial third of the clavicle [11,12]. Advantages of this route include the subclavian vein's relatively constant position in all ages in reference to surface landmarks, stability, and less tip migration with patient movement, and comfort for the

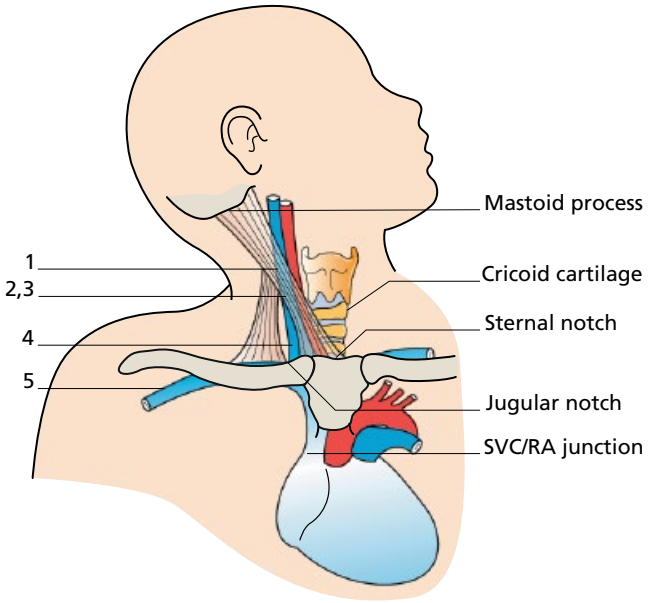

Figure 19.2 Sites for central venous cannulation of the superior vena cava. 1: high approach, midway between mastoid process and sternal notch; 2, 3: middle approach using apex of muscular triangle or cricoid cartilage; 4: low approach using jugular notch; 5: lateral approach to subclavian venipuncture. *Source*: Reproduced from Andropoulos et al [31] with permission of Wolters Kluwer. RA, right atrium; SVC, superior vena cava.

awake patient [13,14]. Disadvantages include an incidence of pneumothorax, especially with an inexperienced operator, and an occasional inability to dilate the space between the clavicle and first rib. Also, in 5–20% of patients, subclavian catheters will enter the contralateral brachiocephalic vein or ipsilateral internal jugular vein instead of the SVC [15].

Technique: A small rolled towel is positioned vertically between the scapulae, steep Trendelenburg position is used, and the arms are restrained in neutral position at the patient's sides. This position maximizes the length of subclavian vein overlapping the clavicle, and moves the vein anterior, bringing it in close proximity to the posterior surface of the clavicle [11]. The right subclavian vein should always be the first choice (see section "Ascertainment of correct position of central venous catheters"). Turn the head toward the side being punctured (i.e. toward the right for a right-sided line). This position will compress the internal jugular vein on that side and prevent the guidewire from entering it, especially in infants [16], which may lead to complications such as dural sinus thrombosis [17]. It will not, however, prevent the guidewire from crossing the midline and entering the contralateral brachiocephalic vein [16]. The needle is bent upwards in midshaft at a 10–20° angle to ensure a very shallow course. In our experience the puncture site that is most successful is 1–2 cm lateral to the midpoint of the clavicle [11], directly lateral from the sternal notch, with the needle directed at the sternal notch. Contact the clavicle first to ensure a shallow angle of incidence to minimize the risk of pneumothorax. Then, the needle is "walked" carefully underneath the clavicle and advanced slowly with constant aspiration until blood return is achieved. Advancing the needle only during expiration is recommended to minimize the risk of pneumothorax. Having an assistant manually ventilate the patient will facilitate this process. If not successful, the needle is withdrawn slowly with gentle aspiration, because about 50% of infant subclavian veins are cannulated during withdrawal due to compression or kinking of the vein during needle advancement. Slow, controlled, careful needle manipulation, especially in small infants, must be emphasized. After the vein is entered, advance the guidewire; there should be no resistance. Look for PAC, sometimes only one or two, as a sign that the wire is in the heart. If no dysrhythmias are seen, withdraw the wire, rotate it 90° clockwise, and advance it again until PAC are seen. Use a dilator (be very careful not to advance it too far – only far enough to expand the space between the clavicle and first rib) and pass the catheter to the desired depth using one of the guidelines noted in section "Height- and weight- based formulae".

Complications during subclavian catheterization occur when a needle angle of incidence is too cephalad, resulting in arterial puncture, or too posterior, resulting in pneumothorax. If the needle course remains shallow, just underneath the clavicle, and directed straight horizontally at the sternal notch, complications are rare. Advancing the needle too far in infants may result in puncture of the trachea.

External jugular vein

Advantages of this approach are its superficial location and thus low risk of arterial puncture. The disadvantage is that the younger the patient, the less likely it is that the guidewire will pass into the atrium; the success rate is less than 50% if the patient is less than 1 year of age, and only 59% in patients less than 5 years [18,19]. Positioning is the same as for the internal jugular approach, the vein is punctured high in its course, and the guidewire is passed. Often it can be observed turning medially toward the SVC. If no resistance is felt, and PAC are seen, or the guidewire is visualized on the transesophageal echocardiogram (TEE), then passage has been successful. Because of the low success rate of central cannulation from the external jugular vein approach, our practice is to use the internal jugular vein first in all patients.

Femoral vein

The femoral vein has long been used for central venous catheterization in pediatric patients, with no greater infection or other complication rate compared to other sites [20,21].

Technique: The patient is positioned with a rolled towel under the hips for moderate extension. The puncture site should be 1–2 cm inferior to the inguinal ligament (line from the anterior superior iliac spine to the symphysis pubis), and 0.5–1 cm medial to the femoral artery impulse, with the needle directed at the umbilicus. Ultrasound guidance (see section "Ultrasound guidance for vascular access") is important for the greatest chance for first-pass, atraumatic placement. The guidewire is passed, ensuring no resistance. A vessel dilator is used, and then the catheter is passed all the way to the hub to position the tip in the mid IVC. It is important to puncture the vessel well below the inguinal ligament, to minimize the risk of unrecognized retroperitoneal bleeding. Bleeding below the inguinal ligament is easily recognized and treated with direct pressure.

Several studies have conclusively demonstrated that in the absence of increased intra-abdominal pressure or IVC obstruction, mean central venous pressure as measured in the IVC below the diaphragm is identical to that measured in the right atrium in patients with and without congenital heart disease [22–26]. The only caveat is in the patient with an interrupted

IVC with azygous vein continuation into the SVC, a condition commonly encountered in patients with the heterotaxy syndromes. The equivalence of IVC and right atrial pressures under these conditions has not been evaluated, but the catheter can be used as any other central line for infusion of drugs and fluids. See Video clip 19.2.

Ascertainment of correct position of central venous catheters

Correct placement of central venous catheters (CVC) is essential to prevent complications (see section "Complications of vascular access") and to give accurate intravascular pressure information. The tip of a central venous catheter should lie in the SVC, parallel to the vein wall, to minimize the perforation risk. Many authorities recommend placement in the upper half of the SVC, where the tip will be above the pericardial reflection in most patients, thus minimizing the risk of tamponade if perforation occurs [27]. In small patients the SVC is often short, i.e. 4–5 cm total length, and the pericardium is usually opened during cardiac surgery in these patients, providing drainage in case of perforation. In addition, the risk of arrhythmias is present with a catheter positioned in the right atrium. Various methods to determine correct placement are discussed as follows.

Radiography and echocardiography

The chest radiograph is considered the gold standard for correct placement, but obtaining and processing a chest radiograph is time consuming, costly, and usually not necessary in the operating room. A chest radiograph should be obtained immediately postoperatively (Fig. 19.3), position of intravascular catheters ascertained, and adjustments made by the anesthesiologist if necessary. It is important to note that an anteroposterior radiograph may miss malposition in one of several ways. The most common is for an SVC catheter to be directed posteriorly down the azygous vein, which may not be detected by anteroposterior radiograph alone. Ideally, the tip of the catheter should be parallel to the SVC wall, in the mid SVC, but in any case it should be above the SVC–RA junction. The position of the pericardial reflection is variable in infants and young children, and radiographic landmarks such as the carina to ascertain tip placement above the pericardial reflection are not reliable [28].

If TEE is utilized for cardiac surgery, the tip of the central catheter can usually be visualized in the region of the SVC–RA junction; this is easily done before surgery starts and is a very accurate method of ascertaining correct position [15] (Fig. 19.4).

Electrocardiographically-guided placement

The intravascular electrocardiogram (ECG) may be used in children to guide correct CVC placement [29,30]. Either a 0.9% or 3% saline-filled lumen with special ECG adaptor, or a guidewire within the lumen attached to a sterile alligator clip and leadwire substituted for the right arm surface ECG lead may be used. Entry of the catheter tip into the right atrium is signified by the sudden appearance of a P atriale, an exaggerated, large, upright P wave. The catheter tip is then pulled back 1–2 cm into the desired position in the SVC. The success rate for proper placement in the reported studies has been 80–90%, but there have been no controlled studies in children comparing this method to other methods. This method also requires special equipment that is not always available.

Height- and weight-based formulae

A large study of CVC placement in infants and children undergoing congenital heart surgery developed formulae for correct insertion depth based on height and weight [31] (Table 19.2). CVC were inserted in the right internal jugular or subclavian vein and postoperative radiograph studies were used to determine the tip position in reference to the SVC–RA junction. The

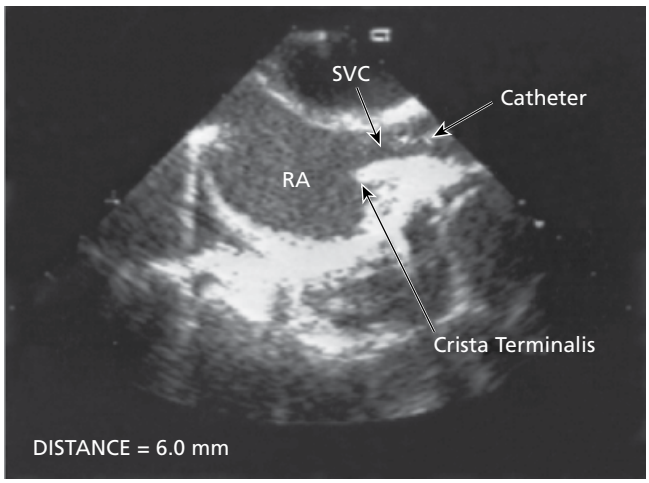

Figure 19.4 Transesophageal echocardiographic image of the superior vena cava (SVC)–right atrial (RA) junction in the sagittal plane in an infant. The tip of the right internal jugular catheter is in the SVC, 6 mm above the RA. *Source:* Reproduced with permission from Andropoulos et al [15] with permission of Wolters Kluwer.

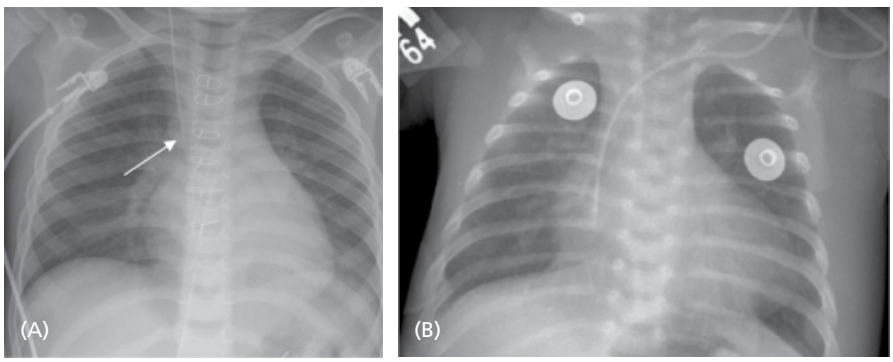

Figure 19.3 (A) Postoperative chest radiograph with the tip of a right internal jugular vein catheter in proper position in the mid superior vena cava. (B) Tip of catheter malpositioned, deep in the right atrium.

length of catheter inside the patient was added to this distance to determine the position of the SVC–RA junction, and formulae developed that would predict placement above the RA, in the SVC, 97.5% of the time (95% confidence interval 96–99%). All catheter tips predicted to be in the atrium using these data would be high in the RA within 1 cm of the SVC–RA junction, minimizing any perforation risk. The formulae are simple and easily implemented because weight and height can be easily measured in all patients undergoing surgery.

For patients with height less than 100 cm:

$$(\text{Height} \div 10) - 1\,\text{cm}$$

is the correct insertion distance, i.e. a 75 cm patient would have the catheter secured at 6.5 cm for either the right internal jugular or the subclavian route.

For patients with height 100 cm or greater:

$$(\text{Height} \div 10) - 2\,\text{cm}$$

is the correct distance. The caveats to this seemingly useful technique are that for the internal jugular vein, the puncture site is high, exactly midway between the mastoid process and the sternal notch; and for the subclavian, the puncture site 1–2 cm is lateral to the midpoint of the clavicle. If different puncture sites are utilized, the operator must adjust the formulae accordingly. Also, the formulae have not yet been evaluated for accuracy in a prospective fashion.

Percutaneously inserted central catheters

Percutaneously inserted central catheters (PICC) have been utilized in the neonatal nursery for more than a decade, and have become standard practice for ill newborns expected to require prolonged venous access. The complication rate for these catheters is very low, and they are usually relatively easy to insert into the central circulation via the antecubital, saphenous, scalp, hand, axillary, or wrist veins, when placed by experienced, skilled personnel. Such personnel include nurses [32] or physicians placing them at the bedside, or in the interventional radiology suite [33] with ultrasound and fluoroscopic guidance. The key to successful placement is early access, before all large visible superficial veins are injured from attempts at peripheral intravenous placements. For this reason, the PICC line is optimally placed in the critically ill newborn in the first 12–24 h after admission. Like all CVC, PICC occasionally cause complications such as perforation of the atrium, or embolization of a portion of the catheter [34]. The infection rate is very low.

Technique: A suitable vein should be identified. The branches of the basilic vein on the medial half of the antecubital fossa offer the highest success rate because of their large size and direct continuation with the axillary and subclavian veins. The cephalic vein tributaries can also be used, but are less likely to pass into the axillary vein. Other sites, e.g. the saphenous, hand, and scalp veins, are cannulated as for a peripheral intravenous catheter. The site is prepared and draped, and appropriate local anesthesia and/or intravenous analgesia are administered. The vein is entered using a large break-away needle or angiocatheter, and a 2 Fr non-styletted silicone catheter flushed with heparinized saline is passed with forceps a distance measured from the entry site to the SVC–RA junction. Continued easy passage without resistance, and continuous ability to aspirate blood signify proper placement. A radiograph, with injection of diluted contrast if needed, should be obtained prior to use. Proper catheter tip position is in the SVC or IVC, not in the right atrium. Occasionally the PICC line will not pass centrally, i.e. into the intrathoracic portion of the subclavian vein or further, or into the IVC. In this case it should be considered no differently than a peripheral venous line. For central PICC lines, any centrally delivered medication or fluid may be used, i.e. parenteral nutrition, dopamine, CaCl, etc. The 2 Fr PICC lines are too small for rapid fluid boluses or blood products, therefore inadequate as the sole prebypass access for cardiac surgery, or for other major surgery. Recently, 3.5–4 Fr soft polyurethane double-lumen PICC lines, with two 22 ga lumens, have become available, and can be placed using modified Seldinger technique with a central vein placement rate of 66% [35]. Alternatively, 3 Fr PICC lines, placed with the aid of ultrasound and fluoroscopic guidance with a guidewire in the interventional radiology suite, may be used in newborns with caution, especially in the SVC position, because of the risk of thrombosis [36]. In older infants and children these larger catheters are preferred. Tan et al [37] reported a series of 124 such catheters in cardiac surgical neonates, noting a low thrombosis rate of 1.6%, and a low infection rate of 3.6 per 1000 catheter days, with a median onset of 37 days; thus these catheters can be extremely useful in this population.

Table 19.2 Recommended length of superior vena cava central venous catheter (CVC) insertion in pediatric patients based on weight: right internal jugular or subclavian veins

Patient weight (kg)	Length of CVC insertion (cm)
2–2.9	4
3–4.9	5
5–6.9	6
7–9.9	7
10–12.9	8
13–19.9	9
20–29.9	10
30–39.9	11
40–49.9	12
50–59.9	13
60–69.9	14
70–79.9	15
80 and above	16

KEY POINTS: CENTRAL VENOUS ACCESS

- Indications include monitoring central venous pressure (CVP), administering vasoactive infusions, and securing access for cases with large fluid shifts or blood loss
- The right internal jugular vein is the most direct route to the SVC, and the tip is properly positioned more often than subclavian vein catheters
- Femoral venous catheters measure CVP in the IVC and are accurate reflections of intrathoracic CVP in the absence of increased intra-abdominal pressure
- Height- and weight-based formulae, ultrasound, and radiography are used to place the tip of a CVP catheter in the SVC and not the right atrium

Arterial access

Tables 19.3 and 19.4 display recommended catheter sizes for arterial access based on site and patient weight.

Radial artery

This is the preferred location in the newborn if an umbilical artery line is not possible or needs to be replaced, and in virtually all other patients. Placement on the same side as an existing or planned systemic-to-pulmonary artery shunt is avoided, e.g. a right-sided modified Blalock–Taussig shunt.

Technique: The wrist is extended slightly with rolled gauze, and the fingers taped loosely to an armboard, with the thumb taped separately in extension to tether the skin surface over the radial artery (Fig. 19.5). An angiocatheter flushed with heparinized saline is used as a "liquid stylet" to increase the rapidity of flashback of blood into the hub of the needle after aseptic preparation. The skin is punctured at a 15–20° angle at the proximal wrist crease at the point of maximal impulse of the artery. Palpation is the usual method of identifying the artery, but audio Doppler localization can be helpful if the pulse is weak. Lighter planes of anesthesia provide stronger pulses and increase the success rate of cannulation. The first attempt, before any hematoma formation or partial dissection of the artery, always yields the greatest chance for success, so the operator should optimize conditions, e.g. positioning, lighting, and identification of the vessel. Puncture of the artery with the needle is signified by brisk flashback. The needle and catheter are then advanced 1–2 mm into the artery, and an attempt is made to thread the catheter primarily over the needle its full length into the artery. Threading should have minimal resistance and is signified by the continuing flow of blood into the hub of the needle. If threading is not successful, the needle is replaced carefully in the angiocatheter, and the needle and catheter can be passed through the back wall of the artery. Then the needle is removed, and a 0.015″ guidewire with flexible tip can be used to assist threading of the catheter. The catheter is pulled back very slowly, and when vigorous arterial backflow occurs, the guidewire is passed, and the catheter threaded over the guidewire into the artery [38]. Minimal resistance signifies successful threading. If threading is unsuccessful, further attempts may be made at the same site or at slightly more proximal sites to avoid areas of arterial spasm, thrombosis, or dissection. The circulation distal to the catheter should be assessed by inspection of color and capillary refill time of fingertips and nailbeds, and quality of signal from a pulse oximeter probe. A recommended technique for securing the catheter is with a clear adhesive dressing and transparent tape so that the insertion site and hub of the catheter are visible at all times. See Video clip 19.3.

Table 19.3 Recommended arterial catheter sizes: radial, dorsalis pedis, posterior tibial, brachial arteries

Weight	Radial/DP/PT arteries	Brachial artery
<2 kg	24 ga	Not recommended
2–5 kg	22 ga	24 ga
5–30 kg	22 ga	22 ga
>30 kg	20 ga	22 ga

DP, dorsalis pedis; PT, posterior tibial.

Table 19.4 Recommended arterial catheter sizes: femoral, axillary arteries

Weight	Femoral/axillary arteries
<10 kg	2.5 Fr, 5 cm long
10–50 kg	3 Fr, 8 cm long
>50 kg	4 Fr, 12 cm long

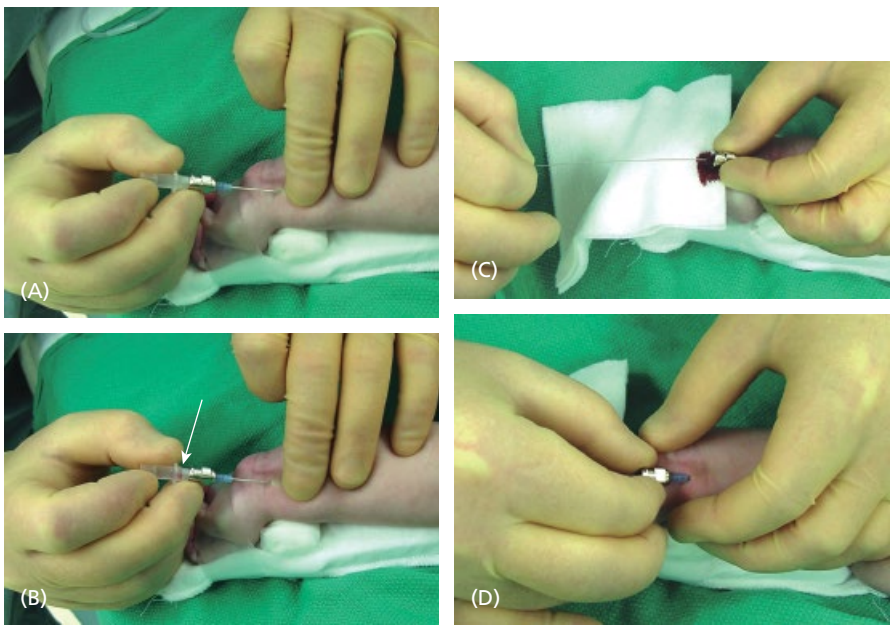

Figure 19.5 Insertion of a radial arterial catheter in an infant. (A) The radial artery is approached with a saline-filled angiocatheter, at the proximal wrist crease. (B) Rapid flashback of arterial blood (*arrow*) is noted with arterial puncture using liquid stylet technique. (C) A 0.015″ guidewire is inserted and threaded into the artery. (D) The angiocatheter is threaded over the guidewire.

Femoral artery

The superficial femoral artery is a large vessel that is easily accessible in almost all patients [39] and is a logical second choice for cardiac surgery when radial arterial access is not available. In infants, especially patients with trisomy 21, transient arterial insufficiency develops in up to 25% of patients after arterial catheterization when 20 ga (3 Fr) catheters are used [39]. For this reason, in the author's institution the smallest commercially available catheter, 2.5 Fr (equal to 21 ga), is used in patients weighing less than 10 kg (see Table 19.4).

Technique: A small towel is placed under the patient's hips to extend the leg slightly to neutral position. Slight external rotation, with the knees restrained by taping to the operating room bed, fixes adequate position. After sterile preparation and draping, the course of the superficial femoral artery is palpated and punctured 1–2 cm inferior to the inguinal ligament, to avoid puncturing the artery above the pelvic rim where a retroperitoneal hematoma could develop. If the pulse is weak, as in the case of aortic arch obstruction, use of audio Doppler effectively identifies the course of the vessel. The puncture technique varies and may include direct puncture with an angiocatheter, or Seldinger technique using the needle in the commercially supplied kit, or a 21 ga butterfly needle with the extension tubing removed. All of the above are flushed with heparinized normal saline to increase the rapidity of flashback. A small flexible guidewire, 0.015″ or 0.018″, is used. It is normally possible to thread a polyethylene catheter over the guidewire without making a skin incision; under no circumstances is dilating the tract and artery with a dilator recommended, which could cause arterial spasm, dissection, or bleeding around the catheter if the puncture site is large. The catheter is secured by suturing around the entry site of the catheter and wings around the hub. Distal perfusion is immediately assessed, and a pulse oximeter probe is placed on the foot for continuous monitoring and early warning of arterial perfusion problems.

Brachial artery

The brachial artery has been successfully used for monitoring for cardiac surgery in children, but using this site for arterial monitoring should generally be avoided because it has poor collateral circulation compared to the radial, femoral, and axillary arteries. Theoretically, there should be a higher incidence of arterial insufficiency with this site, but a study by Schindler et al, of 386 brachial artery catheters in infants and children undergoing cardiac surgery, documented no permanent ischemic damage, and only three temporary arterial occlusions, when 22 and 24 ga catheters were used [40]. This site should only be used in situations when there are limited other options, e.g. a right upper extremity arterial line is required to monitor pressure during cross-clamping for repair of coarctation of the aorta, or during bypass for aortic arch hypoplasia or interruption.

Technique: A 24 ga catheter should be used in patients under 5 kg. The arm is restrained in neutral position on an armboard, and the arterial impulse is palpated above the elbow crease, well above the bifurcation into radial and ulnar arteries. Cannulation proceeds as for the radial artery. Meticulous attention to distal perfusion must be paid at all times, and the catheter removed for any signs of ischemia. Pulse oximeter monitoring of distal pulses will provide early detection of perfusion problems. The catheter should be removed or replaced with a catheter in a site with better collateral circulation as soon as possible after the repair.

Axillary artery

The axillary artery is large and well collateralized, and several series in critically ill children have demonstrated this to be a viable option with a low complication rate when other sites are not accessible [41,42]. However, given the potential morbidity of an ischemic arm and hand, and the theoretical problem of intrathoracic bleeding, this puncture site should be considered a site of last resort when there are limited options.

Technique: The arm is abducted 90° and extended slightly at the shoulder to expose the artery. The artery is palpated high in the axilla and punctured using an angiocatheter, which is then exchanged over a guidewire for a longer catheter, or by primary Seldinger technique. A catheter that is too short (e.g. 22 ga 1″ long) will often be pulled out of the vessel with shoulder extension. Therefore, the shortest recommended catheter is 5 cm long (see Table 19.4). Careful attention must be paid to distal perfusion, as with the brachial artery. Tip position should be ascertained by chest radiograph, and should not lie deeper than the first rib. The proximity to the brachiocephalic vessels makes it imperative that the catheter be flushed very gently by hand after blood draws, and that no air bubbles or clots ever be introduced, because of the risk of retrograde cerebral embolization.

Umbilical artery

The umbilical artery is accessible for the first few days of life, and is the site of choice for newborns requiring surgery in the first week of life (see Fig. 19.1). The complication rate is lower with the catheter tip placed in the high position, i.e. above the diaphragm, versus the low position, i.e. at the level of the third lumbar vertebra [43]. The catheter can be left in place for 7–10 days. A relationship to intestinal ischemia and necrotizing colitis has been demonstrated [44], and enteral feeding with an umbilical artery catheter in place is controversial [45]. Umbilical catheters are most commonly inserted by the neonatal staff in the delivery room or neonatal ICU shortly after birth. The technique involves cutting off the umbilical stump with an umbilical tape encircling the base to provide hemostasis, dilating the umbilical artery, and blindly passing a 3.5 Fr catheter a distance based on weight, then assessing position as soon as possible radiographically. Lower extremity emboli, vascular insufficiency, and renal artery thrombosis have all been described [46]; however the overall risk is low and this site is highly desirable because it is a large central artery yielding accurate pressure monitoring [47] during all phases of neonatal surgery, and preserves access for future interventions.

Temporal artery

The superficial temporal artery at the level just above the zygomatic arch is large and easily accessible in newborns, particularly the premature infant. It was widely used in the 1970s in neonatal nurseries [48] but rapidly fell out of favor with the realization that significant complications, e.g. retrograde

cerebral emboli, were disturbingly common [49,50]. It should only be used when a brachiocephalic pressure must be measured for the surgery in the face of an aberrant subclavian artery, so that the only way to measure pressure during cross-clamping or on bypass is via direct aortic pressure, or temporal artery pressure [51]. Examples are coarctation of the aorta, aortic arch interruption, or hypoplasia, with an aberrant right subclavian artery that arises distal to the area of aortic obstruction [52]. The catheter must be used only during the case, blood drawing and flushing should be minimized, and it must be removed as soon as possible after the repair.

Technique: A 24 ga catheter is used for newborns. The artery is palpated just anterosuperior to the tragus of the ear, just superior to the zygomatic arch. A very superficial angle of approach, i.e. 10–15°, is used, and the artery is cannulated as described for the radial artery.

Dorsalis pedis/posterior tibial arteries

These arteries are often easily cannulated and quite useful for monitoring and blood sampling during surgery when radial arteries are not available. Superficial foot arteries should not be used for cardiopulmonary bypass cases, because of the well-known peripheral vasoconstriction, and vasomotor instability in the early postbypass period, which is more pronounced with these arteries than with the radial artery.

Technique: Dorsalis pedis – the foot is plantar flexed slightly to straighten the course of the artery, which is palpated between the second and third metatarsal. A superficial course is taken and the artery cannulated. Posterior tibial – the foot is dorsiflexed to expose the artery between the medial malleolus and the Achilles tendon. The artery is often deep to the puncture site, so a steeper angle of incidence is required.

A recent study assessed the suitability of the posterior tibial and dorsalis pedis arteries, versus the radial artery, in patients with a median age of 13 months [53]. The first phase of the study measured the diameter and cross-sectional areas of the arteries by ultrasound, and the second was the randomized trial in 275 subjects. The posterior tibial artery was similar in size to the radial artery (1.4 ± 0.3 versus 1.3 ± 0.3 mm) but larger than the dorsalis pedis artery (1.0 ± 0.2, $p < 0.001$). First-attempt success rate with the posterior tibial artery was similar to the radial artery (75% versus 83%), but higher than the dorsalis pedis artery (45%, $p < 0.001$). The posterior tibial artery would appear to be the artery of choice for a pedal arterial line if other arteries are not available.

Ulnar artery

The ulnar artery should only be used as a last resort when other options are not available, because its use is usually only considered when radial artery attempts have been unsuccessful or thrombosed by past interventions. There is a high risk of ischemia of the hand if both the radial and ulnar artery perfusion is significantly compromised. Despite this, one series of 18 ulnar artery catheters in critically ill infants and children had an ischemia rate not different from radial and femoral artery catheters of 5.6% [54]. With the increasing use of high-resolution ultrasound for arterial catheter placement (see section "Ultrasound guidance for vascular access"), it is evident that at times the ulnar artery appears to be of larger diameter than the radial artery in some patients, particularly in Down syndrome. If this is the case, some anesthesiologists will attempt the ulnar artery as the first cannulation attempt site.

Arterial cutdown

Cutdown of the radial artery is a reliable and often efficient method to establish access for congenital heart surgery, and other major surgery when other arterial access has failed or is not available. Despite the speed and ease of access for a cutdown, available literature indicates a higher rate of bleeding at the site, infection, failure, distal ischemia, and long-term vessel occlusion compared to percutaneous techniques [55,56].

Technique: The arm is positioned as for percutaneous radial catheterization. After surgical preparation and draping, an incision is made at the proximal wrist crease between the styloid process and the flexor carpi radialis tendon, either parallel or perpendicular to the artery. Sharp and blunt dissection is carried out until the artery is identified, and it is isolated with a heavy silk suture, vessel loop, or right-angle forceps. It is no longer considered necessary to ligate the artery distally to prevent bleeding, and in fact the artery may remain patent after a cutdown if not ligated distally. The simplest and very effective technique is to cannulate the exposed artery directly with an angiocatheter, in the same manner as for percutaneous radial artery catheter placement. The catheter is then sutured to the skin at its hub, and the incision closed with nylon sutures on either side of the catheter. Removal entails cutting the suture at the hub of the catheter, removing the catheter, and applying pressure for a few minutes until any bleeding stops. The remaining skin sutures can be removed at a later date.

KEY POINTS: ARTERIAL ACCESS

- Indications include beat-to-beat blood pressure monitoring in cases with potential for hemodynamic instability, and need for frequent blood testing for arterial blood gases, hemoglobin, or other testing
- The radial artery is the preferred site for most arterial cannulations
- The femoral artery is a large vessel that is often second choice if the radial arteries are not available
- The posterior tibial artery is larger and more reliable than the dorsalis pedis artery
- The ulnar, brachial, axillary, and temporal arteries should only be utilized if other sites are not available, and the catheter should be removed as soon as possible

Percutaneous pulmonary artery catheterization

Percutaneous pulmonary artery (PA) catheterization has a limited role in pediatric anesthesia for several reasons. The small size of many patients precludes placement of adequate sized sheaths and catheters, and many patients in whom PA catheter monitoring would be desirable have intracardiac shunting, invalidating results of standard thermodilution cardiac output measurements and confusing mixed venous oxygen saturation (SvO_2) measurements. In addition, the frequent need for

right-sided intracardiac surgery makes PA catheterization undesirable. Thus, when PA pressure or SvO_2 monitoring is indicated, transthoracic PA lines are the most common method in congenital heart surgery. The availability of continuous central venous oxygen saturation catheters, and the perception that the risk:benefit ratio for PA catheter placement is most often unfavorable, limit the indications for this technique.

The most common indications for percutaneous PA catheterization in pediatric anesthesia are in patients over 6 months of age able to accept a 5 or 6 Fr introducer sheath in the femoral or internal jugular vein. Patients having surgery on left heart structures who do not have intracardiac shunting, who are at risk for left ventricular dysfunction or pulmonary hypertension, may benefit from the information available. Examples include aortic surgery, aortic valve repair or replacement, subaortic resection or myomectomy for hypertrophic cardiomyopathy, and mitral valve repair or replacement. In addition, major surgery, i.e. liver transplant in larger patients, may be an indication for percutaneous PA catheterization.

Technique [57]: An oximetric catheter is recommended. Commercially available models are 5.5 Fr, or 8.5 Fr, and thus require a 6 Fr or 9 Fr sheath, respectively. The 5.5 Fr catheter should be used in patients under 50 kg, and the 8.5 Fr in patients over 50 kg. The sheath is placed into the internal jugular, femoral, or subclavian veins as described above. The preferred sites of insertion are the right internal jugular, left subclavian, or femoral vein because of the direct path and curvature of the catheter. If an oximetric catheter is used, it is calibrated prior to insertion. The balloon integrity should be tested before insertion by inflating the recommended volume of air or CO_2, and the sterility sleeve is inserted before placement. The PA and CVP ports are connected, flushed, and calibrated before insertion. The PA catheter is inserted 10–15 cm with the balloon deflated, depending on patient size. The balloon is inflated, and the catheter advanced slowly toward the tricuspid valve, whose position is indicated by enlarging V waves on the CVP trace. The catheter is advanced through the tricuspid valve by advancing during diastole until the characteristic right ventricular trace is visible, with no dicrotic notch, and a diastolic pressure of 0–5 mmHg. Then, the catheter is advanced carefully through the pulmonary valve during systole, until the characteristic PA tracing is visible, with a dicrotic notch and higher diastolic pressure. The catheter is then advanced gently until the pulmonary capillary wedge pressure tracing is obtained, at which time the balloon is deflated so the PA tracing rapidly returns. Difficulty with advancing through the pulmonary valve may be assisted by counterclockwise rotation of the catheter while advancing, positioning the patient right side down, and giving a fluid bolus, or by using TEE to visualize the tip and guide subsequent attempts [58]. The catheter must not be left in the wedge position except for brief periods because of the risk of pulmonary artery rupture and lung ischemia distal to the catheter. During bypass, the catheter can be pulled back several centimeters to reduce the risk of perforation on bypass.

Information obtainable with a PA catheter includes right atrial pressure, pulmonary artery pressure, and pulmonary capillary wedge pressure (PCWP). In the absence of mitral valve stenosis or pulmonary venous or arterial hypertension, PA diastolic ~ PCWP ~ LAP ~ left ventricular end-diastolic pressure, which is proportional to left ventricular end-diastolic volume, the classic measure of preload [59]. Despite the presence of pulmonary hypertension or residual mitral stenosis (diagnosed with postoperative TEE), information from the PA catheter can still be used to direct therapy.

Cardiac index may be measured by standard thermodilution methods, with care taken to input the correct calculation constant into the monitor software according to the catheter size and length, and volume and temperature of injectate. The average of three consecutive injections made in rapid succession at the same point in the respiratory cycle, i.e. expiration, will optimize conditions to achieve an accurate measurement during steady-state conditions. Vascular resistances and stroke volume can also be calculated, using the formulae in Table 19.5 [59,60].

Hemodynamic data represent only half of the information available from an oximetric PA catheter. The other half consists of oxygen delivery and consumption measurements and calculations, which may also be used to guide therapy in the critically ill patient with low cardiac output syndrome [59,60] (Table 19.6). They require either measurement of mixed venous

Table 19.5 Derived hemodynamic parameters

Formula	Normal values		
	Adult	**Infant**	**Child**
$CI = \frac{CO}{BSA}$	2.8–4.2 L/min/m^2	2–4	3–4
$SVI = \frac{SV}{BSA}$	30–65 mL/beat/m^2	40–75	40–70
$LVSWI = \frac{1.36 \cdot (MAP - PCWP) \cdot SVI}{100}$	45–60 g · m/m^2	2–40	30–50
$RVSWI = \frac{1.36 \cdot (PAP - CVP) \cdot SI}{100}$	5–10 g · m/m^2	5–11	5–10
$SVRI = \frac{(MAP - CVP) \cdot 80}{CI}$	1500–2400 dyne · s · cm^{-5} · m^2	900–1200	1300–1800
$PVRI = \frac{(PAP - PCWP) \cdot 80}{CI}$	250–400 dyne · s · cm^{-5} · m^2	<200	<200

BSA, body surface area; CI, cardiac index; CO, thermodilution cardiac output; CVP, central venous pressure; LVSWI, left ventricular stroke work index; MAP, mean arterial pressure; PAP, pulmonary arterial pressure; PVRI, pulmonary vascular resistance index; RVSWI, right ventricular stroke work index; SVRI, systemic vascular resistance index; SV, stroke volume; SVI, stroke volume index.

Table 19.6 Derived oxygen delivery/consumption parameters

Formula	Normal values		
	Adult	**Infant**	**Child**
Arterial O_2 content $CaO_2 = (1.39 \cdot Hb \cdot SaO_2) + (0.0031 \cdot PaO_2)$	18–20 mL/dL	15–18	16–18
Mixed venous O_2 content $CvO_2 = 1.39 \cdot Hb \cdot SvO_2 + 0.0031 \cdot PvO_2$	13–16 mL/dL	11–14	12–14
Arteriovenous O_2 content difference $avDO_2 = CaO_2 - CvO_2$	4–5.5 mL/dL	4–7	4–6
Pulmonary capillary O_2 content $CcO_2 = 1.39 \cdot Hb \cdot ScO_2 + 0.0031 \cdot PcO_2$	19–21 mL/dL	16–19	17–19
Pulmonary shunt fraction $Q_s/Q_t = 100 \cdot (CcO_2 - CaO_2)/(CcO_2 - CvO_2)$	2–8%	2–8	2–8
O_2 delivery index $DO_2I = 10 \cdot CO \cdot CaO_2/BSA$	450–640 mL/min/m^2	450–750	450–700
O_2 consumption index $VO_2I = 10 \cdot CO \cdot (CaO_2 - CvO_2)$	85–170 mL/min/m^2	150–200	140–190

Hb, hemoglobin; PaO_2, partial pressure of oxygen in arterial blood; PvO_2, partial pressure of oxygen in mixed venous blood; PcO_2, partial pressure of oxygen in pulmonary capillary blood; Q_s, pulmonary shunt blood flow; Q_t, total pulmonary blood flow; SaO_2, measured arterial oxygen saturation; ScO_2, measured pulmonary capillary oxygen saturation; SvO_2, measured mixed venous oxygen saturation.

and systemic arterial saturations from blood samples from the tip of the PA catheter and arterial line (measured by co-oximetry, not calculated), or substitution of these values with SvO_2 from the oximetric catheter (a valid assumption if properly calibrated), and pulse oximeter value instead of measured systemic saturation. There are data from adult and pediatric critical care literature suggesting that the ability to increase and maximize both oxygen delivery and consumption may improve outcome and is a predictor of survival from critical illness, including postoperative cardiac surgery [61–64].

Ultrasound guidance for vascular access

Numerous studies demonstrate that ultrasound guidance, either two-dimensional visual ultrasound [65], or audio Doppler ultrasound, improves the outcome of central venous cannulation, in both children and adults [66,67]. Use of these methods leads to fewer attempts, decreased insertion time, fewer unintended arterial punctures, and fewer unintended arterial catheter placements. The consensus of many experts in the field of vascular access is that use of these guidance techniques should be considered standard of care. A recent meta-analysis of eight controlled trials of two-dimensional ultrasound guidance versus landmark method for internal jugular or subclavian vein access in children combined data from 760 patients [68]. With ultrasound the relative odds of successful placement was 1.32 ($p = 0.003$), the number of attempts was lower by -1.26 ($p < 0.001$), and there was a trend toward lower risk of arterial puncture and time to cannulation.

In recent years ultrasound for arterial cannulation has been the subject of an increasing number of case series and several controlled trials, and has also increasingly become standard practice. Finally, peripheral venous access with ultrasound guidance has been the subject of numerous recent reports and clearly offers advantages over landmark or blind techniques when venous access is difficult, including lower number of punctures and time to cannulation [69,70] (Fig. 19.6).

A 9.2 MHz pencil-thin audio Doppler probe can be gas sterilized and reused. The probe is applied to the site, and the course of the artery and vein are ascertained by their characteristic audio profiles: high-pitched, intermittent, systolic flow for the artery, and low-pitched, continuous venous hum for the vein. The probe is centered over the loudest signal, perpendicular to the skin surface, and the vessel is punctured

Figure 19.6 Greater saphenous vein (GSV) peripheral access using ultrasound guidance. The ultrasound image is a short-axis view of the tip of the IV catheter inside the vein. *Source:* Reproduced from Triffterer et al [69] with permission of Elsevier.

exactly in the axis of the center of the probe. A "pop" followed by the continuous sound of blood aspiration can often be heard when the vessel is entered. The guidewire, dilator, and catheter are then passed as described previously. A variation of the audio Doppler technique is a device with the Doppler probe within the needle [71]. However, these needles are expensive, direct comparison has not shown them to be superior to visual ultrasound for cannulation, and because the lumen of the needle is partially occluded by the Doppler probe, flashback of blood is slow and unreliable.

Two-dimensional ultrasound, either in the form of commercially available devices for CVC cannulation only (Sonosite®), or surface probes on standard echocardiography machines, can be used to image large vessels (Fig. 19.7A). The color Doppler feature on the latter may be particularly useful to identify desired vessels during difficult vascular access. The internal jugular vein is the most frequently accessed vessel with ultrasound, and it is visualized superficial to and lateral to the carotid artery. The internal jugular vein is also easily compressible with the probe and is gently pulsatile, while the carotid artery is round, difficult to compress with probe pressure, and very pulsatile (Fig. 19.7B). The probe is held directly over the desired vessel, with the goal of puncturing it exactly in the midline. The needle can be seen indenting and then puncturing the vessel during correct placement (Fig. 19.7C).

Two-dimensional ultrasound is particularly useful to clarify the anatomy after several previous attempts have been made. One can identify the vessel in the midst of a hematoma that has formed, or recognize overlap of the artery and vein. Once the vessel has been punctured and the guidewire passed, ultrasound can be used to visualize the guidewire in the lumen of the vessel by scanning closer to the heart. Ultrasound methods are described most often for the internal jugular vein, but are also useful for the femoral and subclavian veins. It should also be noted that real-time ultrasonographic visualization of needle insertion, vessel puncture, and guidewire passage of the internal jugular vein in infants results in fewer attempts and faster cannulation than merely marking the skin after ultrasound visualization followed by blind puncture of the vessel [72]. Several case series of central venous cannulation in very small infants have been published in which two-dimensional ultrasound safely guided catheter placement even in premature neonates down to weights of 1.0 kg or lower [73].

Audio Doppler can be used to assist in the cannulation of any artery, and is particularly useful when pulses are diminished from previous attempts, hypotension, or vasospasm. Two-dimensional ultrasound can also be used to cannulate radial arteries: Schwemmer et al found that this technique resulted in a 100% success rate, versus 80% for the traditional palpation method, and also resulted in a higher success rate on the first attempt and lower number of attempts [74]. Two-dimensional ultrasound was also demonstrated to be superior to audio Doppler for radial artery cannulation in patients <12 kg when used by anesthesia residents or fellows with no or little experience with ultrasound-guided cannulation [75]. The overall success rate in this randomized study was 65% in the ultrasound group and 46% in the audio Doppler group ($p = 0.048$).

The technique for arterial cannulation with ultrasound involves visualizing the artery in short-axis cross-sectional area, and inserting the needle tip until it can be seen puncturing the arterial wall and resting within the lumen. The artery can be seen as pulsatile, and color-flow Doppler can also aid in its identification. A newer approach involves the longitudinal view of the artery, which allows a longer length of the needle to be visualized to ensure that is within the artery lumen and not puncturing the back wall of the artery [53] (Fig. 19.8). A controlled study of short- versus long-axis imaging for radial artery cannulation in 97 infants and children revealed no difference in success rate (94% short axis versus 98% long axis), time to successful cannulation, or complications [76]. The posterior artery wall puncture rate was much higher in the short-axis group (96% versus 18%, $p < 0.001$); the clinical significance of this is unclear.

KEY POINTS: ULTRASOUND GUIDANCE FOR VASCULAR ACCESS

- Accumulating data suggest that two-dimensional ultrasound for central venous access increases success rate, decreases number of attempts, and may decrease arterial puncture rate and time to cannulation
- Arterial access, particularly in infants and small children, can be facilitated with ultrasound, and both short- and long-axis views may be helpful
- Peripheral venous access, especially where no vein is visible, can be significantly facilitated by two-dimensional ultrasound

Interpretation of intravascular pressure waveforms

Arterial waveforms

The normal systemic arterial pressure waveform changes with progression distally from the central arterial circulation, e.g. ascending aorta, distally to abdominal aorta and femoral arteries, and then to the peripheral arteries such as the radial and dorsalis pedis/posterior tibial arteries [59] (Fig. 19.9). In general, the more central sites will produce less peaked systolic pressure waves with slightly lower systolic pressure readings. The dicrotic notch is pronounced in the central arteries. With distal progression, pulse wave amplification will produce a higher peaked systolic pressure wave with a slightly higher systolic pressure. This is most pronounced in the arteries of the foot, where the systolic pressure may be 5–15 mmHg higher than in the ascending aorta. The mean and diastolic pressures change very little with progression. This concept is very important in interpreting arterial pressure tracings. The postbypass arterial tracing is frequently dampened with catheters in small distal arteries, e.g. radial or foot arteries [77]. This usually resolves within a few minutes after bypass. For particularly long and difficult operations with long bypass and cross-clamp times, or in major non-cardiac cases with substantial blood loss and hemodynamic instability, it may be useful to place catheters in larger arteries, e.g. femoral or umbilical, or to measure the pressure directly in the aortic root immediately after bypass to ascertain an accurate arterial pressure.

The arterial pressure tracing can yield more information than simply the systolic and diastolic blood pressures [78,79]. The slope of the upstroke of the pressure wave may be an indicator of systemic ventricular contractility, i.e. the steeper the upslope, the better the contractility. Significant reductions in contractility flatten the upslope. The position of the dicrotic notch may give an indication of peripheral vascular resistance. In infants, the normal dicrotic notch is in the upper half of the pressure wave. With low peripheral resistance, as in arterial runoff through a patent ductus arteriosus, the dicrotic notch is lower on the descending limb of the waveform, due to diastolic runoff into the pulmonary artery, resulting in a relatively longer period of ventricular systole. The area under the curve of the systolic portion of the arterial tracing increases with increased stroke volume. Finally, a hypovolemic patient will often exhibit more pronounced respiratory variation during positive pressure ventilation, as the stroke volume decreases when positive pressure impedes an already limited venous return (Fig. 19.10). Computerized pulse-contour

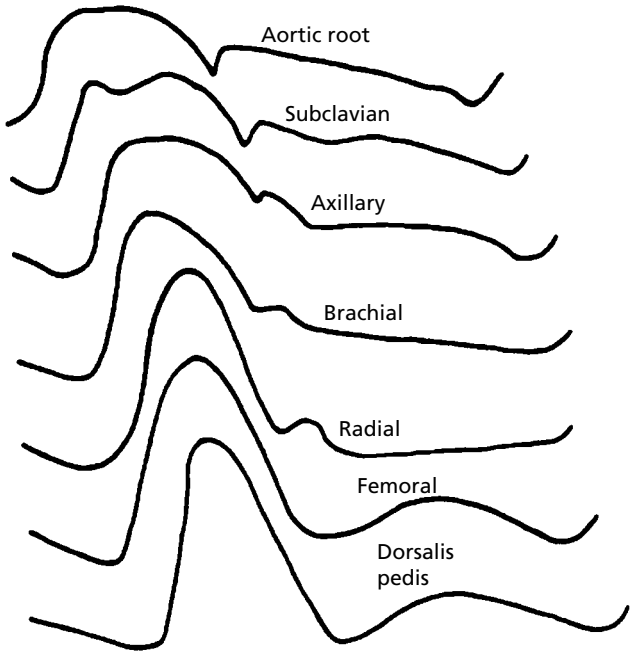

Figure 19.9 Progression of the arterial pressure tracing from the root of the aorta to more peripheral arteries. Pulse wave amplification produces a higher systolic peak and slightly lower diastolic pressure in the smaller distal arteries, especially the dorsalis pedis. *Source:* Reproduced with permission from Reich et al [59] with permission of Elsevier.

analysis of the arterial pressure waveform has been used to measure stroke volume (see section "New techniques in pediatric intravascular monitoring").

Mechanical and electronic components of the intravascular pressure measurement system are important considerations when interpreting waveforms [59]. The shortest possible large-bore, stiff plastic tubing should be used. Minimizing the number of stopcocks and connections will also improve the fidelity of the transmitted pressure wave. Thorough flushing before use to produce a bubble- and clot-free fluid path is critical. Periodic recalibration at the right atrial level is important to account for "drift" in the transducer setting. When ringing or overdamping is recognized, some monitor models offer adjustment of electronic filter frequency. The routine setting should be 12 Hz. If the arterial tracing is underdamped, e.g. overshoot producing an artificially high spike as the systolic pressure, filter frequency may be decreased as low as 3 Hz to compensate. Conversely, if overdamped, the filter frequency may be increased to as high as 40 Hz. Mechanical devices (ROSE®, accudynamic®) may also be inserted to

change the resonance frequency and/or damping factor of the system. Under no circumstances should a bubble be intentionally introduced into the system to produce increased damping effect. Appropriateness of resonance frequency may be tested by flushing the system from a pressurized bag of heparinized saline, stopping suddenly, and observing the number and amplitude of oscillations required to return to baseline waveform. Proper damping is signified by one oscillation below, and one above the mean before return to normal waveform [80,81].

Failure of arterial pressure monitoring systems is always possible during surgery, due to mechanical problems such as kinking or clotting of the catheter. Spasm of the artery is more common than in adults, and the artery may be compressed, such as aberrant right subclavian compression from a TEE probe, or compression of an axillary artery from a sternal retractor. A back-up oscillometric blood pressure cuff should always be present, preferably placed on a different extremity than the arterial catheter.

Central venous, right and left atrial waveforms

Normal atrial (i.e. central venous) pressure waveforms consist of the A, C, and V waves corresponding to atrial contraction, closure of the tricuspid or mitral valves, and ventricular contraction. Normal right atrial A wave pressure is lower than V wave pressure, which is usually less than 10 mmHg. Changes from the normal tracing can give important information about the hemodynamic status and cardiac rhythm of the patient. For example, when atrioventricular synchrony is lost, as in junctional ectopic tachycardia or supraventricular tachycardia, the A wave disappears and the V wave enlarges considerably, reflecting backwards transmission of ventricular pressure through an ineffectively emptied atrium (Fig. 19.11). Determining the cardiac rhythm from the ECG is often difficult at rapid heart rates because the P wave of the ECG is indiscernible. The left or right atrial waveform can give crucial added information in this situation, clearly retaining the A wave in cases of sinus tachycardia. Competency of the AV valves can also be assessed from the atrial tracing. Mitral or tricuspid regurgitation will produce a large V wave on the left atrial tracing. It is often very useful to record the vascular pressure tracings in sinus rhythm at baseline for later comparison.

New techniques in pediatric intravascular monitoring

Cardiac output monitoring

Because traditional percutaneous, balloon-tipped pulmonary artery catheterization is limited in small children and those with intracardiac shunting, several other recent methods to measure cardiac output and oxygen delivery in patients with congenital heart disease have been applied. Lithium dilution cardiac output (LiDCO) uses a standard central line in the SVC or even a peripheral intravenous catheter, and a special

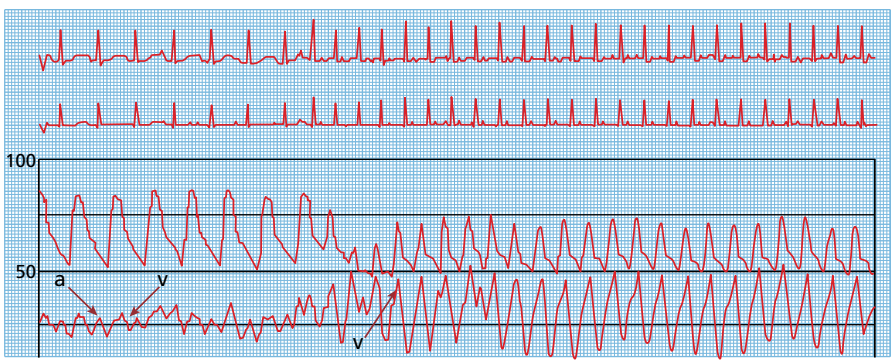

Figure 19.11 ECG demonstrating normal sinus rhythm in the first third of the panel, with onset of supraventricular tachycardia. Note the arterial pressure tracing with a 12–15 torr decrease in systolic pressure, and the loss of the A wave on the central venous pressure tracing, with the appearance of large V waves with a systolic pressure increase from 10 to 16 mmHg.

femoral artery catheter equipped with a lithium-detecting electrode. A dilute solution of lithium chloride is injected into the vein, and arterial blood is withdrawn into the lithium electrode. The cardiac index is related to the area under the curve of the change of lithium concentration. This method has been demonstrated to have reasonable correlation with thermodilution cardiac output in children after congenital heart surgery. In a study of 48 measurements in 17 patients 2.6–34 kg, correlation between LiDCO and thermodilution cardiac output was good ($r^2 = 0.96$, mean bias -0.1 ± 0.31 L/min [82].

Transpulmonary thermodilution cardiac output uses a similar principle as LiDCO, with temperature as the indicator instead of lithium concentration. Cold saline is injected into a CVC, and via a thermistor placed in a femoral artery, a time temperature curve is derived that correlates reasonably well with standard thermodilution cardiac output as measured by a standard pulmonary artery catheter [83]. Lithium and thermodilution methods are limited to patients without any intracardiac shunting, significantly restricting their use in congenital heart disease. A recent systematic review of 14 adult studies and two pediatric studies assessing the reproducibility of transpulmonary thermodilution with three injections determined that the reproducibility was within 6.1 ± 2.0% in adults and 3.9 ± 2.9% in children [84]. This method would appear to be suitable to follow trends in cardiac output in critically ill children.

Yet another newer method is pulse-contour analysis of the arterial waveform (PiCCO), which relates the contour and area under the curve to the stroke volume, and thus the cardiac output. This continuous method is periodically calibrated using the transpulmonary thermodilution cardiac output as described previously (again making the method invalid with intracardiac shunting), and demonstrated a good correlation with transpulmonary thermodilution in a study of 24 pediatric patients after cardiac surgery ($r^2 = 0.86$, mean bias 0.05 ± 0.4 L/min/m^2) [85].

A related measure is pulse pressure variation, noted previously under interpretation of arterial pressure waveforms. During positive pressure ventilation, variation in pulse pressure derived from the arterial line has been reported to be proportional to the degree of hypovolemia and fluid responsiveness in adults [86]. Commercial systems are available to quantify this variation, and in one study of acute normovolemic hemodilution in children undergoing cranial vault surgery the increase in pulse pressure variation correlated well with the estimated blood volume during the blood removal phase [87].

Attempts have been made to relate pulse pressure variation to pulse oximeter plethysmographic variation, which depends on variability to light absorption over the cardiac cycle in response to positive pressure ventilation and is a feature built into new pulse oximeters [88] (Fig. 19.12). One study in 45 ventilated critically ill children demonstrated strong correlation ($r = 0.84$, $p < 0.0001$) and close agreement (bias +1.44 ± 6.4) in variation of the two indices [88]. However, another study in adolescent scoliosis surgery patients found a small bias of −0.56% in measurements, but a very wide range of limits of agreement of >20%. Neither study assessed fluid responsiveness to this measure. More data are required before recommending this parameter for pediatric patients.

Central venous oxygen saturation monitoring

Monitoring of intravascular oxyhemoglobin saturation using reflectance catheters has been used in the umbilical artery, pulmonary artery, and adult-sized central venous catheters for a number of years, but only recently have standard pediatric sized 4 and 5 Fr, double- and triple-lumen central venous catheters become available for routine use to measure central venous oxygen saturation ($ScvO_2$) in pediatric patients. In 16 pediatric patients undergoing cardiac surgery, Liakopoulos

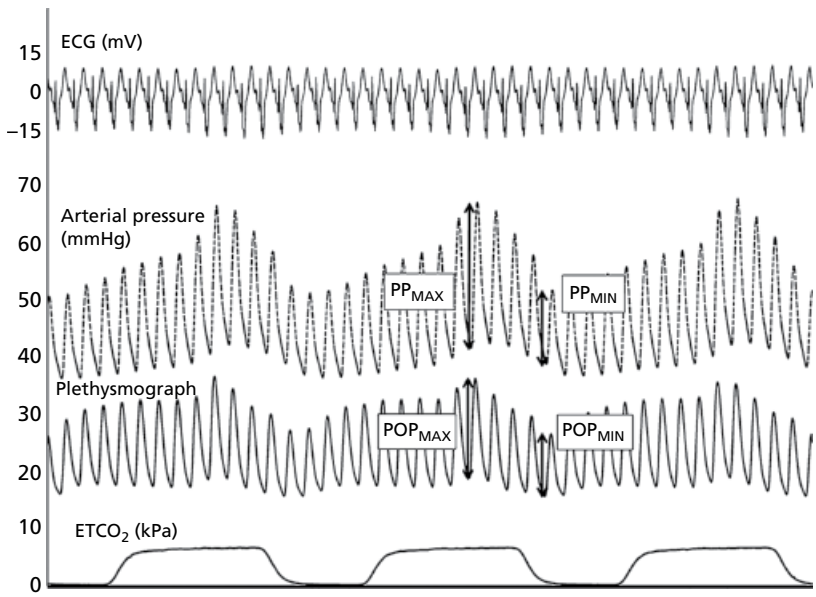

Figure 19.12 Plethysmographic signal variation versus pulse pressure variation to assess volume status. Simultaneous display of waveforms; plethysmograph is from pulse oximeter signal. ECG, electrocardiogram; $ETCO_2$, end-tidal carbon dioxide; POP, plethysmographic variation; PP, pulse pressure. *Source:* Reproduced from Chandler et al [88] with permission of Springer Nature.

et al demonstrated good correlation between $ScvO_2$ as measured with the catheter, versus blood co-oximetry (r^2 = 0.88, bias −0.03 ± 4.72%) [89] (Fig. 19.13). The advantage of this method is that it is an accurate measure of oxygen delivery that is independent of intracardiac shunting and thus may have better utility in the congenital heart disease patient. Two subsequent studies in a total of 28 pediatric cardiac surgery patients yielded mixed results: one showed minimal bias and narrow variability, and the other demonstrated a small bias but a wide 95% limit of variability of over 15% [90,91]. More outcome data are needed for this technique, but it may be useful as an adjunct for continuous monitoring of oxygen delivery in major cases.

Emergency vascular access

Intraosseous access to the venous circulation has been described for use during a crisis when no other venous access is available, e.g. during cardiopulmonary resuscitation or shock [92]. Rarely, it may be required for emergency resuscitation in the operating room or intensive care unit, and it is therefore necessary for the pediatric anesthesiologist to be familiar with the technique. Normally this procedure is used only in small children, and the flat surface of the proximal tibia is used. Commercially available 14 or 16 ga intraosseous needles, or 16 ga bone marrow aspiration needles may be used. The site is aseptically prepared, the skin is punctured, and the outer bony cortex is contacted. With a boring motion, the needle is advanced through the outer cortex into the marrow space, heralded by a sudden loss of resistance. Infants have active marrow production in long bones, and when the stylet is removed and the needle aspirated, bone marrow should appear in the hub. Rapid infusion of 10 mL normal saline without extravasation confirms proper placement, and emergency drugs and fluids may be administered. They reach the central circulation via the bone marrow sinusoids, which connect to the emissary veins from the bony cortex, and then to the larger veins draining into the central circulation. Drugs injected intraosseously, e.g. epinephrine, reach the heart slightly more slowly than when injected into a central vein, but the peak drug levels are not different [92]. Intraosseous needles should be available for the rare crisis in the operating room or intensive care unit. Intraosseous needles should be replaced as soon as possible with conventional peripheral or central venous access.

Newer intraosseous access systems are now available with a drill-like driver that inserts a premeasured length needle into the intraosseous space and has a custom connector and fixation dressing (Fig. 19.14) [93]. Complications of intraosseous access can be severe and mostly involve extravasation of caustic substances like calcium chloride when the needle is malpositioned or dislodged. These include compartment syndrome with need for fasciotomies, and amputation [94,95]. Intraosseous access should be used for life-threatening emergencies only, requires constant checking for proper needle position, and should be removed as soon as possible after standard vascular access is obtained.

KEY POINTS: NEW TECHNIQUES IN PEDIATRIC INTRAVASCULAR MONITORING

- Lithium dilution, transpulmonary thermodilution, pulse contour analysis, and pulse pressure variation can be used to monitor cardiac output but have limited and mixed data in pediatrics
- Continuous central venous oxygen saturation monitoring correlates moderately well with co-oximetry and can be used as a trend monitor of oxygen delivery and consumption
- Intraosseous access in the flat surface of the tibia of infants and small children can be used in life-threatening emergencies to infuse emergency drugs and fluids

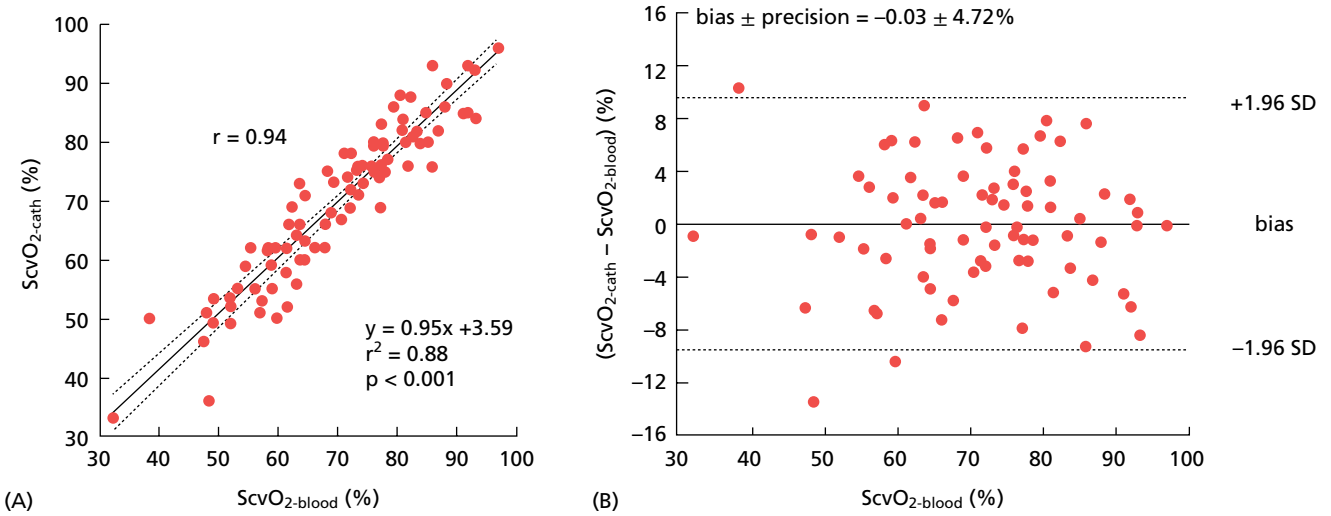

Figure 19.13 Central venous oxyhemoglobin saturation ($ScvO_2$) in the superior vena cava, comparing blood co-oximetry to fiberoptic reflectance spectroscopy. Complications of vascular access

Thrombosis

Thrombosis is the single most frequent complication, especially among infants. Central venous thrombosis secondary to vascular access develops in 5.8% of neonatal patients, which is ten times that of older patients, and accounts for 40–50% of central venous thromboses after congenital heart surgery [96]. The frequency significantly decreases in patients over 6 months of age. Factors that contribute to the risk of thrombosis include: (1) large-bore catheters in small vessels, i.e. larger than 4 Fr in small infants; (2) duration of cannulation exceeding 7 days; (3) venous stasis due to extreme fluid restriction or low cardiac output; (4) infusion of high-osmolarity fluids, i.e. concentrated dextrose in parenteral nutrition fluids; and (5) hypercoagulable states [97]. Other risk factors for thrombosis include protein C resistance due to factor V Leiden mutation, prothrombin mutations, methylenetetrahydrofolate reductase mutations [98], elevated preoperative C-reactive protein [99], and arterial catheterization with the use of vasoconstrictors such as norepinephrine, vasopressin, or terlipressin [100]. Immediate consequences of SVC thrombosis include SVC syndrome [101] with increased intracranial pressure and chylothorax from ineffective drainage of the thoracic duct into the SVC. IVC thrombus leads to ascites, renal, and intestinal dysfunction, and edema of the lower abdomen and extremities. The patient must be assessed carefully for signs of thrombosis, and suspicion of thrombosis should be evaluated by ultrasound examination. Treatment modalities include removing the catheter, heparinization, thrombolytic agents such as tissue plasminogen activator and urokinase [102–104], antithrombin III replacement [105], and surgical thrombectomy. Mortality from SVC thrombosis is reported to be as high as 33% and it is therefore critical to try to prevent this complication, preferably by avoiding SVC catheters in patients under 4 kg. Thrombosis also leads to a higher rate of infection [106,107]. Heparin-bonded catheters may decrease the rate of thrombosis and do not increase risk of bleeding [106,108]. They may also lead to a lower rate of catheter colonization and infection [109]. However, it is currently not possible to bond both heparin and antibiotics to the same catheter. In patients with occlusion of central veins from previous catheters, magnetic resonance venography may be useful in identifying patent veins for future interventions [110].

Thrombosis or dissection of an artery is a serious complication that must be treated immediately. Immediately after arterial catheter placement it is important to inspect the extremity distal to the catheter, comparing it to the other extremity, and palpate distal pulses. Absence of a pulse, pallor, slow capillary refill, cool temperature, and no flow by color Doppler examination are all signs of arterial compromise. Placement of a pulse oximeter probe distal to the catheter serves as a continuous monitor and provides early warning of vascular insufficiency. Transient compromise to perfusion immediately after catheter placement due to arterial spasm or during low-output states may be observed. However, when extremity

perfusion is significantly compromised, treatment by removal of the catheter, use of vasodilators, warming the extremity, heparin, thrombolytics, surgical consultation for thrombectomy, fasciotomies, or surgical reconstruction is indicated. Modern high-resolution Duplex ultrasound scanning can quickly and accurately diagnose the location, size, and consequences to blood flow of an arterial thrombus and should be obtained if this is suspected [111].

Malposition/perforation

Central venous catheter tips should not lie in the right atrium. Adult and pediatric studies have consistently demonstrated a higher rate of heart and great vessel perforation with associated cardiac tamponade when catheter tips are in the atrium [27,112–116]. Perforation is also less common with right-sided lines, e.g. right internal jugular or subclavian, because the catheter tip is parallel to the vein wall. The catheter tips of left-sided lines are frequently at a 45–90° angle of incidence to the SVC or atrium, and mechanical models demonstrate that this position is more likely to lead to great vessel perforation [117]. Finally, 5–10% of patients with congenital heart disease have a left SVC [116], which most often drains into the coronary sinus or left atrium, and both of these sites are undesirable locations for a catheter tip [118]. Thus the ideal position of a CVC is in the mid SVC with the tip parallel to the vein wall (see Fig. 19.3). Soft polyurethane or silicone catheters are also much less likely to perforate than stiffer polyethylene catheters [117]. Perforation is recognized by inability to consistently aspirate blood, an abnormal waveform, and signs and symptoms of pericardial tamponade or hemothorax. Treatment involves aspiration of all the blood possible through the catheter and establishing alternative access, intravascular volume replacement, and drainage of the pericardial or pleural blood, by needle, tube, or surgical exploration.

Many authorities recommend positioning the tip of the catheter in the superior half of the SVC, above the pericardial reflection. This recommendation is based on the theoretical concept that if there is a perforation, cardiac tamponade will not be produced, and also the catheter tip will be above the SVC bypass cannula and thus yield accurate CVP measurements on cardiopulmonary bypass [119]. There are several problems with this approach in pediatric anesthesia and surgery, particularly in small patients. First, the SVC is often only 4–5 cm long, leaving little room for error in placement. It is preferable to have the catheter slightly too deep in the SVC, because this will lead to accurate pressure measurements and proper infusions of drugs and fluids. When a multilumen catheter is positioned too high, a proximal port may not be intravascular, leading to extravasation of important or caustic drugs and fluids [120]. In addition, the pericardium is usually opened in congenital heart surgery, and drained postoperatively, rendering placement above the pericardial reflection unnecessary. Many series of catheter placements in children document that the internal jugular route results in tip placement in the SVC or RA 98–100% of the time, whereas the subclavian route has a 5–15% incidence of catheter malposition, i.e. across the midline in the contralateral brachiocephalic vein or up the ipsilateral internal jugular vein. A recently published randomized trial of internal jugular versus subclavian catheters in pediatric cardiac surgery confirmed this, with 17 of 128 (13.2%) subclavian catheters malpositioned versus 2 of 139 IJV catheters (1.4%), $p < 0.001$ [121].

Despite numerous previous reports of cardiac perforation by central venous catheters, and the publication of studies documenting height- and weight-based formulae for depth of insertion of SVC catheters in infants [31], reports of cardiac perforation resulting in death or necessitating surgical exploration by sternotomy continue to occur [122].

When IVC catheters are used, accurate CVP measurements are usually obtained whether the tip of the catheter is above or below the diaphragm. Umbilical venous catheters should be above the level of the diaphragm at the IVC–RA junction, but not in the RA [123] to ensure passage through the ductus venosus and parallel position to the IVC wall [124]. In a series of 128 portal vein thromboses in neonates, 73% of them had an umbilical venous catheter and in half of them it was malpositioned; this constituted a major risk factor for poor outcome [125].

A recently described complication of femoral venous catheters is inadvertent placement in the lumbar venous plexus, which may result in paraplegia from epidural hematoma or infusion of vasoconstrictive substances [126,127]. Catheterization of the lumbar venous plexus usually occurs when there is partial or total occlusion of the IVC from previous interventions, and the guidewire passes posteriorly through collateral circulation into the lumbar plexus. This malposition may be suspected during insertion when resistance to catheter passage is encountered, or the catheter will not thread its entire length. An anteroposterior radiograph reveals an abnormal catheter course, often appearing to be more lateral than normal. A lateral radiograph will definitely diagnose such malposition where the catheter tip passes posterior to the vertebral bodies. The catheter must be removed immediately and the patient assessed for neurological deficit if this malposition is discovered. Retroperitoneal hematoma from perforation of the femoroiliac vessels by the catheter or guidewire can also occur [128].

Inadvertent arterial puncture can usually be prevented by the use of an ultrasound guidance system for CVC placement as described in the section "Ultrasound guidance for vascular access." However, if this complication occurs, the following general principles are useful. After needle puncture, if there is any question about whether the vessel is an artery, remove the needle immediately, elevate the area, and maintain firm pressure for 5–10 min. A small-bore needle puncture of the carotid or femoral artery, e.g. 20 ga or smaller, is not usually an indication to cancel surgery. If a larger hole is created in the artery, i.e. a dilator and the catheter have been placed, pressure transduction can be used to confirm the location. In this case, a discussion with the surgeon must ensue. Normally, the catheter can be removed, and pressure held without consequences unless a very large catheter was used, e.g. introducer sheath or large-bore CVP catheter, in which case surgical exploration and repair should be undertaken. In most cases of elective cardiac surgery, it is prudent to postpone the case if a large hole has been made in the artery. The case can usually be safely performed 24 h later if no bleeding has occurred. In emergency or urgent cases which must proceed despite a large hole in the artery, the neck or groin should be prepped into the field for exploration if excessive bleeding or hematoma formation occurs.

Pneumothorax

This complication is most frequent with the subclavian approach, but also may occur with the internal jugular approach, especially with the low puncture sites, e.g. jugular notch approach. To avoid this complication with the subclavian approach it is important to advance the needle only during expiration. A very shallow approach, with the needle directed just posterior to the clavicle and at the sternal notch, is also important. For the internal jugular vein a higher puncture site, and limiting the caudad advancement of the needle to stop above the clavicle will usually prevent this complication [129].

Continuous aspiration should be performed as the needle is advanced using a saline-filled syringe. If air is aspirated as the needle advances, attempts at venipuncture should stop immediately, and careful monitoring for compromise of ventilation and hemodynamics should ensue. A chest radiograph should be obtained to make the diagnosis if the start of surgery is not imminent, and pleural drainage by needle, catheter, or tube should be undertaken if indicated. The pleura can be opened on that side after sternotomy if pneumothorax is diagnosed or suspected.

Infection

Catheter-related sepsis results in significant morbidity, some mortality, prolongation of ICU stay, and increased expense. The incidence of arterial catheter related infection is low. A study of 340 arterial catheters in children revealed a 2.3% incidence of local site infection, and 0.6% catheter sepsis [130]. However, CVC-associated bloodstream infection is a major problem. There is strong evidence that several strategies may be employed to reduce this complication [131]. The first is the use of full barrier precautions, e.g. sterile gown, mask, gloves, and careful septic technique, during insertion [5]. Second, chlorhexidine has been shown to be superior to other antiseptic solutions. Finally, antibiotic bonding to the resin of the catheter will reduce infection [132]. This can be done in several ways, i.e. antibiotics already embedded in the resin (minocycline/rifampin or chlorhexidine/silver sulfadiazine) or applied at the time of insertion by soaking the outer and inner surfaces of the catheter in a negatively charged antibiotic at 100 mg/mL concentration such as vancomycin, cefazolin, or other cephalosporins. Antibiotic is slowly released from the catheter, delaying and reducing colonization and reducing the incidence of catheter sepsis. The increased cost per catheter is about $20, but one episode of catheter sepsis is estimated to cost $14,000 in 1995 dollars [132]. In a study of antibiotic-impregnated catheters in 225 critically ill children, minocycline–rifampin-coated catheters delayed the onset of infection in those patients who were infected to 18 days, from 5 days in non-antibiotic catheters [133]. Central venous catheters indwelling for more than 5–7 days have an increased incidence of colonization and sepsis [134] as well as vessel thrombosis. Suspicion of catheter sepsis should be followed by peripheral blood culture, and blood culture from the central line. The catheter should be removed when possible and the tip cultured. Institute antibiotic therapy empirically tailored to the most common institution-specific pathogens, and provide coverage for *Staphylococcus epidermidis*, which continues to be a common pathogen in catheter-related sepsis. A comprehensive, systematic intervention program to prevent central line-associated bloodstream infections in a very busy cardiac ICU, including insertion, access, and maintenance protocols, and a protocol for timely removal of central lines, reduced the infection rate from 7.8 infections per 1000 catheter days to 2.3 infections per 1000 catheter days [135]. A recommended central line insertion bundle is displayed in Box 19.1.

Arrhythmias

Other complications associated with vascular access procedures include arrhythmias. Ectopic atrial tachycardia, in particular, has been associated with a catheter tip in the right atrium [136,137]. Atrial fibrillation has also been associated with CVC placement [138]. More commonly, arrhythmias occur with the passage of the guidewire [139] and include isolated PAC, supraventricular tachycardia, and, if the guidewire is advanced into the right ventricle, premature ventricular contractions and even ventricular tachycardia or fibrillation. Complete heart block has also been described during guidewire passage in small infants [140]. Great care must be taken when passing the guidewire to stop advancing it when significant arrhythmias are encountered, and when advancing the catheter over the wire to retract the wire as the catheter is advanced. Patients particularly at risk for significant arrhythmia are those with a known history of arrhythmia and also those with significant right ventricular hypertrophy.

Systemic air embolus

Systemic air embolus is a constant threat for patients with central or peripheral venous catheters and intracardiac shunting [141], particularly two-ventricle patients with right-to-left shunting, and single-ventricle patients in infancy who have obligate mixing of systemic and pulmonary venous return in the systemic ventricle. Air may lodge in the coronary arteries (especially the right), pulmonary artery, or cerebral vessels, leading to potentially serious complications. Observation of the TEE, or transcranial Doppler ultrasound as used for neurological monitoring, reveals rapid passage of any introduced systemic venous air into the aorta and cerebral circulation. For this reason, meticulous attention must be paid to prevent introduction of air into the systemic venous circulation as much as possible. Precautions include thorough de-airing of all intravenous infusions before connection to the patient, de-airing of continuous flush central venous lines, air filters on continuous infusions, and careful technique when injecting drugs and fluids. The latter involves holding any syringe upright, flushing fluid from the proximal intravenous tubing into it, and aspirating and tapping the syringe first before injecting so that any air is trapped at the superior aspect of the syringe. Constant vigilance of all infusions, and use of TEE as a monitor for intracardiac air and the transcranial Doppler for systemic arterial air, may reduce the risk of significant air embolus.

Other complications

Thoracic duct injury, chylothorax [142], brachial plexus injury, cervical dural puncture [143], phrenic nerve injury [144], vertebral arteriovenous fistula [145], Horner syndrome [146], and tracheal puncture have also been described. These

complications can essentially be eliminated with skilled personnel using ultrasound-guided techniques to accurately identify the location of the vessel.

Finally, embolization of catheter or guidewire fragments sheared off during difficult insertion procedures occurs occasionally [17]. Never withdraw a guidewire or catheter through a needle if any resistance is encountered. If resistance is encountered, the guidewire and needle, or catheter and needle, must be withdrawn completely from the vessel together as a unit.

KEY POINTS: COMPLICATIONS OF VASCULAR ACCESS

- Thrombosis is the most common complication of venous and arterial access; arterial thrombosis must be promptly diagnosed and treated
- Malposition and perforation are more common in small infants, and with left-sided intrathoracic central venous catheters
- Infection of central catheters can be reduced using an insertion and maintenance bundle of care

Respiratory monitoring

The continuous monitoring of ventilation in the anesthetized patient is the standard of care for pediatric anesthesia [147]. Inadequate ventilation is one of the most frequent causes of patient injury in the American Society of Anesthesiologists' Closed Claims database [148], including in pediatric patients. This section will review methods of respiratory monitoring, including inspection and auscultation, pulse oximetry, capnography and anesthetic gas monitoring, and the monitoring of ventilation volumes and pressures.

Inspection and auscultation

Although not often emphasized due to the proliferation of technology to monitor ventilation, inspection of the patient for adequate and symmetrical chest rise, lack of signs of inspiratory or expiratory obstruction, and lack of cyanosis or pallor representing inadequate oxygenation is an important monitoring technique for every anesthetized patient. The precordial or esophageal stethoscope, although used less frequently in recent years [149], is still very useful for continuous auscultatory monitoring of respiration and heart tones, and serves as an adjunct to the electronic devices used for every case. A standard stethoscope is essential equipment to have available at all times to assess ventilation, as equipment failures occur.

Pulse oximetry

Pulse oximetry uses the unique light absorption characteristics of oxy- and deoxyhemoglobin to estimate the arterial oxygen saturation (SpO_2). In standard pulse oximetry, two wavelengths, 660 and 930 nm are used, transmitted through tissue to a detector that uses an algorithm to measure only the pulsating, arterial portion of oxyhemoglobin and filters out absorption due to non-pulsating capillaries, veins, and bone and soft tissue [150]. The widespread clinical availability of pulse oximetry since the mid 1980s has done more to change anesthetic and critical care practice in the past three decades than any other single monitor. Despite the obvious intuitive value of measuring SpO_2 to prevent arterial desaturation episodes, to date there are only four published large controlled trials of pulse oximetry and outcome, all in adults, and although these trials demonstrated reduced incidence of perioperative hypoxemia, they did not demonstrate a difference in outcomes [151].

The utility of pulse oximetry in pediatric anesthesia was conclusively shown by Coté et al in two studies [152,153]. The first was a single-blind study of 152 patients where all had pulse oximetry but in half the data were not available to practitioners whereas in the other half the monitor and alarms were available. Major desaturation (<85% for >30 s) occurred more frequently in the blinded group (35 versus 11, $p = 0.021$). The pulse oximeter diagnosed hypoxemia before cyanosis and bradycardia were evident. In a second single-blind study of pulse oximetry and capnography in 402 patients, 260 ventilation problems were detected in 153 patients; blinding the oximeter data increased the number of patients experiencing major desaturation events (31 versus 12, $p = 0.003$), blinding the capnograph data had less effect, with only five of 59 major desaturation events first diagnosed by the capnograph, versus 41 by the oximeter and 13 by the anesthesiologist. These studies firmly established the utility of the pulse oximeter in preventing and diagnosing major desaturation events, and were the cornerstone of the current requirement for pulse oximetry in all pediatric anesthetic and sedation cases.

Pitfalls, problems, and artifacts of pulse oximetry

There are a variety of manufacturers of pulse oximeters, and the instructions for each should be followed carefully, particularly the proper disposable or reusable probe size for each patient. In small infants less than 3 kg it is often desirable to wrap the disposable probe around the hand or foot, as these will allow light transmission but are often more secure than their tiny digits. Bright ambient light should be shielded by covering the probe. Despite the ubiquitous use of pulse oximetry, it should be remembered that there are a myriad of manufacturers and proprietary algorithms for signal acquisition and averaging, and that in the normal arterial oxygen saturation ranges >90%, pulse oximetry is accurate to ± 2%, with potentially less accuracy at SpO_2 <90% [150].

Cyanotic congenital heart disease (CHD) is common in pediatric anesthesia, and several studies have compared SpO_2 to measured blood arterial oxyhemoglobin saturations in cyanotic CHD using co-oximetry. Schmitt et al [154] studied 56 children with cyanotic CHD undergoing cardiac surgery with two simultaneous steady-state measurements comparing SpO_2 to co-oximeter measured arterial blood oxygen saturation (SaO_2) in each patient. The linear regression between SpO_2 and SaO_2 was 0.91; however, using Bland–Altman analysis, the bias and precision between the two methods was very close when SpO_2 was >80%, but much worse when SpO_2 was <80%, with the pulse oximeter overestimating the measured arterial saturation by 5.8%, and two standard deviations of precision being only 10%. In a more recent study using two modern generation pulse oximeters, Torres et al [155] made 122 paired

observations in 46 children with acyanotic and cyanotic CHD after cardiopulmonary bypass, and found that in patients with SpO_2 <90%, the bias was 3–6%, with the oximeter reading higher than the measured blood saturation, with precision 5–6%. Thus, although the pulse oximeter is an excellent trend monitor in cyanotic CHD, it will consistently overestimate the true arterial saturation, especially with SpO_2 <80%.

Poor peripheral perfusion states are common in pediatric anesthesia due to hypothermia, hypovolemia, cardiogenic shock, and many other etiologies. Since pulse oximetry relies on adequate perfusion of the digits so the device can detect oxyhemoglobin saturation in pulsating tissue, vasoconstriction that accompanies these conditions can prevent detection of minimal levels of arterial pulsation and prevent the pulse oximeter from functioning. Villanueva et al [156] studied 19 children 2–60 kg requiring arterial catheters for surgery, and measured the accuracy and functioning of two older generation pulse oximeters in response to low perfusion states induced both by inflation of a blood pressure cuff and by clinical conditions, using seven perfusion variables (age, weight, core and skin temperature, hemoglobin, pulse pressure, and laser Doppler blood flow). They compared bias in 94 paired measurements between SpO_2 and measured arterial hemoglobin saturation. Overall, bias was within ±2%. Factors increasing bias included decreased weight, decreased pulse pressure, decreased core temperature, and decreased laser Doppler flow. The strongest predictor of inaccurate readings was skin temperature <30°C. In the six instances of oximeter failure to function, low skin temperature was present in all. Pulse oximetry can also serve as a perfusion monitor in an extremity or digit distal to an arterial catheter, i.e. radial or femoral; if an adequate pulse oximeter plethysmograph signal is present, it is a sign of adequate perfusion.

Intravascular dyes that absorb light in the same range as hemoglobin predictably will affect SpO_2. Among the commonly used dyes, methylene blue produces a significant, short-lived, artifactual desaturation. Indocyanine green produces a less profound desaturation effect, and indigo carmine's effect is even less profound [157]. Although the light absorption spectrum of bilirubin has some overlap with hemoglobin, hyperbilirubinemia has been shown to have little effect on the accuracy of pulse oximetry [158]. Fetal hemoglobin also has little effect on the accuracy of pulse oximetry [159].

The usual sites on the extremities for pulse oximetry occasionally are unavailable due to burns, trauma, surgery on the extremities, or congenital malformations. In these cases, conventional pulse oximeter probes have been placed on the earlobe, bridge of nose, buccal mucosa, tongue, and penis [160–162]. More central locations (buccal mucosa, tongue, nose) will experience desaturation and resaturation changes significantly earlier than the distal sites on the hand or foot [163]. In cases where major vascular structures may be occluded during surgery or where access to the extremities is limited (cardiac surgery), it is often helpful to place two or more pulse oximeter probes, on both upper and lower extremities, in case of failure of one site to function.

Newer developments in pulse oximetry

Newer generation pulse oximeters developed over the past 10–15 years (Masimo Signal Extraction and Rainbow Technologies, Masimo Corp. Mission Viejo, CA, and Nellcor N-395 and N-595, Nellcor-Puritan Bennett Corp, Pleasanton, CA), have been designed to address some of the limitations of the older technology, and to extend the capabilities of pulse oximetry to measure new parameters, such as total hemoglobin, and perfusion by quantifying the plethysmographic signal. The new technologies incorporate more sensitive electronic filtering designed to detect true arterial pulsation during motion, or poor peripheral perfusion. In a study of 75 children monitored in the postanesthesia care unit where motion artifact is a frequent problem, Malviya et al [164] studied the new versus the old technology and determined that the new technology correctly determined the 27 true desaturation events of SpO_2 <90% 100% of the time, whereas the older technology was successful only 59% of the time. In addition, false alarms were reduced by 50% with the new technology.

The newer technologies use up to eight wavelengths of light, and are capable of determining accurate SpO_{2in} the presence of abnormal hemoglobins, including carboxyhemoglobin and methemoglobin [165]. With increasing concentrations of either of these abnormal hemoglobins, conventional two-wavelength pulse oximetry reads an SpO_2 that converges toward 85%, the isosbestic point for normal hemoglobin. However, because both of these substances have higher affinity for hemoglobin than oxygen, the true oxygen saturation is significantly lower. The additional wavelengths will detect these abnormal hemoglobins and also measure a true SpO_2, and thus are important additions if the patient is at risk for these conditions. Despite this technological advance, unless the patient is at risk for carbon monoxide inhalation such as after a burn injury, or methemoglobinemia such as with high-concentration nitric oxide inhalation, its utility in routine pediatric anesthesia is limited. Another novel use of the new technology is to measure total hemoglobin; this is proportional to the total absorption of light in the light path, but depends on a constant SpO_2 and blood volume, i.e. changes in the amount of hemoglobin in the light path due to changes in intravascular volume can be confused with changes in absolute hemoglobin concentration. With these caveats, this non-invasive estimation of hemoglobin concentration has reasonable accuracy and could find clinical utility as a trend monitor [165]. Finally, despite these advances in technology, Robertson and Hoffman [166] found that two different late generation pulse oximeters performed significantly differently under adverse clinical conditions in terms of rejection of data, and that as SpO_2 decreased, particularly to <70%, there was significant disagreement, with a bias of 3–7% at these low saturations.

Pulse oximetry can serve as a more objective index of peripheral perfusion by converting the pulsatile component of the light absorption signal into an electric signal that represents the plethysmograph at that particular location. Displaying this signal continuously can serve as a useful estimate of tissue perfusion in that location, i.e. a strong beat-to-beat signal variation represents adequate tissue perfusion. In addition, the degree of respiratory variation of arterial pulse pressure with positive pressure variation can be an important measure of fluid status, i.e. the greater the respiratory variation in the pulse pressure, the greater the relative hypovolemia; intravascular fluid administration will often reduce this respiratory variation [167]. Because the plethysmograph

derived from pulse oximetry is derived from arterial pulsations, it is now being used as a non-invasive monitor of volume status. As noted above, the variation in the plethysmographic waveform amplitude of the pulse oximeter has been shown to correlate well with variation in arterial pulse pressure intraoperatively and in the ICU in adult patients; pediatric data are sparse and the correlation with arterial pulse pressure variation not as strong. Future study will be required to determine whether this modality could be used clinically.

All of these cited data suggest that pulse oximeter values, particularly under challenging clinical conditions, should always be interpreted in light of the clinical condition of the patient and other respiratory and circulatory parameters.

Capnography

Monitoring of end-tidal carbon dioxide (CO_2) is a requirement for all general anesthetics, both to confirm the initial correct placement of endotracheal tubes and other airway devices, and also to continuously monitor adequacy of ventilation [147]. Most capnographs utilize infrared light to quantify CO_{2in} the exhaled gas, and there are two major configurations: mainstream and sidestream. Mainstream capnography uses an in-line detector in the breathing circuit near the connector of the endotracheal tube. It requires disposable cuvettes and frequent calibration. Advantages are rapid response time, and no aspiration of gas from the breathing circuit. Disadvantages include a bulky apparatus that may place tension on the endotracheal tube. Sidestream capnographs aspirate gas from the breathing circuit at the elbow distal to the Y-piece. Advantages include lightweight small-bore tubing for aspiration and automatic calibration. Disadvantages include a relatively slower response time and potential for aspiration of large volumes of gas up to 200 mL/min, which may be problematic with small infants and low fresh gas flows. Microstream capnography uses lower gas aspiration volumes of 50 mL/min or less [168].

After direct laryngoscopy to visualize an endotracheal tube through the vocal cords into the trachea, capnography is the gold standard to confirm correct placement of the endotracheal tube. However this method is certainly not foolproof, and false-positive detection of CO_2 with a waveform may be seen with esophageal intubation and detection of CO_2 introduced into the stomach with mask ventilation – this yields low values of end-tidal CO_2 which disappear within 5–6 breaths. A tube seated at or just above the larynx can detect CO_2 but be at risk for dislodgement. Falsely negative CO_2 detection with correct endotracheal tube placement may be seen in cardiac arrest or very low cardiac output states where pulmonary blood flow is insufficient. It may also be seen with severe bronchospasm preventing gas exchange.

A normal end-tidal CO_2 tracing has a rapid upslope, a long flat plateau with minimal upslope, rapid return to baseline of zero without rebreathing, and immediate transition into the next inspiration (Fig. 19.15A). Common findings include separation between end-expiratory and the next inspiration with a large endotracheal tube leak (Fig. 19.15B). If the exhaled CO_2 does not return to baseline of zero, rebreathing may be occurring, often caused by a faulty expiratory valve or by increased deadspace in the breathing system, i.e. by a condenser humidifier too large for the patient's tidal volumes (Fig. 19.15C).

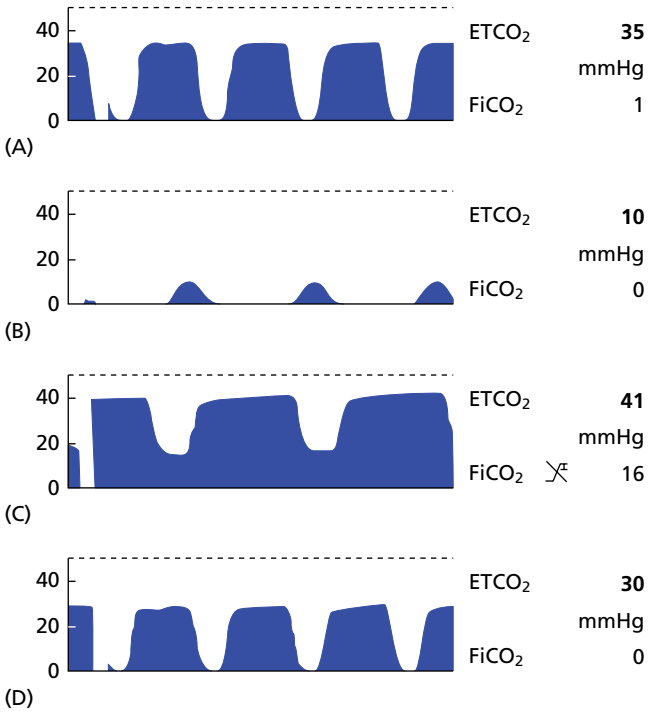

Figure 19.15 Common capnography variants. (A) Normal: note rapid upslope and flat plateau with minimal inspired CO_2. (B) Large leak: causes include large endotracheal tube leak, or partial disconnection of sampling line. (C) Rebreathing CO_2: causes include increased anatomical deadspace in patient or circuit, exhausted CO_2 absorber, addition of inspired CO_2. (D) Large $ETCO_2$–$PaCO_2$ gap: $PaCO_2$ was 40 mmHg in this patient with cyanotic heart disease.

A steep expiratory upslope often signifies expiratory obstruction, most often from bronchospasm. Oscillations of the $ETCO_2$ values during the plateau phase usually signify minimal ventilator volumes caused by displacement of the lungs by the cardiac stroke volume.

Besides monitoring the adequacy of ventilation, the purpose of capnography is to estimate, as accurately as possible, the patient's arterial CO_2 tension to avoid hypercapnea and its undesirable effects on pulmonary artery and intracranial pressure, and hypocapnea and its undesirable effects in decreasing cerebral blood flow. The difference between end-tidal and arterial CO_{2in} patients with normal heart and lungs, and no increase in anatomical or physiological deadspace, is less than 3–5 mmHg. In pediatric anesthesia, the gap is often larger, and there are several causes. Deadspace in the breathing circuit (an extension of the anatomical deadspace where there is flow of gas, but no gas exchange, thereby diluting the exhaled CO_2) is a common cause, especially in small patients. The deadspace volume in endotracheal tubes, endotracheal tube connectors, condenser humidifiers, Y-pieces and elbows, and mainstream capnographs will often cause a significant underestimation of the arterial CO_2. Generally, the smaller the patient, the greater the effect. Premature infants less than 1.5 kg in weight are especially affected [169]. Using small-volume endotracheal tube connectors, placing condenser humidifiers proximal to the CO_2 sampling line, or using special endotracheal tubes with a CO_2 sampling lumen that extends to the tip of the endotracheal tube have all been used to increase the accuracy of capnography in small patients [170–172] (Fig. 19.16C). Cyanotic CHD is another common cause in

pediatrics. Right-to-left intracardiac shunting causes blood to bypass the lungs, reducing pulmonary blood flow and thus the volume of blood relinquishing CO_2 to the exhaled gas. The end-tidal to arterial CO_2 gap may be 15–20 mmHg or greater with significant cyanosis [173] (Fig. 19.15D). The relationship varies with each patient, but in general the more cyanotic the patient (greater reduction in pulmonary blood flow), the greater the CO_2 gap. Improving pulmonary blood flow, such as by the placement of a systemic to pulmonary artery shunt, will decrease the end-tidal to arterial gap. Patients with significant pulmonary hypertension with or without intracardiac shunt will often have a large gap. A decreasing end-tidal to arterial CO_2 gap often signifies increased pulmonary blood flow, accompanied by improvement in pulmonary hypertension or cardiac output. Finally, intrapulmonary shunting, such as that caused by lobar consolidation from pneumonia or atelectasis, causes a variable increase in end-tidal to arterial CO_2 difference, depending on the accompanying degree of hypoxic pulmonary vasoconstriction.

Capnography is useful for monitoring of ventilation in patients without an endotracheal tube. Although the deadspace is increased under a facemask, capnography is effective to monitor the adequacy of tidal volumes with spontaneous or assisted mask ventilation. Similarly, the deadspace is slightly increased with the larger-bore airway of the laryngeal mask airway, but monitoring of CO_2 is essential when this device is used. Finally, monitoring ventilation with a divided, CO_2 sampling nasal cannula during spontaneous ventilation with a natural airway during sedation and monitored anesthesia cases is now common practice and is especially useful when there is not direct proximity to the patient, i.e. MRI scanner [174].

As with any monitor using a mechanical–electrical interface, spurious capnograms and end-tidal CO_2 values can be caused by equipment malfunction or failure. A partially disconnected CO_2 sampling line or cracked connector can entrain room air and artificially lower end-tidal CO_2 values. A CO_2 sampling line occluded by exhaled moisture or secretions will read little or no end-tidal CO_2. Automatic machine calibration at inopportune times, i.e. immediately after intubation, as well as other malfunctions make it necessary to possess adequate clinical skills of auscultation by precordial, esophageal, or standard stethoscope.

Anesthetic agent monitoring

Most modern anesthetic gas concentration monitors are sidestream units combined with capnography, and use polychromatic infrared analyzers that detect each of the halogenated agents individually, as well as CO_2, N_2O, and O_2. These units are easy to use and calibrate, economical to operate, reliable, and reasonably accurate. Mass spectroscopy has greater accuracy and also can measure nitrogen concentration, which is important in the diagnosis of pulmonary embolus. However these units are more expensive and have largely been superseded by the infrared monitors. Although the modern units are fairly accurate, deviations as high as 5–11% relative value are seen with infrared when compared to the gold standard gas chromatography [175]. Thus, although it is important to measure inspired and end-tidal anesthetic concentrations, assessment of the relative anesthetic depth of the individual patient is critical. As with capnography, newer microstream technology that minimizes deadspace will both improve response times and allow for aspiration of smaller volumes of gas from the breathing circuit for sampling, which is important in the care of small infants [176].

Ventilatory volumes and pressures

Modern anesthesia machines have the capability to measure airway pressures, volumes, and flows using spirometry combined with pneumotachygraph technology; however, in most cases these parameters are not measured at the patient airway but at some point proximal to all the connections of the circle breathing system. This configuration introduces the potential for significant error in measurement of pressures and tidal volumes, particularly in small patients weighing less than 5–10 kg with tidal volumes <100 mL, because of the compression volume of the circle system. In other words, the average plastic disposable circle system has a compliance volume loss

of 1–3 mL per cmH_2O of pressure during inspiration; as much as 60 mL tidal volume is delivered not to the patient but rather to the circle system, with peak pressures of 20 cmH_2O above end-expiratory pressure (Fig. 19.16 A–C). Badgwell et al [177] determined that with a standard disposable pediatric circle system and standard adult anesthesia bellows the total compliance volume of the system is about 190 mL, with a peak inspiratory pressure of 20. It is obvious that with small infants the anesthesia machine readout may be very inaccurate. There are two potential solutions to this problem. First, newer generation modern anesthesia machines can calculate an exact breathing circuit compression volume during a preanesthesia machine check; during volume ventilation, additional volume is added to each breath equal to the compliance compensation volume [178]. This is only accurate if the circle system configuration is not changed after the machine check, i.e. if a distensible breathing circuit is extended to its full length, the compliance volume changes. Also, some systems will limit the extent of compliance compensation allowed for small tidal volumes less than 100–200 mL as a safety measure, so that sudden large inappropriate tidal volumes are not delivered to small patients in the event of a change in compression volume. The second method to solve this issue is to use a spirometry system that is attached to the proximal end of the endotracheal tube so that volumes and pressures are measured at the airway; this is possible with a variety of systems, whether integrated into the anesthesia delivery system or as standalone units made for infants.

KEY POINTS: RESPIRATORY MONITORING

- Pulse oximetry is a mandatory monitor and is accurate over a wide range of arterial saturations and perfusion states
- Capnography is an essential monitor and can be used to aid in diagnosis of expiratory obstruction, disconnection, inadequate ventilation, and inadequate cardiac output
- Modern anesthetic machines can more accurately measure small tidal volumes and flows using microprocessor-controlled compliance compensation techniques

Temperature monitoring

Accurate monitoring of temperature during general anesthesia is an accepted standard of care in pediatric patients, because changes in body temperature are anticipated in these patients for a variety of reasons. The physiology of maintenance of body temperature, methods of achieving this, and complications of temperature homeostasis are discussed in Chapter 45. Measurement of temperature has been simplified by easy availability of thermocouple standalone probes, or with esophageal stethoscopes, bladder catheters, skin temperature probes, tympanic membrane probes, or pulmonary artery catheters with incorporated thermistors. Central core temperature is best measured in the esophagus, rectum, or nasopharynx. These sites are generally accepted to be the most accurate, and will be equivalent if the probes are placed properly. This means in the mid-esophagus, at least 2–5 cm into the rectum, and in the case of nasopharyngeal temperature, with the probe inserted to a depth equal to the distance from the nares to the tragus of the ear, placing the tip of the probe under the cribriform plate and thus in closest proximity to the brain. Axillary temperature is often simple and convenient, especially in short pediatric cases, but several minutes may be required for temperature equilibration, and readings will be about 1°C lower. For major intra-abdominal, intrathoracic, or intracranial cases, or surgery in small infants, a core temperature site should be chosen. For monitored anesthesia care or sedation cases, temperature monitoring should be readily available and used if temperature change is anticipated. If the brain is particularly at risk, i.e. intracranial or cardiopulmonary bypass cases, actual brain temperature may be up to 2°C above rectal temperature [179]. Measurement of skin temperature, i.e. sole of the foot, versus core temperature may provide added information to assess the degree of heat loss or peripheral vasoconstriction during major surgery. With thermal homeostasis and adequate peripheral perfusion, skin temperature at the sole of the foot should be no more than 5°C below core temperature.

Urinary monitoring

Monitoring of urine output with a bladder catheter is important for major surgery, where significant blood loss, fluid shifts, or hemodynamic change are anticipated. Although influenced by a multitude of factors, a urine output of 1 mL/kg/h or greater is generally assumed to indicate adequate intravascular volume status and perfusion to the kidneys. Low or absent urine output can be due to mechanical obstruction of the tubing, hypovolemia, or antidiuretic hormone secretion, with hypovolemia by far the most frequent cause. Although it is possible, measurement of urinary sodium and osmolarity is rarely performed intraoperatively. Excessive urine output can be caused by hypervolemia, hyperosmolarity of the urine as seen in hyperglycemia (renal glucose threshold approximately 180 mg/dL in infants and children, may be lower in neonates), osmotic agents such as mannitol, or diuretics such as furosemide. The color of the urine may provide important information: hematuria can be seen with hemolysis from cardiopulmonary bypass or a transfusion reaction, tea-colored urine from myoglobinuria during malignant hyperthermia or significant muscle crush injury. Cloudy urine may be from calcium oxalate crystals, proteinuria with concentrated urine, or urinary tract infection.

Blood gas and other point-of-care testing

Rapid point-of-care testing, either in the operating room or in close proximity with rapid turnaround time, has made real-time monitoring of multiple parameters possible, especially for major surgery associated with significant blood loss, or in unstable patients in whom frequent assessment of blood gas values, hemoglobin, and other parameters is important to guide patient care. There are a variety of machines available, but among the most useful is the point-of-care blood gas machine that also measures electrolytes, hematocrit, glucose, ionized calcium, measured oxygen saturation, and lactate values (Fig. 19.17). Modern machines can make all of these

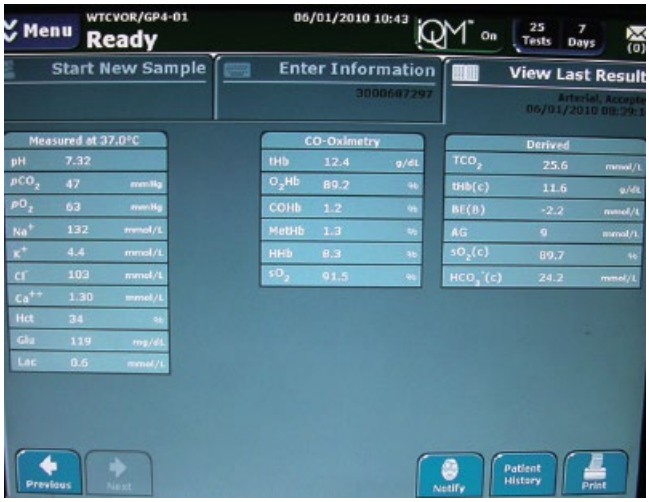

Figure 19.17 Point-of-care monitor for blood gases, electrolytes, hematocrit, ionized calcium, glucose, lactate, co-oximetry. 0.5 mL heparinized blood sample, 80 s measurement time, temperature correction.

measurements on 0.5 mL or less of heparinized whole blood, with results available in less than 2 min. Temperature correction algorithms and electronic recording of values make these machines suitable for electronic medical records. In cardiac surgery, major trauma, neonatal, spine surgery, thoracic surgery, and other major surgical cases, measuring these parameters at regular intervals may provide rapid early warning of major changes in the patient's condition, e.g. metabolic acidosis, or significant anemia or worsening A-aO_2 gradient, that are not evident from standard monitoring, and are available significantly sooner than sending the sample out to the hospital's regular clinical laboratories. Other rapid tests available as point-of-care tests include rapid coagulation assessment with partial thromboplastin time, thromboelastography, or rapid platelet function tests, potentially directing specific therapy to improve coagulation in the individual patient. For all new modalities, an analysis of the cost:benefit ratio and careful assessment of the potential to improve outcomes is important. See Chapter 12 for further discussion of coagulation monitoring.

Neuromuscular transmission monitoring

Accurate assessment of the status of neuromuscular blockade in children is important when non-depolarizing neuromuscular blocking agents are utilized, because simply relying on an estimate of the half-life of the drugs is notoriously inaccurate [180]. Standard nerve-stimulating devices utilize a current of 30–80 mA, and the most common method is to utilize the train-of-four scheme. The most common and standard placement for leads is to use small ECG leads placed over the ulnar nerve so that thumb adduction via the activation of the adductor pollicis brevis nerve can be observed. Any "fade" in the amplitude of contraction, observed visually, indicates residual neuromuscular blockade. The absence of any contraction with the train of four, or contraction only after a tetanic stimulus of 50 or 100 MHz, indicates dense neuromuscular blockade and that reversal with neostigmine or other anticholinesterase agents should not be attempted. Other sites, such as the peroneal nerve or facial nerve, may also be utilized, the latter with caution because direct muscle contraction may be observed, causing an underestimation of the degree of blockade.

Central nervous system and somatic monitoring

Near-infrared spectroscopy

Near-infrared spectroscopy (NIRS) is used to measure both cerebral and somatic oxyhemoglobin saturation. Since its now classic description in 1977 by Jobsis [181], this technology has been the subject of over 1000 publications, and because of its non-invasive compact, portable nature, and potential to measure tissue oxygenation in the brain and other organ systems during surgery and critical illness, is gaining more widespread clinical use. This section will examine the technical aspects of NIRS, parameters measured, and clinical uses in adult and pediatric cardiac and non-cardiac surgery and critical care, evidence for effectiveness in improving clinical outcomes, and pitfalls and complications of NIRS usage.

Technical concepts of near-infrared spectroscopy

NIRS is a non-invasive optical technique used to monitor brain tissue oxygenation. Most devices utilize two to four wavelengths of infrared light at 700–1000 nm, where oxygenated and deoxygenated hemoglobin have distinct absorption spectra [182–184] (Fig. 19.18). Commercially available devices measure the concentration of oxy- and deoxyhemoglobin, using variants of the Beer–Lambert equation:

$$\log\left(\frac{I}{I_0}\right) = \varepsilon_\lambda LC$$

where I_0 is the intensity of light before passing through the tissue, I is the intensity of light after passing through the tissue, and the ratio of I/I_0 is absorption. Absorption of the near-infrared light depends on the optical path length (L), the concentration of the chromophore in that path (C), and

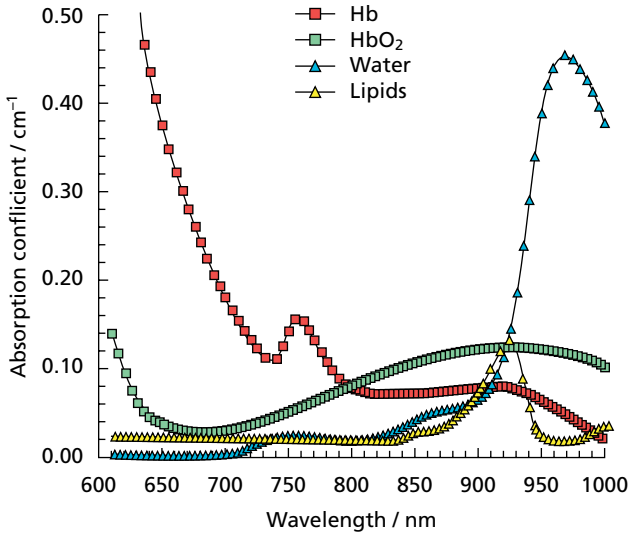

Figure 19.18 Absorption spectrum of oxyhemoglobin, deoxyhemoglobin, water, and lipids. *Source*: Courtesy of Somanetics Corporation.

the molar absorptivity of the chromophore at the specific wavelength used (ε_λ).

Cerebral oximetry assumes that 75% of the cerebral blood volume in the light path is venous, and 25% is arterial. This 75:25 ratio is derived from theoretical anatomical models. Watzman et al [185] attempted to verify this index in children with CHD by measuring jugular venous bulb saturation and arterial saturation, and comparing it to cerebral saturation measured with frequency-domain NIRS. The actual ratio in patients varied widely, but averaged 85:15.

In the various models of cerebral oximeters currently on the market, the sensor electrode is placed on the forehead (Fig. 19.19A) below the hairline. A light-emitting diode (LED) or laser emits infrared light that passes through a "banana-shaped" tissue volume in the frontal cerebral cortex to two or three detectors placed 3–5 cm from the emitter. The screen displays regional cerebral oxygen saturation (rSO_2) and trend over time (Fig. 19.19B). By using different sensing optodes and multiple wavelengths, extracranial and intracranial Hb absorption can be separated. Narrow arcs of light travel across skin and skull but do not penetrate the cerebral cortex. Deep arcs of light cross skin, skull, dura, and cortex (Fig. 19.20). Subtracting the two absorptions measured, shallow from deep, leaves absorption that is due to intracerebral chromophores, and this processing renders the cerebral specificity of the oximeter (Fig. 19.21). However, the accuracy of NIRS is confounded by the light scattering that alters the optical path length; the available commercial clinical devices solve this problem differently. The depth of light penetration is 2–4 cm.

There are several cerebral oximeters that are currently widely commercially available, including the INVOS 5100, NIRO 200, Foresight, and Equanox. Of these, the Somanetics INVOS system (Somanetics, Inc. Troy, MI, USA; INVOS 5100) is in common use and has disposable probes including an adult probe for patients over 40 kg, as well as a pediatric probe designed for patients 4–40 kg which uses a different algorithm that takes into account the thinner skull and extracranial tissues compared to the adult [186]. More recently a neonatal probe has become available and is easier to apply as it conforms well to the smaller forehead shape. It uses two wavelengths, 730 and 810 nm, has one LED and two detectors, spaced at 3 cm and 4 cm apart from the emitter, and uses spatially resolved spectroscopy (Fig. 19.22). The distinct absorption coefficients of oxy- and deoxyhemoglobin permit measurement of the relative signals from these compounds in the light path (Fig. 19.20), and the INVOS device reports oxyhemoglobin/total hemoglobin (oxy- + deoxyhemoglobin) × 100, as the measured regional cerebral oxygen saturation (rSO_2), in percentage. The rSO_2 is reported as a percentage on a scale from 15% to 95%. A subtraction algorithm based on probe size removes most of the transmitted shallow (3 cm detector) signal, leaving over 85% of the remaining signal derived from brain frontal cortex. This device is approved by the US Food and Drug Administration (FDA) for use in children and adults as a trend-only monitor. It is compact, noninvasive, and requires little warm-up. A signal strength indicator displays adequacy of the detected signal. The device

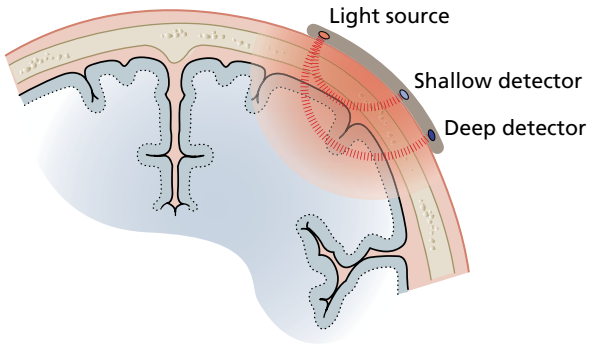

Figure 19.20 NIRS method. A light or laser-emitting diode emits light that passes through the skin, skull, meninges, and into a small portion of the frontal cerebral cortex. Some light is scattered, and some is absorbed by oxy-and deoxyhemoglobin. A portion passes through tissues and is detected by a shallow and a deep detector, 3 and 4 cm respectively from the light source. The shallow component is subtracted out, leaving mostly intracranial signal. *Source*: Courtesy of Somanetics Corporation.

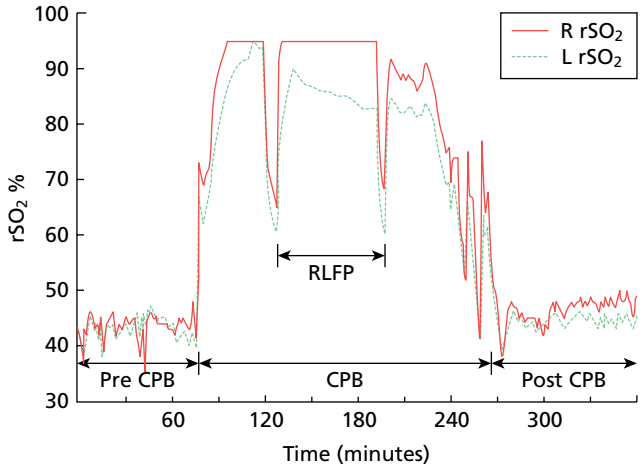

Figure 19.22 Typical changes in regional cerebral oxygen saturation (rSO_2) during cardiac surgery in a neonate with hypoplastic left heart syndrome undergoing Norwood stage I palliation, with cardiopulmonary bypass (CPB), regional cerebral low flow perfusion (RLFP), and deep hypothermic circulatory arrest (DHCA). Note precipitous decline at minute 115 with onset of DHCA for atrial septectomy, and again at minute 185 for replacement of aortic cannula.

does not depend on pulsatility like a pulse oximeter, and operates at all temperatures. Cerebral blood volume index (Crbvi) can also be calculated, representing the total hemoglobin in the light path, which may be used as an estimate of cerebral blood volume; however, this application is only FDA approved for research purposes, not for clinical use.

The NIRO 200 (Hamamatsu Photonics, Hamamatsu, Japan) uses three wavelengths of near-infrared light (775, 810, and 850 nm), emitted by a laser diode and detected by a photodiode. It uses spatially resolved spectrophotometry, and the three wavelengths allow better determination of light path length according to the Beer–Lambert law, which allows calculation of absolute concentrations of oxygenated and total hemoglobin. The NIRO 200 reports a tissue oxygenation index (TOI) as well as hemoglobin indices including changes in total hemoglobin and oxy- and deoxyhemoglobin. The probes are not disposable, but are attached with a disposable probe holder. This device may potentially be more accurate than the INVOS system due to the increased number of wavelengths of light, however it is not FDA approved for use in the USA.

A more recent FDA-approved device is the Foresight monitor (Casmed; Branford, CT). This device uses four wavelengths of light: 690, 778, 800, and 850 nm. The purpose of the additional wavelengths is to better discriminate non-hemoglobin sources of infrared absorption, which may lead to a more accurate calculation of oxygenated and total hemoglobin concentrations [187]. The Foresight monitor reports the percentage of oxygenated hemoglobin to total hemoglobin as a cerebral tissue oxygen saturation ($SCTO_2$), and is marketed as an absolute cerebral tissue oxygen saturation. Currently available probes are disposable and are appropriate only for patients 2.5–8 8 kg and >40 kg.

The Equanox device (Nonin Medical, Plymouth, MN, USA) is now also FDA approved, and uses four wavelengths from 730 to 880 nm. This monitor also utilizes a dual emitter/dual detector sensor and dynamic compensatory algorithms that effectively eliminate scalp and skull light absorption contamination. This allows greater focus on brain tissue and automatic adjustment for variations in tissue optical properties to improve accuracy over a wide range of age and physiological conditions. In 100 pediatric patients with CHD and measured cerebral oxygen saturations of 34–91%, the monitor values were compared to a weighted average of measured jugular venous bulb saturation and arterial saturation and found to have excellent correlation, with mean bias of 0.5%, precision 5.39%, and correlation coefficient of 0.88 [188].

Comparison between these commercial devices reveals differences in measured values due to the different numbers of wavelength, and subtraction algorithms, thus making direct data comparisons difficult [183]. However, regardless of the device used, it is important to remember that all devices measure combined arterial and venous blood oxygen saturation, and cannot be assumed to be identical to $SjvO_2$. Maneuvers to increase arterial oxygen saturation, i.e. increasing FiO_2, will increase cerebral oxygenation as measured by these devices, but the $SjvO_2$ may remain unchanged.

The Foresight device is still relatively new and comparison data with the INVOS are not available. However, the Foresight monitor may predict a more accurate value for the true brain saturation compared to the INVOS monitor that will make between-patient comparisons easier. The Equanox monitor also has the advantage of measuring absolute brain tissue saturation, and excellent correlation with blood oximetry.

Early attempts to validate the non-invasive measurement of cerebral oxygen saturation in children with CHD compared the $SjvO_2$ and rSO_2. In 40 infants and children [189] undergoing congenital heart surgery or cardiac catheterization, the correlation for paired measurements was inconclusive except for infants less than 1 year of age. In 30 patients undergoing cardiac catheterization, an improved correlation r = 0.93 was found [190], and there was a linear correlation between changes in arterial CO_2 and cerebral saturation.

Somatic near-infrared oximetry

Using the same principles of unique light absorption spectra of hemoglobin species, NIRS has also been used to measure tissue oxygenation in skeletal muscle, i.e. quadriceps, forearm, or thenar eminence muscle, in adults and children [191]. In addition, a probe placed over the flank at the T10–L2 level will measure tissue saturation in skeletal muscle and, in small infants, renal oxygenation, due to the small light penetrance distance needed in these small patients [192] (Fig. 19.23). Finally, mesenteric saturation has also been measured in infants with a probe placed in the midline between the umbilicus and the symphysis pubis [193].

Parameters monitored with near infrared spectroscopy

To simplify terminology, the term rSO_2, for regional oxygen saturation, will be utilized for the remainder of this chapter, regardless of the device used. Cerebral rSO_2 measurements are an estimate of venous-weighted oxyhemoglobin saturation in the sample volume illuminated by the light path, i.e. the frontal cerebral cortex in most situations. rSO_2 can be altered by any of the factors that affect cerebral oxygen supply:demand ratio and is especially affected by the unique features of the cerebral circulation, including cerebral autoregulation and alterations in cerebral blood flow according to $PaCO_2$. Any factor that decreases cerebral oxygen

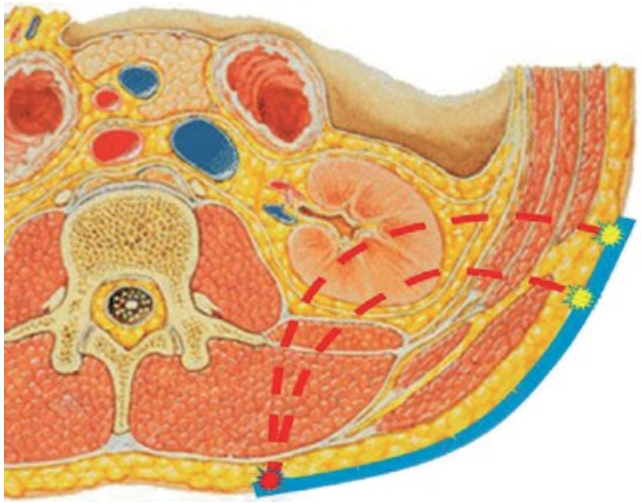

Figure 19.23 Principles of somatic NIRS. In a neonate or small infant, a NIRS probe placed on the flank over the T10–12 area measures the oxyhemoglobin saturation of the tissues in the light path, particularly muscle and renal tissue beds. *Source*: Courtesy of George Hoffman MD.

Box 19.2: Factors affecting cerebral oxygen consumption and delivery

Factors decreasing $CMRO_2$ and generally increasing rSO_2

- Hypothermia
- Increasing sedation, anesthesia, analgesia with benzodiazepines, opioids, dexmedetomidine
- Treating seizures

Factors increasing oxygen delivery to brain and generally increasing rSO_2

- Increasing $PaCO_2$
- Increasing hemoglobin
- Increasing cardiac output
- Increasing FiO_2 or other ventilatory maneuvers to increase SpO_2
- Increasing mean arterial pressure (outside limits of autoregulation, i.e. hypotension)
- Increasing CPB flow rate
- Increasing CPP
- Minimizing cerebral venous pressure to increase CPP, i.e. obstructed venous bypass cannula

$CMRO_2$, cerebral metabolic rate for oxygen; CPB, cardiopulmonary bypass; CPP, cerebral perfusion pressure; rSO_2, regional brain oxygen saturation.

consumption will generally increase rSO_2, and any factor that increases oxygen delivery to the brain will also generally increase rSO_2. Box 19.2 lists some of the common alterable clinical factors that can be used to change rSO_2. Since cerebral rSO_2 is influenced by arterial oxygenation, improving this parameter will often increase rSO_2, even if $SjvO_2$ is little altered.

For pediatric patients undergoing congenital heart surgery, baseline rSO_2 varies with cardiac lesion [184]. The baseline cerebral saturation is about 70% in acyanotic patients without large left-to-right intracardiac shunts breathing room air. On room air, rSO_2 for cyanotic patients, or acyanotic patients with large left-to-right intracardiac shunts, is usually 40–60%; hypoplastic left heart syndrome (HLHS) patients receiving <21% FiO_2 preoperatively have lower rSO_2, averaging 53%, versus those receiving FiO_2 0.21 and 3% inspired CO_2, where rSO_2 averages 68% [194].

Taking into account pediatric cardiac surgery outcome data, some practitioners would consider a relative decline from a baseline of 20% or more (e.g. from a baseline of 60% to a nadir of 48%) cause for intervention. The software on most oximeters will continuously calculate this relative difference from baseline. Other practitioners would use an absolute value of rSO_2 of 50% as cause for intervention.

Cerebral oximetry reflects a balance between oxygen delivery and oxygen consumption by the brain ($CMrO_2$). The cerebral oxygen content will therefore be affected both by the arterial saturation of hemoglobin and the hemoglobin concentration. There then must exist a cerebral saturation value, or ischemic threshold, below which brain injury is likely due to oxygen deprivation as demand outstrips supply. In a neonatal piglet study using frequency-domain NIRS [195], Kurth et al showed that cerebral lactate levels rose at rSO_2 values of 44% or lower; major EEG changes occurred when the cerebral saturation declined to 37%, with reductions in cerebral ATP levels when oximetry readings were 33% or lower. This concept was confirmed in another neonatal piglet model using hypoxic gas mixtures for 30 min at normothermia, demonstrating that rSO_2 >40% did not change EEG or brain pathology obtained 72 h later; rSO_2 30–40% produced no EEG changes, but at 72 h there were ischemic neuronal changes in the hippocampus, and mitochondrial injury occurred. At rSO_2 <30%, there was circulatory failure, EEG amplitude decreased, and there was vacuolization of neurons and severe mitochondrial injury [196]. Finally, in a similar piglet model, the hypoxic-ischemic cerebral saturation-time threshold for brain injury found rSO_2 of 35% for 2 h or more produced brain injury [197]. In general, most pediatric clinical studies use either 20% below established baseline or an oximetry reading of 45–50% for the threshold for treatment based on evidence of new MRI lesions or clinical examination that brain injury is more likely to develop under these circumstances [198,199].

In the absence of absolute criteria for intervention to prevent neurological injury (see section "Outcome studies of near-infrared spectroscopy"), each anesthesiologist must take into account the unique pathophysiology of each patient and the monitoring system used, and decide on criteria for intervention, much like all of the other physiological variables measured for surgery and critical care.

Clinical data in pediatric cardiac surgery

Changes in cerebral oxygenation have been characterized during cardiopulmonary bypass in children with or without deep hypothermic circulatory arrest [200]. rSO_2 predictably decreases during deep hypothermic circulatory arrest (DHCA) to a nadir approximately 60–70% below baseline values obtained pre bypass [200]; the nadir is reached at about 40 min, after which there is no further decrease. At this point it appears that the brain does not continue the uptake of oxygen, and interestingly this time period appears to correlate with clinical and experimental studies suggesting that 40–45 min is the limit for safe duration for circulatory arrest [201,202]. DHCA initiation at a higher temperature results in a faster fall in rSO_2, reaching the nadir sooner [203]. Reperfusion immediately results in an increase in rSO_2 to levels seen at full bypass flow before DHCA.

The question often arises whether bilateral cerebral hemisphere NIRS monitoring is necessary. In a study of 20 patients undergoing a special cardiopulmonary bypass (CPB) technique, antegrade cerebral perfusion, via the right innominate artery, half of the patients had a left–right difference of >10%. [204]. In 60 neonates undergoing surgery with conventional bypass, only 10% had a greater than 10% difference between left and right sides at baseline, and this difference persistent in only one patient [205]. Based on these data, bilateral monitoring is probably necessary only when special CPB techniques are used for aortic arch reconstruction, or when anatomical variants, i.e. bilateral superior vena cavae or abnormalities of the brachiocephalic vessels, are present.

Treatment of low rSO_2

Whether during adult or pediatric cardiac surgery with CPB, the general approach to treating low rSO_2 is similar and involves increasing oxygen delivery to the brain or decreasing oxygen consumption. One approach to treatment is displayed in Box 19.3.

In critical care medicine, cerebral NIRS has been used to monitor adequacy of cerebral oxygen delivery and as a surrogate for adequacy of global oxygen delivery in patients after cardiac surgery and patients on extracorporeal membrane oxygenation (ECMO) or ventricular assist devices [187,206]. Changes in rSO_2 have a close correlation with changes in mixed venous saturation (SvO_2) in both single- and two-ventricle patients after congenital cardiac surgery [207,208].

Clinical uses of somatic near-infrared spectroscopy in pediatric surgery and critical care

NIRS can be used to measure tissue oxygenation in surgery and critical illness and because of its non-invasive, continuous nature has intuitive appeal in conditions where low cardiac output and other causes of shock would benefit from such continuous monitoring.

Somatic NIRS using a probe placed on the flank at T10–L2 has been studied in a series of neonates after and during single-ventricle surgical palliation by Hoffman et al [192]. In nine neonates undergoing CPB with regional cerebral perfusion (RCP), mean cerebral rSO_2 pre bypass was 65% and somatic rSO_2 59%, and during RCP cerebral rSO_2 was 81% versus 41% somatic rSO_2, signifying relative tissue hypoxia due to lack of perfusion to subdiaphragmatic organs during this technique. After CPB, cerebral rSO_2 decreased to 53%, but somatic rSO_2 increased to 76% [192]. In 79 postoperative neonates undergoing Norwood stage I palliation for hypoplastic left heart syndrome, a cerebral–somatic rSO_2 difference of <10% significantly increased the risk for biochemical shock, mortality, or other complications [209] (Fig. 19.24). Mean somatic rSO_2 <70% was associated with a significantly increased risk of prolonged ICU stay, shock, and other complications.

Somatic NIRS has also been used to measure mesenteric rSO_{2in} neonates and infants after cardiac surgery, with a probe placed on the abdomen between the umbilicus and symphysis pubis. In a study of 20 patients, Kaufman et al [210] compared mesenteric NIRS and flank NIRS at T10–L2 to gastric pH measured by tonometry and lactate values. In 122 simultaneous measurements made in the first 48 h after surgery, mesenteric rSO_2 correlated significantly with gastric pH (r = 0.79), serum lactate (r = 0.77), and SvO_2 (r = 0.89). These correlations were all better than those using flank NIRS. The authors concluded that mesenteric NIRS is a sensitive monitor of splanchnic tissue oxygenation and may have utility in managing these patients and improving outcomes. In a recently published study of 214 neonates undergoing Stage I palliation for HLHS, low somatic and cerebral NIRS values in the first six postoperative hours predicted early postoperative mortality and need for ECMO [211].

These studies lend credence to the idea that NIRS-directed targeted interventions could be utilized to improve oxygen delivery to tissues and organs, and potentially improve

Box 19.3: Treatment algorithm for low cerebral oxygen saturation (rSO_2)

1. Establish baseline rSO_2 on FiO_2 0.21, $PaCO_2$ 40 mmHg, stable baseline hemodynamics, awake before induction of anesthesia, or pre bypass if possible
2. Treat decreased rSO_2 of >20% relative value below baseline, or <50% absolute value
3. Pre/post bypass (in order of ease/rapidity to institute):
   a. Increase FiO_2
   b. Increase $PaCO_2$
   c. Increase cardiac output/O_2 delivery with volume infusions, inotropic support, vasodilators, etc.
   d. Increase depth of anesthesia
   e. Decrease temperature
   f. Increase hemoglobin
4. During CPB:
   a. Increase CPB flow and/or mean arterial pressure
   b. Increase $PaCO_2$
   c. Increase FiO_2
   d. Decrease temperature
   e. Increase hemoglobin
   f. Check aortic and venous cannula positioning
   g. Check for aortic dissection

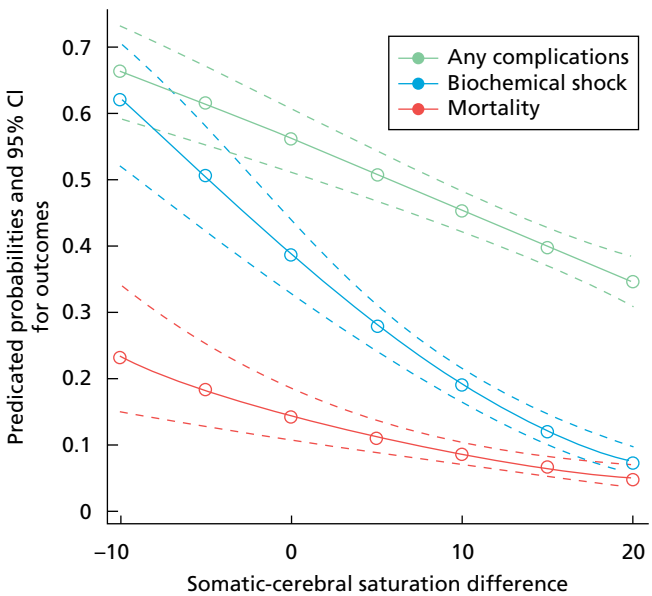

Figure 19.24 Relationship between somatic rSO_2–cerebral rSO_2 difference, and the incidence of complications in 79 patients in the 48 h after Norwood stage I palliation for hypoplastic left heart syndrome. *Source:* Reproduced from Hoffman et al [209] with permission of Elsevier.

outcomes from surgery, anesthesia, and critical illness. To date, there is a lack of such published studies, but the non-invasive continuous nature of NIRS monitoring should make such studies more likely to be performed.

Outcome studies of near-infrared spectroscopy

There is increasing evidence from pediatric cardiac surgery studies that prolonged low NIRS values are associated with adverse short-term neurological outcomes. Dent et al [198] studied 15 neonates undergoing the Norwood operation who underwent preoperative, intraoperative, and postoperative rSO_2 monitoring. A prolonged low rSO_2 (>180 min with rSO_2 <45%) was associated with a higher risk of new ischemic lesions on postoperative MRI when compared to the presurgical study, with a sensitivity of 82%, specificity of 755, positive predictive value of 90%, and negative predictive value of 60%. Therefore both the extent of decreased cerebral saturation (ischemic threshold) and the time spent below this ischemic threshold are important in predicting the development of new postoperative brain injury by MRI.

There is additional clinical evidence suggesting that low cerebral saturations correlate with adverse neurological outcome. In a study of 26 infants and children undergoing surgery utilizing DHCA [200], three patients had acute neurological changes – seizures in one, and prolonged coma in two – all of whom manifested low rSO_2. In these three patients, the increase in rSO_2 was much less after the onset of CPB, and the duration of cooling before DHCA shorter. In a retrospective study of multimodality neurological monitoring in 250 infants and children undergoing cardiac surgery with bypass [199], relative cerebral oxygen desaturation of more than 20% below prebypass baseline resulted in abnormal events in 58%. If left untreated, 26% of these patients had adverse postoperative neurological events.

In a study of 16 patients undergoing neonatal cardiac surgery with NIRS monitoring and pre- and postoperative brain MRI, six of 16 patients developed a new postoperative brain injury; these patients had a lower rSO_2 during the aortic cross-clamp period versus those without new brain injury (48% versus 57%, p = 0.008) [212]. In a study of 44 neonates undergoing the Norwood operation, who were tested at age 4–5 using a visual–motor integration (VMI) test, the first 34 patients did not have NIRS monitoring, and the last 10 did have NIRS monitoring with a strict treatment protocol for low rSO_2 values <50%. No patient with NIRS monitoring had a VMI score <85 (normal is 100), versus 6% without NIRS monitoring. Mean rSO_{2in} the perioperative period was associated with VMI score, with no patient with mean rSO_2 ≥55 having VMI less than 96 [213].

Toet et al [214] studied 20 neonates undergoing the arterial switch operation and monitored rSO_2 for 4–12 h preoperatively, intraoperatively, and 36 h postoperatively, without intervention. Seven patients had a mean preoperative rSO_2 ≤35%, and two of these patients had significantly abnormal Bayley Scales of Infant Development Scores at 30–36 months, of 1–2 standard deviations below the normal population mean.

Kussman et al [215] studied 104 infants aged 9 months or less undergoing complete two-ventricle repair of transposition of the great arteries, tetralogy of Fallot, or ventricular septal defect. Bilateral NIRS was monitored during the intraoperative period, and for 18 h postoperatively, but no intervention was made on the basis of rSO_2 values. The aim of the study was to evaluate changes in rSO_2 and to determine association between low rSO_2 and early postoperative outcomes, including death, stroke, seizures, or choreoathetosis. An rSO_2 threshold of 45% was chosen as the cut-off for analysis. pH stat blood gas management and hematocrit of 25–35%, along with brief DHCA and some low-flow bypass, was utilized. Eighty-one of 104 patients had no desaturation below 45%, 12 had brief desaturation below 45% for 1–39 min, and 11 had more prolonged desaturation of 60–383 min. Because no patient in the study died or suffered any neurological complication, the relationship between low rSO_2 and early neurological outcome could not be determined. There was also not a relationship between low rSO_2 and postoperative cardiac index, lactate, severity of illness, or days ventilated, in the ICU or hospital. Thirty-nine of these patients had a period of DHCA, and important data about the rate of decline of rSO_2 under optimal CPB conditions were reported (Fig. 19.25). (The important finding is that brief periods of DHCA <30 min did not result in nadir values of rSO_2, suggesting that this technique does not deplete the brain of oxygen stores and lending more credence to the idea that this practice is safe. The lack of an association between rSO_2 and early gross neurological outcomes is not unexpected, given that these were all two-ventricle patients, completely repaired, with normal arterial oxygen saturations postoperatively. The low incidence and severity of cerebral desaturation in this population have been previously described [216] (Fig. 19.26).

Another potential benefit of routine NIRS monitoring is to avert the rare but very real and devastating potential

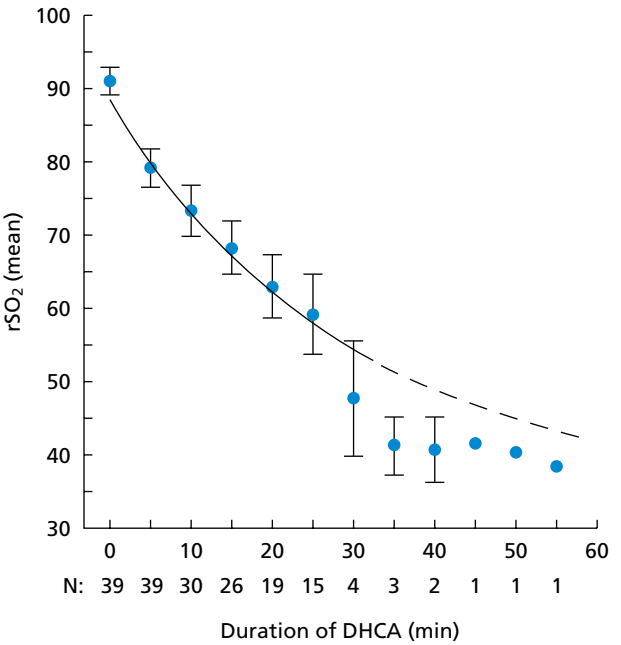

Figure 19.25 Pattern of cerebral rSO_2 during deep hypothermic circulatory arrest (DHCA) in 39 infants with D-transposition of the great arteries who underwent ≥5 min of DHCA. Data are presented as mean ± 1.96 SEM. The number of subjects (N) available for analysis at 5 min intervals of DHCA is shown. The fitted non-linear exponential decay curve (solid line) is base on data from 0 to 30 min with higher weight given to mean rSO_2 values calculated with more subjects. The fit is extrapolated beyond 30 min (dashed line). *Source:* Reproduced from Kussman et al [215] with permission of Wolters Kluwer.

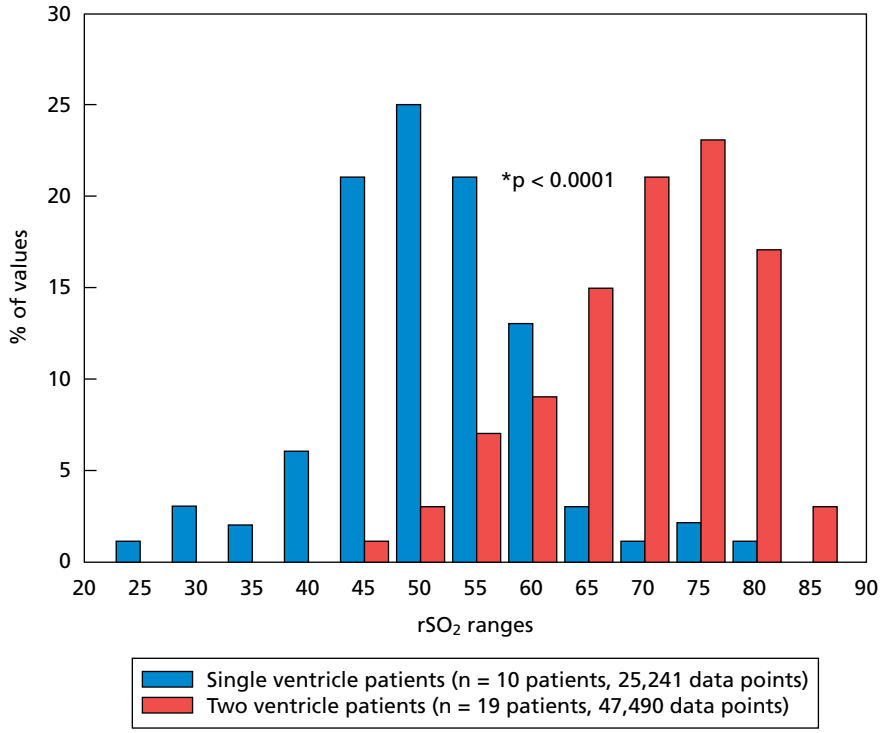

Figure 19.26 Frequency of rSO_2 values recorded at 1 min intervals in the first 48 h postoperatively in neonates undergoing repair of hypoplastic left heart syndrome (single-ventricle patients) or D-transposition of the great arteries (two-ventricle patients). *Source:* Reproduced from Andropoulos et al [216] with permission of Wolters Kluwer (CCC).

neurological disaster from cannulation problems, where rSO_2 declines dramatically from cannula malposition and cerebral arterial or venous obstruction, yet all other bypass parameters are normal [217,218]. In neonates and infants it is clear that mixed venous saturation in the bypass circuit bears very poor association with cerebral saturation, emphasizing the point that intracerebral desaturation may go unnoticed [219].

In a systematic review of 56 publications describing 1300 patients in whom NIRS monitoring was used for CHD in the operating room, ICU, and cardiac catheterization laboratory, Hirsch et al [220] concluded that the technology did serve as a reliable, continuous, non-invasive monitor of cerebral oxygenation. Additional recent patient cohorts document an association between low cerebral oxygen saturation in the perioperative period for congenital heart surgery and lower neurodevelopmental outcome scores at 1–5 years of age [221–223]. However, to date there have not been any published prospective, randomized, controlled studies of NIRS monitoring versus no NIRS monitoring, with short- or long-term follow-up in pediatric patients. Many centers where NIRS is now in routine clinical use will not have sufficient equipoise to conduct such a study.

A recent prospective study of 453 infants under 6 months of age undergoing non-cardiac and non-neurological surgery revealed only a 2% incidence of significant cerebral oxygen desaturation (<50% absolute value, or >30% below baseline value). These periods of cerebral desaturation were very brief, representing only 0.1% of anesthetic time [224].

Transcranial Doppler ultrasound

Transcranial Doppler ultrasound (TCD) is a sensitive, real-time monitor of cerebral blood flow velocity and emboli during congenital heart surgery. Currently available instruments utilize pulsed-wave ultrasound at 2 MHz frequency, which is range-gated, emits a power of 100 mW, and has a sample volume length of up to 15 mm. A display of the frequency spectrum of Doppler signals is easily interpreted, and peak systolic and mean flow velocities, in cm/s, are displayed, as well as a pulsatility index which is equal to the peak velocity minus the end-diastolic velocity, divided by the mean velocity.

The most consistent and reproducible technique for clinical use in patients of all ages is to monitor the middle cerebral artery (MCA) through the temporal window, which can usually be found just above the zygoma and just anterior to the tragus of the ear [225]. Several transducer probes are available, ranging from very small disk probes suitable for infants and children, to larger, heavier probes for adolescents and adults. The depth of the sample volume and angle of insonation are adjusted until the bifurcation of the MCA and the anterior cerebral artery (ACA) is detected. This is heralded by a maximal antegrade signal (positive deflection, toward the transducer) from the MCA, accompanied by retrograde flow (negative deflection, away from the transducer) of the same or very similar velocity and waveform, as the MCA flow. The same location should be monitored for an individual patient. Insonation at the MCA–ACA bifurcation also offers the advantage of minimizing interpatient variability. In addition, the MCA supplies the largest volume of tissue of any of the basal cerebral arteries [226]. In infants, an alternative site for monitoring is through the anterior fontanelle, using a hand-held pencil-type probe, placing the probe over the lateral edge of the fontanelle and aiming caudally, at a greater depth than for the temporal window.

TCD has been used extensively in pediatric cardiac surgical research to examine cerebral physiology in response to CPB, hypothermia, low-flow bypass, regional low-flow perfusion

to the brain, and circulatory arrest. Hillier et al [227] used TCD to study cerebrovascular hemodynamics during hypothermic bypass with DHCA in 10 infants, finding that cerebral blood flow velocity did not return to baseline levels after DHCA. Calculated cerebral vascular resistance (mean arterial pressure – central venous pressure/CBFV) was increased immediately after DHCA and remained so until the end of bypass. The observed decrease in cerebral blood flow velocity during cooling was thought to be due to decreased metabolic demand by the brain and thus less blood flow, although α-stat strategy was used. This could be explained by relative cerebral vasoconstriction during cooling in smaller arterioles downstream to the MCA and ACA, since these large arteries do not change their caliber in response to changes in $PaCO_2$ [228]. TCD of the MCA through the temporal window was used to describe the cerebral pressure–flow velocity relationship during hypothermic bypass in 25 infants less than 9 months old. Cerebral blood flow velocity was examined over a wide range of cerebral perfusion pressures (varying from 6 to 90 mmHg), and at three temperatures: normothermia (36–37°C), moderate hypothermia (23–25°C), and profound hypothermia (14–20°C). Cerebral pressure flow autoregulation was preserved at normothermia, partially affected at moderate hypothermia, and totally lost at profound hypothermia, results that agree with previous research done using xenon to quantitate cerebral blood flow [229].

TCD has also been utilized to determine the threshold of detectable cerebral perfusion during low-flow cardiopulmonary bypass. Zimmerman et al [230] studied 28 neonates undergoing the arterial switch operation with α-stat pH management. At 14–15°C the pump flow was sequentially reduced to 0 mL/kg/min. All patients had detectable cerebral blood flow down to 20 mL/kg/min, while one had no perfusion at 20 mL/kg/min, and eight had none at 10 mL/kg/min, leading the authors to conclude that 30 mL/kg/min was the minimum acceptable flow in this population. Finally, Andropoulos et al [231] used TCD of the MCA to determine the level of bypass flow necessary during regional low-flow perfusion for neonatal aortic arch reconstruction. They studied 34 neonates undergoing the Norwood operation or aortic arch advancement and established a baseline mean cerebral blood flow velocity (22 cm/s) under full-flow bypass (150 mL/kg/min) using pH stat management at 17–22°C. They then used TCD to determine how much bypass flow was necessary to match this value, finding that a mean of 63 mL/kg/min was necessary.

Cerebral emboli are a frequent threat during open-heart surgery in children. Emboli are easily detected by TCD, although this is subject to artifacts such as electrocautery and physical contact with the ultrasound transducer [232]. The number of emboli detected in the carotid artery during pediatric congenital heart surgery did not appear to correlate with acute postoperative neurological deficits [232]. However, acute drops in cerebral blood flow detected by TCD can allow for adjustment of aortic or superior vena cava cannulae, which may avert neurological disaster [233].

Although TCD is a useful research tool, and in some centers a monitor that is utilized for special CPB techniques such as regional cerebral perfusion, the complexity of the equipment and attainment of a consistent signal, and the lack of convincing long-term outcome data render TCD a monitor that is not routinely used in pediatric cardiac surgery.

Electroencephalographic technologies

The standard electroencephalogram (EEG) employing between two and 16 channels has been utilized in congenital heart surgery [199]. It is a rough guide of anesthetic depth, and can document electrocerebral silence before DHCA [234]. EEG is affected by several factors including anesthetic agents, temperature, and CPB. Impracticalities of the use of an intraoperative EEG include electrical signal interference and complexity of placement and interpretation. Newer devices using processed EEG technology are more user-friendly and have been extensively reviewed [235,236]. The value of perioperative EEG monitoring in congenital heart surgery is unclear. For example, HLHS neonates frequently have a normal perioperative EEG yet frequently demonstrate abnormalities on pre- and postoperative brain MRI suggestive of ischemia [187].

The Bispectral Index (BIS) monitor (Aspect Medical Systems, Nantick, MA, USA) is currently promoted to guide the depth of anesthesia. BIS sensor electrodes are applied to the forehead and temple producing a frontal-temporal montage, which connects to a processing unit. The device is easy to use, electrodes are easy to place, and the monitor requires no calibration or warm-up time. Via a proprietary algorithm of the Aspect Corporation, BIS uses Fourier transformation and bispectral analysis of a one-channel processed EEG pattern to compute a single number, the Bispectral (BIS) Index [237]. This index ranges from 0 (isoelectric EEG) to 100 (awake) with mean awake values in the 90–100 range in adults, infants, and children [238]. Depth of sedation is difficult to predict using BIS scores due to significant individual variability and anesthetic agent [239]. For BIS to be effective as a monitor of the depth of anesthesia, one would have to know exact BIS values for each anesthetic administered for an individual patient, thus reducing its value [240]. BIS can be used to recognize EEG burst suppression, or electrical silence, which could be useful during DHCA. The monitor displays a real-time EEG waveform but is subject to motion artifact, EMG activity, and radiofrequency interference from electrical equipment in the operating room. Few or no data exist in children on the use of other EEG devices such as the Physiometrix®, Narcotrend®, or Cerebral Function Monitor® [235]. During CPB, hemodilution and hypothermia alter pharmacokinetics and pharmacodynamics, which can lead to awareness under anesthesia. The overall incidence of awareness in adults undergoing cardiac surgery varies from 1.1% [240] to 23%, which is more than in general surgical procedures [241,242]. The incidence of awareness under general anesthesia is similar in children [243]. Although there are no documented reports of awareness under anesthesia in children undergoing heart surgery, BIS monitoring may still be useful to detect a level of awareness.

In a cohort of children undergoing open heart surgery with an anesthetic tailored for "fast-tracking," BIS scores increased during rewarming, a period considered at risk for awareness under anesthesia [244]. However, in this study, and in a similar study in infants less than 1 year of age [245], BIS did not correlate with stress hormone levels, a surrogate for light levels of anesthesia, nor with plasma fentanyl levels. At present there is little evidence to support the use of BIS in neonates and infants undergoing anesthesia and therefore the value of BIS to assess burst suppression during DHCA is in further doubt. This is due to the different sleep-arousal patterns in this subset.

Because of the similarities of the full EEG in children over age 12 to the adult EEG, processed EEG monitoring in older children above the age of 12 years will produce similar patterns to those of the adult; therefore it would appear more logical to use these devices in older patients, and especially under special anesthetic techniques, i.e. total intravenous anesthesia for spine surgery in the adolescent [246,247].

Recent publications of processed EEG methods in anesthetized children include assessments of amplitude-integrated EEG (aEEG), and spectral edge frequency at 90%, in children 24 days to 14 years of age [248]. These parameters can discriminate between anesthetized and awake states in older children, but in younger children the aEEG changes were less pronounced and the spectral edge changes either could not discriminate between states or responded paradoxically. Another study of a parameter termed permutation entropy in children aged 3–15 years determined that this parameter performed in similar fashion to the BIS Index; younger children were not tested [249].

Recent studies utilizing multilead EEG as a research tool have reported fascinating developmental changes and differences in different-aged pediatric patients at various stages and depths of anesthesia, including relative predominance of alpha waves and EEG coherence and discontinuity [250,251]. These studies emphasize the significant differences with age and development, and that any processed EEG algorithms must take these into account for valid application to all pediatric age groups. As of this writing there are no clinically available processed EEG monitors that accomplish this for young children.

KEY POINTS: CENTRAL NERVOUS SYSTEM AND SOMATIC MONITORING

- Near-infrared cerebral and somatic spectroscopy is an accurate indicator of oxygenation in cardiac and critically ill patients, can guide therapy, and correlates with early mortality and neurodevelopmental outcomes
- Transcranial Doppler ultrasound is a sensitive real-time indicator of cerebral blood flow velocity in major vessels and can be used for specialized bypass techniques such as regional cerebral perfusion
- Processed EEG technologies can be utilized to monitor depth of anesthesia in older children; existing devices are not accurate in infants and younger children due to developmental changes in the EEG

Point-of-care ultrasound

For more than a decade, high-resolution portable ultrasound devices have been available, first for central venous and arterial access, and then as an indispensable tool for regional anesthesia (see Chapter 20). In recent years, point-of-care ultrasound (POCUS) for other organ systems has been practiced in pediatric anesthesia after adaptation from adult medicine areas such as emergency medicine and surgery for rapid abdominal examination for trauma and other surgical conditions. The same portable ultrasound machines, with the proper probe and image parameter selection, can be used to image the heart, lungs, airway, gastric contents, abdomen, and bladder to assist in rapid diagnostic or procedural applications [252].

Transthoracic cardiac echocardiography affords excellent views, especially in infants and small children. The basic parasternal long and short axis, apical, and subxiphoid views are learned relatively easily. This modality can be extremely useful during unexpected hemodynamic deterioration to assess myocardial contractility, pericardial effusion, intracardiac air, or thrombus [253,254]. Response to therapies such as intravascular volume or resuscitation drugs can be assessed (Fig. 19.27).

Ultrasound of the airway has been utilized to confirm endotracheal intubation in children and neonates, and also to determine the position of the tip of the endotracheal tube in the mid trachea [255–258] (Fig. 19.28). In a recent meta-analysis of nine pediatric studies for a total of 460 ultrasounds for tracheal intubation, ultrasound had a sensitivity of 0.92–1.0 for confirming successful intubation, with a specificity of 1.0. Lung ultrasound to assess pleural sliding to confirm intubation had a sensitivity and specificity of 1.0. Tracheal tube depth assessment by visualizing the tip of the ETT had a sensitivity of 0.91–1.0, with specificity of 0.5–1.0 [258].

Ultrasound of the lung can be used to diagnose lung consolidation, pleural effusion, pneumothorax, and pulmonary edema (Fig. 19.29). A recent randomized controlled trial of 122 pediatric cardiac surgery patients utilized periodic lung ultrasound to guide recruitment maneuvers in intubated patients [259]. The incidence of postoperative desaturation was lower (27% versus 64%, $p < 0.001$), as was the duration of postoperative ventilation (26 versus 38 h, $p = 0.048$), in the intervention group.

Ultrasound of gastric contents can be utilized to assess the volume and composition of gastric contents (Fig. 19.30). In a study of 143 children undergoing non-elective surgery, 90% of

children had ultrasound images that were interpretable [260]. Using a 0 –2 grading scale for fluid or solids in the gastric antrum, 7% of children with grade 0 antrum (no contents), 65% with grade 1 (fluid in one view), and 95% with grade 2 (fluid in two views, or solid material) had gastric volumes above the 0.8 mL/kg threshold for increased aspiration risk. Gastric ultrasound led to a change in induction plan (i.e. rapid sequence or not) in 51% of patients.

CASE STUDY

A 3-year-old, 14.2 kg, 95 cm tall boy presented for major resection of stage IV Wilms tumor with inferior vena cava (IVC) extension [261]. He presented 3 months before the scheduled surgery with significant right-sided abdominal distension and pain. He did not have any other medical problems, and did not exhibit the phenotype of any genetic syndrome. Initial imaging with MRI revealed a unilateral large renal tumor with renal vein and IVC extension to just below the right atrium. Fine needle aspiration with computed tomography guidance revealed Wilms tumor with favorable histology. There were no intracardiac masses, but there were eight pulmonary nodules. Because of the IVC extension near the right atrium, preoperative chemotherapy with vincristine, actinomycin D, and doxorubicin was initiated. Long-term central venous access (Port-a-Cath®) was placed via the left subclavian vein 1 week after diagnosis. Echocardiography the day before surgery revealed normal cardiac anatomy and function, without intracardiac shunting, masses, or valvular disease. Tumor mass could be seen in the IVC just below the right atrium. Chest radiograph was clear. Vital signs were: blood pressure 120/85 mmHg, pulse 125 bpm, respiration 28/min, temperature 36.5°C, SpO_2 98% on room air. Preoperative laboratory studies included normal electrolytes, blood urea nitrogen (BUN) 16 mg/dL, creatinine 0.6 mg/dL, hemoglobin 10.5 g/dL, white blood cell count 7500/mm^3, platelet count 156,000/mm^3, and normal prothrombin and partial thromboplastin times, international normalized ratio (INR), and liver function tests.

A combined surgical procedure with cardiac and general surgeons was planned, via a right thoracoabdominal incision with CPB standby. Four units of irradiated, cytomegalovirus (CMV)-safe packed red blood cells (PRBC) were cross-matched. Because of the anticipated large blood loss and plan to leave the trachea intubated postoperatively, epidural analgesia was not used. After premedication with midazolam 2 mg IV, the patient was transported to the operating room where late generation pulse oximeter, ECG, and automated oscillometric blood pressure cuff were placed. After preoxygenation, anesthesia was induced with propofol 2 mg/kg, fentanyl 3 µg/kg, and vecuronium 0.3 mg/kg. After tracheal intubation with a 4.5 mm cuffed orotracheal tube, a 22 g right radial arterial catheter was placed. Because of the need to cross-clamp the IVC for tumor resection, a 20 g peripheral intravenous catheter (PIV) was placed in the right, and 18 g PIV in the left antecubital vein using ultrasound guidance. The patient's blood volume was estimated to be 75 mL/kg, or 1065 mL. It was decided that transfusion would be initiated at hematocrit of 25%, so allowable blood loss was calculated as 1065 mL × (32%-25%)/32% = 232 mL. Because of the anticipated large blood loss and fluid shifts, and variation in cardiac output, a continuous central venous oxygen saturation ($ScvO_2$) catheter was placed in the right internal jugular vein (IJV). Full sterile barrier precautions and ultrasound guidance were used, the IJV was entered first pass, and a 4.5 Fr double-lumen $ScvO_2$ catheter was secured at 8 cm after confirmation of guidewire placement in the vein. A pediatric transesophageal echocardiography (TEE) probe was placed to monitor for intracardiac tumor emboli, and cardiac filling and function. A 10 Fr urinary catheter and rectal temperature probe were placed, a full-body forced air warming blanket placed under the patient, and he was positioned in left lateral decubitus position. Anesthesia was maintained with isoflurane, 0.5–1.5% end-tidal concentration, and intermittent boluses of fentanyl, midazolam, and vecuronium.

The surgical plan was to perform the thoracoabdominal incision, expose the right kidney and tumor with retroperitoneal dissection, and then cross-clamp the IVC to debulk the tumor and prevent emboli. If it was not possible to cross-clamp above the tumor, a short period of CPB was planned to remove the IVC and right atrial tumor. The IVC was cross-clamped successfully with retraction of the right lung, after intravascular volume loading with 15 mL/kg 5% albumin resulting in an increase of central venous pressure (CVP) from 5 to 10 mmHg. A large decrease in venous return, accompanied by decrease of CVP to 3 mmHg, decreased blood pressure to 55/35 mmHg, and increase in heart rate to 135 bpm with a decrease in $ScvO_2$ from 74% baseline (calibrated with a measured oxygen saturation drawn from the CVP catheter) to 44% ensued. The end-tidal CO_2 also decreased from 37 to 23 mmHg, reflecting decreased cardiac output and pulmonary blood flow, but TEE revealed no evidence of pulmonary embolus. During the 30 min of IVC cross-clamp, necrotic but non-friable tumor mass was resected from the IVC down as far as possible toward the renal veins. Blood loss was 350 mL during this phase, and was replaced with 2 units PRBC, with an additional 6 units ordered at that time. Intermittent boluses of calcium chloride ($CaCl_2$), 10 mg/kg, and a low-dose epinephrine infusion of 0.03 µg/kg/min were used during this period to augment cardiac output and vascular tone, because of the intermittent hypotension and decrease in $ScvO_2$ to 40–50% range. After de-airing, and repair of the IVC incision, the cross-clamp was released and the patient suffered a period of bradycardia to a heart rate of 50 bpm, hypotension to 45/25 mmHg, arterial desaturation to 88%, and decreased $ScvO_2$ to 30%. This responded to two 10 µg/kg boluses of epinephrine, sodium bicarbonate 2 meq/kg, intravascular volume infusion with 5% albumin 10 mL/kg, additional $CaCl_2$, and hyperventilation. Using a point-of-care system in the operating room, arterial blood gases after cross-clamp removal and resuscitation revealed a pH of 7.25, $PaCO_2$ of 34 mmHg, PaO_2 of 250 mmHg, base deficit of -13, and lactate of 8.5 mmol/L, with hematocrit of 32%. End-tidal CO_2 had been as low as 18 mmHg, and returned to 32 mmHg after the period of cross-clamp. TEE revealed no tumor emboli during this period, but depressed biventricular function after removal of the cross-clamp. After additional sodium bicarbonate and increasing epinephrine to 0.05 µg/kg/min, biventricular function normalized.

The resection of kidney and tumor, retroperitoneal lymph node dissection, and removal of tumor from renal veins and the remainder of the IVC required 6 additional hours of surgery. Hourly values of vital signs, blood gas values, hematocrit, blood loss, and $ScvO_2$ are listed in Table 19.7. Urine output became bloody 2 h into the resection, and was maintained at 2 mL/kg/h with intravascular volume infusions without adding diuretics. Temperature was maintained at 35.5–36.5°C throughout the case with a forced air warming blanket set at 38°C, warmed intravenous fluids, colloids, and blood, with the fluid warmer set at 41°C, and room temperature warmed to 25°C, as well as the use of a condenser humidifier. A tissue factor-activated thromboelastogram (TEG) was sent 4 h into the case and with turnaround time of 20 min revealed a significant coagulopathy with prolonged r and K times, reduced α angle, and reduced maximum amplitude. This occurred after a total blood loss of 1000 mL, and resulted in infusion of half a pheresis unit of platelets (equivalent to three random single units), one unit of fresh frozen plasma (FFP), and two units of cryoprecipitate to treat the thrombocytopenia, hypofibrinogenemia, and depleted coagulation factors indicated by the severely abnormal TEG. Five hours into the resection the serum K+ level was 6.3 mmol/L, presumably secondary to transfusion of the 12 units of PRBC to that time. As serum glucose was 288 mg/dL at the time, the hyperkalemia was treated with regular insulin three units, 25% dextrose 0.5 mL/kg, $CaCl_2$, and sodium bicarbonate, and by the next hour K+ was 4.4 mmol/L. At the end of the case total blood loss was estimated to be 3250 mL, and the patient received 14 units PRBC, four units FFP, 8 units cryoprecipitate, and two full pheresis units of platelets. Additional fluids were 300 mL of 5% albumin and 100 mL Plasmalyte®. Urine output total was 250 mL. Total fentanyl dose was 150 μg/kg. TEE during the case revealed no evidence of air or tumor embolus, variable biventricular function and filling, but by the end of the case hemostasis had been achieved, cardiac function was normal, and epinephrine weaned to 0.02 μg/kg/min. The patient was transported with his trachea intubated to the pediatric intensive care unit after loading with 0.3 mg/kg of morphine, and additional midazolam. He was extubated 48 h later, and made an excellent recovery without significant end-organ dysfunction and with intact neurological status.

The case illustrates the use of continuous hemodynamic monitoring, including $ScvO_2$, to instantaneously guide treatment during a major tumor resection with wide hemodynamic swings due to massive blood loss, cross-clamping the IVC, and impendence of venous return during IVC compression. In addition, TEE was used to rule out tumor emboli. Hourly rapid point-of-care testing of arterial blood gases, electrolytes, hematocrit, glucose, lactate, and ionized calcium, as well as rapid TEG, was used to direct therapy to restore intravascular volume, cardiac output and oxygen delivery, and the coagulation system. End-organ injury was prevented by effective management guided by intensive monitoring.

CHAPTER 20
Pediatric Regional Anesthesia

Claude Ecoffey
Pôle Anesthésie-Samu-Urgences-Réanimations et Médecine Interne-Gériatrie, Hôpital Pontchaillou, Université de Rennes 1, Rennes, France

Introduction

Pediatric regional anesthesia has attained widespread use internationally because of its efficacy and safety; its use is supported by the existence of extensive data from the international literature underlining the safety and efficacy of this technique [1–4]. Recently the European Society of Regional Anaesthesia and Pain Therapy and the American Society of Regional Anesthesia and Pain Medicine have jointly published a practice advisory on controversial topics and on recommendations on dosage of local anesthetics and adjuvants in pediatric regional anesthesia [5,6]. Safer drugs and dedicated pediatric tools are the keys to success. This is so despite the fact that general anesthesia is necessary in most children for the regional block to be performed easily, safely, and effectively [5]. Indeed, the benefit to risk ratio is excellent, especially for peripheral blocks, even when beginners perform these blocks. Use of ultrasonography has improved the safety of pediatric regional anesthesia [7,8]. All the regional blocks require thorough knowledge of the sonoanatomy and anatomical landmarks, and specialists in pediatric anesthesiology should supervise trainees closely in order to prevent repeated errors [9]. Despite the well-known benefits of regional anesthetic techniques, clinical failures can occur during their application. Ultrasound guidance has been shown to improve block characteristics, resulting in shorter block performance time, higher success rates, shorter onset, longer block duration, reduction in volume of local anesthetic agents required, and better visibility of neuraxial structures and spread of local anesthetic.

Embryology and developmental physiology of the peripheral nervous system and age

The nervous system and the spinal cord are not fully developed at birth, and several morphological particularities must be considered. There are some differences in the anatomy of the spinal cord meninges between a neonate and an adult. During the embryonic period, the spinal cord fills the spinal canal, but from the fetal period onward, the growth of the spinal canal exceeds that of neural structures; consequently, the caudal end of the spinal cord and the dural sac occur at progressively higher levels. The tip of the spinal cord is at L3 at birth and L1–2 at 1 year. In the same way, the meninges are at S3 at birth and S4–5 at 1 year. In addition, infants and children weighing less than 15 kg have a relatively high

Gregory's Pediatric Anesthesia, Sixth Edition. Edited by Dean B. Andropoulos and George A. Gregory.

volume of cerebrospinal fluid (CSF), 4 mL/kg bodyweight, compared with adult values of 2 mL/kg bodyweight. The contents of the epidural space in infants differ from those in adults. Instead of having mature, densely packed fat lobules, divided by fibrous strands, infants have spongy, gelatinous lobules with distinct spaces permitting the wide longitudinal spread of injected solutions.

The spine undergoes significant morphological and structural change throughout childhood and adolescence. At birth, it displays a simple regular flexure throughout, so that any epidural needle with the same orientation can be inserted in any given intervertebral space. With the development of the cervical flexure in the sitting position, i.e. head position sustained upright, and subsequently that of the lumbar lordosis with the development of standing and walking, the orientation of the epidural needle must be modified accordingly. During infancy and early childhood, the vertebrae remain cartilaginous; ossification of the vertebrae is a progressive phenomenon. The ossification nucleus can be damaged by improper epidural block technique. Due to the late osseous fusion of the sacrum, intervertebral epidural approaches can be performed at all sacral levels throughout childhood.

Myelination begins in cervical neuromeres during the fetal period and continues downward and upward until the 12th year of life [10]. In an infant, the fiber diameter is smaller, the myelin sheath thinner, and the internodal distance smaller, so a lower concentration of local anesthetic is needed to achieve the nerve block and to avoid toxic effects. Furthermore, the relative resistance to epidural blockade of the L5–S1 nerve roots observed in adults does not occur in pediatric patients because of the smaller diameter of nerve fibers. The local distribution is excellent due also to the fact that nerve envelopes are loosely attached to underlying nerve structures, which favors the spread of local anesthetics along the nerves and the roots.

There are important differences between infants, small children, and adults in the physiological effects of central blocks. It is a constant finding that the incidence of clinically significant hypotension and bradycardia following spinal or epidural anesthesia is lower than in adult patients [11]. Blood pressure and cardiac index are not modified by the block despite the absence of prior intravenous volume loading and the high level of sympathetic blockade [12]. There is less vasodilatation in infants than in older children and adults, and infants respond to high thoracic sympathetic blockade by reflex withdrawal of vagal parasympathetic tone to the heart [13].

Local anesthetics and toxicity

Amide local anesthetics used for regional anesthesia in pediatric patients are potent sodium channel blockers, and thereby they block impulse conduction in axons. Local anesthetics (LAs) have other actions that may contribute both to local and systemic toxicities and to beneficial systemic actions on inflammatory responses [10] or chronic pain conditions. Amide local anesthetics are potent sodium channel blockers with marked stereospecificity, which consistently influences their action, especially their toxic action on the heart. At toxic concentrations, they induce severe arrhythmias with the potential for cardiac arrest.

The primary local anesthetic agents used in pediatric regional techniques are 2-chloroprocaine, lidocaine, bupivacaine, ropivacaine, mepivacaine, and tetracaine. The pharmacology of local anesthetics in children is similar to that in adults [14]. Nonetheless, volumes of distribution of local anesthetics in neonates and infants are larger compared to adults, thus preventing high serum drug concentrations from occurring after a single injection. The larger volume of distribution of local anesthetics in children reduces peak plasma concentrations after a single bolus dose. However, due to the longer elimination half-life, the risk of drug accumulation after a continuous infusion or several injections is increased. The volume of distribution of ropivacaine is smaller than that of bupivacaine in adults and probably in children. 2-Chloroprocaine 2% or 3% has a short time to onset of action and a short duration of action. Lidocaine 0.5–2% has a short time to onset and medium duration of action. It can be used for peripheral blocks or epidural anesthesia. Bupivacaine 0.1–0.5% has a longer onset time and duration of action than lidocaine or 2-chloroprocaine but has a greater potential for severe cardiotoxicity than other agents. It can be used for peripheral blocks, spinal anesthesia, and caudal or epidural anesthesia and analgesia. Tetracaine 1% is used for spinal anesthesia. Mepivacaine is approximately equally potent to lidocaine and can safely be used for peripheral nerve blocks. Mepivacaine can provide a rapid onset of block, with a shorter duration of motor block that may allow for rapid recovery in the postoperative period. Ropivacaine 0.2–1% and levobupivacaine 0.25 –0.5% may replace the racemic mixture of bupivacaine because of their decreased potential for central nervous system toxicity and cardiotoxicity. Ropivacaine differs from bupivacaine in various aspects: it is a pure S-enantiomer and its lipid solubility is markedly lower; these characteristics can significantly improve the safety profile of ropivacaine. Levobupivacaine, the S-enantiomer of racemic bupivacaine, is less cardiotoxic while showing similar local anesthetic properties and the potency of racemic bupivacaine. Indeed, several cases of central nervous system toxicity have been reported after inadvertent intravascular administration of ropivacaine or levobupivacaine in adults, but only some cases of cardiovascular toxicity have been reported to date [15,16]. The outcome of these inadvertent intravascular administrations was favorable, even in a neonate [17].

Pharmacokinetic factors

When injected into the body, the pure isomers do not undergo interconversion, meaning they do not transform into the usual racemic compounds.

LAs bind to blood components – erythrocytes and serum proteins such as α1-acid glycoprotein (AAG) and albumin [14]. These different buffer systems have different levels of importance; AAG is by far the most important because it is specific. The red blood cells play a lesser role in sequestration of LA, with only 15–22% of bupivacaine molecules bound in erythrocytes at varying total concentrations of the LA [18]. This buffer system may become important when the LA blood concentration is very high beyond toxic concentrations and with anemia (red blood cells bind less than 15% of molecules

of LA when the hematocrit is <30%). Binding of amide LA to serum proteins is more important. Like all weak bases, amides are mainly bound to AAG and serum albumin [14]. AAG concentration is 50–80 times lower in plasma than is albumin, particularly in infants. The determination of serum albumin LA binding is characterized by a low affinity but a high capacity, while the affinity of binding to AAG is high but the capacity is low.

AAG is the main serum protein involved in the binding of LA. Because AAG is a major acute-phase protein, its concentration rapidly increases when inflammatory processes develop, particularly during the first 6 h of the postoperative period [19]. In addition, the affinity of LA increases with the inflammatory processes; acidosis decreases this affinity. Neonates and infants have a lower AAG concentration in serum compared to adults [20], therefore their free fraction of LA is increased accordingly (Fig. 20.1). This has important clinical implications since, at least at a steady state, the toxic effects of LAs are directly related to the free (unbound) drug concentration. In summary, there are no differences in protein binding between R- and S-enantiomers of bupivacaine, at least when the concentrations, even toxic, are observed in clinical practice [21].

After passing through the bloodstream, the amide LAs are excreted by the liver. This phase involves the cytochrome P450. The clearance of bupivacaine, like that of ropivacaine and levobupivacaine, ranges from 3 to 6 mL/kg/min. The renal clearance is low, therefore the main metabolism of these agents is hepatic metabolism. Local anesthetics are metabolized by cytochrome P450 (CYP). The main CYP isoforms involved are CYP3A4 for lidocaine and bupivacaine [22] and CYP1A2 for ropivacaine [23]. CYP3A4 is not mature at birth but is partly replaced by CYP3A7 [24]. At 1 month of age, the intrinsic clearance of bupivacaine is only one-third of that in adults, and two-thirds at 6 months. CYP1A2 is not fully mature before the age of 3 years. Indeed, the clearance of ropivacaine does not reach its maximum before the age of 8 years [25]. However, at birth this clearance is not as low as expected [26], even with levobupivacaine [27], and ropivacaine and levobupivacaine may be used even in younger patients. Finally, the S- and R-enantiomers of LA kinetics are very similar, and the slight differences that have been described do not have any clinical consequences.

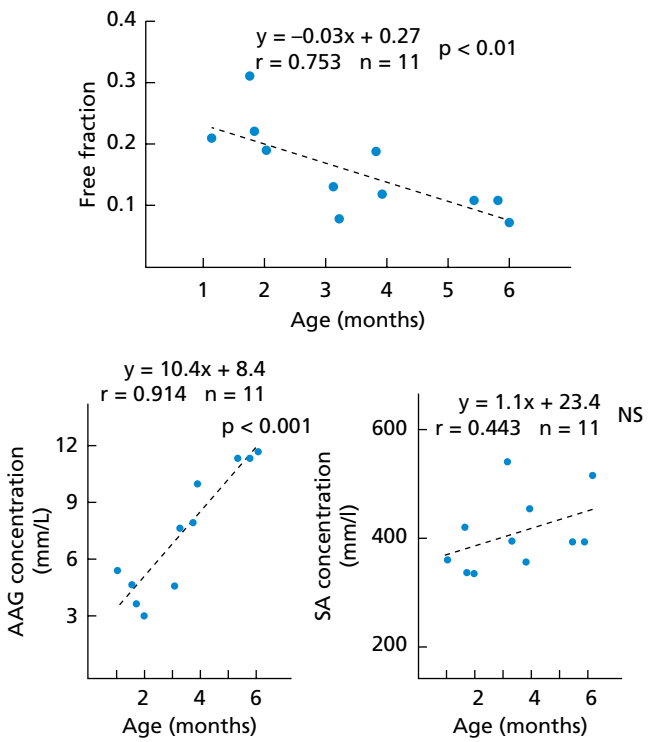

Figure 20.1 The major proteins involved in binding and the relationship between their concentrations and age (AAG, α1-acid glycoprotein; SA, serum albumin) (*bottom panel*), and the relationship between free fraction of bupivacaine in serum and age (*top panel*). The free fraction is increased until at least 6 months of life. *Source*: Reproduced from Mazoit et al [14] with permission of Wolters Kluwer.

Pharmacodynamic factors

The R- and S-enantiomers of a LA molecule have different pharmacodynamic effects on the myocardium and the nerve. The physiology of nerve activity is the summation of numerous complex events and interactions. A simple explanation is that in most cases modulation of impulse frequency and not modulation of amplitude is more important in blocking function of the nerve. Upon the basic background activity is imposed an added impulse, for example a painful stimulus. The effects of LAs can be improved when the signal they are trying to block increases in frequency. Thus, in addition to the basic block (tonic block), there is added a nerve blockade (phasic block) whose intensity will increase with the frequency of discharge of the nerve, or the heart rate in the case of myocardial toxicity. Purkinje fibers of the myocardium are more sensitive to the blockade of sodium channels by LA than other fibers or myocytes. While heart rate is rather slow (between 40 and 200 beats/min), the frequency of nerve impulses is much faster. Therefore, the nerves, when stimulated, are immediately blocked due to this high frequency of baseline activity, while the intensity of heart block increases with tachycardia. This is the physiological explanation for the preferential nerve block, well before any cardiac toxicity. The S-enantiomers are unique in that they cause phasic blocks smaller than the R-enantiomers (and therefore than the racemic mixtures). In the nerve, this difference is small because sodium channels involved at this level are minimally sensitive to the phasic block, because baseline frequency of nerve discharge is already rapid. In the heart the difference is more important [28,29]. When the heart rate increases, the S-enantiomers increase the block of the sodium channels they generate much more slowly than the racemic mixtures (the difference between ropivacaine and levobupivacaine remains the same, equal to the difference in power level of the nerve) [28] (Fig. 20.2). However, although there is no intrinsic difference between newborn and adult animals, phasic block (the one that increases with frequency) plays a very important role (Fig. 20.3) [30] and we can well imagine that an infant, whose heart beats at 150 beats/min, is significantly more sensitive than an adult, whose heart beats at 75 beats/min. In addition, elevated cardiac output in children tends to accelerate the vascular absorption of drugs from tissue, producing higher initial plasma concentrations and decreased duration of action.

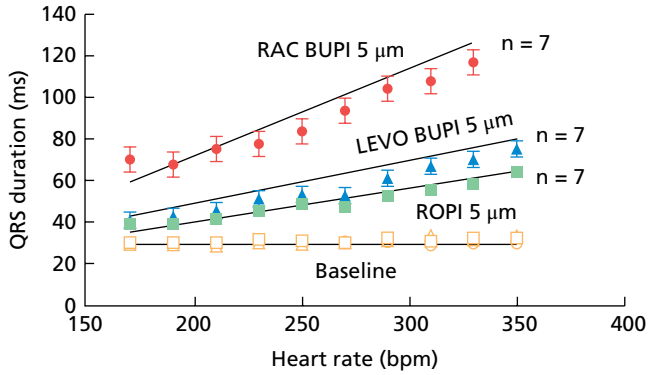

Figure 20.2 Rate dependence of QRS widening. QRS duration was measured at varying frequencies on isolated rabbit heart with racemic bupivacaine (RAC BUPI), levobupivacaine (LEVO BUPI), and ropivacaine (ROPI). The faster the heart rate, the more rapidly QRS widening occurred. *Source:* Reproduced from Mazoit et al [28] with permission of Wolters Kluwer.

The S-enantiomers levobupivacaine and ropivacaine cause moderate vasoconstriction, whatever the concentration range studied.

Adjuvants

The therapeutic index of LAs in infants may be so narrow that the maximum safe infusion rates of the amides are too low to provide sole analgesia for most major surgery in the thorax and the abdomen. This would indicate a need to combine LAs with either opioids or clonidine or, more recently, dexmedetomidine (or S+ ketamine, not available in some countries) to provide safe synergistic analgesic effects while maintaining safe LA dosing, administering acetaminophen and non-steroidal anti-inflammatory drugs (NSAIDs) to provide an additional systemic analgesic effect, and permitting low-dose intravenous opioids as rescue analgesics [6] (Table 20.1).

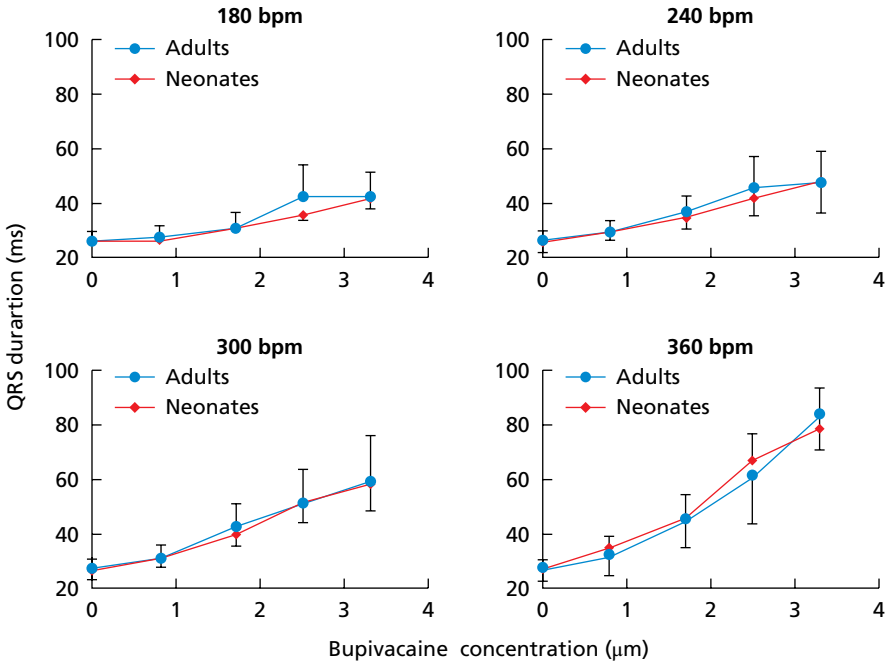

Figure 20.3 QRS widening as a function of bupivacaine concentration in the perfusate. The block is rate dependent, but no difference was found between adult and newborn rabbits. *Source:* Reproduced from Simon et al [30] with permission of Wolters Kluwer.

Table 20.1 Adjuvants to local anesthetics for regional anesthesia in children

Adjuvant	Route	Dose	Comments
Morphine	Epidural (C, L, T) single shot	30–50 µg/kg	
	Intrathecal	0.01–0.02 µg/kg	
Fentanyl	Epidural (L, T) single shot	1–2 µg/kg	
	Epidural continuous	0.2 µg/kg/h	
Sufentanil	Epidural (C, L, T) single shot	0.5–0.75 µg/kg	
	Epidural continuous	0.1 µg/kg/h	
Clonidine	Epidural (C, L, T) single shot	1–2 µg/kg	
	Epidural continuous	0.08–0.12 µg/kg/h	
	Intrathecal	1 µg/kg	
	Peripheral nerve blocks	1–2 µg/kg	
Dexmedetomidine	Epidural (C)	1–2 µg/kg	
	Peripheral nerve block	0.3 µg/kg	
Ketamine	Epidural (C, L, T) single shot	0.25–0.5 mg	S-ketamine is active isomer; do not administer intrathecally because of spinal cord apoptosis

C, caudal, L; lumbar; T, thoracic. See text for further details.

Intrathecal and epidural opioids were first administered to human subjects in 1979 [31], and since that time they have been proven to provide effective and prolonged analgesia. The presence of high concentrations of opioid receptors in the spinal cord makes it possible to achieve analgesia with small doses of morphine administered in either the intrathecal or epidural space. Intrathecal and epidural morphine produce more profound and prolonged analgesia than comparable morphine doses administered parenterally, and are capable of relieving both visceral and somatic pain. The use of morphine by the epidural route, either caudal [32] or lumbar [33], gives prolonged analgesia (more than 12 h with a single injection of morphine) following abdominal, thoracic, and cardiac surgery, and allows respiratory physiotherapy without pain. In addition, intrathecal morphine injection has been used to obtain postoperative analgesia following cardiac surgery or spinal fusion. A systematic review of post-thoracotomy analgesia concluded that a thoracic epidural infusion of LA with an opioid provided the most consistently effective analgesia [33]. The usual doses of epidural morphine range from 30 to 50 μg/kg. For single doses of epidural fentanyl, the dose range is 1–2 μg/kg, and for sufentanil 0.5–0.75 μg/kg. The dose for intrathecal morphine is 0.01–0.02 μg /kg. Continuous epidural infusion of LA can be combined with fentanyl 0.2 μg/kg/h or sufentanil 0.1 μg/kg/h. This improvement in analgesia has to be balanced against the high incidence of undesirable side-effects, which include respiratory depression (which may occur several hours after initial administration), nausea, vomiting, pruritus, and urinary retention [34]. Nalbuphine when administered for treatment of side-effects after epidural morphine is better than naloxone to treat pruritus and vomiting/nausea [35]. For peripheral nerve blocks, there was little evidence for any analgesic benefit of using opioid analgesics in brachial plexus block over systemic administration.

Clonidine acts at the dorsal horn level, reducing the release of substance P. It gives an antinociceptive potentiation, prolonging the analgesic effect of bupivacaine or mepivacaine. The sedation provided by epidural clonidine, due to an action at the locus coeruleus level, is dose dependent: sedation does not occur with a dose of 1 μg/kg or less, it is only apparent with a dose of 2 μg/kg or more. Usually, it is not considered a drawback for the pediatric patient (the child is both pain-free and quiet) and children are easily aroused. No side-effects have been described: no respiratory depression or hypotension (only with 5 μg/kg is there moderate hypotension). For continuous epidural infusion, clonidine doses lower than 0.08 μg/kg/h were not associated with any measurable effect, whereas doses of 0.08 μg/kg/h or greater produced both clinically and statistically significant improvements in postoperative analgesia [36]. Because a dose of 0.12 μg/kg/h was sufficient to provide excellent analgesia, higher doses may not be advisable as there is excessive sedation with no increase in analgesia. Dexmedetomidine has recently been shown to have positive effects as an adjuvant both for caudal and peripheral nerve blocks in children [37,38]. This drug does also seem to be associated with acceptable safety features and may, thus, be a new interesting alternative in this setting.

Ketamine is a potent anesthetic whose action occurs through the antagonism of N-methyl-D-aspartate receptors, present also at the spinal level and involved in pain modulation. Older studies were performed using the preservative-containing formula in adults and in children. Newer studies performed with preservative-free ketamine, both the racemic and the isomeric drug, show that a dose of S-ketamine ranging between 0.25 and 0.5 mg/kg is optimal for prolonging the pain relief provided by LA [39]. However, ketamine has been found to cause increased apoptosis when it is spinally administered [40].

Dexamethasone can be used in the context of postoperative analgesia. Indeed, the administration of systemic dexamethasone in the setting of a long-acting LA solution prolongs the analgesic duration of a single-injection caudal block compared with long-acting local anesthetic [41]. No safety data exist to add dexamethasone to perineural LAs.

The addition of bicarbonate reduces the pain on injection [42]. It alters the pKa of the solution, making the local anesthetic available in the active cationic form. See Chapter 37 for further discussion of pain management.

KEY POINTS: EVIDENCE-BASED CONCLUSIONS AND CLINICAL ADVICE FROM THE ESRA–ASRA JOINT COMMITTEE PRACTICE ADVISORY ON RECOMMENDATIONS ON LOCAL ANESTHETICS AND ADJUVANTS DOSAGE IN PEDIATRIC REGIONAL ANESTHESIA [6]

- Clonidine or morphine can be used to prolong the duration of spinal blockade
- Racemic ketamine and S-ketamine have been used as a neuraxial adjunct. Nevertheless, ketamine is not recommended for intrathecal use due to possible apoptosis in the spinal cord
- Dexmedetomidine prolongs postoperative analgesia when used as an adjunct to caudal blocks
- Synthetic opioids do not produce any relevant effect when used as adjuvants to caudal blocks in children. Fentanyl does not potentiate the effect of either bupivacaine or ropivacaine in caudal blockade
- Dexamethasone is not recommended as a neuraxial adjuvant in children
- α_2-adrenoceptor agonists can prolong the duration of peripheral nerve blocks in children

Systemic toxicity

Reports in humans suggest that lipid emulsion (Intralipid®) is an effective therapy for cardiac toxicity from high systemic concentrations of ropivacaine and bupivacaine, even in patients for whom conventional resuscitation is ineffective [43]. The solubility of long-acting LAs in lipid emulsions and the high capacity of binding of these emulsions most probably explain their clinical efficacy in case of toxicity. The long-chain triglyceride emulsion Intralipid appears to be about 2.5 times more efficacious than the 50/50 medium-chain/long-chain Medialipide® emulsion [44]. No data exist

in pediatrics except for a recent case in which a 20% lipid infusion was used to successfully treat a ventricular arrhythmia after a ropivacaine and lidocaine injection in a psoas compartment block in a healthy 13-year-old child was administered [45]. Indeed, a bolus of 1.5 mL/kg and then an infusion of 0.5–1 mL/kg/min of Intralipid in combination with usual resuscitation should be useful to treat LA cardiac toxicity in children.

Lipid rescue is preferably administered via a central venous catheter, but in its absence peripheral veins can also be used. A 20% lipid emulsion bolus over 1 min is recommended with an initial dose of 1.5 mL/kg, immediately followed by 10–20 μmcg/kg atropine and small boluses of 10 μg/kg epinephrine in order to limit the increase in heart rate which is deleterious as discussed previously [28]. Chest compressions should not be interrupted. The intralipid bolus can be repeated, with a maximum of 4 mL/kg/min. The lipid infusion is to be maintained at a rate of 0.5 mL/kg/min until hemodynamic recovery.

Lipid infusions act as an antidote to LA intoxication and should be readily available for emergencies, much in the way that type O-negative blood and dantrolene are now available universally. Intralipid has a low cost and a shelf-life of up to 1 year. The guidelines for the management of severe LA toxicity provide essential information and should be available in all hospitals, particularly in units where local anesthetics are administered. See Chapter 45 for further details of management of LA toxicity.

Local tissue toxicity

Skeletal muscle toxicity is a rare and uncommon side-effect of LAs, although experimental data show that intramuscular injections of these agents regularly result in calcified myonecrosis [46]. All LAs that have been examined are myotoxic: the extent of muscle damage is dose dependent and worsens with serial or continuous administration. Pathophysiologically, increased intracellular Ca^{2+} levels appear to be the most important element in myocyte injury [47]. Lipophilicity also determines the extent of Ca^{2+} release by local anesthetics, as effects of racemic bupivacaine and levobupivacaine were significantly more pronounced than those of ropivacaine isomers [48]. Consequently, a rank order of myotoxic potency (ropivacaine < bupivacaine < levobupivacaine) is suggested. The clinical impact of LA-induced myotoxicity is still controversial. Only a few case reports of myotoxic complications in adults after LA administration have been published. In particular, the occurrence of clinically relevant myopathy and myonecrosis has been described after continuous peripheral blocks; some experimental data have shown more toxicity in young animals [49], therefore particular attention must be paid with prolonged continuous infusion in infants.

Several studies have revealed that LAs might irreversibly damage chondrocytes in articular cartilage, which may contribute to cartilage degeneration [50]. Bupivacaine especially showed profound chondrotoxic effects in experimental models, and although these results cannot be directly extrapolated to the clinical setting, caution should be exercised in the intra-articular use of this agent. Ropivacaine seems to be less chondrotoxic than bupivacaine [51], whereas the chondrotoxic potency of levobupivacaine has yet to be assessed.

Blocks for infants and children

Advantages of regional anesthesia

Regional anesthesia, in combination with light general anesthesia, provides several advantages for the pediatric patient [5]. The most significant advantage, as demonstrated by several authors, is intra- and postoperative pain relief.

Regional anesthesia is also useful when general anesthesia is technically difficult or is associated with increased morbidity and mortality, such as in the case of the ex-premature infant with the risk of postanesthetic apnea [52], the child with severe chronic respiratory disease [53], or the child with myopathy [54]. Regional anesthesia may offer an alternative to general anesthesia in children with a history of malignant hyperthermia.

Compared with general anaesthesia, a central neuraxial block may reduce the 0–30-day mortality for patients undergoing surgery with intermediate to high cardiac risk [55].

Disadvantages of regional anesthesia

Regional anesthesia requires extra time to perform the block and allow it to become effective. Therefore, the use of an induction room will smooth the operating room work. If general anesthesia is needed to perform the block, an assistant can be helpful in supporting the airway and monitoring the patient during performance of the block. Critics of this combined technique suggest that one may be exposing the child to the risks and complications inherent in both. This fear, however, is more a theoretical consideration than a practical one. Indeed, the recent Pediatric Regional Anesthesia Network (PRAN) study has shown a trend of fewer complications of regional anesthesia with the practice of placing blocks in anesthetized patients. The pediatric anesthesia community should consider regional anesthesia after induction of general anesthesia a safe technique, and this should remain the prevailing standard of care [56].

Therefore, pediatric anesthesiologists now view regional anesthesia as an adjunct to general anesthesia, in much the same way that a neuromuscular blocking agent or intravenous narcotic supplements general anesthesia with a volatile agent [57].

Choice of regional anesthesia in children

Although blocks that are commonly used in adults are not always suitable for children, some regional blocks are particularly useful in children. The last Association of French Speaking Paediatric Anesthesiologists (ADARPEF) study has clearly shown a transition in practice from predominantly central blocks to an increased number of peripheral nerve blocks, including catheter techniques (Tables 20.2 and 20.3) [3]. The most common extremity blocks were axillary, both lateral and popliteal sciatic, femoral and iliofascial block. Face and trunk blocks represented the largest proportion of peripheral blocks. Trunk blocks were used significantly more often (41%). They are characterized by the emergence of techniques that were not clearly accounted for by the first ADARPEF study, i.e. (in order of decreasing frequency) ilioinguinal, paraumbilical, pudendal, and thoracic and lumbar

paravertebral blocks [1]. Facial blocks were now widely used for facial and reconstructive surgery, particularly in cleft palate repair.

This is the reverse of the PRAN study [4] (Table 20.4), which recorded more caudals than trunk blocks. Indeed, single-injection caudal blocks were the most frequently performed (44% versus 32% in the last ADARPEF study), compared to trunk blocks (19% versus 41% in the last ADARPEF study). In Europe the same trend is observed if we compare France with other countries: caudals constituted 12% in France versus 33% in Europe (22,224 general anesthetics, 19.6% with combined general/ regional anesthesia; unpublished data from APRICOT study from the European Society of Anesthesiology).

In addition, the last ADARPEF study recorded a significant number of catheter placements [3]. They were inserted for central as well as peripheral regional anesthesia, most of them being neuraxial. Indeed, neuraxial continuous epidural analgesia is one of the preferred techniques for obtaining pain relief in children (particularly postoperative pain relief in younger children). Perineural catheters have become a common practice, primarily in hip and foot surgery. Several prospective studies demonstrated the benefits of continuous peripheral nerve blockade after orthopedic procedures in children. Placement of a brachial plexus catheter for pain control is less common in children than in adults. The emergence of peripheral nerve catheter techniques allows provision of postoperative pain relief for the majority of orthopedic surgeries using regional anesthesia techniques [58,59] and to treat complex regional pain syndrome in adolescents [60]. The last ADARPEF study confirmed this emergence of peripheral catheters, mainly axillary and sciatic popliteal, and recorded slightly fewer neuraxial catheters than the United Kingdom audit, which reported 10,633 epidural catheters (about 2000 per year) [2]. These results confirmed a retrospective report from a single institution (10,929 regional anesthetics performed during a 17-year period) revealing a decrease in central neuraxial blocks [61]; continuous postoperative analgesia via perineural catheters emerged as routine practice in children in the late 1990s following both peer recommendations and evolution of devices. More recently the PRAN study also reported more neuraxial (thoracic and lumbar) catheters and lower

extremity catheters (femoral, sciatic, and lumbar plexus) [4]. The practice of continuous pediatric peripheral regional anesthesia is different from adults due to the lack of surgery for total knee prosthesis.

Regional blockade with or without general anesthesia

Without general anesthesia

Most children do not like needles or injections. Small, frightened children are unlikely to keep still unless well sedated. Thus LA techniques alone are not usually used in children under about 8–10 years of age. After that age, a cooperative child who has had the procedure explained may tolerate a block for such procedures as suturing lacerations, reduction of a fracture, or minor procedures on the extremity. Adequate sedation and/or the presence of a reassuring parent facilitate the procedure. New methods of giving sedatives, opioids, and LAs transdermally will be of great benefit to peripheral LA techniques in the conscious child. The use of ultrasonography is helpful to perform peripheral blocks in an awake child, due to the lack of the painful elicited motor responses with the nerve stimulator technique previously used.

In addition there are concerns that anesthetic agents may have a direct toxic effect on the developing brain of preterm infants, even after reaching postmature age [62]. It is proposed that spinal anesthesia may avoid the risk of anesthetic-related neurotoxicity and possibly improve neurodevelopmental outcomes in preterm infants requiring surgery for inguinal hernia at a postmature age. However, the recent GAS study did not find a difference in neurodevelopmental outcome at age 2 years in a 722-subject multicenter randomized controlled trial of spinal versus general anesthesia [63]. Chapter 46 has an extensive discussion of anesthetic neurotoxicity.

With general anesthesia

In children, regional anesthesia is often combined with light general anesthesia, but there must be justifiable advantages to the child. Such potential advantages were summarized earlier. In addition, general anesthesia decreases central nervous system (CNS) toxicity and dysrhythmias caused by LAs [64,65]. The decision to intubate the trachea or to use a laryngeal mask airway should be based on the usual criteria, such as a full stomach, upper abdominal surgery, or the need to maintain adequate ventilation. If indicated, the trachea should be intubated before the block is begun.

Techniques for performing regional anesthesia

Patient monitoring

Monitors should be applied and functions tested before the block is performed. In particular, the electrocardiogram should be adjusted so that the P wave, QRS complex, and upright T wave can be seen clearly. Baseline systolic blood pressure and heart rates should be noted.

Skin preparation

Bacterial colonization of epidural and caudal catheters in children occurs at a rate of 6–35%. Gram-positive organisms are most common, although gram-negative colonization may also occur, particularly with caudal catheters. Children under 3 years of age are also most likely to have colonization of caudal catheters. Despite high rates of colonization, serious epidural infections are exceedingly rare. Chlorhexidine may be better than povidone–iodine for reducing the risk of catheter colonization in children [66].

Test dose

While placement of regional blocks under general anesthesia is considered standard practice in children, the search for the ideal "test dose" to reduce the risk of inadvertent intravascular injection continues. The original "test dose" described an increase in heart rate and blood pressure following intravenous (IV) administration of epinephrine 0.5 μg/kg, which is equivalent to 0.1 mL/kg IV injection of LA with epinephrine 1:200,000. In children these hemodynamic changes vary with the anesthetic agent used (halothane, sevoflurane, or isoflurane) and whether prior atropine has been administered. However, an increase in heart rate of 10 beats per minute above baseline occurring within 1 min of injection of 0.1 mL/kg of local anesthetic with 1:200,000 epinephrine is a reasonable predictor of intravascular injection for children anesthetized with sevoflurane. Monitoring the ECG changes, i.e. >25% change in T wave or ST segment changes irrespective of the lead chosen, is considered by some to be more specific and more reliable [67].

These changes have been questioned as it seems that similar changes in heart rate, blood pressure, and T wave may be seen following a painful stimulus (surgical incision). The temporal relationship is important, and a secondary drop in pulse rate detected after IV epinephrine distinguishes this from the

response seen after a painful stimulus [68]. Nonetheless, LA solution should be administered slowly over a period of at least 60–120 s, irrespective of the type of block, with repeated aspirations.

KEY POINTS: EVIDENCE-BASED CONCLUSIONS AND CLINICAL ADVICE FROM THE ESRA–ASRA JOINT COMMITTEE PRACTICE ADVISORY ON TEST DOSE [5]

- Because of the difficulty interpreting a negative test dose, test dosing should remain discretionary
- Injection of a LA solution should be performed slowly, in small aliquots, and with intermittent aspiration and observation of the ECG
- Any modification of the T wave or of the heart rate within 30–90 s after the injection of a test dose should be interpreted as an accidental IV injection until disproven
- Ultrasound may help to avoid or visualize accidental intravascular needle placement in peripheral blocks, but data are lacking in pediatric regional anesthesia to determine the value of these techniques

Sympathetic blockade

A clinically significant decrease in blood pressure related to sympathectomy from neuraxial blocks is rare in children younger than 8 years of age [11]. Volume loading before such blocks, commonly practiced in adults, is unnecessary in this age group. In older patients, the sympathetic block results in a slight (20–25%) but consistent decrease in blood pressure. Even in adolescents, however, fluids or vasopressors are rarely required to treat the hemodynamic effects of central neuraxial blocks.

More recently, the GAS study showed that spinal anesthesia reduces the incidence of hypotension and the need for intervention to treat if compared with sevoflurane anesthesia in young infants undergoing inguinal hernia repair [69].

Contraindications

Contraindications to central neuraxial blocks are few and similar to those in adults. These include coagulopathy, infection at the insertion site, true LA allergy, and abnormal superficial landmarks or lumbosacral myelomeningocele because of the risk of malposition of the cord or dural sac. Progressive neurological disease is a relative contraindication, primarily because of medico-legal concerns. The safety of central neuraxial techniques in the presence of a ventriculoperitoneal shunt has not been studied. Risks and benefits in these patients should be carefully considered on an individual basis.

Although it is rare to encounter opposition to the use of peripheral nerve blocks, certain conditions may call for a judicious avoidance of them. Relative contraindications include local infection, generalized sepsis, coagulopathy, predisposition to compartment syndrome, and parental or child dissent.

Ultrasound in regional anesthesia

A significant problem in regional anesthesia is that a large number of techniques still do not achieve a success rate of close to 100%. Indeed, the key to successful regional anesthesia has always depended on the accuracy of needle and LA placement in relation to the nerve structures to be blocked. In 1994, Kapral et al introduced ultrasound guidance into regional anesthesia [70]. About 10 years later, Marhofer et al introduced this technique into pediatric regional anesthesia practice [71]. Real-time ultrasound guidance allows the demonstration of the target, whether it is nerve, fascial plane, or anatomical space, and the monitoring of the distribution of the injected LA. Furthermore, ultrasound guidance with a high-frequency linear or hockeystick probe allows the anesthesiologist to reposition the needle in case of maldistribution of the LA. There is evidence to support ultrasound for various outcomes in pediatric regional anesthesia (Table 20.5) [72].

The possibility of visualizing the nerve structures as well as important nearby anatomical structures (e.g. vessels, pleura, and peritoneum) most likely reduces the incidence of inadvertent complications due to misplacement of the tip of the blocking needle. The reduced volume of LA needed to produce an adequate block should also reduce the risk for systemic toxicity due to rapid absorption of LAs from the injection site (Table 20.6). Indeed, using a conventional up–down technique and measuring the cross-sectional area of the ulnar nerve in the proximal part of the forearm [73] and of the sciatic nerve [74] in adults, a 95% median effective dose for an ulnar nerve block with 1% mepivacaine was estimated to be as low as 0.11 mL/mm^2 nerve, corresponding to a total volume of 0.7 mL to achieve an effective ulnar nerve block, and a 99% median effective dose to be 0.10 mL/mm^2 to achieve an effective ulnar nerve block. Thus, there is good evidence that effective peripheral nerve blocks can be achieved by using considerably smaller volumes of LAs when using ultrasound guidance.

More randomized controlled studies with significant outcomes are likely required to evaluate the potential for ultrasound compared to nerve stimulation technique to reduce complications of regional anesthesia in children. Because serious complications fortunately are very rare following peripheral nerve blockade in infants and children [1,3,4], it is unlikely that even large-scale studies will prove ultrasound guidance to be superior to other approaches with regard to the rate of complications. However, it does not seem reasonable to expect that the use of ultrasound should result in an increased rate of complications. To date, studies in adults have shown a lower incidence of IV LA injection and a trend to less nerve damage with ultrasonography compared to nerve stimulation [75,76]. Training in the use of ultrasound-guided techniques is now widespread [9], and ultrasound-guided techniques now predominate [77,78]. Indeed, the PRAN data have shown that peripheral nerve blocks are very often used for infants and children in the USA, and the use of ultrasound guidance may be driving that practice for many of these blocks [4].

Table 20.5 Statements of evidence and grades of recommendation for ultrasound guidance regional anesthesia outcomes

Evaluated outcomes	Statements of evidence	Grade of recommendation
Peripheral nerve blockade		
Reduces block performance time		
No evidence found	N/A	N/A
Hastens block onset		
Ultrasound guidance reduces onset of sensory block for upper extremity PNBs	Ib	B
Improves block success		
Ultrasound guidance does not improve block success rates in upper extremity PNBs when compared with nerve situation guidance	Ib	B
Ultrasound guidance improves the intraoperative block success for PNBs at the trunk	Ib	A
Improves block quality		
Ultrasound guidance prolongs analgesia for upper and lower extremity blocks	Ib	A
Ultrasound-guided blocks at the anterior trunk improve early postoperative pain relief for inguinal and umbilical procedures	Ib	B
Reduces local anesthetic dose		
Ultrasound guidance reduces the volume of local anesthetic required for successful perioperative analgesia in PNBs	Ib	A
Ultrasound guidance achieves sufficient intraoperative analgesia using minimal volumes (0.1 mL/kg) of local anesthetic for blocks of the nerves in the anterior trunk	Ib	B
Neuraxial anesthesia		
Clear visibility of landmarks		
Ultrasound enables sufficient visibility of the dura mater and ligamentum flavum in neonates, infants, and children	Ib	A
Good prediction of depth to LOR	III	B
Preprocedural ultrasound imaging offers a moderate prediction of the depth to LOR	III	B
Visibility of needle puncture of LOR		
Ultrasound offers visibility of a needle within the epidural space in neonates	III	B
Visibility of catheter (directly or indirectly)		
Ultrasound guidance can directly detect catheters during advancement in some young infants	III	B
Ultrasound guidance can confirm epidural catheter placement via surrogacy during injection of fluid	III	B
Reduces bone contact		
Bone contact can be reduced in most cases in infants and children using real-time ultrasound guidance	III	B

Table 20.6 Reduction of local anesthetic volume with ultrasound guidance

Technique	Ultrasound guidance dosages	Landmark dosages
Supraclavicular block [119]	0.3 mL/kg	0.5 mL/kg
Infraclavicular block [118]	0.2 mL/kg	0.5 mL/kg
Sciatic block [127]	0.2 mL/kg	0.3 mL/kg
Femoral block [127]	0.15 mL/kg	0.3 mL/kg
Rectus sheath block [154]	0.1 mL/kg each side	0.3 mL/kg
Ilioinguinal block [143]	0.1 mL/kg each side	0.4 mL/kg

Neuraxial blocks

Caudal block

This is the most useful pediatric central block, as it is widely applicable and technically simple. It can provide analgesia for surgery up to and including the umbilicus. This technique can be used successfully in neonatal rectal surgery [79].

Performance of a caudal block

The anesthetic agent is injected through the sacral hiatus, which is formed by failure of fusion of the fifth sacral vertebral arch. The hiatus is easily palpated in children as a triangular shaped depression bounded on either side by the sacral cornua (Figs 20.4, 20.5). Following induction of general anesthesia, the child is placed in the lateral position with the knees drawn up, the upper knee being flexed more than the lower. The best approach to the sacral hiatus is found at the apex of an equilateral triangle based on a line drawn between the two posterior superior iliac spines. A short beveled 22 ga needle is inserted at 45° to the skin. When the needle pierces the sacrococcygeal membrane and enters the sacral canal, a distinct "pop" is felt. Then the needle is advanced an additional 0.5–1 cm, depending on the child's age, on a plane parallel to the spinal axis. After aspiration to exclude bone marrow, dural puncture, or venipuncture, incremental doses of LA should be injected.

We do not recommend the use of caudal epidural catheters because of the risk of sepsis due to the proximity of the anus. Therefore, caudal block is a single-shot technique. The lumbar epidural route is preferred if reinjection is needed, or in children weighing more than 20–25 kg, to reduce the total amount of LA used. In this group of patients, we may use the lumbar epidural block as a single-shot technique. Moreover, if we want to prolong caudal block and to avoid a lumbar catheter, it is possible to use clonidine.

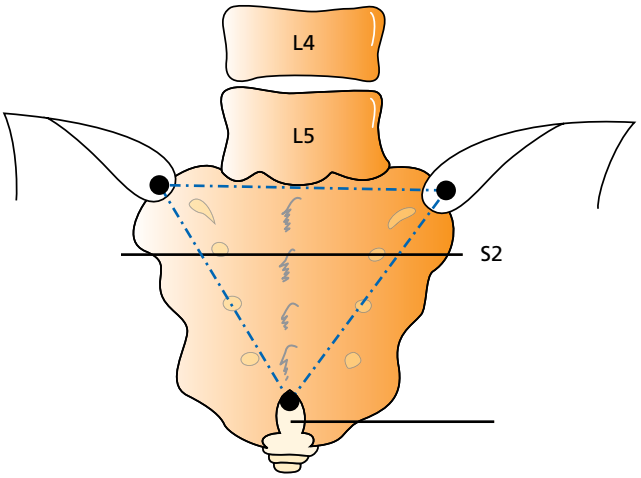

Figure 20.4 Bony landmarks for a caudal block. See text for further details.

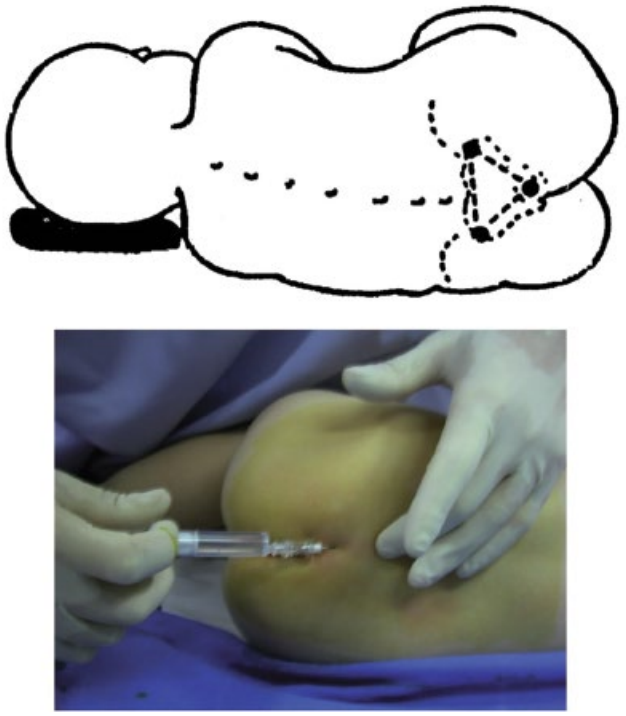

Figure 20.5 Cutaneous landmarks and needle injection for a caudal block. See text for further details.

Local anesthetic dosage

Several dosage regimens have been recommended, but the author prefers the bodyweight method. Thus, 0.25% bupivacaine 0.5 mL/kg for lumbosacral areas (i.e. orthopedic surgery of lower limb) and 1 mL/kg for the thoracolumbar area (i.e. herniorrhaphy and orchidopexy) is administered [80]. It has been shown that caudal analgesia with a larger volume of diluted ropivacaine (0.15%), i.e. 1.5 mL/kg, provides better quality and longer duration after discharge than a smaller volume of more concentrated ropivacaine [81]. However, caudal block with a high volume of LA can cause a greater increase in intracranial pressure than caudal block with a low volume of LA [82]. On the other hand, caudal block with 1 mL/kg of LA can also result in a significant increase in intracranial pressure.

Unfortunately, with ultrasound technique only a small correlation between injected volumes of LA and the cranial spread of caudally administered LAs was observed. The recent PRAN data reported a large variation in LA dose used in caudal blocks [83]. Indeed, the data suggest that approximately 25% of patients undergoing a caudal block receive a LA dose, i.e. >2 mg/kg, that has the potential to cause LA toxicity.

Use of ultrasound guidance

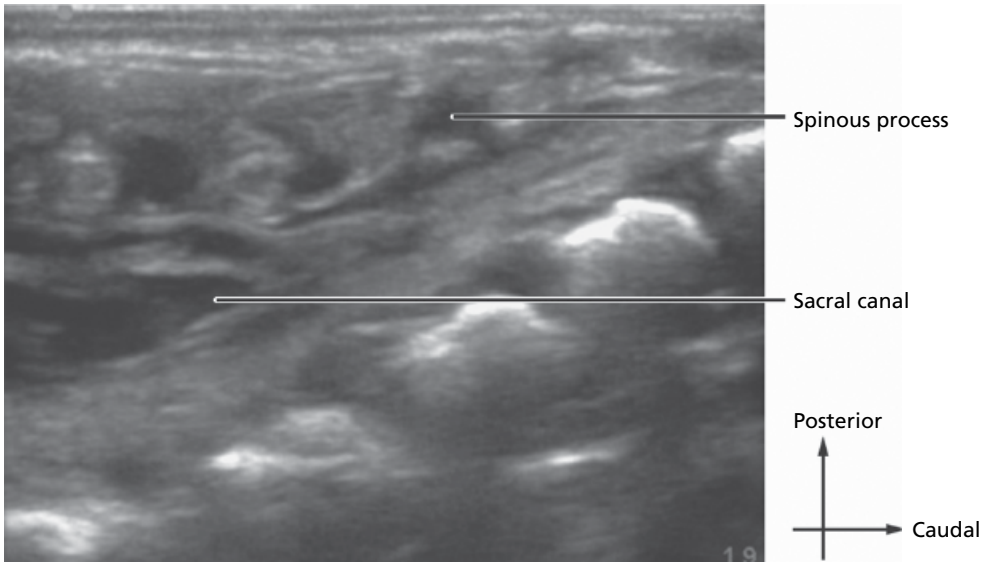
Ultrasound can be used to identify the sacral hiatus in obese children and can also be used to monitor whether the LA solution is injected in the correct anatomical location (Fig. 20.6). It is also feasible to monitor the cephalad spread of LAs within the caudal–epidural space [84]. In addition, the classic bony landmarks that comprise the vertex of an equiangular triangle formed by the inferior to posterior superior iliac spines as the location of the sacral hiatus are inaccurate in children younger than 6 years because in these patients the angle formed by the two lines connecting each posterior superior iliac spine and the real sacral hiatus is more than 60° [85]. Ultrasound may be a good alternative method of determining the location of the sacral hiatus in children with obscure anatomical structures and obesity (Fig. 20.6). However, so far there are no widely published data to support that ultrasound assistance does in fact provide any substantial benefits compared with a traditional landmark-based technique. Nonetheless, sacral hiatus injection with ultrasound-guided technique offers a reliable caudal block for pediatric inguinal hernia repair with the advantages of easier performance and fewer complications, i.e. bloody tap, compared with traditional sacral canal injection [86]. See Video clip 20.1.

Epidural block

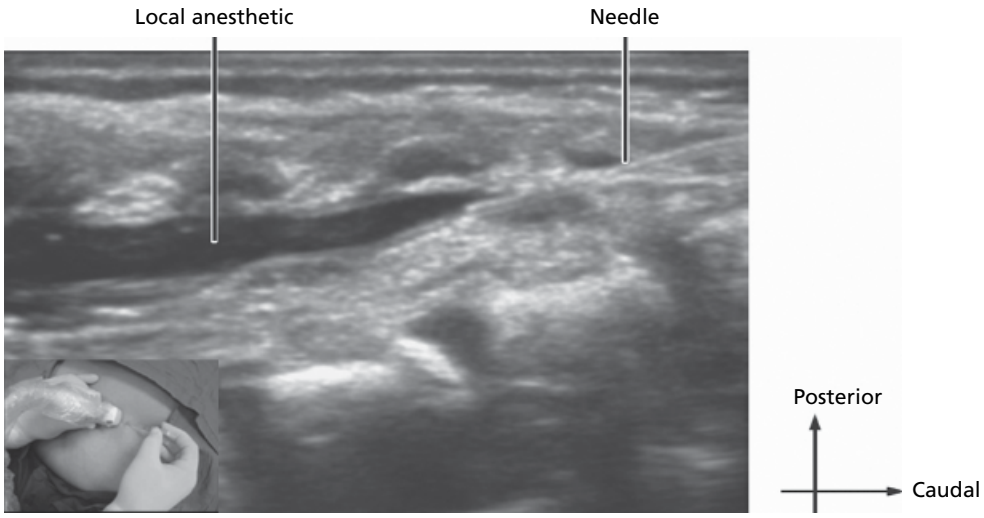
The greatest advantage of epidural block is the long-term analgesia it provides following major surgery of the chest and abdomen and some orthopedic procedures, with continuous LA injection combined with administration of opioids or clonidine [2,87,88].

Performance of an epidural block

As described previously with the caudal block, general anesthesia is first introduced. The technique of lumbar epidural anesthesia in children is similar to that in adults. The smaller the patient, the narrower the epidural space, and modifications of equipment are required if the epidural needle and catheter are to be safely placed and dural puncture avoided. The midline approach is preferred. However, the distance between the skin and epidural space depends on the age of the child. We use an 18 ga Tuohy needle (10 cm length) with a 20 ga epidural catheter in children older than 4 years and a 19 ga Tuohy needle (5 cm length) with a 21 ga epidural catheter in children younger than 4 years. The puncture is performed at the L3–4 or L4–5 interspace in order to decrease the potential risk of trauma to the spinal cord. Indeed, in infants the spinal cord may extend lower than the L2–3 interspace. The correct positioning of the Tuohy needle is ascertained by the loss-of-resistance (LOR) technique with an air-filled syringe instead of saline to avoid diluting the very small volumes of anesthetics used. Nonetheless, a patchy analgesia has been



(A)



(B)

Figure 20.6 Ultrasound imaging of the caudal region. (A) Before local anesthetic injection. (B) After local anesthetic injection. See text for further details.

reported with use of a large volume of air [89], and case reports of venous air embolism cause many pediatric anesthesiologists to prefer the saline LOR method [90].

KEY POINTS: EVIDENCE-BASED CONCLUSIONS AND CLINICAL ADVICE FROM THE ESRA–ASRA JOINT COMMITTEE PRACTICE ADVISORY ON LOSS-OF-RESISTANCE TECHNIQUE [6]

- Different experts support the use of either air LOR or saline LOR techniques
- The combination of air and saline may represent a better alternative, minimizing the risk of injecting air and reducing the volume of saline
- In neonates and infants, the volume of air should be limited to less than 1 mL and air injections should not be repeated if multiple attempts are made
- An air embolism with hemodynamic consequences is rare when air LOR is used, but air LOR should not be used in the presence of a right-to-left cardiac shunt

The catheter should be threaded with minimal resistance, and the tip should be placed as close as possible to the spinal nerves innervating the area of the surgical field, with no more than 2–4 cm of catheter inserted into the epidural space, as measured from the end of the needle. Luer lock adapters with bacteriostatic filters are connected to the free end of the catheter. Thoracic epidural analgesia may be provided for

upper abdominal and thoracic surgery, with the catheter tip placed at the level of the spinal dermatome innervating the area of the incision. After induction of general anesthesia and positioning the patient in the lateral decubitus position, the thoracic spine should be extended maximally by drawing knees to chest and flexing the cervical spine with chin to chest (paying attention to airway patency), with an assistant steadying the patient with a hand on the sternum to provide counterpressure during needle placement. Because of the more acute caudad angulation of the spinous processes of the thoracic vertebrae compared to the lumbar vertebrae, a more cephalad angulation of the epidural needle is required to pass between the spinous processes. A midline approach is used, and very careful attention paid to progress of needle excursion in the interspinous ligaments and ligamentum flavum. Because of lack of calcification of these ligaments, especially in younger children, the loss of resistance felt when passing through the ligamentum flavum is not as distinct. These features in younger children, coupled with the small distances involved and the presence of the spinal cord during thoracic epidural anesthesia, make ultrasound guidance potentially a very important technique to improve accuracy of placement [72,78].

Local anesthetic dosage

As for caudal anesthesia, ropivacaine 0.2% or levobupivacaine/bupivacaine 0.25% is used. A dose of 0.5 mL/kg is used for lumbar epidural initial loading (0.3 mL/kg thoracic epidural initial loading), and 0.25 mL/kg for subsequent "top-up" in order to obtain intraoperative analgesia. After injection into the epidural space, absorption into the bloodstream follows a biphasic process [91]. The buffering properties of the epidural space are important and prevent a rapid rise in concentration. Sometimes, in order to have better muscle relaxation, it is possible to use the LA in combination with intravenous muscle relaxants.

To obtain pain relief in the postoperative period a continuous infusion of 0.1–0.125% bupivacaine or levobupivacaine, or 0.1% ropivacaine, can be used. Epidural infusions of ropivacaine provided satisfactory pain relief in neonates and infants less than 1 year old [92]. As plasma concentrations of unbound ropivacaine are not influenced by the duration of the infusion, ropivacaine can be safely used for postoperative epidural infusion for 48–72 h. Levels of unbound ropivacaine were higher in the neonates than in the infants, but well below threshold concentrations for CNS toxicity in adults, i.e. ≥0.35 mg/L [93]. In the first weeks of life ropivacaine infusion should be used with more caution. Because of concerns about toxicity due to accumulation of amide LAs in infants and young children, chloroprocaine could be an alternative; indeed, continuous chloroprocaine epidural infusion appears to be an efficacious postoperative analgesia modality for neonates, infants, and children [94–96].

The disadvantages of continuous bupivacaine epidural infusion are a high risk of urinary retention and motor block of the legs. The latter can cause anxiety in children between 4 and 8 years old, who may not understand why they cannot move their legs. The use of ropivacaine or levobupivacaine could be useful in decreasing the risk of motor blockade [97].

KEY POINTS: EVIDENCE-BASED CONCLUSIONS AND CLINICAL ADVICE FROM THE ESRA–ASRA JOINT COMMITTEE PRACTICE ADVISORY ON RECOMMENDATIONS ON LOCAL ANESTHETICS AND ADJUVANTS DOSAGE IN PEDIATRIC REGIONAL ANESTHESIA FOR EPIDURAL ANESTHESIA [7]

- The local anesthetic dose for lumbar or thoracic epidural should not exceed 1.7 mg/kg of ropivacaine, bupivacaine, or levobupivacaine
- Continuous epidural anesthesia can be performed with a dose of 0.2 mg/kg/h for infants less than 3 months, 0.3 mg/kg/h for children 3 months to 1 year, and 0.4 mg/kg/h for children >1 year

Use of ultrasound guidance

Willschke and colleagues have investigated the potential usefulness of ultrasound assistance when performing epidural anesthesia in infants and children [98,99]. In addition, they compared epidural catheter placement using either the traditional landmark-based technique or ultrasound assistance and found a reduction in performance time by visualization of the distance between the skin and epidural space [100] (Fig. 20.7) and fewer episodes of bone contact when using ultrasound. The described technique does, however, require a very skilled assistant handling the ultrasound probe, and, apart from the need for a "skilled third arm," there is also interference between the operator and the ultrasound probe. Karmakar et al reported the use of ultrasound- assisted epidural blockade using a spring-loaded syringe in adults [101]. Such a modification of the technique makes it possible for a single operator to perform the block (holding the ultrasound probe in one hand and the Tuohy needle/spring-loaded syringe in the other). This may represent a modification of this approach that makes ultrasound assistance clinically valuable in the context of epidural blockade also. Finally, a simple preprocedural ultrasonography examination of the spine accurately delineates the underlying relevant anatomy, and permits assessment of the depth of the epidural space, which is relevant information in infants and children.

Spinal block

This block is a useful technique in the ex-premature infant scheduled for inguinal herniorrhaphy because it is the only form of pediatric regional anesthesia in which the block is routinely performed and the operation carried out on a conscious patient. It is well known that ex-premature infants are more prone to complications such as apnea, hypoxia, and bradycardia during the first postoperative hours following general anesthesia [52, 102], despite the fact that a recent trial and cohort studies suggest that an exposure of less than an hour does not increase the risk of poor outcome [103]. Moreover, premature infants with a history of bronchopulmonary dysplasia may be at even greater risk of developing postanesthetic complications because of the depressant effects

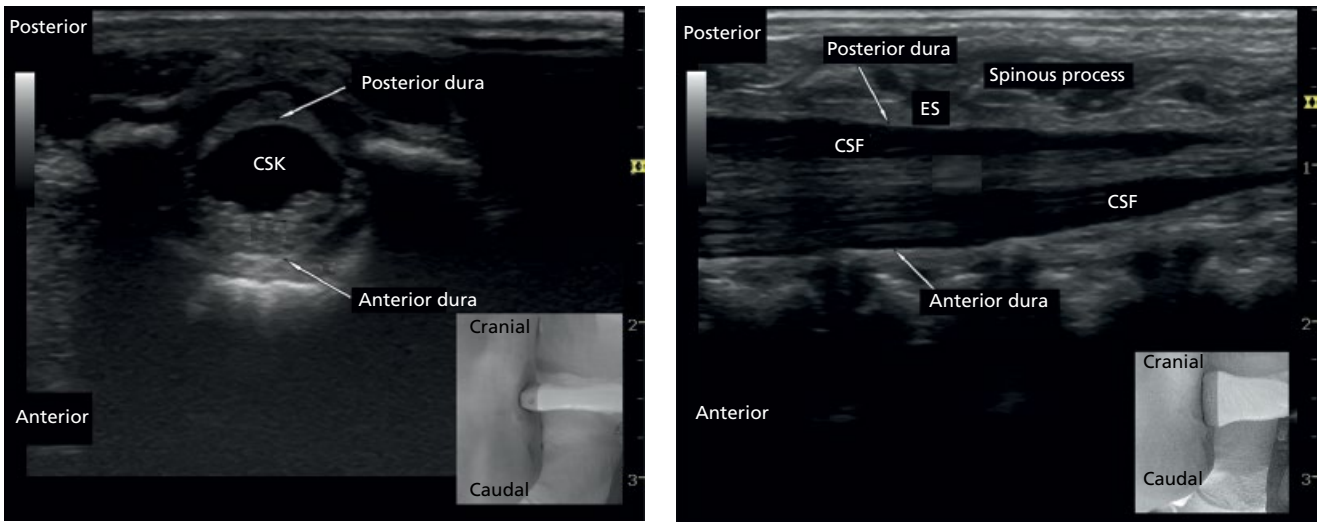


Figure 20.7 Ultrasound imaging of the epidural region. (A) Transverse view. (B) Paramedian longitudinal view. CSF, cerebrospinal fluid; ES, epidural space. See text for further details.

of halogenated agents on intercostal muscles, lung volumes, and chemo- and baroreceptor responses.

Avoiding general anesthesia is therefore very useful. Preclinical studies have consistently found that most general anesthetics produce accelerated apoptosis in the developing brain of animals. Spinal block in a conscious infant is a recognized technique that allows the avoidance of general anaesthesia and the potential risks associated with it.

Performance of a spinal block

As discussed with epidural block, the subarachnoid puncture should be made caudal to L3 to avoid possible damage to the spinal cord. The puncture is performed with the child turned in the lateral position with lower extremities flexed and the neck extended. It has been shown that hypoxemia occurs during lumbar puncture in the sick neonate when the infant's neck is flexed for the spinal tap [104]. A 22 ga, 3.5 cm styletted (or 25 ga 1.5 cm) lumbar puncture needle is inserted in a midline position. An unstyletted needle increases the risk of development of an epidermoid tumor. The needle is advanced slowly, and the stylet is frequently removed in order to watch for the free-flowing return of CSF.

Local anesthetic used

The most common local anesthetic used is 0.5% tetracaine with 5% dextrose: 0.13 mL/kg in infants weighing less than 4 kg, and 0.07 mL/kg in infants weighing more than 4 kg [102]. Tetracaine is no longer available in some countries. Hyperbaric bupivacaine or isobaric levobupivacaine or ropivacaine can also be used [105,106]. The duration of spinal block is shorter in infants than in adults, probably due to the larger volume of CSF. Indeed, a relationship between duration of motor blockade and age has been reported [11]. In addition, there is a proportionally greater blood flow to the spinal cord with a more rapid uptake of drugs from the subarachnoid space. These phenomena are most pronounced in preterm infants compared to full-term infants. The timing in relation to the baby's feeding requirements is important for two reasons. First of all, the crying of a hungry baby renders a hernia repair much more difficult. Therefore, a pacifier can usually keep the baby quiet, and the upper limb should be immobilized. Recently dexmedetomidine has been proposed as sedative agent [107]. Second, hypotension from sympathetic block following the spinal anesthesia can occur if fasting is prolonged [108].

In older children, there are few indications for spinal block, due to the short duration of postoperative analgesia. Nonetheless, the child with a full stomach scheduled for a testicular torsion should be a good candidate for a spinal block without sedation. The usual dosage of 1% tetracaine plus 10% glucose is 1 mg per year of age (below 3 years, 0.2 mg/kg). The other LAs can be also used in older children.

KEY POINTS: EVIDENCE-BASED CONCLUSIONS AND CLINICAL ADVICE FROM THE ESRA–ASRA JOINT COMMITTEE PRACTICE ADVISORY ON RECOMMENDATIONS ON LOCAL ANESTHETICS AND ADJUVANTS DOSAGE IN PEDIATRIC REGIONAL ANESTHESIA FOR SPINAL ANESTHESIA [6]

- Spinal anesthesia with tetracaine, bupivacaine, levobupivacaine, or ropivacaine can be performed with a dose of 1 mg/kg for newborn and/or infant and a dose of 0.5 mg/kg in older children (>1 year of age)

Use of ultrasound guidance

Caudal anesthesia has been shown to be technically less difficult than spinal anesthesia and to have a higher success rate. Its application as awake regional anesthesia technique in these patients seems more appropriate than spinal anesthesia [109]. However, theoretically, ultrasound could be used to help predict or determine (if used in real-time) the depth to

reach either the subarachnoid space or some depth within the spinal canal [110]. Nonetheless, the failure rate of spinal anesthesia was low; a bloody tap on the first attempt at lumbar puncture was the only risk factor significantly associated with block failure [111]. See Video clip 20.2.

Peripheral nerve blocks

Brachial plexus and branches

Fractures of the upper extremity, especially at the elbow and wrist, are common injuries during the summer months when children are outside playing on jungle gyms and skateboards. These patients often present in the late afternoon or early evening having eaten just prior to the traumatic event. Surgery focuses on reduction and realignment procedures with hardware insertion and casting. Use of sedation may complicate the anesthetic considerations of a full stomach. Brachial plexus blockade may be established with a variety of effective techniques. In addition, the use of ultrasound guidance is very useful [112,113].

Interscalene approach

There are few indications for interscalene brachial plexus blocks in the pediatric population, and few case reports have been published describing ultrasound-guided interscalene block in children [114]. With the patient positioned supine and head turned slightly to the contralateral side, in a transverse oblique plane at the level of the cricoid, the anechoic compressible internal jugular vein and pulsatile carotid artery are visualized medial to the anterior scalene muscle and deep to the triangular-shaped sternocleidomastoid muscle. The roots of the brachial plexus appear as distinct hypoechoic oval or round bodies arranged in a cephalocaudal orientation in between the bulky anterior and middle scalene muscles (Fig. 20.8). No serious adverse events were reported in prospectively collected data [115]. The upper limit of the confidence interval for these events is similar to that in awake or sedated adults receiving interscalene blocks. Based on these results, placement of interscalene blocks under general anesthesia in children is no less safe than placement in awake adults.

Periclavicular blocks

The *supraclavicular or infraclavicular approach* to the brachial plexus is recommended for elective or emergency surgery of the upper limb when lesions are located above the elbow or when the limb cannot be moved, either because of severe pain or because of the nature of the lesion itself [116]. Specific contraindications are acute or chronic respiratory insufficiency or whenever the surgery mandates bilateral supraclavicular block, due to the possibility of phrenic block. Some side-effects can occur: stellate ganglion block with a Horner syndrome, risk of damage to the vertebral artery or the large blood vessels of the neck, or pneumothorax. Because of the high risk of potentially serious side-effects, most anesthesiologists have avoided the supraclavicular and the infraclavicular approach in children, in whom the anatomical relations are even closer than in adults. With the introduction of ultrasound guidance, the supraclavicular or infraclavicular approach to the brachial plexus is once again becoming popular for children.

For the supraclavicular approach, the probe is first placed in a coronal oblique plane at the lateral end of and just above the upper border of the clavicle. It is then moved medially until an image of the subclavian artery appears in the middle of the screen (Fig. 20.9). At this location, the plexus is located superior and lateral to the artery, and the neurovascular structures are noted to be above the first rib. In the supraclavicular fossa, the divisions of the brachial plexus are visualized as a cluster of hypoechoic nodules immediately cephalad and lateral to the anechoic pulsatile subclavian artery and above the first rib. Using an in-plane technique, the needle is advanced into the plexus, and after aspiration, LA is injected until circumferential spread around the plexus trunks is seen (0.2 mL/kg may suffice depending on the age of the patient and accuracy of needle tip placement). Few published data are reported [117].

For the infraclavicular approach, the child is placed supine with the arm adducted, elbow flexed, and forearm placed on their abdomen. A linear probe is placed transversely below the clavicle to capture an image of the brachial plexus (presumably the cords surrounding the subclavian artery). The needle is inserted out of plane, 1 cm from the inferior aspect of the probe, and directed slightly cranially to direct it toward the lateral border of the plexus. The LA spread is viewed surrounding the plexus. However, the vertical infraclavicular brachial plexus block, which is very popular in adults, is dangerous in children because of its proximity to the cervical pleura [118]. In a prospective, randomized study, Marhofer et al compared ultrasound-guided and old nerve stimulator-guided infraclavicular brachial plexus blocks in children with upper extremity fractures [119]. The sensory and motor block characteristics were better in the ultrasound-guided group at 10 min after the completion of the block procedure.

De José María et al demonstrated that ultrasound-guided supraclavicular plexus block is as effective as ultrasound-guided infraclavicular plexus block in children aged 5–15 years [120]. However, the supraclavicular plexus block appeared to be associated with fewer failed blocks when compared with the infraclavicular approach. These data imply that, in experienced hands, a supraclavicular block is a safe and useful alternative for pediatric hand and arm surgery. See Video clip 20.3.

Axillary approach

The axillary approach to the brachial plexus was introduced into pediatric regional anesthesia in 1960 and is frequently used because of its low complication rate [121]. The indication for the axillary approach is elective or emergency surgery on the forearm and the hand. The specific contraindications are axillary lymphadenopathy or when the situation requires that the limb be immobile, such as with intense pain or an unstable fracture.

There is no original report of ultrasound-guided axillary block in children. The patient is positioned supine with the arm abducted to 90° and flexed at the elbow. With the probe placed perpendicular to the anterior axillary fold, a short-axis view of the neurovascular bundle can be obtained (Fig. 20.10). The nerves are pictured as distinct hypoechoic nodules with internal hyperechoic punctuations typically situated lateral (median nerve), medial (ulnar nerve), and posterior (radial nerve) to the anechoic pulsatile axillary artery. It is noteworthy that the

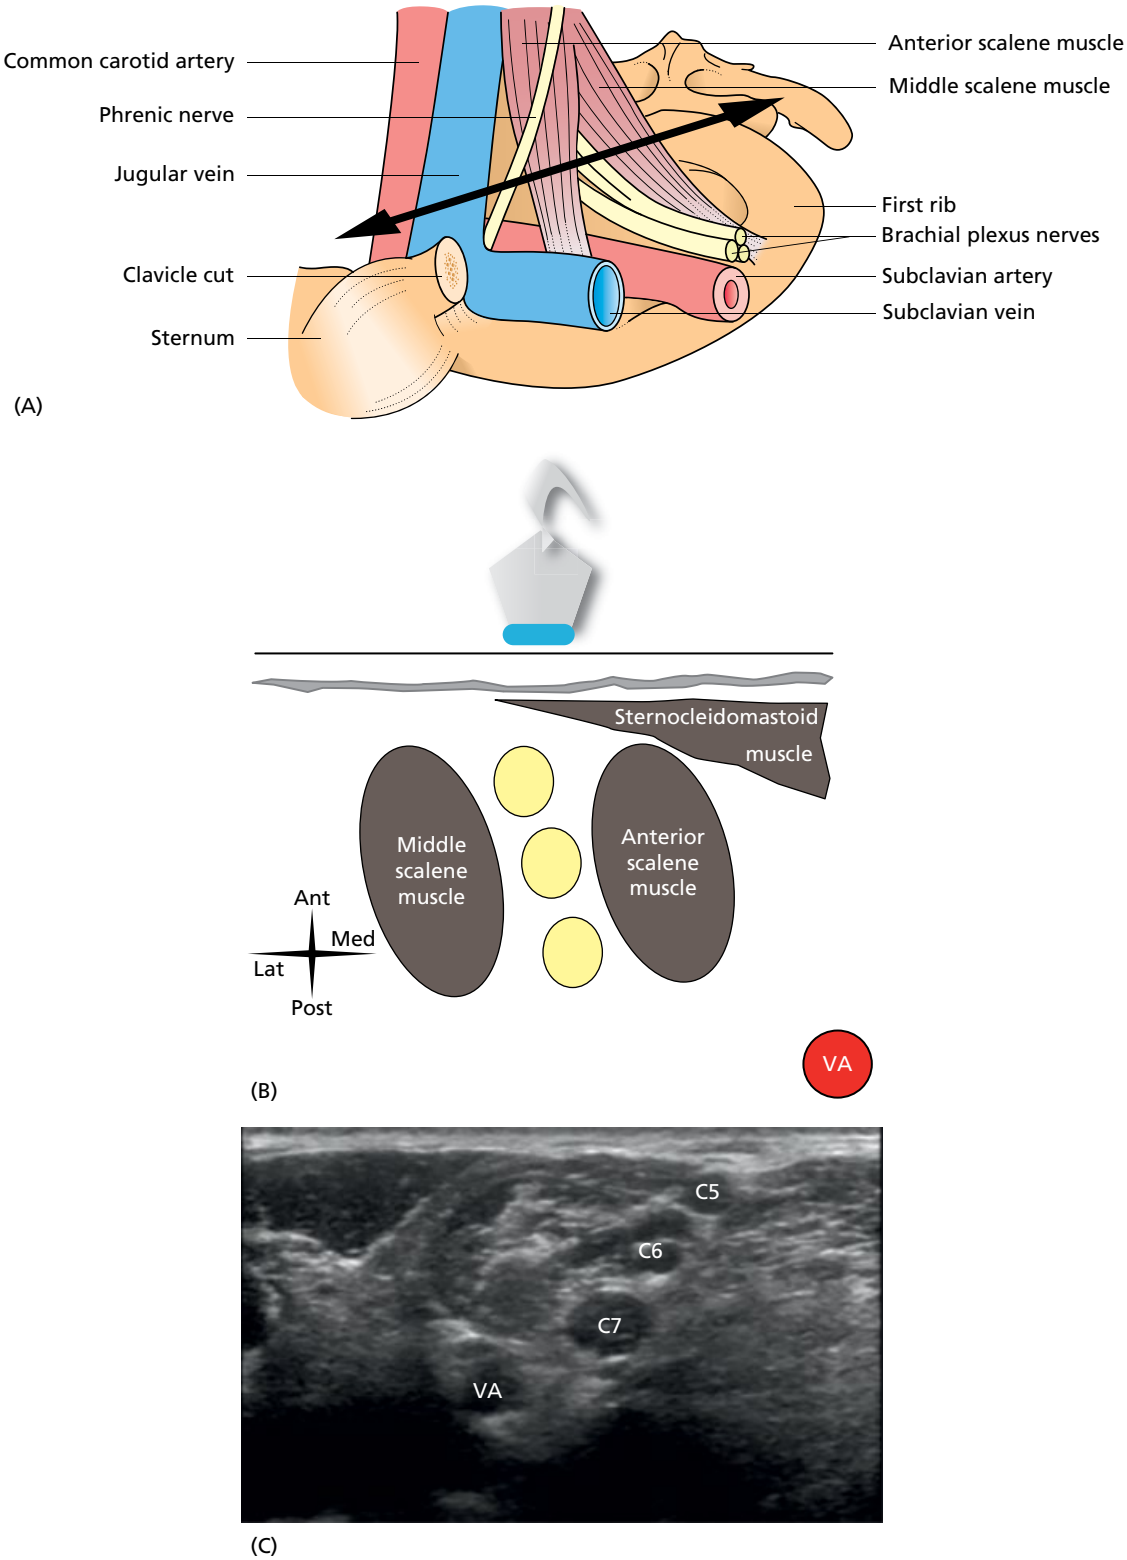

Figure 20.8 The interscalene region. (A) Anatomy. (B) Ultrasound imaging. The ultrasound probe is depicted at the top of the figure. location of these three nerves relative to the axillary artery can be highly variable. This block could be performed with similar techniques to those used in adults. A single needle insertion at this location facilitates the blockade of the radial, median, and ulnar nerves. It is important to note that the musculocutaneous nerve is situated outside of the axillary neurovascular sheath. Specifically, it lies between the biceps brachii and coracobrachialis muscles and is often blocked separately from the radial, median, and ulnar nerves [122]. In addition, topographic variations of the four main nerves at the axilla were found to be numerous [123,124]. A volume of 0.25–0.3 mL/kg is used (do not use more than 20 mL).

Lumbar plexus and branches

The lumbar plexus originates from the nerve roots from T12 to L5. Its branches include the femoral, genitofemoral, lateral femoral cutaneous, and obturator nerves. The innervation of the skin, muscles, periosteum, and joints of the hip, thigh, and knee make blockade of the lumbar plexus particularly useful in pediatric patients. Analgesia for lower extremity procedures in children frequently involves areas innervated by branches of the lumbar plexus. Procedures involving joint or bone realignment, especially with insertion of hardware, are common, particularly in disabled children where the ability to sit upright in a wheelchair or to manage transfers from chair to bed and vice versa is vital to reducing their dependence on the family or nursing staff. In those with cerebral palsy, lengthening of muscle and tendons is equally important. Unfortunately these children may suffer from long periods of muscle spasm and pain following surgery. Due to their disabilities, communication regarding the efficacy of pain relief may be very difficult. Regional techniques, which effectively block the development of muscle spasm, eliminate the need for benzodiazepines and their supposed muscle relaxant effect. A clearer sensorium facilitates care delivery and assessment of pain relief. Congenital hip dislocation that does not respond to immobilization in plaster may require open reduction. In this setting, unilateral blockade of the lumbar plexus or bilateral blockade from a central approach makes life easier for all concerned.

Psoas compartment block

Posterior lumbar plexus block represents one of the most challenging techniques in terms of both ultrasound imaging and needle guidance. It should therefore only be performed or supervised by experienced clinicians. The clinical value of this technique has not yet been studied systematically. The well-recognized advantage of a posterior approach to the lumbar plexus is a reliable block of the femoral nerve, obturator nerve, and lateral cutaneous nerve of the thigh with a single injection.

Patients are placed in the lateral decubitus position, and the iliac crest and spinous processes are identified. The ultrasound probe is placed lateral to the midline, and the L4 or L5 transverse processes are located. Deep to the transverse process are the erector spinae and quadratus lumborum muscles. Beyond this, within the psoas major muscle, is the lumbar plexus. Because of this anatomical location, the plexus is often difficult to demarcate because it has similar echogenicity to the muscle [125].

In addition to the difficult performance of this posterior lumbar approach, one concern about this technique is that systemic LA toxicity might occur because of the rapid absorption of large volumes or because of inadvertent injection into one of the large paravertebral blood vessels [45]. Bilateral spread is also a known side-effect of posterior lumbar plexus block.

Femoral block

The area anesthetized by a femoral block will be the quadriceps group of muscles, the periosteum of the shaft of the femur, the skin on the anterior aspect of the thigh, the medial part of the leg, and a small portion of the foot. It originates from the L2, L3, and L4 nerve roots. The indications are analgesia in patients with fracture of the femur [126] and surgery on the thigh, and analgesia for knee and leg surgery in combination with a sciatic block.

The femoral artery is the key landmark when using ultrasound guidance for femoral nerve blockade [127,128]. Indeed, the femoral nerve is anatomically lateral to the femoral artery and vein (Fig. 20.11). With the probe placed perpendicular to the nerve axis (i.e. coronal oblique) at the level of and parallel to the inguinal crease, the nerve appears lateral to the large, circular, pulsatile and anechoic femoral artery. An in-plane or out-of-plane approach can be used to guide the needle to the lateral portion of the femoral nerve and circumferentially surround it with local anesthetic. A volume of 0.25–0.3 mL/kg is used (do not use more than 20 mL). See Video clip 20.4.

Fascia iliaca compartment block

The fascia iliaca compartment block blocks the femoral nerve in all cases, and the lateral cutaneous nerve of the thigh and the obturator nerve is blocked in 75% of cases [129]. To perform the block, the child is placed in the supine position. The ultrasound probe is placed in the inguinal region and, following observation of femoral artery, the probe is moved a little lateral so that the iliopsoas muscle is identified as a hypoechoic area lateral to the artery and femoral nerve. Local anesthetic is injected between the fascia iliaca layer and iliopsoas muscle after passing the fascia iliaca layer.

Sciatic nerve

With contributions from the lumbar roots (L4, L5) and the sacral roots (S1, S2, S3), the sciatic nerve is the largest in the body. It provides innervation to the posterior thigh and the entire leg distal to the knee (excluding the medial component). The indications for sciatic nerve block include analgesia for trauma of the leg and foot. In elective surgery, a sciatic nerve block can be performed for surgery on the foot in combination with a femoral nerve block. Thus, any operation on the lower limb can be performed. In addition, pediatric orthopedic procedures on the lower extremity below the knee are performed primarily for congenital deformities such as talipes equinovarus and structural imbalances caused by cerebral palsy. Leg length discrepancy may also require prolonged treatment with an external fixator. In this setting, any leg

length that can be obtained early with excellent analgesia from regional blockade will shorten hospital stay and reduce the associated expenses. The sciatic nerve can be blocked throughout its anatomical course using the subgluteal, anterior thigh, or popliteal approaches in children.

Gray et al published the first report on ultrasound-guided peripheral nerve block in children in 2003, in which they performed a sciatic nerve block in the subgluteal region of a 7-year-old [130]. More recently, studies of ultrasound-guided sciatic nerve blockade using a subgluteal approach have been published [128,131]. The subgluteal approach to the sciatic nerve requires the patient to lie in either the lateral decubitus position, with the hip and knee flexed, or in the prone position. In these positions, the ultrasound probe is placed between the greater trochanter and the ischial tuberosity (Fig. 20.12). The gluteus maximus muscle is identified, and deep to this is the sciatic nerve. An in-plane or out-of-plane technique can be used to advance the needle with ultrasound guidance to the nerve. The optimal needle insertion point is approximately halfway between the greater trochanter and the tip of the coccyx – a landmark readily palpable in neonates and infants [132]. The sciatic nerve appears predominantly hyperechoic and is often elliptical in a short-axis view.

The anterior approach to sciatic nerve blockade requires the patient to be in the supine position. This technique allows for the completion of the sciatic nerve block in non-anesthetized patients. With the patient's leg abducted and laterally rotated, the probe is placed inferior to the inguinal crease. The femur is identified, and the probe is moved medially to reveal the sciatic nerve in its location deep and medial to the femur.

A caudal-to-cephalad scan can effectively locate the sciatic nerve in the posterior popliteal fossa at a location where the tibial and common peroneal components have yet to separate. The child is placed prone or can remain in the supine position. At the popliteal crease, a transversely positioned linear probe captures the tibial and common peroneal nerves, the former located medially and lateral to the adjacent popliteal vessels (Fig. 20.13). The tibial nerve is often located in close proximity to the tibial artery and the tibial vein. The nerve appears round-to-oval and hyperechoic compared with the surrounding musculature. The hyperechoic border of the femur (condyles) may be apparent. The tibial nerve can be followed proximally to the junction with the common peroneal nerve, merging together to form the sciatic nerve. The sciatic nerve can be blocked here, or the tibial and common peroneal nerves can be specifically targeted at this location. See Video clip 20.5.

Continuous peripheral nerve blocks

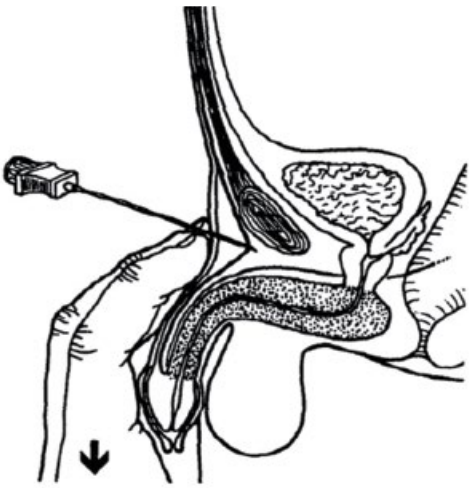
Single-shot peripheral blocks are now widely used in children but they can provide analgesia only for few hours. These blocks are even safer than central ones, but few studies have described continuous peripheral nerve block in children, except recently infraclavicular block [133] and sciatic block [58,134]. The indications for placing a catheter for continuous peripheral nerve blocks are severe pain, long intraoperative time requiring redosing, and the need for pain control for many days. Otherwise, painful rehabilitation and physiotherapy are probably the main indication, because good rehabilitation can only be performed if pain is under control. In adults, performance of such blocks has become daily clinical practice supported by a large quantity of data, providing effective analgesia, and allowing active physiotherapy that is essential for optimal functional recovery. Catheters can be maintained in position for several days and the patient is sometimes sent home with a catheter infusion [135]. One study has reported the efficacy of continuous peripheral nerve blocks with elastomeric disposable pumps associated with initial Bier blocks for the treatment of recurrent complex regional pain syndrome in children [136]. All the studies published so far underline the efficacy and safety of analgesia via a peripheral catheter, and no complications or side-effects linked to the long-term infusions have been described with only a few accidental removals and some drug leakage [136]. They are at least as efficient as epidural analgesia but produce fewer side-effects [135,137]. Sometimes a combination of peripheral blocks as a continuous sciatic block with a femoral single-shot block for tourniquet pain and light general anesthesia provides good intraoperative conditions for leg and foot surgery and adequate postoperative pain relief. Additional sedation to minimize the discomfort of a cast may be a consideration in the first 24 h [132]. As continuous regional analgesia is considered a safe and efficacious technique for postoperative pain relief in children after lower limb surgery, the feasibility of patient-controlled regional analgesia in a similar acute pain situation was evaluated. Both techniques are efficacious and satisfactory. However, patient-controlled regional analgesia with ropivacaine 0.2% can provide adequate postoperative analgesia for pediatric orthopedic procedures with smaller doses of ropivacaine and lower total plasma concentrations of ropivacaine than with continuous regional analgesia [138].

Other nerve blocks

Penile nerve block

The indication is surgery on the foreskin (phimosis, paraphimosis, circumcision). The anatomical landmark is the pubic symphysis (Fig. 20.14) [139]. The puncture is performed with a needle 22 ga in caliber and 30 mm in length. After gently pulling the penis downward, each pubic ramus is identified about 0.5 (infant) to 1.0 cm (older children) lateral to the symphysis pubis on either side, and immediately below the right and left inferior rami of the pubic bone. The needle is introduced at the puncture site, perpendicular to the skin. Penetration is halted in the subpubic space, after distinct elastic recoil is felt, corresponding to the crossing of the deep membranous layer of the superficial fascia. The depth of insertion correlates with age (8 mm for a newborn, 30 mm for a young adult). The same procedure is repeated on the opposite side. The volume should be 0.1 mL/kg for each side with 0.5% ropivacaine or levobupivacaine without epinephrine [140]. Epinephrine is absolutely contraindicated because it can lead to spasm of the dorsal arteries of the penis with subsequent ischemia and necrosis of the glans.

The use of ultrasound guidance is still debated. By placing a probe sagittally along the shaft of the penis, the subpubic space can be located as a triangle containing the deep penile fascia (inferiorly), the pubic symphysis (superiorly), and the membranous layer of the superficial (Scarpa's) fascia (Fig. 20.15). In a case report, Sandeman and Dilley describe placing a linear probe sagittally along the shaft of the penis to view the subpubic space [141]. Ultrasound-guided penile block improved the efficacy of the block compared with the landmark technique in terms of postoperative pain during the first postoperative hour and time to first requirement for postoperative analgesia [142].



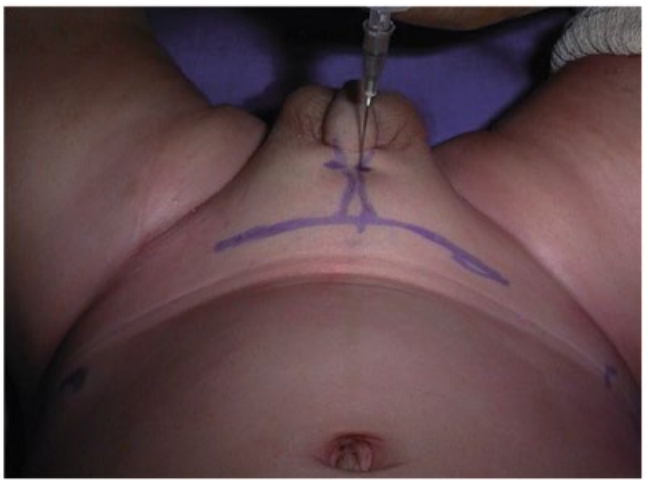


Figure 20.14 Anatomy and landmarks of a needle approach for a penile block. The anatomical landmark is the pubic symphysis. After gently pulling the penis downward, the two points are marked just below the pubic symphysis, each pubic ramus about 0.5–1.0 cm on either side of the pubic symphysis. The puncture is performed with a 22 ga needle, 30 mm in length. See text for further details.

Ilioinguinal iliohypogastric block nerve block

The main indication is hernia repair. This peripheral nerve block is one of the best-studied with regard to the use of ultrasound guidance [143–147]. After placement of a linear or hockeystick probe along the anterior superior iliac spine (ASIS) with the probe oriented toward the umbilicus, the three layers of the abdominal wall muscles can be recognized. The ilioinguinal nerve and iliohypogastric nerves are seen as two hypoechoic structures between the internal oblique and transversus abdominis muscles (Fig. 20.16). A short-beveled needle (e.g. 22 ga, 40 mm with facette tip) is used. A reliable endpoint for the inexperienced practitioner of ultrasound-guided ilioinguinal/ iliohypogastric nerve block may be the transversus abdominis /internal oblique plane where the nerves are reported to be found in 100% of cases [146]. Using postinjection ultrasonographic control, Weintraud et al were able to show that the use of the classic landmark-based approach resulted in only 14% of the injections being made at the correct anatomical location [145]. Not surprisingly, the overall success rate of the ilioinguinal/ iliohypogastric nerve block was found to be only 61% in this study. In a prospective randomized study by Willschke et al, the use of an ultrasound-guided ilioinguinal/ iliohypogastric nerve block was compared with the landmark-based approach concerning efficacy of the two techniques [143]. It was clearly demonstrated that the use of the ultrasound-guided technique was associated with a significantly higher success rate, as evidenced by a reduced hemodynamic reaction to skin incision (4% versus 24%) and a considerable reduction in the number of patients needing supplemental analgesia in the recovery room (6% versus 40%). The same authors showed in a further study that a substantial reduction in the volume of LA (traditionally recommended volume 0.4–0.5 mL/kg) is possible when using ultrasound guidance. Using a modified up–down technique, they found that an effective ilioinguinal/ iliohypogastric nerve block can be achieved using a volume of LA as low as 0.075 mL/kg when using ultrasound guidance [144]. Weintraud and colleagues published a study in which plasma concentrations following either landmark-based or ultrasound-guided ilioinguinal/ iliohypogastric nerve block were analyzed following the administration of equal volumes and amounts of ropivacaine (0.25 mL/kg of 0.5%) [147]. Somewhat surprisingly, the maximum plasma concentration (C_{max}) was found to be higher and the time to maximum concentration (T_{max}) shorter when ultrasound guidance was used, indicating more rapid absorption when the LA was injected at the correct anatomical position. The most likely explanation for this unanticipated finding is that, when the LA is deposited between the fasciae of the internal oblique and the transversus abdominis muscle, the area of absorption will increase substantially compared with when the drug is mainly injected intramuscularly. Finally, a more recent study suggests that the needle should be placed much closer to the ASIS than the previously described anatomical landmark. In neonates, the LA needle should be inserted approximately 3 mm from the ASIS on a line drawn between the ASIS and the umbilicus [148].

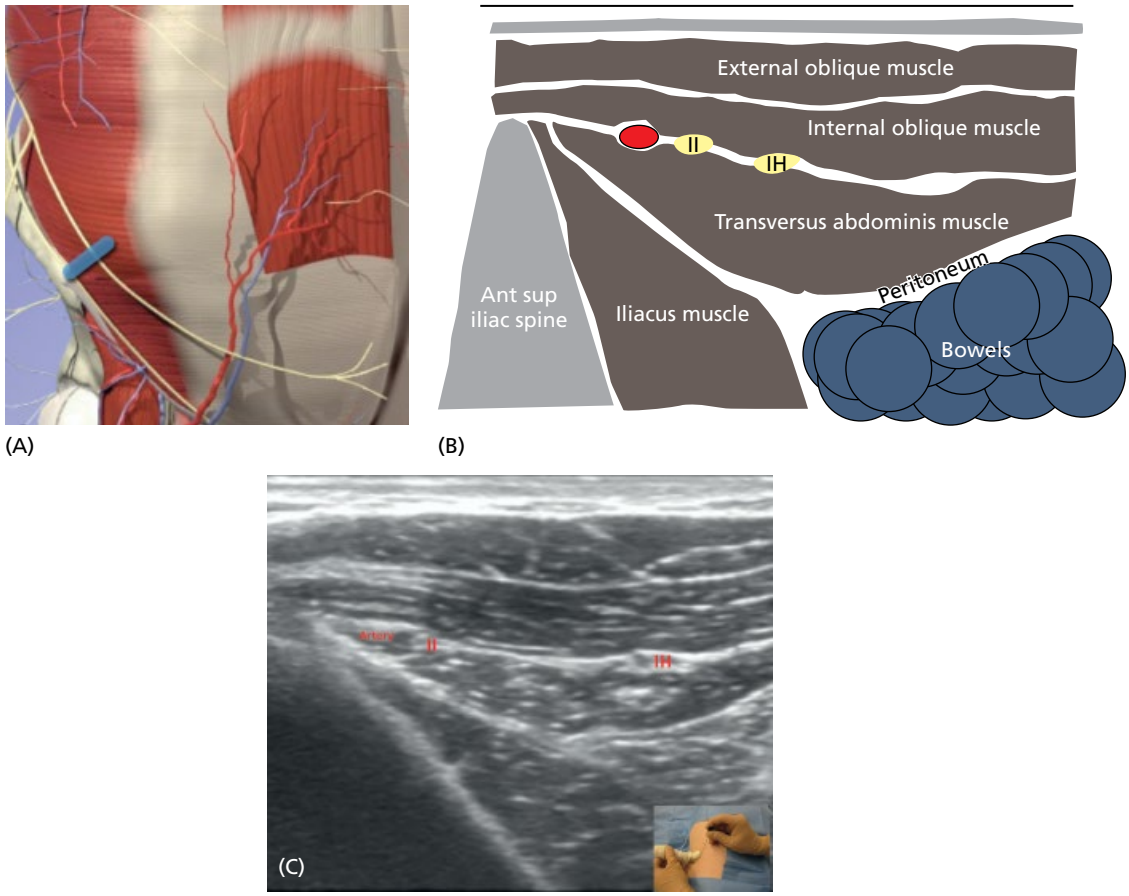

Figure 20.16 The abdominal region. (A) Anatomy. (B) Ultrasound imaging. After placement of a linear or hockeystick ultrasound probe along the anterior superior iliac spine with the probe oriented toward the umbilicus, the three layers of the abdominal wall muscles can be recognized. The ilioinguinal nerve and iliohypogastric nerves are seen as two hypoechoic structures between the internal oblique and transversus abdominis muscles. (C) Ultrasound image. II, ilioinguinal nerve; IH, iliohypogastric nerve. See text for further details.

Transversus abdominis plane block

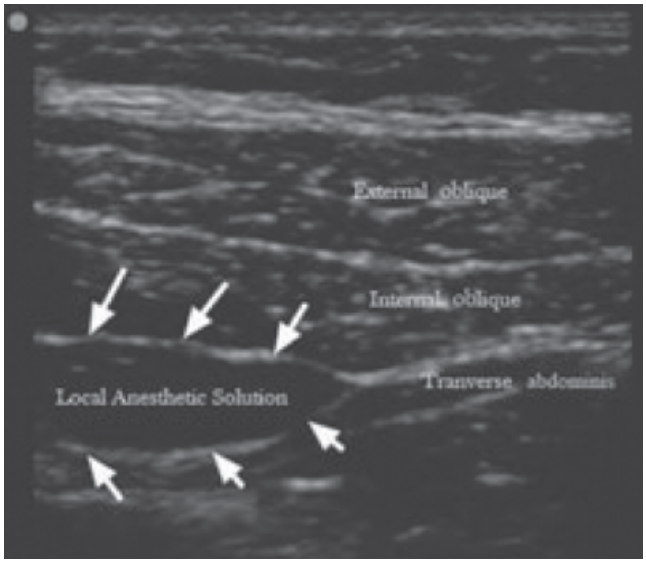
The transversus abdominis plane (TAP) block is increasingly being used to provide analgesia after surgery involving the abdominal wall. The block requires injection of LA into a plane between the transversus abdominis and the internal oblique muscle. A cadaver study demonstrated that with an ultrasound-guided single injection of 20 mL of aniline blue dye in the TAP, the ninth thoracic nerve (T9) was not surrounded by the injectate, whereas the segmental nerves T10, T11, T12, and L1 were surrounded by the injected dye in 50%, 100%, 100%, and 93% of the cases, respectively [149]. Ultrasound can help the practitioner readily visualize the muscle layers at the lateral abdominal wall, though it does not allow clear distinction between the individual muscles (Fig. 20.17). Linear and parallel hyperechoic striations are apparent, beneath which lies a hypoechoic-appearing region representing the peritoneum [150]. The external oblique abdominal muscle will lie superficial, overlying the internal oblique and transversus abdominis muscles. As for the rectus sheath and umbilical blocks, the nerves (in this block the lower thoracic and first lumbar spinal nerves) will not be viewed with clarity because they would appear with similar echogenicity as the muscle layers and travel tangentially to the ultrasound beam axis at this location. A short-beveled needle (e.g. 22 ga, 80–100 mm with facette tip) is used. A low risk of LA toxicity in neonates has been reported after a TAP block [151].

TAP block represents an interesting and effective regional anesthetic technique for pain relief after abdominal surgery due to a wide LA spread [152]. TAP block provides superior analgesia compared with wound infiltration in the setting of a multimodal analgesic regimen. The upper incidence of overall complications associated with the TAP block in children was 0.3% in a recent PRAN study [153]. Complications were very minor and did not require any additional interventions. Future studies should define the risks and benefits, and compare them with epidural techniques, which can be considered the "gold standard" for the provision of abdominal analgesia.

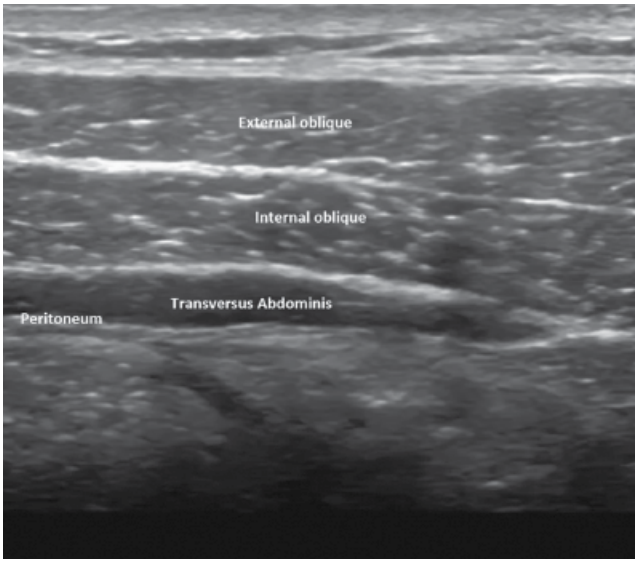
Quadratus lumborum block

The quadratus lumborum (QL) block was described in 2007 by Blanco and colleagues, and has been described for use in children for analgesia for abdominal and pelvic surgery, including pelvic and hip osteotomy [154]. Current literature describes four different approaches to this block, but the basic principle is to deposit LA anterior, posterior, lateral, or directly into the QL muscle [155]. From there, LA spreads between the posterior aspect of the QL muscle and the thoracolumbar fascia to block the intercostal nerves, and potentially into the thoracic paravertebral space to block the nerves exiting from the dorsal nerve roots (Fig. 20.18).

(A)



(B)



(C)

Figure 20.17 The transversus abdominis plane (TAP) region. (A) Anatomy. (B, C) Ultrasound imaging of the abdominal wall between the costal margin and the iliac crest reveals three muscle layers, separated by a hyperechoic fascia: the external oblique, the internal oblique, and the transversus abdominis muscles. The nerves of the abdominal wall are not visualized consistently. See text for further details. *Source:* Reproduced from Suresh and Chan [150] with permission of John Wiley and Sons.

LA can spread rostral–caudal as well, increasing the dermatomal coverage for a single-injection block. Despite this, a recent cadaver study documented spread of dye only to surround the intercostal nerves and not into the paravertebral space to affect the nerve roots [156]. The posterior QL block shares characteristics with the posterior TAP block [157].

To perform the anterior QL block, the patient is placed in the lateral decubitus position, with sterile preparation and draping from the subcostal area to iliac crest [155]. A low-frequency convex ultrasound probe is vertically oriented above the iliac crest (Fig. 20.19), and the needle is inserted in the triangle of Petit until placement anterior to the QL is confirmed (Fig. 20.20A). The needle tip is placed at the anterolateral border of the QL at the junction of QL with transversalis fascia, and the LA is injected. Using ultrasound, the LA is confirmed to be deep to the transversus abdominis aponeurosis (Fig. 20.20B).

A newly published randomized controlled trial of QL block versus TAP block in children undergoing lower abdominal surgery (inguinal hernia and orchidopexy) assessed outcomes of each block. In 53 patients 1–7 years of age, QL block was superior to TAP block at 1–24 h for FLACC score (faces, legs, activity, cry, consolability); p = 0.002–0.022. Additionally, time to first IV analgesia was 10 h in the TAP group versus 15 h in the QL group [158].

Rectus sheath block and umbilical block

To perform the rectus sheath block, the probe is placed just below the umbilicus (i.e. above the arcuate line). The anterior and posterior aspects of the rectus sheath and the enclosed rectus abdominis muscle are visualized. The sheath appears hyperechoic with multiple linear layers, lying on the anterior and posterior aspects of the rectus muscle. Willschke et al [159] and de Jose Maria et al [160] stated that their injection site was situated at the location where an optimal view of the posterior sheath was obtained. A short-beveled needle (e.g. 22 ga, 40 mm with facette tip) was inserted in an in-plane

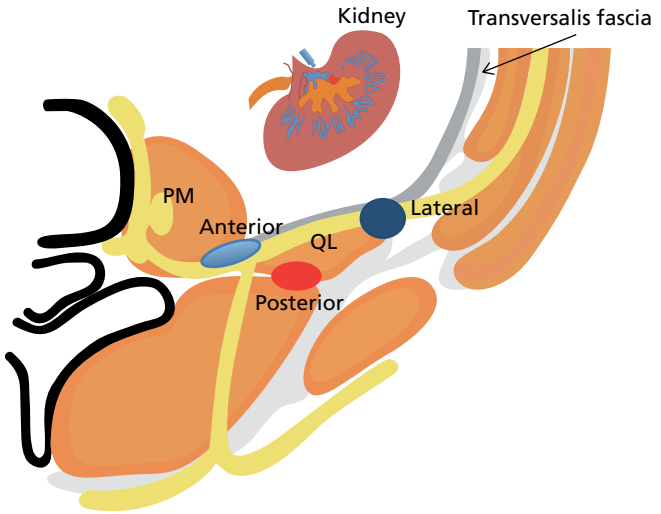


Figure 20.18 Anatomical view of quadratus lumborum (QL) block (anterior, lateral, and posterior). The lateral QL block injects the local anesthetic lateral to the QL muscle. The posterior QL block injects the local anesthetic posterior to the QL muscle. The anterior QL block injects the local anesthetic between the psoas major (PM) muscle and the QL muscle. approach at the inferior edge of a linear probe, using an angle most suitable for the depth of the sheath. The needle tip was placed just inside the rectus sheath near the posterior aspect of the rectus abdominis muscle.

Paravertebral block

A paravertebral block has been used to provide postoperative pain relief for adults and children in a variety of settings [161,162]. Satisfactory pain relief has been demonstrated for unilateral thoracotomies and urological surgery. Potential complications are pneumothorax and vascular puncture; hypotension is rare due to the lack of sympathectomy [163]. Indeed, the increased popularity of the paravertebral block can be attributed to its relative safety and comparable efficacy when compared with epidural analgesia [164].

Ultrasonographically, the transverse process of the thoracic vertebra and rib are identified at the appropriate thoracic level [165] (Fig. 20.21A, B). The transducer is moved cranially until an intercostal ultrasound view is obtained, indicated by visualization of the parietal pleura. An in-plane needle insertion approach from lateral to medial is

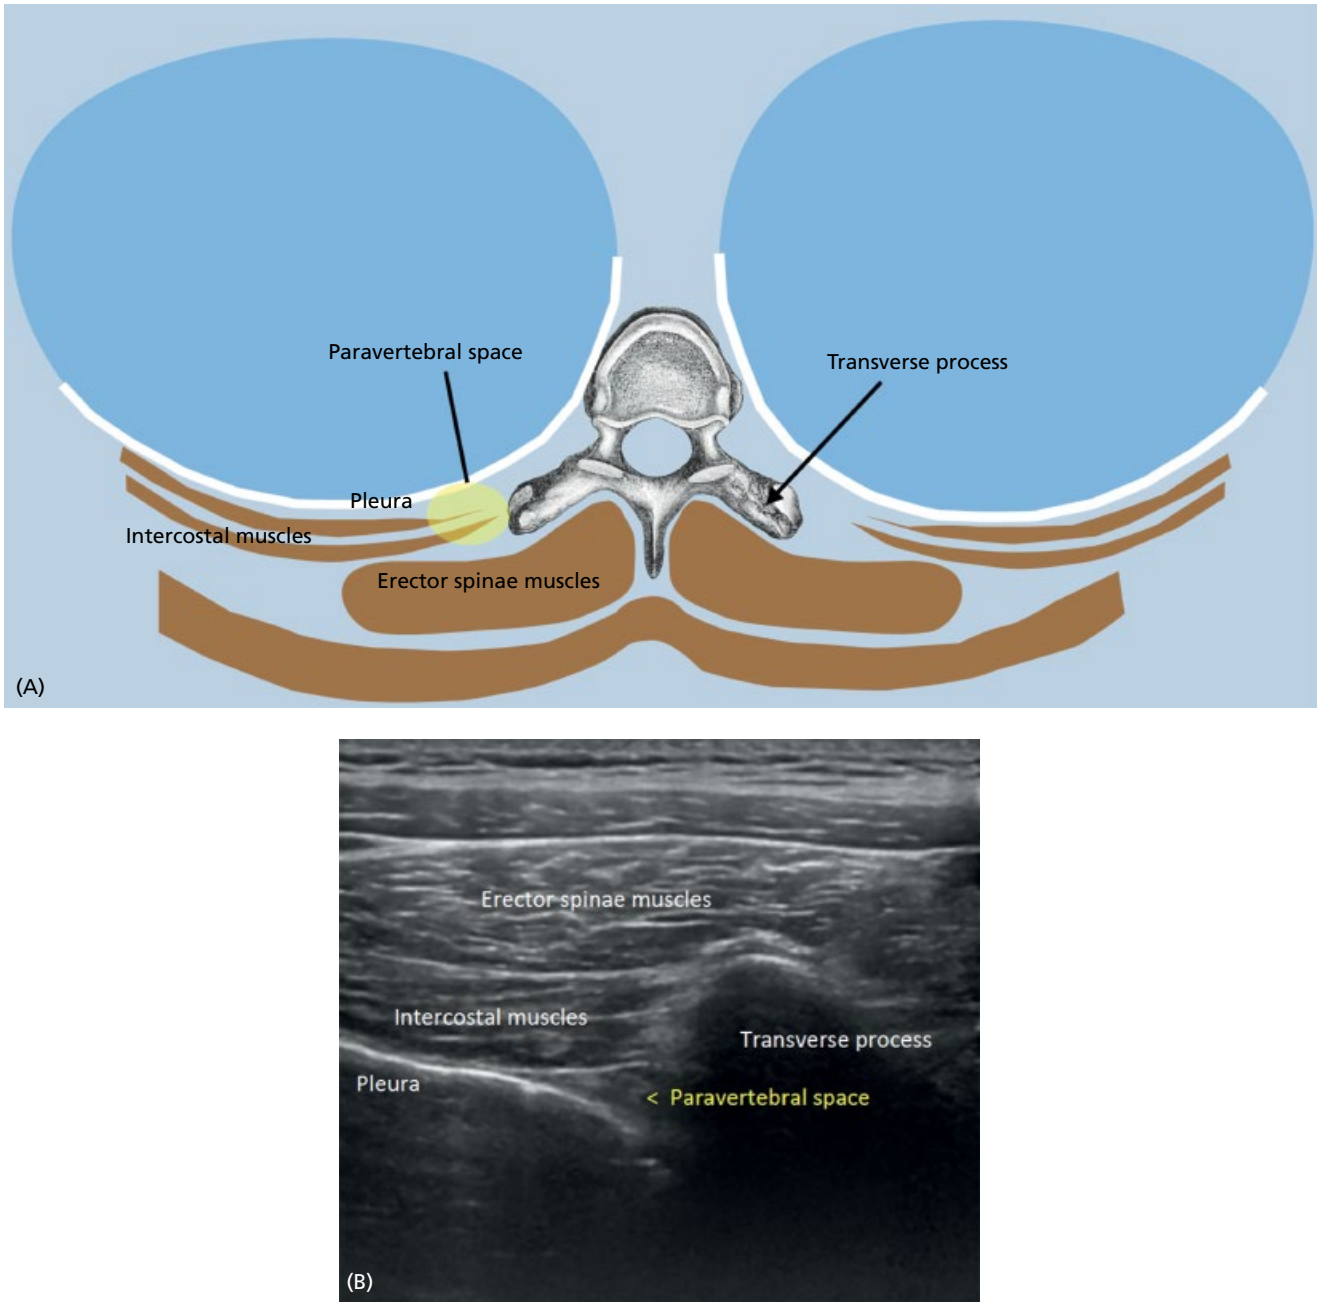

Figure 20.21 The paravertebral region. (A) Ultrasound anatomy. The paravertebral space is a wedge-shaped area positioned between the heads and necks of the ribs. The superior costotransverse ligament forms its posterior wall, the anterolateral wall is the parietal pleura with the endothoracic fascia, and the medial wall is the lateral surface of the vertebral body and intervertebral disk. used, and a total of 0.2–0.3 mL/kg of LA is injected through the needle and a subsequently threaded catheter, while the spread of LA is observed. An ultrasound-guided out-of-plane paravertebral block with the ultrasound probe positioned longitudinally to the paravertebral area has also been described.

Infraorbital nerve block

The infraorbital nerve is the terminal branch of the second division of the trigeminal nerve and is purely sensory. It leaves the skull through the foramen rotundum and enters the pterygopalatine fossa. There it exits the infraorbital foramen, dividing into four branches – the inferior palpebral, the external nasal, the internal nasal, and the superior labial. These branches innervate the lower lid, the lateral inferior portion of the nose and its vestibule, the upper lip, the mucosa along the upper lip, and the vermilion. This block can be used to provide postoperative analgesia and to favor early feeding resumption after cleft lip repair in infants [166,167]. It can also be used for nasal septal reconstruction or rhinoplasty, and in patients undergoing endoscopic sinus surgery.

Different approaches are used, including intraoral and extraoral; recently a suprazygomatic approach has been described [167]. For the intraoral approach, after palpation of the infraorbital foramen, the upper lip is folded back and a 27 ga needle is advanced to the infraorbital foramen parallel to the maxillary premolar [166]. By placing a finger at the level of the infraorbital foramen, the cephalad progression of the needle is checked. A volume of 0.5–1 mL of 0.25% levobupivacaine with 1:200,000 epinephrine is injected after careful aspiration. For the suprazygomatic approach, the needle puncture was located at the angle formed by the superior edge of the zygomatic arch below and the posterior orbital rim above. The ultrasound transducer allowed visualization of the pterygopalatine fossa, limited anteriorly by the maxilla and posteriorly by the greater wing of the sphenoid. The needle was advanced using the out-of-plane approach, and the needle tip was easily identified during movements.

Complications of blocks and their treatment

Performing a regional block may result in different complications, most of which can be avoided by learning the correct technique, using an appropriate device, and applying the basic safety rules. Despite the fact that most regional anesthetic techniques are performed under sedation or general anesthesia, large prospective and retrospective studies have demonstrated a low complication rate, particularly with peripheral nerve blocks, and fewer long-term sequelae when compared with adults having the same procedure.

Complications related to the device used

Block needles are used blindly and may thus damage a nerve trunk, especially when inserted without careful regard for nerve anatomy. Vascular lesions may lead to compressive hematoma and, at spinal levels, definitive paraplegia. If a spinal hematoma is suspected, a diagnosis must be established urgently by magnetic resonance imaging or computed tomography, and surgical treatment must follow immediately. Attempted peripheral nerve blocks can produce other injuries such as arterial wounds and pneumothorax, the presenting symptoms of which can be delayed by several hours. The technique of determining the nerve/space location may produce complications. These include nerve damage while seeking paresthesias, and complications related to the medium used for the LOR technique while locating the epidural space. The latter include dilution and increase in the injected volume of LA with saline headache, patchy anesthesia, lumbar compression, multiradicular syndrome, subcutaneous cervical emphysema, or venous air embolism. Headache is the most common complication of dural puncture in adults; its occurrence is less common in children. Treatment includes keeping the patient in a supine position, hydration with intravenous fluids, analgesia, and an autologous epidural blood patch (0.3 mL/kg) [168], which is not always free of complications. Failure to respond to the blood patch warrants further investigation. The use of caffeine or sumatriptan (a 5-HT_{1D} receptor agonist) has not been reported in children.

Complications of catheters

Insertion of an epidural catheter can lead to several complications: misplacement, kinking, knotting, rupture (especially if attempts are made to withdraw the catheter through the epidural needle). Secondary migrations into the subarachnoid space, a blood vessel, the subdural space, or the paravertebral space are sometimes reported. Leakage around the puncture point occurs in approximately 10% of cases, and inadvertent removal is not infrequent; several pediatric cases of catheter infection have also been reported. Some complications, such as cutting and knotting, become apparent only on removal of the catheter; in most cases, they are directly related to the length of catheter introduced into the epidural space, which usually should not exceed 2–4 cm. The frequency of catheter-related complications has been noted to be as high as 11% in a pediatric series [169]. The incidence of catheter malfunction (dislodgment/occlusion) is not higher in neonates [170]. Malfunctioning of infusion pumps is not uncommon.

Despite the overall excellent safety record of epidural catheter placement, as noted in the PRAN and ADARPEF studies, rarely, paraplegia has been observed as a complication of epidural catheter placement under general anesthesia. Commenting on a series of four cases of paraplegia, Berde and Greco offered recommendations to improve safety of epidural anesthesia in anesthetized children [171] (Box 20.1). Suspicion of neurological deficit should prompt immediate magnetic resonance imaging of the spine and neurosurgical consultation as appropriate; emergent laminectomy and decompression of the spinal cord in the case of acute epidural hematoma can restore function.

Box 20.1: Provisional recommendations for epidural analgesia safety in anesthetized children

1. Limit epinephrine dosing to the test dose (0.5 μg/kg in 0.1 mL/kg)
2. Prevent or promptly treat severe hypotension
3. Consider severe hypotension following test dosing or loading dosing of an epidural catheter under general anesthesia to be due to subarachnoid placement unless demonstrated otherwise
4. Consider severe hypertension following test dosing or loading dosing to possibly indicate a painful response to intraneural placement
5. Perform loss-of-resistance technique with saline, not air
6. Consider selective use of a Tsui nerve stimulation technique or fluoroscopy, as well as ultrasonography for infants, for cases of direct thoracic puncture under general anesthesia
7. Inject epidural loading doses slowly in anesthetized patients
8. Use dilute local anesthetic solutions for intraoperative epidural infusions
9. In the postanesthetic care unit, document the degree of sensory and motor blockade. If blockade appears dense, stop the infusion and observe for clear regression. If there is no regression at all over the next 3 h, consider emergent spine magnetic resonance imaging and neurosurgical consultation as appropriate. Note that wire-wrapped epidural catheters must be removed prior to magnetic resonance imaging
10. Consider patients receiving high-dose corticosteroids and/or morbid obesity to be at increased risk for epidural lipomatosis and reduced spinal canal compliance

Complications related to faulty technique

Epidural abscess, meningitis, arachnoiditis, radiculopathies, diskitis, and vertebral osteitis have been reported following central blocks. Interposed bacterial filters are effective in preventing contamination. Inadvertent dural puncture with subsequent intrathecal injection of an epidural dose of LA results in total spinal anesthesia, the clinical expression of which is almost immediate respiratory arrest requiring rapid control of ventilation and, in adolescents, cardiovascular collapse. Subdural injection results in a delayed (20 min) and short-duration (60 min) block with an extensive distribution of analgesia (involving cranial nerves up to the fifth pair) but with no or minimal motor and sympathetic blockade. The injection of large volumes may result in excessive spread of the LA, which can reach distant nerves, or in too high levels of epidural/spinal anesthesia with subsequent respiratory failure due to intercostal muscle paralysis (above T4), or even in diaphragmatic paralysis (C4). Interscalene brachial plexus, lumbar plexus, and intercostal nerve blocks may lead to the same complications.

Complications due to the local anesthetic solution

The use of the wrong solutions or additives can lead to definitive neurological damage; a highly effective way to avoid syringe mismatch consists of using a specific cart for regional block procedures. Interruption of blood flow in the artery of Adamkiewicz, due either to the surgical procedure or, hypothetically, to vasoconstriction resulting from the administration of LAs with epinephrine, may result in anterior spinal artery syndrome, which combines definitive loss of lower limb motor function with, at least partially, intact sensory function. Epidural anesthesia has been implicated in the flaring of latent infections (herpes, neuroimmunological diseases such Guillain–Barré syndrome). Of greater concern is the risk of unmasking latent neurological diseases such as spinal cord compression, cerebral tumors, angiomas, or an epidural abscesses. Allergy to aminoamides is rare, and most adverse reactions are related to adrenaline.

Treatment of LA convulsions consists of supplementing the child with oxygen and providing respiratory assistance; if convulsions persist after oxygenation, it is recommended that small intravenous doses of benzodiazepines (diazepam 0.1 mg/kg, midazolam 0.05 mg/kg) or thiopental 4 mg/kg be administered. Persistent convulsions require muscle relaxation (succinylcholine injection 1.5–2 mg/kg), intubation, and assisted pulmonary ventilation to prevent acidosis.

Treatment of LA cardiac arrest: immediate treatment is required, including oxygen supplementation, ventilation, and, if appropriate, external cardiac massage, sodium bicarbonate, and inotropic support. Ventricular tachycardia or fibrillation requires electrical defibrillation. A 20% Intralipid bolus of 1.5 mL/kg and then an infusion of 0.5–1 mL/kg/min is also indicated. See Chapter 45 for more detailed discussion of treatment of LA toxicity including cardiac arrest.

Epidemiology of complications

Complications were rare and similar in both of the ADARPEF studies [1,3]. As reported by the literature, they were more frequent (by four times in the last ADARPEF study) in children aged <6 months than in children aged >6 months. Central regional anesthesia has the highest incidence of complications (seven times higher than peripheral). The incidence was low despite an increase in the use of central neuraxial blockade in the last 12 years. Significant complications are rare, as indicated by results from a UK audit (5 years, 10,633 epidurals performed) reporting permanent residual neurological deficit in a child aged 3 months (1-year follow-up), two epidural abscesses, one case of meningitis, one postdural puncture headache requiring active blood patching, and one drug error resulting in cauda equina syndrome. The UK audit also reported five cases of severe neuropathy/radiculopathy which resolved over a period of 4–10 months using pharmacological therapy in a pain clinic. Thus in this study the incidence of serious complications was 0.09% [2]. The last ADARPEF study [3] records a very low overall morbidity; almost six times lower that in central regional anesthesia. Despite two colonic punctures, that should encourage anesthesiologists to use peripheral rather than neuraxial (including caudal) blocks as often as possible when appropriate.

The use of catheters does not seem to increase the occurrence of complications, even if cardiac toxicity following a secondary injection through a catheter is due to an inadvertent displacement of the catheter. Some complications (at least drug error, wrong side block, lower limbs lifting resulting in extended spinal anesthesia) were avoidable. In the last ADARPEF study, LA toxicity resulted in one case of convulsions [3] while the UK audit only reported two respiratory arrests and one seizure following central regional anesthesia [2]. None of these complications required lipid rescue treatment. Some other complications (prolonged duration of spinal anesthesia in two premature infants, one drug error, and a case of cardiac toxicity without cardiac arrest) were probably also avoidable. It is thus possible to improve the safety of pediatric regional anesthesia if basic precautions are followed.

More recently, the PRAN results confirmed the safety of pediatric regional anesthesia [4]. Out of a total of 14,917 regional blocks, there were no deaths or complications with sequelae lasting more than 3 months. Single-injection blocks had fewer adverse events than continuous blocks, although the most frequent events (43% of all events) in the latter group were catheter malfunctions (kinking, disconnection, or inadvertent dislodgement). Peripheral nerve blocks were frequently used (35%), driven by the widespread use of ultrasound (83% of upper extremity and 69% of lower extremity blocks). This confirms the safety of ultrasound technique for peripheral blocks. However, the incidence of both postoperative neurological syndrome and LA systemic toxicity is similar in children and adults (Tables 20.7 and 20.8).

Table 20.7 Postoperative neurological syndrome (children versus adults).

Regional anesthesia and acute compartment syndrome

In children, the diagnosis of acute compartment syndrome is often more difficult (e.g. preverbal children), and the main warning sign is excruciating pain that is not directly related to the trauma itself. Regional anesthesia has often been considered by surgeons to be responsible for delaying the diagnosis by masking ischemic pain. However, Johnson et al [172] identified the following clinical signs of impending compartment syndrome in the lower limbs: increasing pain with increasing need for analgesics, pain remote from the site of surgery, paresthesia not attributable to analgesia technique, signs of reduced perfusion of the painful site, local swelling, and pain on passive mobilization of the painful site. They also stressed that the nurses and doctors caring for the child in the postoperative period should be aware that he/she is at increased risk for acute compartment syndrome.

KEY POINTS: EVIDENCE-BASED CONCLUSIONS AND CLINICAL ADVICE FROM THE ESRA–ASRA JOINT COMMITTEE PRACTICE ADVISORY ON ACUTE COMPARTMENT SYNDROME [6]

- There is no evidence that regional anesthetics increase the risk for acute compartment syndrome or delay its diagnosis
- A preoperative discussion with the patient's family and the surgical team should inform them of this rare but serious complication
- We suggest the following "best practice rules" to reduce or avoid the risk of compartment syndrome in children undergoing surgery with perioperative regional anesthesia:
  - Use 0.1–0.25% bupivacaine, levobupivacaine, or ropivacaine because they are less likely to mask ischemic pain and/or produce muscle weakness
  - For continuous infusions of bupivacaine, levobupivacaine, or ropivacaine limit concentrations to 0.1%
  - For tibial compartment surgery or other high-risk surgeries for compartment syndrome, restrict both the volume and concentration in sciatic catheters
  - LA additives should be used with caution because they can increase the duration and/or density of the block
  - High-risk patients should be followed up by acute pain services to allow early detection of potential signs and symptoms
  - If acute compartment syndrome is suspected, compartment pressure measurements should be urgently obtained

Caudal analgesia and hypospadias complications

Caudal anesthesia has been utilized frequently for a number of years for hypospadias repair, but in recent publications concerns have arisen about a possible increased rate of postoperative urethrocutaneous fistula development with caudal analgesia compared to penile block. The mechanism is postulated to be penile engorgement from increased blood flow, and tension on the suture lines, leading to suboptimal healing and fistula formation. A prospective, randomized study of penile block versus caudal analgesia in 54 patients revealed a 27% increase in penile volume with caudal analgesia versus 2.5% with penile nerve block ($p < 0.001$); analgesia was improved and longer lasting with the penile nerve block [173]. All five cases of urethral fistula were in caudal block patients. Four subsequent retrospective studies in over 3300 patients have yielded mixed results, with three indicating increased incidence of fistula with caudal analgesia [174,175] and two not finding a difference [176,177].

Conclusion

The goal of regional anesthesia in the pediatric population must always be the provision of effective, safe analgesia with low rates of morbidity and low risk of adverse side-effects. Indeed, safety concerns are prominent because most children coming for surgery and anesthesia are healthy and tolerate systemic opioids with a good safety margin.

Studies have demonstrated a diminished stress response, fewer episodes of hypoxia, greater cardiovascular stability, faster return of gastrointestinal function, a reduced need for postoperative ventilation, and a shorter stay in intensive care in children who have had surgery performed under regional anesthesia.

In this era of evidence-based medicine, purists would claim that further prospective studies with larger sample sizes are necessary to demonstrate that regional anesthesia has significant benefits and offers a better outcome than other forms of analgesia in children.

Finally, ultrasound guidance has been shown to improve the block characteristics and the safety of regional anesthesia in pediatrics.

CASE STUDY

A 7-year-old child was scheduled for primary, elective, unilateral metatarsal osteotomy which was expected to require lengthy administration of potent analgesics and hospitalization of 4–5 days. The anesthetic procedure was combined general anesthesia and regional anesthesia with continuous popliteal sciatic catheter on an ambulatory basis. The parents were therefore required to (1) live within a 1-h drive of the hospital, (2) be able to contact medical staff or nurses 24 h a day, (3) be able to return to the hospital quickly if required, (4) understand a visual analog scale, (5) provide rescue oral analgesics, (6) observe the analgesic device (catheter and elastomeric pump) and the skin under the dressing, and (7) screen for possible local anesthetic-related complications. A peripheral intravenous catheter was placed under general anesthesia just before surgery. After premedication with oral midazolam, anesthesia was induced and maintained using sevoflurane, oxygen, and nitrous oxide via a facemask. Intravenous saline solution, at a rate of 5–10 mL/kg/h, was infused throughout the procedure. The child received an antibiotic and antiemetic prophylaxis (0.2 mg/kg dexamethasone). With the child in the lateral position, ultrasound-guided placement of a peripheral nerve sciatic catheter was performed. We were able to view the catheter exiting the needle tip and during advancement while using long-axis views of the nerves [134]. After confirming the nerve identity using a long-axis plane, the probe was rotated 90°, and the needle and catheter were introduced in-plane at a tangential angle. Injection of local anesthetic confirmed the needle tip and catheter location. The catheter was introduced 15 mm beyond the introducer cannula, affixed securely to the skin by a "U" stitch, covered by a transparent dressing, and taped onto the thigh. After negative aspiration, 0.2 mL/kg of ropivacaine 5 mg/mL was injected in divided doses via the catheter, with gentle aspiration every 2 mL. During the surgical procedure, if intravenous opioid rescue was required, the blockade would be considered ineffective and the catheter removed. Since the surgery lasted more than 1 h, an additional injection of 0.1 mL/kg of the same local anesthetic solution was administered hourly. For the surgical procedure, a tourniquet was applied at the thigh and inflated according to the surgeon's discretion. In the postanesthetic care unit, the sensory and motor blockade of the foot was evaluated. As soon as the child's toe motor function recovered, the sciatic popliteal catheter was connected to a multirate, disposable infusion elastomeric pump (Infusor LV; Baxter, Deerfield, IL, USA), containing 200 mL of 0.2% ropivacaine, with 1.5 µg/mL clonidine (mainly for its sedative effect in children), giving a fixed infusion rate according to the child's weight (0.1 mL/kg, i.e. 2.5 mL/h; infusor-rate possibilities 0.5–5 mL/h). In the hospital, if pain control was considered insufficient, intravenous acetaminophen or opioids were given as rescue. The criteria for discharge from the hospital depended on the presence of a plaster splint (observation day 1 in hospital) and the absence of local postoperative complications. Totally efficient continuous sciatic nerve block, i.e. the ability to ambulate with crutches without assistance or dizziness, and urinary voiding were also required before home discharge. Before home discharge, nurses gave the parents the following training: extensive explanation about the use of the visual analog scale to diagnose pain, elastomeric device surveillance, and evaluation of sensory and motor blockade, spontaneous mobility, and short delay in capillary refill after pressure on the child's test toes. When the child fulfilled the criteria for discharge, the medical staff checked both the child's and parents' comprehension of the provided instructions. The parents agreed never to leave their child alone, and to record (four times daily, at breakfast, lunch, dinner, and bedtime) the following items: changes in behavior, sleep disturbance, quality of appetite, play activity, the occurrence of any adverse effects and technical problems possibly related to the analgesic technique, temperature, evaluation of the blockade and the integrity of the child's dressing, episodes of pain, and the use of an oral rescue analgesic (acetaminophen twice a day, or a combination of acetaminophen and codeine at bedtime). Instructions were provided regarding protection of the anesthetized limb, signs of local anesthetic toxicity, a direct return to the hospital if needed, and 24-h contact information. The elastomeric pump was filled before discharge. At the end of the procedure, the child returned to hospital and met with the medical staff. The parents shared their feelings and observations about the postoperative period at home, and their overall satisfaction. The catheter was then removed, and its distal portion was sent for bacteriological analysis.

A total of 47 children were treated with this protocol in a prospective feasibility study [135]. The main finding of this observational study is that analgesia at home by continuous sciatic nerve block with an infusion elastomeric pump is effective, with pain control rated excellent or good in 89% of patients. It is also feasible and associated with no major complications in this study, and enables children to experience ambulatory or shortened hospital stays [135]. Another interesting point is that parents trained by nurses readily understood the method of pain screening, and managed the analgesic device well.

Introduction

In 1963, Sir (Albert) William Liley, a New Zealand perinatologist, was the first to demonstrate that fetal diagnosis and treatment were possible when he administered a intraperitoneal blood transfusion to treat Rh disease-induced fetal hydrops (erythroblastosis fetalis) [1]. He had determined the severity of rhesus isoimmunization by analyzing the spectral absorption from a sample of amniotic fluid. Others attempted exchange transfusion by directly cannulating fetal vessels through a small uterine incision. Early results were not encouraging and further attempts at fetal intervention were initially abandoned [2]. A decade later, G.C. Liggins, another New Zealand perinatologist, demonstrated the beneficial effects of maternal glucocorticoid administration to augment fetal surfactant production in fetuses at risk for respiratory distress syndrome [2]. In 1981, after careful experimentation in sheep [3–5] and monkeys [6], the first successful human fetal surgery was performed at the University of California San Francisco by Michael Harrison to treat lower urinary tract obstruction-induced bilateral hydronephrosis by creating a vesicostomy [7].

Fetal surgery would not have been possible without the improvements in sonographic resolution that occurred in the early 1980s. Advances in prenatal diagnosis substantially improved the ability to recognize and more precisely delineate fetal anatomy and anomalies. In addition, ultrasound-guided percutaneous umbilical blood sampling (PUBS) was now possible. Associated with these advances in imaging were advances in amniotic fluid analysis for detection of many metabolic disorders and chromosomal abnormalities, assessment of fetal pulmonary maturity, and determination of severity of fetal anemia. Advances in fetoscopy allowed direct visualization of the fetus and diagnostic tissue sampling.

Serial sonographic examinations of fetuses facilitated delineation of the pathophysiology and natural history of congenital diaphragmatic hernia, hydrocephalus, nonimmune hydrops, and obstructive hydronephrosis. However, most anatomical malformations diagnosed *in utero* are unsuitable for antenatal fetal intervention. Thus, only a few fetal malformations are appropriate for intrauterine surgery.

Fetal surgery would also not be possible without the information sharing and collective conceptualization between physicians from a wide variety of disciplines interested in fetal diagnosis and therapy. This was greatly facilitated by Harrison et al's early (1981) organization of a symposium with worldwide experts [8]. A registry for fetal interventions was established and ethical guidelines adopted, leading to the creation of the International Fetal Medicine and Surgery Society and subsequently to the journal *Fetal Diagnosis & Therapy*. These founding guidelines remain relevant with minor modification (Box 21.1) [8,9]. The pioneering work from a few medical centers spawned the field of fetal medicine worldwide. Fetal treatment centers around the world now rely on the expertise of radiologists, geneticists, perinatologists, pediatric cardiologists, neonatologists, social workers, support staff, and many others, as well as fetal surgeons and anesthesiologists.

Before undertaking a specific fetal surgical procedure, its feasibility, safety, and efficacy must be assured. Fetal surgery requires that a fetus has a normal karyotype and an accurately diagnosed and isolated anomaly that has a high probability of death, severe disability, or irreversible harm before fetal lung maturity occurs, and for which removing the lesion might

Gregory's Pediatric Anesthesia, Sixth Edition. Edited by Dean B. Andropoulos and George A. Gregory.

Box 21.1: Guidelines for performing fetal procedures

1. Accurate diagnosis and staging of a condition is possible
2. Singleton fetus with other anomalies contraindicating fetal intervention excluded
3. Progression and severity of the condition is understood and prognosis established
4. Currently no effective postnatal therapy and if not treated before birth the anomaly would result in fetal death, irreversible organ damage, or other severe morbidity
5. *In utero* surgical procedure proven feasible in animal models, reversing deleterious effects of the condition and allowing development to proceed normally
6. Maternal risk is acceptably low
7. Interventions performed in specialized multidisciplinary fetal treatment centers within strict protocols and approval of the local ethics committee, with informed consent of the mother or parents
8. Access to high-level specialized medical care including a high-risk obstetric unit, bioethical counseling, and psychosocial care

Source: Adapted from Sudhakaran et al [9] and Harrison et al [8].

allow development to proceed relatively normally. Accurate and complete diagnosis is required to avoid intervention when the procedure would be futile or when the fetus is so mildly affected that postnatal treatment would be equally effective. There should be a good physiological rationale previously tested in animals and controlled human trials that established efficacy and safety of the procedure. Family counseling for risks and potential benefits must be comprehensive and include options for elective termination of pregnancy or continuation of pregnancy without therapy. Consent must also include a discussion that the surgery and potential benefits for the fetus might incur risks for the mother. Maternal risk should be small, and careful preoperative assessment is mandatory to ensure that the risk is acceptably low [10].

Fetal surgical interventions are broadly categorized into three different kinds of procedures. *"Open procedures"* involve maternal laparotomy and hysterotomy and uterine stapling to seal membranes to the endometrium and provide myometrium hemostasis. Most myelomeningocele repairs, resections of congenital pulmonary airway malformations (CPAMs), and sacrococcygeal teratoma debulking are performed "open." Open procedures are technically the most complicated of fetal procedures and entail the most risk, particularly for separation of membranes, preterm premature rupture of membranes (PPROM), preterm labor and delivery, infection, hemorrhage, pulmonary edema, and fetal complications that include heart failure, intracranial hemorrhage, and fetal demise. Chorioamniotic membrane separation can cause amniotic bands, umbilical cord strangulation, and fetal demise [11]. Preterm delivery causes significant morbidity and mortality for fetuses that otherwise might benefit from these interventions. Consequently, preoperative, intraoperative, and postoperative tocolysis is crucial.

Fortunately, overall maternal risks are minimal, but include blood loss, blood transfusion, infection, placental abruption, and pulmonary edema from tocolysis [10,12]. Location of the uterine incision mandates cesarean delivery for all subsequent pregnancies after open procedures secondary to increased risk of uterine dehiscence.

The second type of fetal surgery is *"minimally invasive or percutaneous"* and involves intrauterine access using needles or trocars that allow endoscopic or sonographic guided procedures. Minimally invasive procedures are less risky than open procedures, but PPROM is still a major problem. These techniques are employed for fetal blood sampling, treatment of fetal anemia by intrauterine transfusion, percutaneous fetal cardiac valvuloplasty, treatment of obstructive uropathy, thoracoamniotic shunting to mitigate CPAM, treatment of unbalanced blood flow between monochorionic twins, radiofrequency ablation (RFA) of umbilical blood flow of a nonviable twin, and tracheal occlusion by endoluminal balloon placement to treat congenital diaphragmatic hernia. The trend in fetal surgery is to develop minimally invasive techniques to avoid open procedures. An example of this trend is the advancement of myelomeningocele (MMC) repair from an open technique requiring hysterotomy to one where the repair is completed using endoscopic access to the uterus following laparotomy.

The third type of fetal surgical intervention, the *EXIT procedure* (*ex utero* intrapartum treatment) is a modification of cesarean section [13]. EXIT procedures preserve placental gas exchange during surgery and provide time to secure a difficult airway by tracheal intubation or tracheostomy for conditions that would make newborn tracheal intubation unfeasible or very difficult (e.g. cystic hygromas, cervical teratomas). The EXIT procedure is also used for thoracotomy to treat cystic adenomatoid malformation (CCAM, otherwise referred to as CPAM by some), transitioning from placental gas exchange to extracorporeal membrane oxygenation (ECMO) for anticipated pulmonary insufficiency, or complete resection of a giant cervical teratoma.

Fetal surgery: indications, procedures, and outcomes

The following sections summarize the rationale for fetal intervention, a description of both surgical and anesthetic considerations for each procedure, and a review of outcome data. Details of anesthetic techniques are presented in sections that follow.

Congenital diaphragmatic hernia

Approximately 1 in 2000–5000 neonates have a congenital diaphragmatic hernia (CDH). Incomplete fetal diaphragm formation allows the abdominal contents to enter the thoracic cavity and produce varying degrees of pulmonary parenchymal and vascular hypoplasia. Pathophysiological changes include decreased number of alveoli, thickened interstitial tissue and alveolar walls, decreased surface area for gas exchange, reduced lung compliance, and decreased pulmonary vasculature that has medial hyperplasia and adventitial thickening [14]. After birth, hypoxia, hypercarbia, and acidosis induce further pulmonary vasculature constriction and pulmonary hypertension. This increases right-to-left shunting of blood and causes further hypoxia and acidosis. The majority of CDH defects are left-sided, and more than half are associated with other birth defects [15]. Mortality is associated with the degree of pulmonary insufficiency and pulmonary hypertension present [16,17]. Survival has improved

significantly over the past two decades at many tertiary centers. The following elements have led to this improved survival of patients with CDH: (1) removing the herniated abdominal contents from the chest and closing the diaphragm defect postnatally; (2) ventilation techniques that cause less barotrauma (high-frequency oscillation); (3) administration of surfactant; and (4) ECMO. Postnatal CDH survival now typically occurs in more than 70% of patients, but varies widely among centers and is significantly affected by the presence of other defects [18–20].

It was postulated that correction of CDH *in utero* might improve fetal lung development and significantly reduce the degree of pulmonary hypoplasia found at birth. In controlled trials, fetal lamb models of CDH confirmed the benefit of *in utero* repair by decreasing the progression of pulmonary hypoplasia and pulmonary vascular changes and improving newborn survival [3]. Although removing the abdominal contents from the chest and repairing the defect is technically feasible, it is difficult in human fetuses, and this intervention had limited success in those with severe disease [21]. Lessons learned from these patients included that an abdominal patch needed to be placed to prevent increases in intra-abdominal pressure and the associated compromise of the ductus venosus blood flow, and that both a thoracic and an abdominal incision was required to facilitate removing the liver from the chest and placing a diaphragmatic patch. However, replacing the liver in the abdomen often caused acute and severe decreases in cardiac preload and was associated with increased intraoperative fetal mortality [21]. Problems with blood loss from the uterine incision and amniotic fluid leaks after closure were solved by use of a stapling device. However preterm labor remained a significant problem after surgery and caused neonatal morbidity and mortality. Results from a small prospective trial of open fetal surgical intervention comparing *in utero* repair with surgical repair after birth failed to demonstrate improvement with open fetal surgical intervention [17].

Given the difficulties encountered with primary repair of CDH *in utero*, another strategy was pursued. It was known that fetal lungs secrete about 100–125 mL/kg/day of fluid that normally passes through the fetal trachea and mouth into the amniotic fluid. Since fetuses with congenital high airway obstruction cannot expel the fluid, they develop hyperplastic lungs [22]. Reversibly obstructing the trachea causes lung fluid accumulation and allows the developing lungs to expand and grow and decrease the amount of pulmonary hypoplasia [23]. The concept, "plug the lungs until it grows" (PLUG), was tested in fetal lambs and shown to decrease pulmonary hypoplasia and herniation of abdominal contents and improve neonatal respiratory function [24]. Although *in utero* tracheal occlusion decreases much of the pulmonary hypoplasia and hypertension, there are fewer type II pneumocytes and less secreted surfactant. Removing the tracheal obstruction before delivery may reduce this unwanted effect [25,26].

The initial method of creating a reversible, controlled tracheal occlusion during open fetal surgery required both maternal laparotomy and hysterectomy, and involved either an internal tracheal plug or external tracheal clip [27]. Since the clip or plug had to be removed surgically, the EXIT procedure was developed (see section "*Ex utero* intrapartum treatment procedure").

Unfortunately, few patients survived these initial open procedures. Of the first 13 fetuses undergoing this treatment, only 15% survived compared to 38% of fetuses receiving standard postnatal treatment [28]. Preterm labor occurred at 30 weeks' gestation and was a major cause of mortality in the fetal treatment group; the postnatal treatment group was born at 37.5 weeks. A second series of 15 fetuses with CDH treated with external clips at the Children's Hospital of Philadelphia had a 30% survival rate [29], but tracheal occlusion did not consistently improve the lung hypoplasia or postnatal pulmonary function.

Improvements in endoscopic and ultrasound imaging techniques allowed video-assisted fetal endoscopic (FETENDO) techniques to replace open surgical procedures for tracheal occlusion. Application of external fetal tracheal clips by FETENDO improved survival to 75% in eight fetuses [28]. To reduce fetal laryngeal nerve and tracheal trauma, a small balloon was placed in the trachea by percutaneous endoscopic endotracheal intubation at University of California San Francisco (UCSF). The balloon, which is typically used for endovascular occlusion of intracranial aneurysms, is inflated to occlude the tracheal lumen, detached, and left in place until delivery via EXIT procedure (Figs 21.1, 21.2). The balloon is deflated and removed prior to birth by endoscopy.

A prospective randomized controlled trial (1999–2001) compared fetal tracheal occlusion (n = 11) for intrauterine treatment of severe CDH with repair after birth (n = 13) [30]. Eligibility included 22–28 weeks' gestation, a left-sided CDH, herniation of the liver into the left hemithorax, normal karyotype, and a lung to head ratio (LHR) <1.4. LHR is the ratio of cross-sectional area of the contralateral lung to the head circumference as determined by two-dimensional ultrasound. The LHR is a good indicator of the severity of pulmonary hypoplasia and the likelihood of survival [31]. The trial was stopped due to an unexpected high survival rate in the control arm (77% versus 73%). Secondary measures of neonatal morbidity were not different between groups, but PPROM and preterm delivery was more common in the fetal treatment group (30.8 weeks versus 37.0 weeks) [30]. A reason for the lack of difference in morbidity at 90 days may have been overly broad LHR inclusion criterion. Using an LHR of 1.4 likely allowed inclusion of many fetuses who would survive with standard care. Table 21.1 compares outcomes of expectant management and fetoscopic tracheal balloon occlusion in fetuses with left-sided CDH and liver herniation, showing improved outcomes for *in utero* treatment of fetuses with LHR ≤1.0.

Minimally invasive fetoscopy for tracheal occlusion and prenatal tracheal balloon removal before delivery may improve lung growth, minimize effects on type II alveolar cells [32], and avoid morbid EXIT procedures. Comparison of the EXIT procedure to predelivery balloon removal at 34 weeks' gestation in 24 fetuses with severe CDH (LHR ≤1.0 plus intrathoracic liver) that underwent fetal endoscopic tracheal occlusion (FETO) at 26–28 weeks' gestation demonstrated improved 28-day survival (p = .013) in the balloon reversal group (83%) compared to the EXIT group (33%) [33]. There were no instances of maternal hemorrhage, pulmonary edema, or infection. This "plug–unplug sequence" may be more ideal in that the cyclical occlusion

and release may allow pulmonary structural maturation, pulmonary artery remodeling, and pneumocyte maturation [33]. A detachable tracheal balloon is endoscopically placed in the trachea and removed prenatally by a second fetal endoscopic tracheoscopy prior to labor. If premature labor occurs prior to endoscopic removal, an EXIT procedure is occasionally required. Postnatal therapy includes neonatal tracheal intubation, high-frequency ventilation, and nitric oxide or ECMO if needed in addition to surgical repair of the diaphragm.

A recent single-institution prospective observational cohort study compared treatment of severe CDH (LHR <1.0 and liver herniation) using FETO with historic controls [34]. Balloon placement occurred at a mean of 28 weeks' gestation with endoscopic removal at 34 weeks. The *in utero* treatment group showed an increased 2-year survival rate (67% versus 11%) and less need for ECMO. A recent meta-analysis of five trials of severe CDH noted that *in utero* FETO treatment favored survival with an odds ratio of 13 compared to historic controls [35]. Despite these compelling results it is important to

Table 21.1 Postnatal survival rate in fetuses with left-sided congenital diaphragmatic hernia and intrathoracic liver herniation based on fetal lung to head ratio at 23–29 weeks' gestation.

LHR (mm)	Expectant management		Fetoscopic tracheal occlusion	
	n	Survival	*n*	Survival
0.4–0.5	2	0	6	1 (16.7%)
0.6–0.7	6	0	13	8 (61.5%)
0.8–0.9	19	3 (15.8%)	9	7 (77.8%)
1.0–1.1	23	14 (60.8%)	–	–
1.2–1.3	19	13 (68.4%)	–	–
1.4–1.5	11	8 (72.7%)	–	–
≥1.6	6	5 (83.3%)	–	–

understand that these comparative results may contain significant selection bias or improvement in clinical techniques and care with time. Consequently, it is too early to recommend FETO for treatment of CDH as part of routine clinical care [36]. An ongoing multicenter randomized European study titled Tracheal Occlusion To Accelerate Lung (TOTAL) growth started in 2009 [37]. It has two treatment arms that compare standard postnatal management to both early FETO intervention (27–30 weeks' gestation) for severe lung hypoplasia and later FETO intervention (30–32 weeks' gestation) for moderate hypoplasia. Balloons are removed endoscopically at 34 weeks in both of these treatment arms. Because LHR changes during gestation, this trial also utilizes a ratio of observed to expected LHR as a more predictive measure of survival likelihood [38,39]. Trial results are expected to better determine the optimal gestational age for *in utero* intervention. Chapter 22 presents information about postnatal treatment of CDH.

KEY POINTS: CONGENITAL DIAPHRAGMATIC HERNIA

- A lung to head ratio (LHR) of ≤1.0 indicates severe CDH that may be amenable to fetal therapy
- Video-assisted fetal endoscopic techniques to insert a balloon to occlude the trachea, with removal by a second procedure before birth, have resulted in improved survival in recent series
- The TOTAL randomized trial comparing standard postnatal treatment to early or late tracheal occlusion will add important data to management options for CDH

Twin–twin transfusion syndrome

The majority of monochorionic twins have abnormal chorionic blood vessel connections in the placenta that can result in twin–twin transfusion syndrome (TTTS). Normally, the umbilical artery carries deoxygenated blood to the surface of the placenta where it branches, traverses the placental surface, and then descends into capillary divisions where gases and nutrients are exchanged with the maternal circulation. The returning "paired" system consists of a vein that lies directly next to an artery as it returns to the umbilical cord (Fig. 21.3A, B). This vascular configuration is associated with placental cotyledons and represents normal fetal placental vascular anatomy.

In TTTS, a branch from an umbilical artery travels along the surface of the placenta and descends into the cotyledon, where instead of connecting with a paired vein, it connects with an *unpaired* vein that now carries blood to the other twin [40] (Fig. 21.3C, D). With this abnormal arterial–venous (AV) connection, blood moves unidirectionally from one twin to the other. Whether the flow goes to or from either fetus depends on which one contributes the arterial vascular

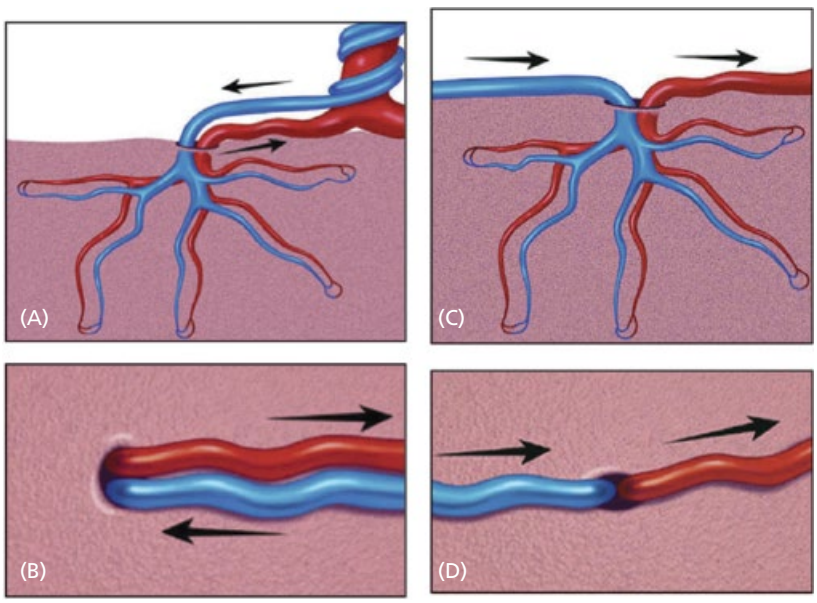

Figure 21.3 (A) Normal angioarchitecture (cotyledon). (B) Superficial view of bidirectional flow into and out of a cotyledon. (C) Abnormal inter-twin connection: arteriovenous anastomosis. connection. These one-way AV connections are common in monochorionic placentas [41], yet only about 10–15% of monochorionic pregnancies have TTTS, which suggests that the abnormal AV connections and overall blood flow are relatively balanced between most fetuses.

The unequal chronic blood flow distribution between the twins causes the symptoms of TTTS [42,43]. Artery-to-artery (AA) and vein-to-vein (VV) end-to-end anastomoses also occur in monochorionic placentas. An AA connection protects against TTTS if it equalizes overall resistances and blood flow between the twins. AA anastomoses are associated with nine times less TTTS [41]. Placental sharing, vasoactive mediators, and abnormal cord insertion may also influence the development of TTTS [44]. This syndrome usually presents at 15–26 weeks' gestation in approximately 10% of monochorionic twin pregnancies [42,45].

The unbalanced flow of TTTS causes hypovolemia, oliguria, oligohydramnios, and intrauterine growth restriction in the donor twin (often referred to as a "stuck" or "pump" twin). This twin is at risk of developing neonatal renal failure, renal tubular dysgenesis and dysfunction, and high cardiac output-induced hydrops fetalis. Part of the mechanism of TTTS may be hypovolemia-induced upregulation of the renin synthesis system, increased angiotensin II, aldosterone, and antidiuretic hormone, which causes further fetal vasoconstriction and reduction of placental blood flow in the donor fetus [46]. The recipient twin has polycythemia, polyuria, polyhydramnios, and hypertrophic cardiomyopathy. The recipient is at risk for hydrops fetalis and fetal death.

A major threat to both twins is polyhydramnios-induced PPROM and preterm labor. Survivors of TTTS are also at risk for central nervous system white matter lesions and long-term disability. The increased risk of impaired neurodevelopment is associated with higher gestational age at intervention, increased severity stage of TTTS, and lower gestational age at birth [47]. Diagnosis of TTTS requires both the presence of a monochorionic diamniotic pregnancy and the presence of a maximal vertical pocket (MVP) <2 cm in one amniotic sac with a MVP >8 cm in the other sac [45]. Multiple staging systems have been developed that are based on progression of the disease and abnormal changes in the twins. These staging systems are helpful for prognosis of outcome, treatment options, and communication between physicians and centers [44]. The Quintero staging system is commonly used and detailed in Table 21.2. TTTS has an overall survival of 85% if it remains in stage I, but higher stages result in ≥80% mortality if untreated, with significant risk of morbidity in survivors [45,48].

A variety of treatment strategies for TTTS have been devised. Each is intended to decrease morbidity and improve survival of one or both twins. These include: (1) serial amnioreduction to control polyhydramnios and decrease preterm labor; (2) surgical microseptostomy of the inter-twin amnion membrane to equalize amniotic pressures; (3) selective fetoscopic laser photocoagulation (SFLP) of selected abnormal inter-twin vascular anastomoses to equalize the resistance and blood flow between the twins; and (4) fetoscopic cord coagulation to selectively terminate the severely affected recipient twin to improve survival of the donor.

Table 21.2 Staging of twin–twin transfusion syndrome severity

Stage	Parameter	Ultrasound criteria
I	Amniotic fluid	MVP <2 cm in donor twin amniotic sac and MVP >8 cm in recipient twin amniotic sac
II	Fetal bladder	Unable to image the fetal bladder in the donor twin during 60 min of observation
III	Flow velocity change in UA, UV, or DV	Absent or reversed UA diastolic flow waveform Pulsatile UV flow waveform Reversed DV a-wave flow waveform
IV	Fetal hydrops	Hydrops in either twin
V	Fetal demise	Absent fetal cardiac activity

DV, ductus venosus; MVP, maximal vertical pocket of amniotic fluid; UA, umbilical artery; UV, umbilical vein.

Amnioreduction

Serial amnioreduction was the first treatment utilized for TTTS and was designed to decrease the morbidity from polyhydramnios in the recipient twin. Amnioreduction was shown to decrease preterm delivery and improve uteroplacental perfusion by reducing intrauterine pressure [49]. Mari et al used international registry data to examine the effects of amnioreduction on 223 sets of twins diagnosed with TTTS before 28 weeks' gestation [50]. They reported medians of two amnioreductions, 3550 mL of fluid removed, and a gestational age at delivery of 29 weeks. Intrauterine death occurred in 18% of recipients and 26% of donors, with an overall survival rate at birth of 78%. By 4 weeks of age, only 60% of infants were alive: 65% of recipients and 55% of donors survived [50]. Possible complications from amnioreduction included infection, placental abruption, PPROM, and preterm labor.

Microseptostomy

Microseptostomy using an ultrasound-guided needle was developed to improve uteroplacental blood flow by equalizing pressures between the two amniotic cavities. In a prospective randomized trial, 73 women with TTTS were treated with either serial amnioreduction or septostomy. No difference was found in either overall perinatal survival (64% versus 70%) or survival of at least one infant in pregnancy (78% versus 80%) [51]. Microseptostomy is seldom used today because it offers no survival benefit, and if a single amniotic cavity is created, there is a risk of umbilical cord entanglement.

Selective fetoscopic laser photocoagulation

In utero SFLP is a minimally invasive procedure that coagulates abnormal communicating vessels between the twins. A Nd:YAG or diode laser is introduced through a semiflexible endoscope. Typically, the fetoscope and laser are inserted percutaneously via a 3 mm cannula into the recipient twin's amniotic sac that has polyhydramnios (Fig. 21.4). Neuraxial blockade or infiltration of local anesthesia at the planned trocar insertion site in the myometrium is commonly employed for anesthesia. Fetoscope placement is determined by placental location and is guided by ultrasonography. Vascular

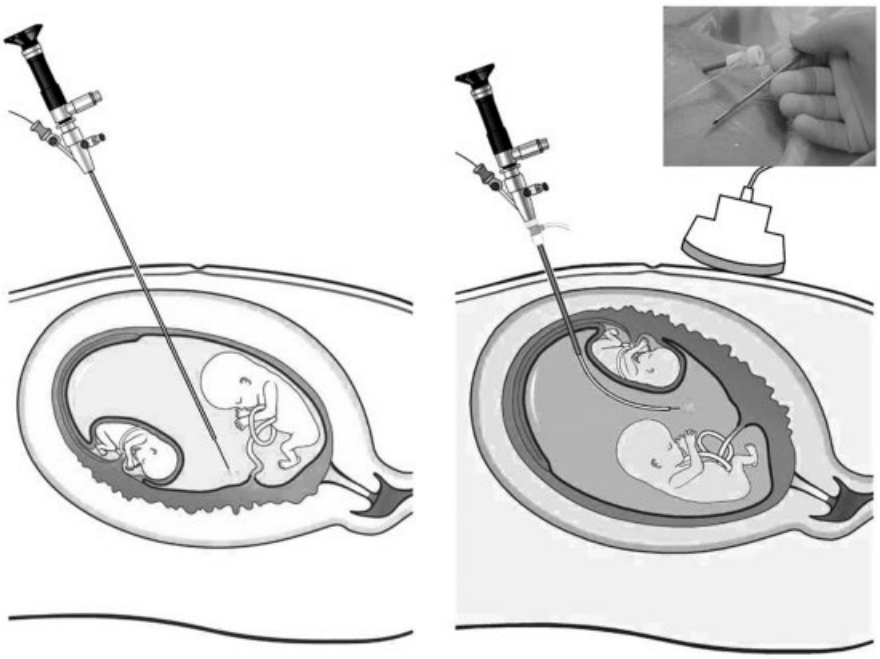

Figure 21.4 Direct insertion of the fetoscope through the sheath – without cannula (*left*). An anterior placenta, with the use of a curved sheath and a flexible cannula (*right*). A photo of the flexible cannula in place (*insert*). anastomoses on the surface of the placenta are directly visualized and ultrasound can be used to determine directional flow in the vessel. Arteries crossing on top of the veins are a darker red color due to oxyhemoglobin desaturation. Using the fetoscope, chorionic plate vessels that cross the membrane separating the amniotic sacs are visually traced to each fetal umbilical cord insertion. Abnormal vessels traveling between twin cord roots are identified and selectively coagulated with the laser [52]. Due to location of the fetuses, placenta, and cord insertions, many procedures require some small degree of non-selective coagulation. Purely non-selective SFLP is associated with higher rates of intrauterine deaths from acute placental insufficiency [53]. Frequently, some of the abnormal twin–twin anastomoses are not visualized and remain intact after laser therapy. Complete obliteration of all connecting vessels is unnecessary for successful outcomes [54,55]. Following laser ablation, an amnioreduction is often performed when the fetoscope is removed to reduce the polyhydramniotic sac to a normal or slightly lower volume. Fetal monitoring and periodic ultrasound imaging are typically performed for 24–48 h after surgery.

A 2004 multicenter prospective randomized trial compared endoscopic laser surgery to serial amnioreduction for TTTS that was diagnosed before 26 weeks' gestation [56]. The study was stopped early because interim analysis demonstrated a benefit to the laser treatment group. The laser group had a greater likelihood of at least one twin surviving at both 28 days (76% versus 56%, $p < .01$) and 6 months of age (76% versus 51%, $p = 0.002$) [56]. The laser treatment group also had significantly fewer neurological complications at 6 months of life. Another prospective randomized multicenter trial of amnioreduction and SFLP found no difference in 30-day mortality for either the recipient or donor twin [41]. Fetal "recipient" mortality was increased for SFLP but was offset by an increase in neonatal "recipient" mortality in the amnioreduction group [41]. The hypertensive cardiomyopathy of the "recipient" twin was an important factor in survival, which might be the result of vasoactive hormones (renin–angiotensin system) from the "donor" that compromise the recipient.

A recent meta-analysis of the literature from 1995 to 2014 examining laser therapy for TTTS noted that fetal survival rates have improved over time with the most recent studies (2011–2014) demonstrating a mean survival rate of 60% for both twins and 88% for at least one of the twins [57]. The rate of significant long-term neurological morbidity in children previously treated with SFLP is 5–18% [45]. Recent modifications of SFLP include use of sequential ablation of the AV, AA, and VV inter-twin anastomoses [58] and the Solomon technique, which creates a photocoagulated line at the inter-twin vascular equator [59]. There is some limited evidence of benefit of these newer techniques regarding improved survival and prevention of TTTS recurrence [60–62].

The most common complication of laser therapy for TTTS is PPROM and preterm labor, but risks also include transplacental entry of the trocar, infection, and hemorrhage. Rarely membrane perforation can result in limb entrapment and tissue ischemia.

In summary, randomized controlled trials and meta-analysis suggest that fetoscopic laser ablation is superior to serial amnioreduction and should be considered as treatment for TTTS to improve both neonatal survival and outcome.

Fetoscopic cord coagulation

In cases where salvage of the recipient twin is unlikely, fetoscopic cord coagulation (FCC) or ligation can be used. It attempts to significantly improve the outcome of the remaining fetus by stopping twin–twin blood flow and its associated morbidities. FCC has also been used following SFLP if the laser therapy worsened fetal condition [41].

KEY POINTS: TWIN–TWIN TRANSFUSION SYNDROME

- In TTTS, a branch from an umbilical artery connects with an unpaired vein that carries blood to the other twin
- The unbalanced flow of TTTS causes hypovolemia, oliguria, oligohydramnios, and intrauterine growth restriction in the donor twin
- Treatments include serial amnioreduction, surgical microseptostomy, selective fetoscopic laser photocoagulation, and fetoscopic cord coagulation

Twin reversed arterial perfusion sequence

In monochorionic twin pregnancies, retrograde blood flow through arterial–arterial anastomoses allows blood to flow from one twin to the other and is known as the twin reversed arterial perfusion (TRAP) sequence. The twin receiving the retrograde flow has a non-functioning heart or acardia. Less commonly, both twins can have cardiac activity and still have the diagnosis of TRAP if the "acardiac" twin has a malformed cardiac mass without effective pumping. This condition is associated with other lethal anomalies that include acephalus. The acardiac twin receives all of its blood flow from the normal or "pump" twin and has no direct placental connection. Blood flows retrograde to the acardiac twin via the normal twin's umbilical artery branches and returns from the acardiac twin via the umbilical vein. Instead of entering the placenta, this blood bypasses the placenta and flows into the normal twin via a venous–venous connection [63]. This puts the normal twin at risk for high-output congestive heart failure, preterm birth, and polyhydramnios [64]. The incidence of TRAP is about 1 in 35,000 live births, affecting about 1% of monochorionic twins and 3% of monochorionic triplets [65,66]. The risk of death for the pump twin is >50% if the condition remains untreated, and 90% if the acardiac twin is >75% of the size of the normal twin [67,68].

Early diagnosis is beneficial for optimal management and is confirmed by documenting retrograde flow to the acardiac twin by ultrasound Doppler imaging. The primary goal of treatment is to stop blood flow between the twins by interrupting the connecting vasculature. Initially this was accomplished by extracting the acardiac twin through an open hysterotomy (Fig. 21.5). Currently, image-guided bipolar or radiofrequency coagulation of the acardiac twin umbilical cord or placental inter-twin anastomoses are the most common and viable options [69]. Other therapeutic options include either percutaneous endoscopic laser ablation of placental vascular anastomoses, selective delivery of the acardiac twin, percutaneous blockage of the acardiac twin's umbilical cord using coils or ligation, and intrafetal injection of alcohol [69]. TRAP treatment procedures are typically done after 16 weeks' gestation but early intervention is ideal to minimize the morbidity to the normal twin. Optimal timing and mode of treatment are yet to be determined. Absence of flow to the acardiac twin is confirmed by ultrasound color Doppler at the end of the procedure and again at 12 or 24 h post procedure.

Figure 21.5 Open selective extraction of an acardiac twin. *Source*: Photo courtesy of UCSF Fetal Treatment Center.

A retrospective study of 60 TRAP cases (mean gestational age 18.3 weeks) from three European centers that used fetoscopic laser coagulation of the placental vascular anastomoses or of the umbilical cord reported a 80% survival rate and a mean gestational age at birth of 37.4 weeks for the pump twin [70]. A single-institution retrospective review of 26 cases of monochorionic diamniotic twins who had TRAP and were treated with RFA noted a 92% survival of the pump twin, who on average was born at 35.6 weeks [71]. A 2014 meta-analysis found the normal twin survival rate to be about 80% for most treatment techniques except use of cord coils or intrafetal alcohol injection [69]. Additionally, earlier treatment intervention was associated with a longer gestation.

Interventions for TRAP are typically performed with infiltration of local anesthesia at the percutaneous device insertion site, but neuraxial anesthesia is also used. The most common complication from the treatment procedures is PPROM.

Myelomeningocele

Open spina bifida or myelomeningocele (MMC) is a non-lethal neural tube defect that occurs early in gestation and results in protrusion and exposure of the meninges and spinal cord through a spinal defect. These neural elements may be injured by exposure to amniotic fluid during gestation, making possible early fetal repair attractive. The definitive cause of MMC remains unknown but is likely multifactorial. Taking folate during pregnancy has decreased the incidence of this lesion to 1 in 3000 livebirths.

Animal studies suggest that the ultimate neural damage results not just from failure of the neural tube to form but from chemical neurotoxicity and secondary neural destruction by components of amniotic fluid or meconium [72]. In sheep, covering the MMC neural defect decreased neurological morbidity and increased the likelihood of normal anal sphincter function [73]. Using somatosensory evoked potentials, Julia et al demonstrated decreased neurological sequelae following *in utero* repair of a surgically created MMC in rabbits [74]. Examination of fetuses with MMC early in gestation showed an open but undamaged cord. Direct trauma to the exposed cord and mutations in the *PAX3* gene have also been implicated in causing MMC [75]. α-Fetoprotein screening of maternal

blood detects MMC during the first trimester and improved ultrasonography allows early detection and the option of pregnancy termination. The 5-year mortality of MMC is about 8% of livebirths; surgical closure in the first days of life is required if MMC is not corrected antenatally [76].

Complications from MMC include hydrocephalus, Arnold–Chiari II malformation, motor and sensory nerve deficits (including paraplegia), bowel and bladder incontinence, spinal cord tethering, sexual dysfunction, and cognitive impairment [77]. Approximately 80% of children with MMC require ventriculoperitoneal shunting for the treatment of hydrocephalus [78]. Despite shunting, permanent deficits including central hypoventilation, vocal cord dysfunction, and swallowing dysfunction can occur secondary to the Arnold–Chiari II malformation. The primary purpose of *in utero* treatment of MMC is to cover and protect the fetal neural contents early in gestation to prevent additional damage by prolonged exposure to the uterine environment.

Open myelomeningocele repair

Utilization of the open fetal surgery approach for MMC repair rapidly increased following the publication of the results of the Management of Myelomeningocele repair Study (MOMS Trial) in 2011 [79]. During the open *in utero* repair (Fig. 21.6), the meninges are separated from the fetal skin and soft tissue layers. In a primary closure (Fig. 21.7A), the dura is closed over the neural placode and the paraspinal myofascial flaps are closed over the dura with a final closure of the skin layer. If primary closure is not possible secondary to the size of the defect, an acellular dermal patch is used to cover the defect (Fig. 21.7B).

The many benefits of prenatal repair revealed as a result of the MOMS study [79] included a decreased need for ventriculoperitoneal shunt placement by 1 year of age (68% versus 98%) as well as decreased actual shunt placement rates (40% versus 82%). In addition, there was decreased hindbrain herniation and improved neurofunctional outcome at 30 months of age with the *in utero* open intervention as assessed by an ability to walk without orthotic device assistance in 42% versus 21% of study children. There were two perinatal deaths in each study group. The trial had been stopped early because of demonstrated efficacy in the prenatal group with only 158 of 183 enrolled patients' data analyzed. Recent follow-up studies on the entire data set demonstrate similar beneficial results of *in utero* intervention with only 70% versus 93% meeting criteria for shunt placement, a decrease in actual shunt placement (44% versus 84%), and independent ambulation in 45% versus 24% [80,81]. These findings clearly have a significant positive impact on the prognosis of the child with a prenatal diagnosis of spina bifida. However, the outcomes for the mothers in this study included a variety of significant complications detailed in Table 21.3 [12,79]. Increased thinning of the uterine wall predisposes to increased risk of uterine rupture with subsequent pregnancies. As a result of this, mothers who have undergone open fetal surgery are committed to cesarean delivery prior to the onset of labor for all subsequent pregnancies. This, together with the increased risk of premature delivery (average gestational age at delivery was 34 weeks), has remained the primary negative aspect to prenatal open surgical repair of MMC.

Fetoscopic myelomeningocele repair

In an attempt to circumvent the undesired consequences of open MMC repair, the fetoscopic approach to MMC repair was explored. The first attempt at fetoscopic repair involved maternal hysterotomy and percutaneous repair through an exteriorized uterus [82]. This was complicated by placental abruption in one case, resulting in abandonment of this approach. Nevertheless, animal studies continued in order to determine the feasibility of this approach [83,84]. Following refinement in animal studies, a few centers are now routinely performing fetoscopic repair of open neural tube defects between 22 and 26 weeks of gestation, either via the percutaneous minimally invasive fetoscopic approach or a "hybrid" procedure involving an initial maternal hysterotomy followed

Table 21.3 Maternal complications for MOMS trial patients*

Maternal outcome	Prenatal (*n* = 78)	Postnatal (*n* = 80)	p
Chorioamniotic membrane separation	30 (33%)	0	<.0001
Pulmonary edema	5 (6%)	0	.03
Oligohydramnios	19 (20%)	3 (3%)	<.001
Placental abruption	6 (7%)	0	.01
Spontaneous rupture of membranes	40 (44%)	7 (8%)	<.0001
Spontaneous labor	39 (43%)	13 (14%)	<.0001
Blood transfusion at delivery	8 (9%)	1 (1%)	.02
Hysterotomy site thin, or partial or complete dehiscence noted at delivery	31 (35%)	N/A	N/A
Mean gestational age at birth (weeks)	34.0 ± 3.0	37.3 ± 1.1	<.0001

* The table lists maternal complications that were significantly different (p <.05) between the prenatal and postnatal repair groups in the Management of Myelomeningocele Study (MOMS) following complete cohort analysis of 183 patients. Other outcomes were evaluated, but only those that were different between the two groups are included. Data for each group are shown as both an absolute number and as a percentage.

by exteriorization of the uterus with trocar insertion and repair of the fetal defect [85–88].

Both the fetoscopic and the hybrid approach to MMC repair are likely to decrease maternal morbidity as the uterus does not have a significant scar that is at risk of dehiscence during labor. Following both of these surgical approaches, the mothers are allowed to labor and have a spontaneous vaginal delivery. The gestational age at delivery for both of these approaches has a wide range (24–40 weeks' gestation) with a mean of 38 weeks or 33 weeks depending on the center [88,89].

Lesions between T1 and S1 are deemed acceptable for fetoscopic repair [85]. Similar to open fetal procedures, pregnant patients with minimal co-morbidities or well-managed chronic disease states are ideal candidates for this fetal intervention.

With the percutaneous minimally invasive endoscopic approach to MMC repair, three or four trocars with an outer diameter of 5 mm each are introduced via the abdominal wall into the maternal amniotic cavity, under ultrasound guidance, using a Seldinger technique. The trocars are carefully positioned to avoid the placenta in the case of an anterior placenta [85]. In the early days of this procedure, partial removal of amniotic fluid was performed followed by partial insufflation of carbon dioxide. However, with refinement of the technique, this has been found to be no longer necessary [85,89]. Fetoscopic repair occurs under partial amniotic carbon dioxide insufflation which helps maintain clear visualization for surgical repair within the uterus.

Humidified carbon dioxide is gradually insufflated into the amniotic cavity, starting at 8 mmHg gas flow pressure, and gradually increased by 2 mmHg increments until an "opening pressure" is attained. The fetus is then properly positioned for surgery and endoscopic repair commences. Depending on the size of the lesion, fetal surgical repair ranges from simple repair with an inert patch to dissection of the placode and closure with one or more collagen and polytetrafluoroethylene patches. Water-tight closure is confirmed by ensuring there is no cerebrospinal fluid leak when gentle pressure is applied to the surface of the repair [85,90].

Although perioperative anesthetic approaches to both minimally invasive and open fetal surgery cases are detailed later in the chapter in the sections "Anesthetic management of fetal procedures" and "Perioperative and procedural considerations," the unique circumstances of this fetoscopic approach to fetal MMC repair warrant the additional description in the following paragraphs.

Anesthetic management and considerations for fetoscopic myelomeningocele repair

On the day of surgery, aspiration prophylaxis is administered and venous compression stockings are also placed on the mother. Prior to commencing the mother's anesthetic, it is important to try to avoid the administration of any maternal anxiolytic or sedative medication as this may result in immobilization of the fetus and may make adequate positioning for surgical repair of the spina bifida lesion challenging. General anesthesia via rapid-sequence induction and endotracheal intubation is routinely required with either the percutaneous or hybrid surgical approach. Monitoring and venous access for the percutaneous minimally invasive approach in the European center that has performed a large number of these particular cases includes insertion of a central venous catheter in addition to standard monitoring of blood pressure, electrocardiography, and non-invasive monitors [91]. Relatively smaller endotracheal tubes compared to those that may be utilized in the non-pregnant female should be considered, due to possible airway edema that may be present in the pregnant woman. For the entirely percutaneous fetoscopic approach, maintenance of anesthesia is accomplished with volatile anesthetic (e.g. desflurane) and an intravenous remifentanil infusion. The opioid remifentanil not only provides analgesia for the mother but also has adequate transplacental passage to provide fetal analgesia and immobility during the procedure compared with diazepam [92]. In addition, an intravenous bolus of the tocolytic agent atosiban is also routinely administered at some European centers prior to induction of anesthesia. An oxytocin antagonist, atosiban is not approved for use in the USA and is only available in Europe. Both routine and invasive monitoring are often employed when this drug is administered and include invasive blood pressure monitoring via an arterial catheter, pulmonary artery catheter assessment of the cardiac output, and estimation of lung water content. The last is utilized to assess the development of or presence of maternal pulmonary

edema during surgery and also in the postoperative phase. Pulmonary artery catheter monitoring is unique to these cases and not a routine part of open approaches to MMC repair.

Intraoperative intermittent assessment of feto-maternal placental circulation and fetal heart rate via ultrasound and echocardiography is frequently employed and this influences surgical maneuvers as well as anesthetic depth. Postoperative pain in patients following percutaneous minimally invasive repair of spina bifida is managed with oral opioid medication.

For the alternative, "hybrid" approach with an initial maternal laparotomy and subsequent fetoscopic repair through trocars inserted into the exteriorized uterus (Fig. 21.8), general and neuraxial anesthesia is administered to the mother. An epidural catheter is placed preoperatively for administration of local anesthetic and opioid infusion after the surgery to manage postoperative pain. General anesthesia is instituted as described previously, with any choice of the volatile anesthetics used for the hybrid approach. The fetus also receives direct intramuscular medication for pain relief and immobility. Implications of the administration of maternal anesthetics are discussed in the sections "Anesthetic implications" for each system.

Once the fetus has been adequately positioned for surgery, intramuscular fetal medications are administered [93]. Most commonly, a combination of analgesic medication (most commonly fentanyl 5–10 μg/kg), muscle relaxant (vecuronium 0.2–0.4 mg/kg) and a vagolytic agent (atropine 0.02 mg/kg) is administered to the fetus prior to commencing the fetoscopic spina bifida repair. Administration of this combination to the fetus may be repeated every 45 min to 1 h depending on the duration of the repair.

Postoperatively, analgesia for the hybrid procedure is routinely accomplished via patient-controlled epidural infusions of a local anesthetic with opioid for 48–72 h, offering both the fetus and mother adequate pain relief. Postoperative tocolysis is achieved with intravenous magnesium sulfate infusion for 24–48 h.

While fetoscopic repair (percutaneous or "hybrid" approach) has potential advantages for both the mother and the fetus with a decreased chance for both uterine rupture and premature delivery, there are still significant areas for concern. A steep learning curve exists for the fetoscopic repair, with the time for completion of these cases being more prolonged than open cases [88,89]. A 2012 study of endoscopic intrauterine MMC repair resulted in a high complication rate for both mothers and fetuses [94]. Of 19 patients, three fetuses died intraoperatively and three procedures were stopped secondary to severe hemorrhage during the procedure. A 2016 phase I trial of endoscopic fetal repair of 10 MMC patients resulted in two of 10 procedures aborted due to loss of uterine access, one fetal and one neonatal demise and PPROM in 100% of cases [95]. Fetal repair in a carbon dioxide-filled environment has also raised concern for fetal hypercarbia and subsequent possible untoward sequelae [96]. Previous fetoscopic studies in sheep have demonstrated significant fetal lamb acidosis; while this has not been directly assessed in human fetuses undergoing surgery in a carbon dioxide-filled uterus, no physiological parameters of the fetus during surgery raise any suspicion of an untoward effect [87]. Absorption of carbon dioxide during this procedure, particularly through open vessels if any occur during surgery, could result in maternal carbon dioxide embolism. However, this has not been reported to date in any of the patients undergoing fetoscopic repair of MMC in the carbon dioxide-filled environment. In some studies, when compared to open MMC repair, fetoscopic MMC repair was associated with increased membrane complications, earlier gestational age at birth, persistent fetal CSF leaks, and increased perinatal demise [77,94,95,97].

Despite these concerns, fetoscopic repair of spina bifida is slowly gaining popularity in different centers. The decreased maternal morbidity, and propensity for vaginal delivery of a near term baby are goals that are difficult to ignore. In addition, the postnatal neurological outcomes are encouraging, with the rate of neurosurgical intervention in children following *in utero* repair being similar to that of the MOMS trial [88,98]; however, assessment of the long-term neurological outcomes of children who have undergone these procedures is needed before definitive proof of benefit of this approach can be conclusively stated. Chapter 25 presents additional detail about postnatal MMC surgery and anesthesia.

KEY POINTS: MYELOMENINGOCELE

- Open fetal MMC repair significantly decreased the ventriculoperitoneal shunt placement rate and improved neurological outcome in the MOMS study
- Fetoscopic MMC repair reduces the risk of premature labor and requirement for cesarean section for subsequent pregnancies
- For either the open or fetoscopic approach, the fetus receives intramuscular fentanyl, vecuronium, and atropine for analgesia and immobility

Congenital pulmonary airway malformations

A congenital pulmonary airway malformation (CPAM) is a discrete pulmonary mass that contains both solid and cystic components that are <1 mm to several cm in diameter and typically isolated to one lung. These malformations were

previously described as congenital cystic adenomatoid malformations (CCAMs). CPAMs have been classified into two types based on ultrasound imaging and size [99]. Malformations containing single or multiple cysts >5 mm in diameter on ultrasound are termed "macrocystic"; they may develop into large solitary cysts several cm in diameter. Smaller lesions with cysts <5 mm of diameter are termed "microcystic"; they appear as solid images on ultrasound. A second-trimester ultrasound can assist in differentiating CPAM from CDH, peripheral bronchial atresia, neurogenic cysts, bronchopulmonary sequestration, and bronchogenic cysts [99]. A histological classification scheme includes five subtypes based on: (1) cyst size; (2) epithelial lining characteristics; (3) wall thickness; and (4) presence of mucus-secreting cells, cartilage, and muscle [100]. The incidence of CPAM is estimated to be 1 in 25,000 pregnancies [101].

Large tumors can result in mediastinal shift, polyhydramnios, pulmonary hyperplasia, hydrops, and fetal demise. The overall fetal outcome depends on CPAM size, tumor growth characteristics, presence of hydrops, and secondary morbidity from large masses that cause a fetal mediastinal shift, pulmonary hypoplasia, or polyhydramnios [102,103]. Fetuses with untreated lesions and hydrops have a survival rate <5% [104]. Smaller CPAMs detected *in utero* without significant compromising effects are resected after birth, usually by excising the affected pulmonary lobe. The CPAM volume ratio (CVR) is the quotient of the calculated CPAM volume and the fetal head circumference normalized for gestational age as determined by ultrasound imaging [105]. A CVR <0.56 was noted to have no adverse effects, >0.56 was associated with an adverse postnatal outcome one-third of the time, and a CVR >1.6 was associated with greater risk of fetal hydrops [105,106]. Bilateral fetal masses or the presence of hydrops are associated with poor outcomes [105,107]. Periodic ultrasound surveillance of CPAM masses is critical because these tumors can grow rapidly and unpredictably. Depending on the mass and its effects, *in utero* intervention or postnatal resection may be chosen.

Possible fetal surgical strategies include aspiration and drainage of cysts using serial thoracocentesis or shunt placement, percutaneous laser ablation, and CPAM resection during open fetal surgery [108]. Aspiration of cysts may improve the condition of the fetus temporarily, but the fluid often reaccumulates. Placement of shunts can produce sustained decompression and resolution of hydrops *in utero*, and allow definitive treatment after birth [109]. Without intervention, large CPAMs may cause significant pleural effusions and pulmonary hypoplasia. Unfortunately, some cystic lesions are compartmentalized and cannot be successfully drained. Thoracoamniotic shunts may be displaced, malfunction, or occlude, and may cause fetal hemorrhage, placental abruption, PPROM, preterm labor, and chorioamnionitis [105,108]. Administration of betamethasone to fetuses with CPAMs and hydrops can improve outcomes [110]. In a series of macrocytic CPAMs treated with thoracoamniotic shunts, 68% of hydropic and 88% of non-hydropic fetuses survived [111].

Solid microcystic CPAMs or other large masses not amenable to drainage or shunting can be resected during open fetal surgery (Fig. 21.9). The lobe containing the lesion is resected during a hysterotomy and fetal thoracotomy [104]. Anesthetic considerations are described in the section "Open fetal surgical procedures." A retrospective review of 30 fetuses with large CPAMs and hydrops had a 50% 30-day survival after birth following open fetal surgical resection [112]. Only 3% (one of 33) of fetuses with similar CPAMs survived without surgical intervention.

Less frequent options include resection during an EXIT procedure, with ECMO, tumor ablation, or percutaneous sclerotherapy. Improved selection criteria and the potential for minimally invasive video-assisted thoracoscopic RFA of the tumor hold promise for improved outcomes [108]. Chapter 26 contains additional information about postnatal treatment of CPAMs.

Sacrococcygeal teratoma

Fetuses with sacrococcygeal teratoma (SCT) are typically diagnosed in the second trimester of pregnancy; the incidence of SCT is 1 in 20,000 to 40,000 livebirths [113]. The lesions can grow to 500–1000 cm^3 [114]. Perinatal mortality is high due to massive tumor enlargement, hydrops, and placentomegaly. Perinatal mortality is estimated at 25–35% [113]. However in one series, the perinatal mortality of 23 fetuses with SCT was 43% [114]. These tumors also cause significant arteriovenous shunting, and the resultant high-output cardiac failure is often the cause of fetal death. Fetuses with large lesions are at risk for intrapartum dystocia, tumor rupture and hemorrhage, and bladder outlet obstruction. Fetal hydrops may be associated with "mirror syndrome," in which the mother develops a hyperdynamic high-cardiac output state similar to that of the fetus and has superimposed symptoms of pre-eclampsia [115].This syndrome increases the risk of fetal mortality and maternal morbidity, with severe maternal complications occurring in 20% of cases [116].

Several SCTs have been successfully removed *in utero* [117]. Tumors are staged based on location using the Altman criteria [118]. Tumors located entirely outside the pelvis (stage 1) are amenable to *in utero* resection, while those completely within the fetal pelvis (stage IV) are not suitable for *in utero* resection. Successful operations for large SCTs require catheterization of a fetal hand or umbilical cord vein to allow blood and fluid resuscitation during tumor resection. Minimally invasive surgery using RFA, embolization, and thermocoagulation of the tumor or its vasculature attempts to reduce the tumor burden and blood supply, but studies are needed to determine the degree of benefit [119].

Fetal urinary tract obstruction

Urinary tract obstructions are detected by ultrasound in approximately 1% of pregnancies [120]. The great majority of these abnormalities have no significant clinical consequence. Only 1 in 5000 livebirths has a lower urinary tract obstruction [121]. The clinical morbidity from fetal urinary tract obstruction depends on the location of the obstruction, severity, duration, age at onset, and gender of the fetus [120]. Congenital bilateral hydronephrosis from obstruction of the fetal urethra has a worse prognosis than unilateral upper urinary tract obstruction. Although the exact etiology may vary, posterior urethral valves are often the cause of bilateral hydronephrosis in male fetuses. Other possible causes include obstruction of the ureteropelvic junction and ureterovesical junction, ectopic ureter, ureterocele, megacystic megaureter, multicystic kidney,

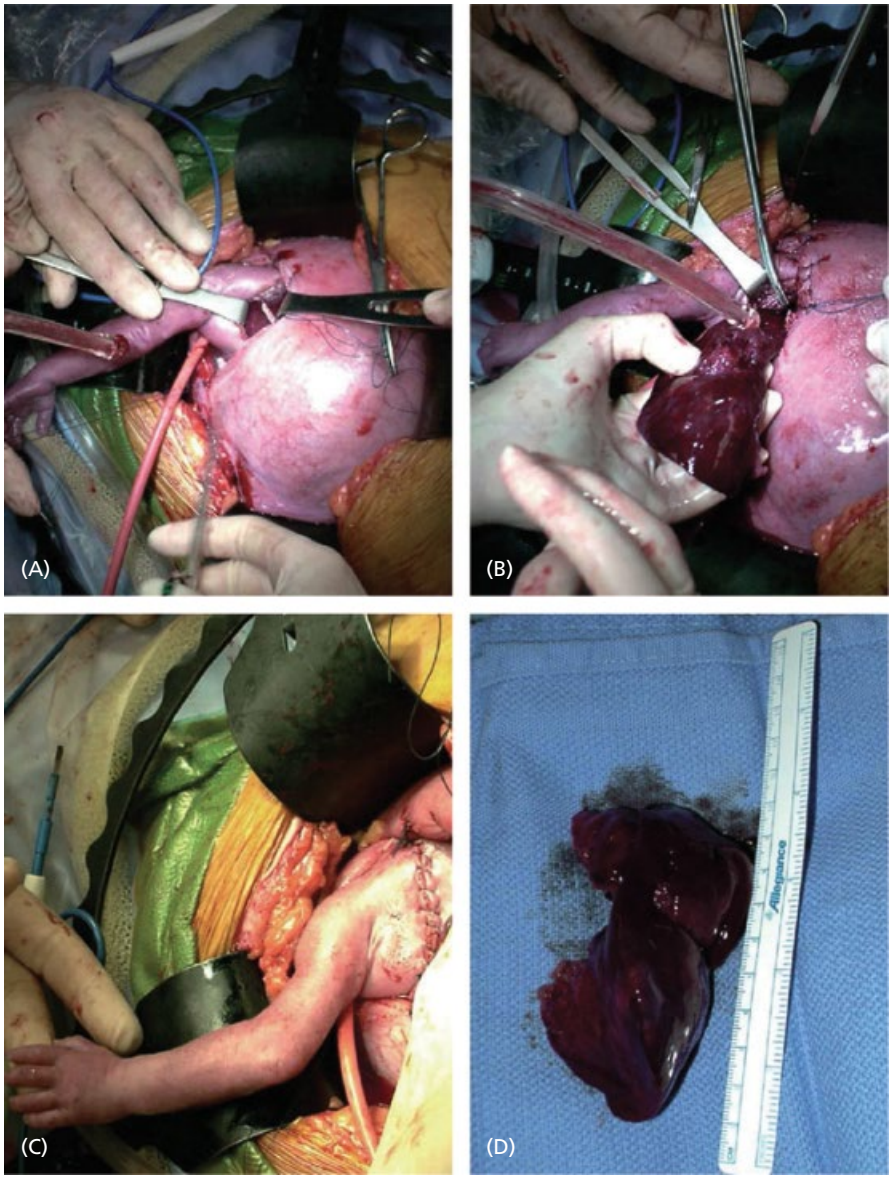

Figure 21.9 (A) Open resection of fetal congenital pulmonary airway malformation (CPAM) with fetal thoracotomy shown. (B) Resected CPAM mass. (C) Primary closure of fetal thoracotomy. (D) Pathology specimen of resected CPAM mass. *Source*: All photos courtesy of UCSF Fetal Treatment Center.

or more complex pathologies [122]. These anomalies are easily detected by ultrasonography and commonly result in oligohydramnios. Before 16 weeks' gestation, a transudate of maternal plasma forms the amniotic fluid; after 16 weeks' gestation, fetal urine is its primary source. An ultrasound grading system based on fetal renal pelvis anteroposterior diameter is used to assess the severity of prenatal hydronephrosis [123]. Not only should an extensive ultrasound evaluation of the entire urinary tract be done, cardiac or neural tube defects should also be sought because they occur more commonly in fetuses with lower urinary tract obstructions [120]. A more recent severity classification system for lower urinary tract obstruction based on amniotic fluid index, renal imaging, and fetal urine chemistry has been proposed [124].

Severe urinary tract obstruction causes oligohydramnios, hydroureteronephrosis, and bladder distension, which in turn cause pulmonary hypoplasia, facial and extremity deformations, renal dysplasia and dysfunction, and deficiencies of abdominal muscle (Fig. 21.10) [125]. These problems significantly reduce postnatal survival, primarily by causing lung hypoplasia. Of livebirths undergoing postnatal correction, more than 25% are dialysis dependent by 5 years of age [126].

Placement of a double pigtail catheter between the fetal bladder and amniotic cavity allows decompression and drainage of the bladder *in utero*. This reduces oligohydramnios and its associated morbidities (pulmonary hypoplasia and umbilical cord compression) and improves renal development. The first intervention for congenital hydronephrosis was performed by open hysterotomy in 1981. The neonate was born at 35 weeks' gestational age and died from lung hypoplasia [125]. Improved selection and placement of vesicoamniotic shunts allowed successful treatment of congenital hydronephrosis [7]. An algorithm with specific criteria was proposed to improve fetal candidate selection and outcome [127]. Components of the algorithm included fetal karyotype, an ultrasound examination searching for additional anatomical abnormalities, and fetal urine sampling to determine the degree of renal dysfunction.

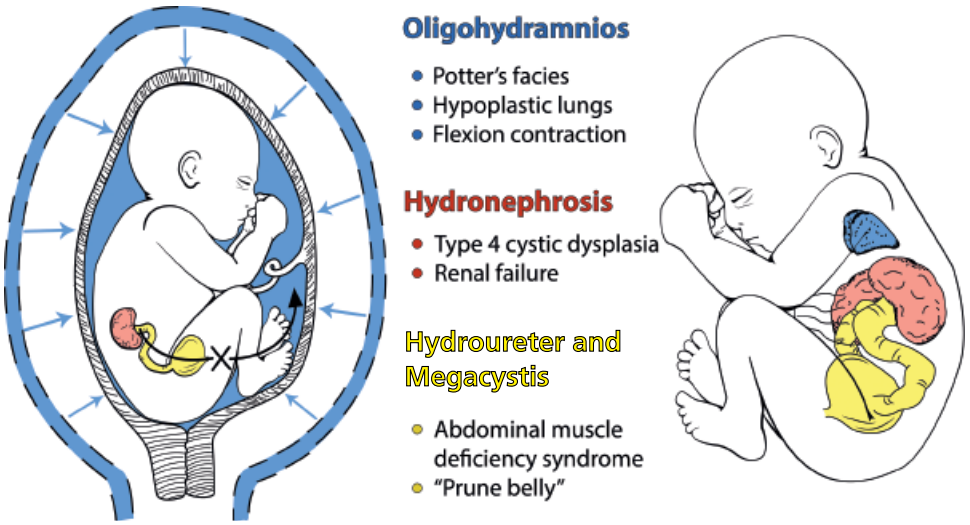

Figure 21.10 Developmental consequences of fetal urethral obstruction. Severe urinary tract obstruction results in significant fetal sequelae that can reduce postnatal survival. Reproduced from Harrison et al [125].

Fetal intervention requires a male karyotype (females often have more complex urinary abnormalities), absence of other structural abnormalities that impact outcome, and the presence of oligohydramnios or decreasing amniotic fluid volume. Serial sampling of fetal urine on three to five occasions, complete bladder drainage, 24–48 h intervals between samples, and assessment of sodium, chloride, calcium, osmolality, protein, and β2-microglobulin improve fetal outcome prediction [120,128]. Increased levels of these components of fetal urine are associated with advanced renal damage and a poor prognosis [129]. Detection of lesions early in gestation, the degree of oligohydramnios, and the presence of additional abnormalities all predict worse outcomes.

Vesicoamniotic catheter shunt (VAS) placement is often difficult because oligohydramnios compromises ultrasound imaging. Potential complications of catheter insertion include catheter occlusion or displacement, chorioamnionitis, PPROM, fetal trauma, abdominal wall defects (gastroschisis), placental separation and hemorrhage, preterm labor, and maternal leakage of amniotic fluid [120]. This minimally invasive intervention requires neuraxial anesthesia or infiltration of local anesthetic into the maternal abdominal wall and uterine musculature. The neonate will require definitive repair of the underlying problem after birth.

A single-institution, retrospective review of 34 VAS placements for heterogeneous causes of obstructive uropathy between 1987 and 1996 reported 50% survival to at least 2 years of age; 43% of survivors had normal renal function [130]. A retrospective review of 20 pregnancies with male fetuses with lower urinary tract obstruction reported overall 1-year survival of 90% and only two neonatal deaths from pulmonary hypoplasia [131]. Eight children had normal renal function, 11 had normal bladder function with spontaneous voiding, and eight had respiratory difficulty [131]. A meta-analysis of studies from 1990 to 2015 noted improved survival with *in utero* shunting compared to conservative management (57% versus 39%) [126]. However, there was no difference in 2-year survival or postnatal kidney function.

Minimally invasive percutaneous cystoscopy with laser ablation of the posterior urethral valves allows direct visualization of the fetal urethra to facilitate diagnosis and provide *in utero* treatment that may reverse pulmonary and renal morbidity, but its efficacy is uncertain at this time [132]. A case-control study compared fetal cystoscopy with VAS and no intervention [133]. Both fetoscopy and VAS improved 6-month survival in severe lower urinary obstruction, and in the subset of fetuses with posterior urethral valves only fetoscopy improved both 6-month survival and renal function. Limited evidence currently supports fetal intervention in lower urinary tract obstruction, as an attempt to reduce pulmonary hypoplasia and improve perinatal survival. Other improvements in kidney and bladder function are also yet to be definitively demonstrated as a result of fetal interventions.

KEY POINTS: CONGENITAL PULMONARY AIRWAY MALFORMATIONS, SACROCOCCYGEAL TERATOMA, AND FETAL URINARY TRACT OBSTRUCTION

- Large CPAMs are treated with cyst drainage, thoracocentesis, thoracoamniotic shunt placement, percutaneous laser ablation, and open fetal surgery
- Sacrococcygeal teratomas outside the pelvis are amenable to *in utero* resection
- Congenital urinary tract obstruction may be treated with vesicoamniotic shunt or fetoscopic laser ablation of posterior urethral valves

Fetal cardiac anomalies

Advances in angioplasty, ultrasound, and maternal–fetal care have allowed for successful fetal cardiac intervention, specifically for cardiac conditions that evolve during the second trimester to early third trimester. Ultrasound imaging provides percutaneous guidance into the left ventricle (for aortic valvuloplasty), right ventricle (for pulmonary valvuloplasty), or atrium (for atrial septostomy), depending on the procedure

required. Percutaneous fetal cardiac intervention has provided benefit for conditions such as aortic stenosis and evolving hypoplastic left heart syndrome (HLHS), established HLHS and restrictive atrial septum, pulmonary artery hypoplasia and hypoplastic right heart syndrome, and also fetal cardiac failure or hydrops fetalis due to structural cardiac disease [134,135]. Fetal aortic valvuloplasty for evolving HLHS, pulmonary valvuloplasty for hypoplastic right heart syndrome, and atrial septostomy for established HLHS are being performed as these procedures have mitigated abnormalities or limitations of cardiac growth and development that may occur *in utero*.

Fetal aortic valvuloplasty is discussed here as a prototype of prenatal cardiac intervention. This percutaneous procedure is performed for critical stenosis of the aortic valve, which results in decreased flow across the transverse aortic arch, reversal of flow across the foramen ovale, and increased left ventricular pressure with resulting myocardial damage. If left untreated, this condition results in HLHS in the postnatal period due to the underdeveloped left heart structures. Fetal aortic valvuloplasty was first described in 1991, but initial reports of successful prenatal intervention were performed in the third trimester [136]. This procedure is now performed during the second trimester or early third trimester and has favorably altered the postnatal course for fetuses with these conditions.

Fetal cardiac interventions are typically performed between 22 and 26 weeks' gestation. Optimal fetal positioning that allows for appropriate access to the necessary valves or area of interest is paramount for the success of this procedure. The most common access for fetal aortic valvuloplasty is through the fetus's anterior left chest wall and left ventricle (Fig. 21.11). The ideal fetal position provides clear access to the left chest wall without any intervening limbs or structures. An 11 cm long, 19 ga needle and stylet is inserted into the maternal abdomen and through the uterine wall, left fetal chest wall, and into the left ventricle. The left ventricle outflow tract should be parallel to the course of the cannula [134]. Inability to adequately position the fetus via external version has resulted in occasional maternal minilaparotomy, exteriorization of the uterus, and manipulation of the fetus to allow an appropriate needle trajectory, although this approach to fetal positioning is rarely employed. After successful entry into the left ventricle, a guidewire is advanced toward the stenotic aortic valve using ultrasound guidance and knowledge of predetermined measurements of the cannula and balloon tip [134].

Technically successful aortic valvuloplasty is described as confirmed insertion of the guidewire across the aortic valve, inflation of the balloon, and immediate observation of increased flow across the aortic valve, plus or minus new aortic regurgitation [137]. The increased flow observed following a technically successful fetal aortic valvuloplasty allows the fetal left ventricle to recover, remodel, and support a biventricular circulation in the postnatal period (i.e. circulation in which the left ventricle is entirely responsible for the baby's cardiac output with no contribution from atrial shunting) [138]. The recent study by Prosnitz and colleagues [138] reported that establishment of partial or exclusive postintervention anterograde flow across the aortic transverse arch was the most significant, independent predictor of postnatal biventricular function. Biventricular function may be present at birth following this prenatal cardiac intervention or may be acquired after a series of operations and/or in the presence of suboptimal diastolic function or pulmonary hypertension. Nevertheless, it is an improvement over the hypoplastic left heart, which is associated with significant morbidity and mortality [139].

Multidisciplinary meetings including the cardiologist, obstetrician, and anesthesiologist are frequently helpful to discuss not only the maternal history and fetal characteristics but also any anticipated difficulty with fetal positioning for

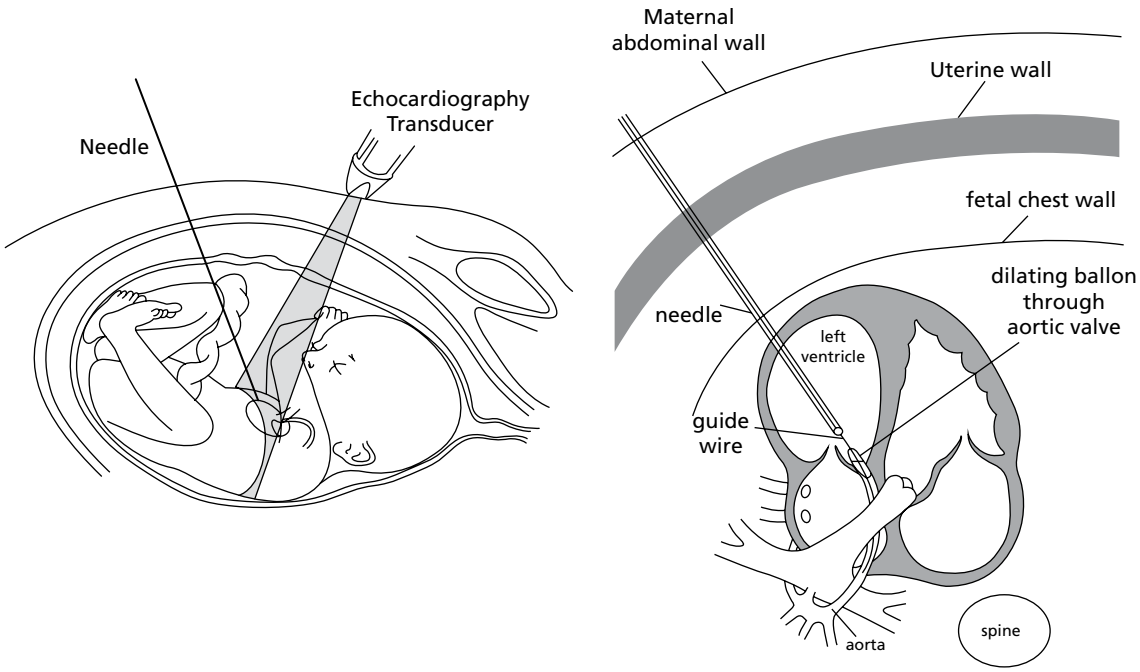

Figure 21.11 Illustration of ideal fetal position and unobstructed course of cannula access for fetal aortic valvuloplasty: through maternal abdomen, uterine wall, fetal chest and into left ventricle of fetus, facing left ventricular outflow tract. *Source*: Reprinted with permission from Tworetzky et al [134] with permission of Wolters Kluwer.

the procedure. Proper fetal position must be ascertained prior to administration of sedatives to the mother in case external version of the fetus would be required. Administration of significant sedation or analgesia to the mother may make fetal positioning more difficult once transplacental passage to the fetus has occurred. As surgical approach and technique for fetal cardiac intervention has been refined, the anesthetic requirement for these procedures has evolved from maternal general anesthesia to neuraxial anesthesia and even local infiltration at the insertion site with minimal intravenous sedation. The last option offers the benefit of easy reversal or discontinuation of sedation for situations in which fetal positioning for the procedure proves problematic. An intravenous remifentanil infusion may be administered to provide maternal sedation for this procedure as with other fetoscopic fetal procedures [92]. It can also potentiate immobilization of the fetus once an adequate fetal position has been ensured and the baby has received intramuscular combination medication of atropine, fentanyl, and muscle relaxant (see section "Minimally invasive and percutaneous procedures").

In some cases, general or regional anesthesia may be chosen to improve the success of external version of the fetus before the procedure starts if initial attempts were unsuccessful. However, avoiding general anesthesia and scheduling the case for a time when the baby is in a better position can also be entertained by the team. This decreases the risks associated with general anesthesia in a pregnant mother.

Traversing the ventricle in particular is associated with an increased risk for fetal hemodynamic instability [135]. Fetal hemodynamic instability, namely bradycardia and ventricular dysfunction, commonly occurs during fetal cardiac intervention. Adequate preparation should therefore be made for fetal resuscitation during the procedure (see section "Minimally invasive percutaneous procedures"). A review of fetal hemodynamic instability during prenatal cardiac intervention procedures revealed that fetal hemodynamics was frequently unstable a few minutes after insertion of the cannula into the heart and also shortly after removal of all instruments from the heart [135]. Hemodynamic instability is to be expected during this procedure due to the nature of the intervention; however, the exact pathophysiology is not clear. One hypothesis includes fetal hypoxia, which may occur due to reduced cardiac output from inferior vena cava compression. Another hypothesis is ventricular dysfunction, which may occur following direct ventricular stretch reflex as a result of cannula-induced depression of the ventricular wall into the ventricular cavity or as a result of cardiac tamponade from hemopericardium. Ventricular dysfunction may also result from torsion of the cannula within the cavity or withdrawal of the dilating balloon from the heart.

Fetal hemodynamic instability may also be related to injury to the fetal conducting system during ventricular access. Reduction in uterine flow due to maternal hypotension could also result in fetal hemodynamic instability, however a review of fetal cardiac intervention cases demonstrated that hemodynamic instability occurred during periods of maternal normotension [135].

In preparation for possible hemodynamic instability during this procedure, several weight-based aliquots of epinephrine (1 μg/kg), epinephrine (10 μg/kg), atropine 20 μg/kg, and calcium gluconate (approximately six syringes each), should be readily available in a sterile fashion for rapid administration by the cardiac interventionalist during the procedure in response to any observed cardiac dysfunction. In some centers, prophylactic atropine is administered at the beginning of the procedure. Prophylactic epinephrine may also be administered through the wire lumen of the balloon after aortic valvuloplasty. Both intramuscular and intracardiac epinephrine concentrations of 1 μg/kg or 10 μg/kg have been utilized depending on the severity of the cardiac dysfunction observed. The latter epinephrine dose appears to have a more rapid and sustained effect.

Hemopericardium has been noted to occur following aortic valvuloplasty; as a result, pericardiocentesis using the valvuloplasty cannula can be attempted prior to withdrawal of the cannula. It is important to note that fetal hemodynamic instability is more common with ventricular access and is observed much less often with transatrial access.

Postnatal biventricular function is the ultimate desired outcome following prenatal cardiac intervention. The ability for this to occur, in the case of aortic stenosis, seems to depend on the size of the left ventricle before the procedure, with a larger preintervention left ventricle predicting better postnatal biventricular function following the procedure. The potential benefits of this procedure must be weighed against possible risks of technical failure, valvular insufficiency, fetal demise, and yet to be determined, potential long-term events. Maternal complications include infection, PPROM, and preterm labor.

An alternative approach to the management of prenatally diagnosed cardiac anomalies is immediate access to postpartum cardiac therapy, otherwise referred to as immediate postpartum access to cardiac therapy (IMPACT) [140]. This approach has been used to manage neonates with prenatally diagnosed HLHS, heart block with associated hydrops fetalis, and giant pulmonary arteriovenous malformation. This multidisciplinary treatment modality typically involves a cesarean delivery in the cardiac operating room suite, and immediate resuscitation of the newborn by pediatric cardiothoracic anesthesiologists, which is quickly followed by surgical or catheter intervention within the first few minutes of life after separation from placental circulation. While this approach to prenatal cardiac lesions has been reported, it has not yet achieved widespread practice, and there are currently no published outcomes on its efficacy. It may be challenging to have this approach widely adopted as the ability to offer newborns such high-level immediate care will vary based on institutional capability.

KEY POINTS: FETAL CARDIAC ANOMALIES

- Fetal aortic valvuloplasty for evolving HLHS, pulmonary valvuloplasty for hypoplastic right heart syndrome, and atrial septostomy for established HLHS are being performed
- Needle and guidewire access through the maternal abdomen and uterus, fetal left chest wall, left ventricle, and across the aortic valve is used for aortic valvuloplasty
- Intramuscular fentanyl, vecuronium, and atropine, continuous echo monitoring, and preparations for resuscitation with epinephrine, atropine, and pericardiocentesis are important for fetal cardiac procedures

Ex utero intrapartum treatment procedure

The *ex utero* intrapartum treatment (EXIT) procedure was originally developed to allow adequate time to manage and secure the airway of fetuses at birth who had undergone *in utero* tracheal occlusion [141]. The EXIT procedure is now widely used for cases in which the neonatal airway may be difficult or impossible to manage, i.e. fetal neck masses and congenital high airway obstruction (CHAOS) [13,142]. The EXIT procedure is also used for other surgical procedures, such as thoracotomy to excise large CPAMs, for separation of conjoined twins, or for transition to ECMO. It is useful for severe lung hypoplasia (e.g. unilateral pulmonary agenesis) and selected cardiac lesions for transition to ventilatory support and/or ECMO, when resuscitation could otherwise be jeopardized by compromised oxygenation [143]. During the EXIT procedure, the neonate is partially delivered by cesarean delivery, and the connection between fetus, placenta, and mother remains intact. This allows gas exchange through the placenta rather than the fetal lungs. Uterine relaxation is necessary to prevent uterine contractions, separation of the placenta from the endometrium, or compromised uterine blood flow. Although most EXIT procedures only require about 30 min, durations of more than 2.5 h have been reported [144]. During this time placental circulation was adequate, as demonstrated by normal umbilical cord blood gases and absence of fetal acidosis at delivery [117].

For fetal surgery to be successful, a multidisciplinary team of fetal surgeons, anesthesiologists, ultrasonographers, maternal–fetal medicine specialists, and dedicated operating room nurses is needed. Maternal considerations, positioning, induction of anesthesia, and tracheal intubation are similar to those with general anesthesia for cesarean deliveries (see section "Open fetal surgical procedures").

Often >2 minimal alveolar concentration (MAC) of maternal volatile anesthetic agent is required to maintain profound uterine relaxation and prevent placental separation from the uterine endometrium. In some cases, periodic boluses of intravenous nitroglycerine (50–200 μg) or a continuous infusion of nitroglycerine (1–20 μg/kg/min) are required in addition to or instead of volatile anesthetic to provide adequate uterine relaxation. In certain cases, EXIT has been successfully accomplished with neuraxial blockade and nitroglycerine [145].

The use of high volatile anesthetic levels often decreases maternal cardiac output and uteroplacental blood flow and results in vasodilation and hypotension. Close hemodynamic monitoring is therefore required. Vasopressors such as phenylephrine and/or ephedrine are administered as needed and are preferred to excessive intravascular volume expansion, which may cause maternal pulmonary edema.

The uterus must be flaccid and atonic for hysterotomy. The location of the placenta and fetus are determined by ultrasound, the uterine incision avoids the placenta, and a stapling device is used to ensure hemostasis [144]. Following hysterotomy, the fetal head and upper torso are partially delivered outside the uterus. Keeping part of the fetus *in utero* helps maintain uterine volume and facilitates fetal warmth. A sterile pulse oximeter probe is applied to the fetal hand for monitoring heart rate and oxygen saturation. Occasionally partial delivery of the fetus causes fetal bradycardia from occult umbilical cord compression; full delivery of the fetus is then necessary. Partial delivery allows placental–fetal gas exchange to continue while the airway is secured or surgery is performed (Fig. 21.12). Volatile anesthetic is transferred to the fetus via the placenta; muscle relaxant, opioid, or resuscitation drugs are given by fetal intramuscular injection (see section "Open fetal surgical procedures"). Fetal well-being is continuously monitored by pulse oximetry (Fig. 21.12) and by periodic echocardiography. The mother breathes at least 50% inspired oxygen to improve fetal oxygenation. Typical fetal saturations prior to intubation are 40–65%. Despite maternal PaO_2 >500 mmHg, fetal arterial PaO_2 is <60 mmHg due to the nature of placental oxygen transfer [146]. Decreases in fetal heart rate or arterial saturation can result from maternal hypotension, placental abruption, umbilical cord compression or kinking, or loss of uterine relaxation. Anesthesiologists play a key role in monitoring the fetus and ensuring its safety by maintaining adequate uterine relaxation and appropriate maternal hemodynamic status.

Figure 21.12 Partial delivery during EXIT procedure with airway secured and pulse oximeter monitor placed on left hand and occluded from light with foil. *Source*: Photo courtesy of UCSF Fetal Treatment Center.

Oral fetal intubation is accomplished by direct laryngoscopy, bronchoscopy, or video-assisted devices using a 3.0–3.5 mm internal diameter (ID) tracheal tube. After the trachea is intubated, pulmonary surfactant is often administered, and the lungs are ventilated. Peak inspiratory pressures are monitored with a manometer and maintained at the lowest pressures required for adequate pulmonary ventilation. Typically, a positive end-expiratory pressure of 5 cmH_2O is used to increase functional residual volume. Before delivery and termination of "placental support," endotracheal tube placement is confirmed by direct observation, auscultation of breath sounds, an increase in fetal SpO_2, and presence of end-tidal CO_2. Fetal pulmonary ventilation typically increases arterial oxygen saturation to >90%. After the baby's oxygen saturation increases, the cord is clamped, the baby is delivered, and neonatologists provide further resuscitation as needed.

Failure of fetal arterial oxygen saturation to rise above 90% with pulmonary ventilation is an indication to initiate ECMO before delivery [147]. This allows time to insert vascular cannulae and initiate ECMO flow before the fetus is removed from placental gas exchange. In other cases, fetal ascites or cystic masses can be decompressed before securing the airway, making it easier to manipulate the head and upper

airway and ventilate the fetal lungs. For longer surgeries, or when intravascular fetal volume or red blood cell mass must be increased, a fetal intravenous catheter is inserted into an upper extremity vein.

Immediately after cord clamping and fetal delivery, the volatile anesthetic is reduced or discontinued and oxytocin is administered to maintain normal postpartum uterine tone. Other agents, such as methylergonovine, prostaglandin-F2α or prostaglandin-E, are used if uterine atony persists. As the concentration of volatile anesthetic is reduced or discontinued, intravenous opioids, propofol, and/or nitrous oxide are administered to provide maternal anesthesia while maintaining uterine tone to complete surgery.

Six case series (4–52 patients) of EXIT determined neonatal outcome [148]. Ninety-seven to 100% of infants were born alive. Average blood loss was 850–1150 mL and the mean time on uteroplacental circulation was 28–45 min. Long-term outcomes of these neonates depended on the severity of the pathology necessitating the EXIT procedure.

Maternal outcomes after EXIT procedures have been excellent. Whenever possible, low transverse uterine incisions are used to decrease the risk of uterine rupture with subsequent pregnancies. Noah et al compared complications in 34 mothers who underwent EXIT procedures to 52 women who underwent cesarean delivery prior to labor [149], and found small increases in both wound complication rates and estimated blood loss in the EXIT procedure group, but no difference in transfusion requirements, postoperative hematocrit levels, and length of hospital stay [149].

KEY POINTS: *EX UTERO* INTRAPARTUM TREATMENT PROCEDURE

- The EXIT procedure is used for fetal neck masses and congenital high airway obstruction, thoracotomy for cystic adenomatoid malformations, separation of conjoined twins, or transition to ECMO
- The neonate is partially delivered by cesarean delivery, and the connection between fetus and placenta remains intact, allowing gas exchange through the placenta rather than the fetal lungs
- Uterine relaxation with >2 MAC volatile anesthetic and/or nitroglycerine is key to anesthesia for the EXIT procedure

Anesthetic management of fetal procedures

Anesthetic management of fetal surgical procedures is similar to anesthesia for non-obstetric surgery during pregnancy. Although the anesthesiologist must optimize fetal well-being and the conditions required for successful surgical and fetal outcomes, the anesthesiologist's paramount focus must be maternal safety. Consequently, anesthesiologists must participate in determining potential maternal risk compared to potential fetal benefit and exclude women in whom the benefit:risk ratio is low. Pregnancy-induced hormonal changes, mechanical effects of a growing uterus, and changes in maternal physiology have important implications for administration of anesthesia. To ensure maternal and fetal safety, the anesthesiologist must understand these physiological changes and how they affect anesthetic management, and must take an active role in perioperative management of both patients.

Unlike other surgical procedures performed during pregnancy for maternal indications (e.g. appendectomy) where the fetus is an innocent bystander, fetal surgery involves two surgical patients, and the anesthesiologist must balance the needs of both. For fetal procedures, the anesthesiologist must consider the fetus' requirements for anesthesia and the perioperative control of uterine tone.

Physiological changes in pregnancy and anesthetic implications

During pregnancy women undergo fundamental changes in anatomy and physiology [150–152]. These physiological changes and the associated morbidities of the fetal procedure place mothers at significantly greater risk for complications during anesthesia than non-pregnant patients. A detailed understanding of these changes and their anesthetic implications is required to prepare for and respond immediately to complications such as fetal distress and maternal hemorrhage. Although the physiological changes of pregnancy affect all organ systems, this section focuses only on cardiovascular, respiratory, and gastrointestinal changes and the anesthetic considerations for these changes in the perioperative period. A more detailed discourse on this subject is found in obstetric anesthesia texts [152].

Maternal cardiovascular system

Hematology

Maternal intravascular volume begins to increase in the first trimester of pregnancy. Larger increases in plasma volume (45–55% at term) than in erythrocyte volume (20–30% at term) cause both an increased intravascular volume and physiological (dilutional) anemia of pregnancy. Although decreased, typical hemoglobin levels are 11 g/dL or greater during pregnancy [152].

Pregnancy induces a hypercoagulable state. Factors I, VII, VIII, IX, X, XII, vWF increase, and factors XI, XIII, and antithrombin III decrease. These changes reduce both prothrombin (PT) and partial thromboplastin time (PTT) by 20%. Platelet levels are normal or reduced by 10%, and the leukocyte count is commonly elevated.

Cardiac output

Cardiac output increases 10% above the pre-pregnant state by 10 weeks of gestation and by about 45% by the third trimester. Increases in both heart rate and stroke volume are responsible for this increase. During labor, maternal cardiac output increases further. Each uterine contraction autotransfuses 300–500 mL of blood into the maternal central circulation. The greatest increase in cardiac output occurs immediately after delivery, when it is elevated by as much as 80% above pre-delivery levels. This abrupt increase in cardiac output is secondary to removal of aortocaval compression, autotransfusion from the contracted uterus, and decreased venous pressure in the lower extremities. These changes in cardiac output are a significant

risk for patients with major cardiac disease, e.g. fixed valvular lesions or left ventricular outflow tract obstruction.

Aortocaval compression

The gravid uterus may decrease preload, cardiac output, and maternal blood pressure by compressing the vena cava of supine pregnant women, especially at term. Venous blood from the lower extremities is redirected to the heart via the azygos, epidural, and vertebral veins. Some degree of vena caval compression is universal and occurs as early as 13–16 weeks of gestation. Approximately 15% of women experience significant hypotension in the supine position late in gestation. In addition, symptoms of nausea, vomiting, diaphoresis, and decreased mental status may accompany the reduction in blood pressure.

Anesthetic implications for the cardiovascular system

The majority of pregnant women experience little supine hypotension because they increase systemic vascular resistance to compensate for reduced venous return. Anesthetic interventions that diminish sympathetic tone (e.g. neuraxial blockade, general anesthesia) exacerbate the effects of vena cava compression and hypotension in supine mothers. Compression of the abdominal aorta by the gravid uterus can also produce lower extremity hypotension and reduced uterine and fetal blood flow that may not be reflected by upper extremity maternal blood pressures. Therefore, supine positioning is to be avoided during the perioperative period in the second and third trimesters of pregnancy. To help preserve uterine blood flow and fetal circulation, the right hip is elevated with a wedge or lateral table tilt. A >25% decrease in maternal blood pressure for >10–15 min may lead to progressive fetal acidosis.

Vena caval compression contributes to lower extremity venous stasis and increases the risk of venous thrombosis and pulmonary embolus. The venous stasis and hypercoagulable state of pregnancy require deep venous thrombosis prophylaxis in the postoperative period (sequential compression devices, low-molecular-weight heparin, increased mobility). In addition, vena cava compression causes epidural veins to dilate, and this increases the risk of accidentally placing an epidural catheter in a vein and injecting local anesthetic intravenously. Consequently, a "test dose" (e.g. 3 mL of 1.5% lidocaine with 1:200,000 epinephrine) is injected in the epidural catheter prior to administering larger (therapeutic) doses of local anesthetic. Increases in heart rate and blood pressure in excess of 20% (intravascular injection), or a rapid loss of lower extremity sensation and onset of motor block (intrathecal injection), are evidence of a misplaced epidural catheter.

Maternal airway and pulmonary system

Upper airway

During pregnancy, the pharynx, larynx, and trachea have increased capillary engorgement and tissue friability, making both laryngoscopy and intubation more challenging. It is frequently appropriate to use smaller cuffed endotracheal tubes (6.0 and 6.5 mm ID) because the larynx may be edematous and narrowed. Because of increased tissue friability, oropharyngeal suctioning and airway instrumentation may induce bleeding.

Ventilation and oxygenation

At term, minute ventilation is increased 45–50% and oxygen consumption more than 20%; functional residual capacity is decreased 20%. Resting maternal arterial CO_2 decreases from 40 mmHg to 30–32 mmHg in the first trimester of pregnancy. Arterial pH is slightly alkalotic (7.42–7.44) due to decreased concentrations of bicarbonate (compensatory metabolic acidosis).

Anesthetic implications for the respiratory system

Airway management by facemask, laryngeal mask, or tracheal intubation can be technically difficult in pregnant women because of their increased anteroposterior chest diameter, enlarged breasts, and laryngeal narrowing. The increased oxygen consumption and decreased oxygen reserve allow more rapid oxygen desaturation during hypoventilation, apnea, and general anesthesia. Obesity exacerbates this desaturation. Pregnancy-induced changes in both airway and respiratory physiology make ventilation and tracheal intubation more difficult and increase the potential for complications. During general anesthesia and controlled ventilation for fetal surgery, the maternal arterial CO_2 should be maintained at physiological levels (30–32 mmHg). Significant additional alkalosis reduces uterine blood flow and causes fetal acid–base abnormalities. Excessive positive pressure ventilation can increase the mean intrathoracic pressure of the mother and decrease cardiac preload, cardiac output, and uterine blood flow [153]. Lastly, an arterial $PaCO_2$ of <20 mmHg can decrease umbilical blood flow [154] and jeopardize the fetus.

Maternal gastrointestinal system

Women beyond 20 weeks' gestation are at risk for regurgitation and aspiration of gastric contents during the induction of anesthesia or with deep sedation. The gravid uterus displaces the stomach cephalad and anteriorly and the pylorus cephalad and posteriorly. The normally intra-abdominal portion of the esophagus is elevated into the thorax, decreasing the competence of the esophageal sphincter. Elevated progesterone and estrogen levels during pregnancy reduce esophageal sphincter tone. The gravid uterus increases gastric pressure, and placental gastrin secretion lowers gastric fluid pH. Consequently, maternal symptoms of gastric reflux increase with increasing duration of pregnancy in most pregnant women. Although gastric emptying is not delayed until the onset of labor, systemic or neuraxial boluses of opioids during surgery can delay gastric emptying and increase the risk of aspiration [155].

Anesthetic implications for the gastrointestinal system

Beyond mid-gestation, or earlier if there are symptoms of gastric reflux, women are at increased risk for pulmonary aspiration of acidic gastric contents and considered to have a full stomach. Current American Society of Anesthesiologists (ASA) guidelines recommend the "timely administration of oral nonparticulate antacids, intravenous (IV) H_2 receptor antagonists, and/or metoclopramide for aspiration prophylaxis" prior to the induction of anesthesia in pregnant women [156]. Rapid-sequence induction of anesthesia and tracheal intubation, utilizing cricoid pressure and a cuffed tracheal tube, are routinely employed during induction of general

anesthesia in pregnant women after mid-gestation. The risk of aspiration during tracheal extubation is similar to that during induction of anesthesia. Consequently, the trachea is not extubated until protective airway reflexes have returned. Nonparticulate antacids (30 mL sodium citrate) work rapidly. Metoclopramide (10 mg IV) when given at least 15 min before the start of anesthesia decreases the risk of aspiration. However, prior opioid administration reduces the effectiveness of metoclopramide [157]. H_2 receptor antagonists also effectively increase gastric pH but require significant time for efficacy.

Maternal central nervous system

The MAC of volatile anesthetics decreases during pregnancy based on studies demonstrating a 40% reduction in animals and a 28% reduction in humans [151,152,158,159]. However, an electroencephalographic study found anesthetic effects of sevoflurane on the brain were similar between pregnant and non-pregnant patients [160]. Additionally, intraoperative awareness rates are increased during cesarean delivery under general anesthesia, and reducing typical anesthetic levels in obstetric patients may not be prudent [161]. The decreased MAC in pregnant women increases the possibility of anesthetic oversedation.

Pregnant women are more sensitive to local anesthetics, which decreases the local anesthetic dose requirement for epidural or spinal anesthesia. This increased sensitivity begins in the first trimester, suggesting a role for biochemical changes (progesterone mediated). Engorgement of epidural veins and the corresponding decrease in the size of the epidural space with advancing gestation may facilitate the spread of local anesthetics.

Uteroplacental and fetal physiology

Uterine blood flow

Uterine blood flow (UBF) increases from approximately 100 mL/min in the non-pregnant state to about 700 mL/min (about 10% of cardiac output) at term. The placenta receives approximately 80% of the UBF and the myometrium 20%. The uterine vasculature has limited autoregulation and is essentially maximally dilated throughout pregnancy. Reduced uterine perfusion pressure, reduced cardiac output, or increased arterial resistance reduces maternal UBF. Decreased perfusion pressure results from systemic hypotension (e.g. hypovolemia, aortocaval compression) and neuraxial or general anesthesia. Decreases in uterine perfusion may result in placental hypoperfusion and fetal hypoxemia and acidosis.

Placental exchange and fetal circulation

The placenta is the interface between the fetal and maternal circulatory systems. Maternal blood is delivered to the placenta by the uterine arteries. Oxygen-poor fetal blood arrives at the placenta via two umbilical arteries, and oxygen- and nutrient-rich blood returns from the placenta to the fetus through a single umbilical vein.

Oxygen transfer to the fetus depends on a variety of factors including: (1) ratio of maternal UBF to fetal umbilical blood flow; (2) oxygen partial pressure gradient; (3) respective hemoglobin concentrations and affinities; (4) placental diffusing capacity; and (5) acid–base status of the fetal and maternal blood (Bohr effect). The fetal oxyhemoglobin dissociation curve is left-shifted (greater oxygen affinity) while the maternal hemoglobin dissociation curve is right-shifted (decreased oxygen affinity). This facilitates oxygen transfer to the fetus. After the first trimester, the fetal–placental blood volume is 120–160 mL/kg, depending on the gestational age [162].

Fetal hypovolemia reduces fetal organ perfusion because the immature sympathetic nervous system and baroreceptor activity are unable to compensate by vasoconstriction. The fetus also has limited capacity to increase cardiac output in response to stresses. Fetuses become rapidly hypothermic when outside the uterus because of transdermal heat loss and immature thermoregulatory vasoconstriction. Fetuses produce their own coagulation factors (which do not cross the placenta). The concentration of these factors increases with gestational age. Despite this increase, fetal blood clotting is less efficient than that in adults.

Maternal–fetal exchange of most drugs and other substances of <1000 Da is principally by diffusion. Transfer of substances across the placenta to the fetus depends on: (1) maternal–fetal concentration gradients; (2) maternal protein binding; (3) molecular weight of the substance; (4) lipid solubility; and (5) the degree of substance ionization. In most instances, the drug concentration in maternal blood is the major determinant of how much drug ultimately reaches the fetus.

Non-depolarizing neuromuscular blockers (large molecular weight and poorly lipid-soluble) and succinylcholine (highly ionized and poorly lipid-soluble) have limited ability to cross the placenta unless given in large doses. Similarly, unfractionated heparin, low-molecular-weight heparins, and glycopyrrolate are highly ionized and do not cross the placenta in significant amounts. In contrast, volatile anesthetic agents, benzodiazepines, local anesthetics, and opioids all have relatively small molecular weights and readily cross the placenta. Weakly basic drugs (e.g. local anesthetics) that cross the placenta in the non-ionized form are ionized in the more acidic fetal circulation and accumulate against a concentration gradient (ion trapping). Therefore, distressed, acidotic fetuses can accumulate high concentrations of local anesthetic. If there is an inadvertent maternal intravascular local anesthetic injection, the fetus often develops bradycardia, ventricular arrhythmia, acidosis, and severe cardiac depression.

The anatomy of the fetal circulation helps decrease fetal exposure to potentially high concentrations of drugs in umbilical venous blood. Approximately 75% of umbilical venous blood initially passes through the fetal liver, which may result in significant drug metabolism before the drug reaches the fetal heart and brain (first-pass metabolism) if the enzymes for metabolism are present (see Chapters 9 and 10). Fetal/neonatal enzyme system activities are lower than those of adults, but most drugs can be metabolized. In addition, drugs entering the fetal inferior vena cava via the ductus venosus are initially diluted by drug-free blood returning from the fetal lower extremities and pelvic viscera. These characteristics of the fetal circulation markedly decrease initial fetal plasma drug concentrations compared to maternal concentrations.

Anesthetic considerations

Adequate uterine blood flow and oxygenation are critical to fetal well-being. Because asphyxiated fetuses cannot increase oxygen extraction, they compensate by redistributing blood flow from the periphery to vital organs. Both hypercapnia and

hypocapnia reduce uterine blood flow, which causes fetal acidosis. In addition to left uterine displacement, normocarbia for the mother (30 mmHg end-tidal CO_2) should be maintained during general anesthesia. When regional or general techniques are used, a FiO_2 of 0.5 or higher is recommended during the procedure. In addition, maintenance of maternal blood pressure near baseline values is critical to fetal well-being. Use of vasopressors and judicious fluid administration are frequently required to maintain normal maternal blood pressure. Despite the historical use of ephedrine, phenylephrine (α-adrenergic) has proven to be a first-line treatment of maternal hypotension when reasonable dosing parameters are used and maternal heart rate is maintained [163].

Impact of anesthesia on the fetus

Of note is the concern for the possible detrimental effect of anesthetic agents on the developing fetal brain. In December 2016, the United States Food and Drug Administration (FDA) issued a safety warning for anesthetic agents that are either γ-aminobutyric acid (GABA) agonists or N-methyl D-aspartate (NMDA) receptor antagonists. The warning specifically states, "repeated or lengthy use of general anesthetic and sedation drugs during surgeries or procedures in children younger than 3 years or in pregnant women during their third trimester may affect the development of children's brains" [164,165]. This warning is based primarily on animal data which suggest there may be a detrimental effect on the developing brain. To date, prospective studies in humans have not definitively supported these findings [166,167]. All volatile anesthetics as well as some intravenous sedatives such as benzodiazepines exert their action by their effect on the GABA receptors. While this warning highlights use of these drugs in pregnant women in the third trimester, the implications for the pregnant mother with a midgestation fetus undergoing *in utero* surgery during which these agents are administered are not clear based on the limited animal studies. As such, some centers that offer fetal intervention or surgery in mid-gestation discuss the FDA warning and the use of inhalational agents with families during the consent process. In addition, based on this warning, attempts are made in some, but not the majority of US fetal treatment centers, to minimize the time of exposure of the mother (and subsequently the fetus) to general anesthesia. Additional intravenous lines, arterial and urinary catheter placement, as well as prepping and draping of the patient, all occur while patient is awake or mildly sedated with non-implicated intravenous agents such as dexmedetomidine or fentanyl. However, it could be argued that the increased maternal pain and stress of performing these procedures prior to induction could also have an impact on both fetal blood flow and chance of preterm labor [168]. Additional discussion of potential anesthetic neurotoxicity in the developing brain is presented in Chapter 46.

KEY POINTS: PHYSIOLOGICAL CHANGES OF PREGNANCY AND ANESTHETIC IMPLICATIONS

- Anesthetic management considerations for fetal surgical procedures are similar those of anesthesia for non-obstetric surgery during pregnancy
- Cardiac output increases 45% by the third trimester, and left uterine displacement is needed to reduce aortocaval compression and improve maternal cardiac output by mid-gestation
- The upper airway has increased capillary engorgement and tissue friability, and minute ventilation is increased by 45–50% at term
- Uterine vasculature has limited autoregulation and is essentially maximally dilated throughout pregnancy

Fetal pain and anesthesia

Whether or when fetuses experience pain and whether fetuses require or benefit from anesthesia for surgical intervention are inadequately understood and remain controversial. Surgical pain is defined as an unpleasant sensory and emotional response to tissue damage and a subjective experience involving cognition, sensation, and affective processes [169]. Although pain is commonly associated with physical noxious stimuli, it is clearly more than nociception or the simple reflex activity of a withdrawal response [170]. Pain is fundamentally a psychological construct that can exist in the absence of physical stimuli (e.g. phantom limb pain). The psychological nature of pain distinguishes it from nociception, which involves activation of nociceptive pathways without the subjective emotional experience of pain. Most definitions of pain suggest the experience is subjective, organized into a conceptual framework, and based on previous painful injuries [169]. While the ability to experience pain must begin at some point and is clearly present in neonates, it is unclear when fetuses actually first feel pain.

Reflex movements and biochemical evidence of a "stress response" can be triggered by a noxious stimulus without involving the cerebral cortex and without conscious pain perception. An example is withdrawal from a noxious stimulus mediated in the spinal cord without conscious perception of pain (Fig. 21.13). This occurs by about 18 weeks' gestational age. Peripheral sensory receptor nociception is transmitted by afferent fibers that synapse on interneurons in the spinal cord and then synapse on spinal cord motor neurons. These motor neurons trigger muscle contractions that cause limb flexion and movement. The stress response can be mediated in the spinal cord, brainstem, or basal ganglia without cortical involvement.

It is generally accepted that experiencing pain requires higher cognitive functioning and cortical recognition that the stimulus is unpleasant. This requires intact neural pathways from the periphery, through the spinal cord, to the thalamus, which relays the stimulus to the primary sensory cortex, the insular cortex, and the anterior cingulated cortex (Fig. 21.14). Peripheral sensory receptor afferents also synapse on spinal cord neurons that project to the thalamus, which relays afferent stimuli to the cerebral cortex and activates many different cortical regions. Sensory receptors and spinal cord synapses required for nociception develop earlier than the thalamocortical pathways required for conscious perception of pain. It is unlikely that fetal perception of pain is possible before pathways from the periphery to the brain and before cortical structures develop. However, the gestational age when pain perception is possible remains unknown.

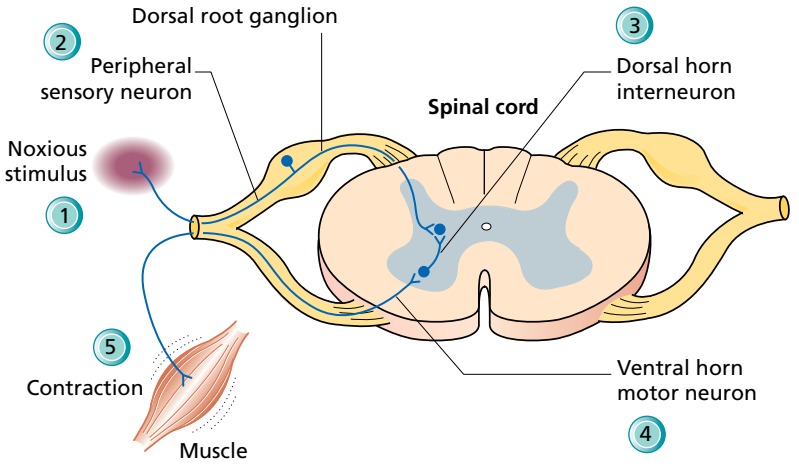

Figure 21.13 Early in development. Reflex responses to noxious stimuli occur before thalamocortical circuits are functional; noxious stimuli trigger reflex movement without cortical involvement. Activated by a noxious stimulus (1), a peripheral sensory neuron (2) synapses on a dorsal horn interneuron (3) that in turn synapses on a ventral horn motor neuron (4), leading to reflex muscle contraction and limb withdrawal (5). *Source*: Reprinted from Lee et al [170] with permission of JAMA.

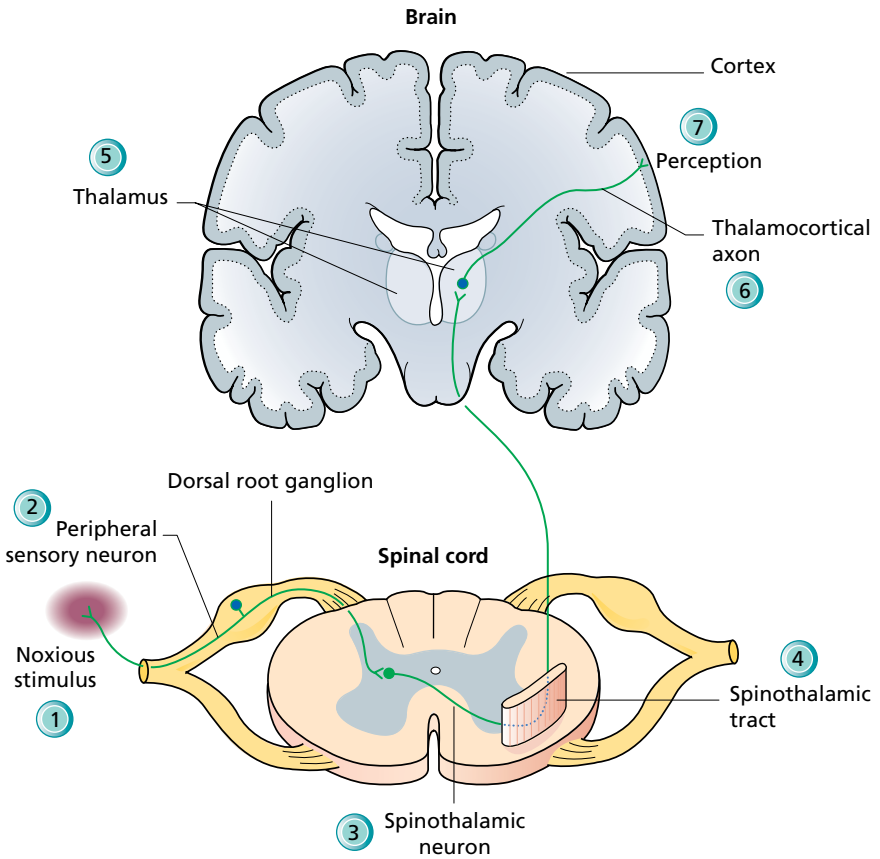

Figure 21.14 Later in development. Noxious stimuli (1) activate peripheral sensory neurons (2) that synapse on spinothalamic tract neurons (3), the axons of which extend up the spinal cord as the spinothalamic tract (4) to synapse on neurons of the thalamus (5). From here, thalamocortical axons (6) synapse on cortical neurons, resulting in the conscious perception of pain (7). *Source*: Reprinted with permission from Lee et al [170] with permission of JAMA.

Nerve terminals for detection of touch, temperature, and vibration (not pain) are present in deep human skin by 6 weeks' gestation and have extended towards the skin surface by 10 weeks [171]. Immature skin nociceptors are likely present by 10 weeks and definitely present by 17 weeks [172]. Nociceptors develop slightly later in internal organs.

Peripheral nerve fibers that control movement first grow into the spinal cord at about 8 weeks' gestation. When these fibers connect with nociceptors is unknown, but in other mammals this is more delayed than other sensory inputs. One human study suggests that nerve fibers from nociceptors do not enter the spinal cord before about 19 weeks [173]. The cerebral cortex develops after the fetal spinal cord and brainstem.

The developing cerebral wall consists of transient fetal zones where neuronal proliferation, cell migration, apoptosis, axonal outgrowth, and synaptogenesis occur according to a highly

specific timetable. Early in development the cerebral cortex is a smooth layer without sulci and gyri and, like the thalamus, has no internal cellular organization [171]. The insular cortex starts developing in humans around 15 weeks' gestation, and the cortical subplate develops at about 13 weeks. The subplate is a temporary structure located one layer deep to the cortical plate. The subplate recedes after 32–34 weeks' gestation, and the cortical plate develops into the six layers of the cerebral cortex [174–176]. The subplate is crucial in cortex development because it serves as a waiting zone for various afferents, including thalamic afferents that are en route to the developing cortex. The subplate is also critical for establishing connections between the thalamus and cortex and for precise organization and laminar relocation of these afferent pathways.

The first fibers from the thalamus reach the subplate by 12 and 18 weeks' gestation and remain in the subplate until cortical plate maturation. By 24 weeks, substantial thalamocortical fibers have amassed in the subplate and have grown into the maturing cortex between 24 and 32 weeks. The gestational age at which thalamic pain fibers reach the human cortex can only be estimated from histological studies of other thalamocortical circuits. Thalamic projections reach the visual subplate at 20–22 weeks [175,177], the visual cortex at 23–27 weeks [178], and the auditory cortical plate at about 26–28 weeks' gestation [179]. The subplate thins in the insula and in areas of the brain where cortical folding occurs early. It disappears after a period of rapid relocation of fibers to the cortex at around 34 weeks' gestation. Massive brain growth and maturation occur after 34 weeks' gestation. This results in the typical cortical sulci and gyri and in development of extensive intracortical pathways and pathways from the cortex to the thalamus, midbrain, and spinal cord.

Given the development of pain pathways and interpretation of cortical function, it is unlikely fetuses experience pain before 24 weeks' gestation (and perhaps significantly later) because the cortex must subsequently undergo considerable development and establish enormously complex and highly integrated neural networking, with dendritic and synaptic rearrangements that occur during late fetal life and infancy and continue into early childhood.

Although development of neural pathways from the periphery to the cortex is important, development of the cortex itself is probably necessary for fetuses to experience pain. The neural networking must also be functional. Although there are no specific electroencephalographic patterns for fetal pain, EEG studies provide some evidence for functionality. Studies at 24 weeks' gestation show the presence of cortical electrical activity only 2% of the time [180]. By 30 weeks, EEG patterns are similar to those of wakefulness and sleep, but they are not continuous and are discordant with fetal behavior. By 34 weeks, electrical activity is present 80% of the time and EEG patterns become more distinct [181–184].

Can the fetus experience pain before there are connections from the periphery to cortex or before there is significant brain electrical activity? Some investigators have postulated that nociceptive information may be transmitted earlier through neurological connections from peripheral tissue through the brainstem and thalamus to the subplate. They argue that the midbrain reticular system is responsible for "consciousness" rather than the thalamocortical system [185]. Although midbrain systems are crucial for the waking state, instincts, orienting, and purposeful behavior, consciousness is widely regarded as a very complex phenomenon for which the cerebral cortex is indispensable. Awareness and wakefulness are different phenomena.

Preterm neonates who undergo surgery with minimal anesthesia have circulatory, sympathoadrenal, and pituitary adrenal responses that are characteristic of stress. These include release of catecholamines, growth hormone, glucagon, cortisol, aldosterone, and other corticosteroids, as well as decreased insulin secretion [186,187]. Anesthesia blunts the neonatal stress response [188]. Opioids also improve the outcome of preterm neonates by attenuating the stress response [189].

In the human fetus, needling of the intrahepatic vein for blood transfusion induces the stress response while needling the insensate umbilical cord does not. This response includes increased plasma β-endorphin and cortisol concentrations and decreased Doppler-determined middle cerebral artery pulsatility index, consistent with redistribution of blood flow to vital organs, including the brain [190,191]. The stress response to intrahepatic vein needling is blunted by 10 μg/kg of fentanyl [192]. Human fetuses elaborate pituitary–adrenal, sympathoadrenal, and circulatory stress responses to noxious stimuli as early as 16–18 weeks' gestation [193,194]. During late gestation, fetuses respond to environmental stimuli (e.g. noises, light, music, pressure, touch, and cold) [195]. However, these physiological stress-related responses or reflexive responses to external stimuli are not necessarily equivalent to the multidimensional, subjective phenomenon we call pain. Reduction in stress hormones is not necessarily indicative of adequate analgesia [196]. The stress response is largely mediated in the spinal cord, brainstem, or basal ganglia, not the cortex.

Two studies used near-infrared spectroscopy to measure changes in cerebral oxygenation over the somatosensory cortex and demonstrated that noxious stimulation of preterm infants caused cortical responses that differed from those of non-noxious stimulation. They concluded that noxious information can be transmitted to the infant cortex from 24 weeks' gestation onward [197,198]. Preterm neonates have cortical evoked potentials after heel lance [199]. Although these studies provide evidence of functional neural activity in the sensory cortex of 24-week-old preterm neonates, the primary sensory cortex is not the only brain area that mediates painful experiences; continued development and organization of the cortex is likely necessary. These were preterm neonates, not fetuses. *In utero*, the low level of oxygen alone may preclude awareness and the ability to experience pain. Furthermore, endogenous neuroinhibitors produced in the placenta (e.g. adenosine, allopregnanolone, pregnanolone, prostaglandin D2, various placental peptide inhibitors) sustain fetal sleep and suppress fetal awareness [200]. Late-gestation fetuses oscillate between REM and NREM sleep 95% of the time. Data suggest that the other 5% of the time they are in a form of indeterminate transitional sleep, suggesting that the fetus is always asleep [201]. Unlike neonates, noxious stimuli do not appear to cause cortical arousal to a wakeful state in fetuses. Wakefulness is a state of arousal mediated by the brainstem and thalamus in communication with the cortex. It must be understood that wakefulness does equal awareness. Thus, the intrauterine environment might keep the fetus from being awake or aware, and from experiencing pain. Maybe awareness is only possible after birth.

Although noxious stimulation might not affect fetal consciousness, it might influence neurological or behavioral development. Circumcision of a non-anesthetized neonate increases the infant's pain response to injections 6 months later, and fetal stress has long-term adverse hormonal effects in young monkeys [202,203]. Consequently, it is possible that noxious stimuli can have adverse long-term neurodevelopmental consequences that could be attenuated or blocked by anesthesia [185], although these effects later in life do not prove that the causal event was experienced as pain.

Anesthetic considerations

Because it is unclear when fetuses feel pain, it seems best to err on the side of providing adequate fetal anesthesia at all gestational ages [204]. Altogether, clinical observations of fetal and neonatal behavior, information about the development of mechanisms of pain perception, and studies of fetal and neonatal responses to noxious stimuli provide a compelling physiological and philosophical rationale for providing adequate fetal anesthesia, especially after 24–26 weeks' gestation. Although we do not know whether or when fetuses experience pain, noxious stimulation causes a stress response, clear evidence that the fetal nervous system is reactive, which could have short- and long-term adverse effects on the developing CNS [205].

Despite unknown fetal capacity for pain perception, fetal anesthesia and analgesia are warranted for fetal surgical procedures. Evidence of fetal pain is unnecessary to justify providing fetal analgesia or anesthesia because doing so serves other purposes, including: (1) inhibition of fetal movement during a procedure; (2) prevention of hormonal stress responses associated with poor surgical outcomes in neonates; (3) prevention of possible adverse effects on long-term neurodevelopment and behavior; and (4) ensuring profound uterine relaxation to prevent contractions and placental separation during open procedures. Anesthesia has been administered to fetuses undergoing surgery since the inception of fetal surgery and continues worldwide.

KEY POINTS: FETAL PAIN AND ANESTHESIA

- Studies as to when fetuses experience pain are not definitive; noxious information can be transmitted to the infant cortex from 24 weeks gestation onward
- Because it is unclear when fetuses feel pain, it seems best to err on the side of providing adequate fetal anesthesia at all gestational ages
- Fetal anesthesia serves other purposes, including inhibition of fetal movement, prevention of hormonal stress responses, prevention of possible adverse effects on long-term neurodevelopment, and ensuring profound uterine relaxation

Perioperative and procedural considerations

Preoperative assessment and considerations

The anesthesiologist should conduct a thorough preoperative assessment of both the mother and fetus. In addition to a standard preoperative history and physical examination, specific details should be obtained regarding how the pregnancy is affecting the mother. The evaluation should include questions about shortness of breath, episodes of syncope or feeling lightheaded, and severity of gastric reflux. Imaging studies should be reviewed because they provide placental location, anatomical information about the fetal lesion, and estimated fetal weight. This information may alter the surgical approach and patient positioning and modify the anesthetic plan. Occasionally general anesthesia might be chosen because maternal position compromises patient safety or the duration of the surgery will be protracted. Most minimally invasive procedures can be performed with just a maternal type and screen, whereas readily available, cross-matched blood is required for open procedures because the risk of hemorrhage is greater. In addition, O-negative, leukocyte depleted, irradiated, CMV-negative blood that is cross-matched against the mother should be readily available for fetuses undergoing open procedures. Maternal IgG antibodies cross the placenta.

Risks and benefits

The primary goal of *in utero* surgery is to improve neonatal outcome compared to interventions performed after birth. The intrauterine environment offers quicker wound healing, decreased scar formation, and an ideal postoperative recovery environment because the placental/fetal circulation provides all of the fetus's nutritional, metabolic, and oxygen requirements.

Risks to the fetus (renal failure, CNS injuries, hemorrhage, chorioamnionitis, demise, postoperative amniotic fluid leaks, membrane separation, abruption, PPROM, preterm labor and delivery) are relatively high. Chorioamniotic membrane separation can cause amniotic bands, umbilical cord strangulation, and fetal demise. Preterm delivery carries significant morbidity and mortality for fetuses that might otherwise benefit from therapeutic interventions if they were born at term.

Maternal safety is of primary concern when developing a fetal management plan. The vast majority of fetal conditions amenable to *in utero* treatment pose no direct maternal risk, but the procedure itself, medications, and possible postoperative complications all carry potential morbidity. Fortunately, serious maternal morbidity is relatively minimal or uncommon [10]. Maternal risks include hemorrhage, wound infection or chorioamnionitis, placental abruption, uterine rupture, and side-effects of tocolytics, including pulmonary edema. In addition, the risks of pulmonary aspiration, difficult ventilation/tracheal intubation, and hemodynamic compromise are increased during pregnancy. Open fetal procedures typically involve a hysterotomy incision that is away from the lower uterine segment, necessitating cesarean delivery for open procedures and all future pregnancies. Future reproductive capabilities do not seem to be compromised [206]. Maternal safety and welfare must be balanced against the risk of fetal death or of caring for a child with a significant morbidity.

Interdisciplinary team

Perioperative care by a multidisciplinary team is essential for success of fetal surgical procedures and care of the mothers. In addition to the anesthesiologist's preoperative assessment, a typical case requires input from ultrasonographers and

radiologists regarding ultrasound and MRI imaging to confirm the diagnosis, detail the abnormal anatomy, and rule out other pathological lesions. Maternal–fetal medicine physicians, geneticists, and neonatologists provide patient counseling, fetal karyotyping, and information about the likely condition of the newborn with or without *in utero* intervention. Fetal surgeons provide details of the procedure and associated risks and outcome potential to the family, and social workers and nurse coordinators address unique family situations, logistics and concerns, and potential psychological issues. Maternal partners are often involved in the process to alleviate potential perceptions of guilt or coercion, depending on the mother's final decision. Regular interdisciplinary meetings with obstetric anesthesiologists, obstetricians, fetal surgeons, neonatologists, maternal–fetal medicine experts, ultrasonographers, operating room staff, nurse coordinators, and social workers allow team communication and provide awareness of patient developments by all caregivers. This maximizes the chances for successful outcomes for both mothers and fetuses. Before undertaking any fetal procedure, members of all disciplines should meet to ensure a complete, detailed, and appropriate plan is in place and needed equipment and personnel are available.

General intraoperative and postoperative considerations

Maternal analgesia and anesthesia for fetal surgery can be provided with local infiltration of the skin and uterine wall, intravenous maternal sedation, neuraxial anesthesia, general anesthesia, or a combination of these techniques.

In addition to the maternal anesthetic plan and the fetal surgical procedure, strategies must be developed for fetal monitoring, fetal analgesia and/or neuromuscular relaxation, management of unanticipated fetal or maternal distress, postoperative fetal and uterine monitoring, and maternal postoperative analgesia. The anesthesiologist must consider the anesthetic requirements of the fetus and appropriate intraoperative fetal monitoring (e.g. fetal heart rate, fetal oximetry, fetal echocardiography, ductus arteriosus flow, umbilical artery flow), and the potential need for fetal intravenous access for fluid resuscitation or blood transfusion. Fetal analgesia and anesthesia can be provided by direct intravenous or intramuscular administration of drugs to the fetus or placental transfer of maternal intravenous agents or general anesthetics. Many anesthetic compounds readily cross the placenta (e.g. induction agents, inhaled anesthetics, opioids, benzodiazepines), but muscle relaxants do so only in small amounts.

Profound uterine relaxation is required for open procedures. Concern for increased uterine tone and initiation of premature labor requires continuous or intermittent postoperative fetal heart rate and uterine activity monitoring, sometimes for days. Maternal postoperative analgesia options include neuraxial opioids, continuous epidural analgesia, patient-controlled intravenous analgesia (PCA), and oral medications.

The anesthesiologist should always be prepared for emergent fetal delivery or uterine evacuation. If maternal cardiac arrest is precipitated by local anesthetic overdose, total spinal anesthesia, or severe hemorrhage, and resuscitation cannot be accomplished in 4 min, the fetus should be delivered emergently even if not viable [207,208]. Emergent cesarean delivery relieves aortocaval compression, improves the effectiveness of resuscitation, and increases the mother's and possibly the fetus's chances for survival.

The following sections are generic descriptions of anesthetic approaches for both minimally invasive and open fetal procedures, and of postoperative management. Approaches vary between fetal treatment centers. The EXIT procedure has been described in the section "*Ex utero* intrapartum treatment procedure" and in the case study at the end of this chapter. Basic anesthetic considerations are similar to those for any woman undergoing surgery during pregnancy [209].

Minimally invasive and percutaneous procedures

Amniocentesis, cordocentesis, intrauterine blood transfusion, needle aspiration of cysts, shunt placement into the fetal bladder or thorax, RFA, and selective fetoscopic laser photocoagulation for TTTS are examples of minimally invasive treatments. These procedures are performed using an ultrasound-guided needle or by inserting a single, small-diameter percutaneous sheath or cannula that allows insertion of an endoscope. Local anesthetic infiltration of the abdominal wall or neuraxial anesthesia is usually adequate. If the procedure involves multiple needle punctures at various locations, large instruments, or a minilaparotomy, neuraxial anesthesia often provides better maternal comfort. Choice of anesthesia technique is based on the surgical approach, anticipated duration of the procedure, and need for postoperative analgesia. Often, the anesthetic is supplemented by minimal or conscious sedation. General anesthesia is rarely necessary. Before the procedure starts, the mother should be appropriately fasted, receive aspiration prophylaxis, have adequate intravenous access, and be fully monitored.

Use of local or neuraxial anesthesia does not provide fetal analgesia or immobility. Supplemental analgesia (opioids), anxiolysis (midazolam), and sedation (low-dose propofol infusion) provided to the mother will sedate her and may provide some fetal immobility and analgesia following placental transfer. A randomized, blinded, controlled trial demonstrated that remifentanil (0.1 μg/kg/min) resulted in more fetal immobility and better surgical operating conditions compared to diazepam [92]. Any maternal sedation regimen must ensure that the mother remains within a level of "conscious sedation" to minimize maternal respiratory depression, loss of maternal airway reflexes, and pulmonary aspiration risk.

Fetal immobilization is unnecessary for certain minimally invasive fetal procedures, such as laser surgery of the chorionic plate (e.g. SFLP for TTTS). However, fetal movement may compromise the success of certain procedures by making them technically difficult or impossible. As an example, in the case of cordocentesis or intrauterine transfusion, fetal movement may be hazardous because displacement of the needle may cause trauma and bleeding, compromise procedure success, and even necessitate emergent delivery. If the procedure requires fetal immobility, muscle relaxants can be administered directly to the fetus. Non-depolarizing neuromuscular blocking agents can be administered to the fetus by ultrasound-guided intramuscular or umbilical venous

administration of rocuronium (2.5 mg/kg IM, 1 mg/kg IV) or vecuronium (0.2 mg/kg IM, 0.1 mg/kg IV). Fetal paralysis with either agent occurs in 2–5 min, with a 1–2 h duration. For long procedures, redosing may be necessary.

For procedures involving noxious stimulation of the fetus (e.g. shunt catheter placement, cardiac septoplasty), intramuscular or intravascular opioid (e.g. fentanyl 10–20 μg/kg) can be administered to the fetus [192]. If general anesthesia is administered to the mother, placental transfer of inhaled anesthetic is sufficient to adequately immobilize and anesthetize the fetus. However, fetal muscle relaxant is often administered if fetal immobility is critical for procedure success.

A plan should be in place for treatment of fetal distress and should include having available weight-appropriate doses of drugs on the sterile field for fetal resuscitation (e.g. atropine 20 μg/kg, epinephrine 1 μg/kg and 10 μg/kg). Persistent fetal bradycardia during minimally invasive procedures may require an emergency cesarean section if the gestational age is compatible with extrauterine viability. Consequently, the anesthesiologist must be prepared to emergently provide general anesthesia for cesarean delivery.

Open fetal surgical procedures

In utero procedures that require a maternal laparotomy and hysterotomy (e.g. open MMC repair, sacrococcygeal teratoma resection) are typically performed under general anesthesia. In addition to the anesthetic considerations required for minimally invasive fetal surgery and for maternal surgery during pregnancy, open fetal procedures have unique considerations. These include: (1) the need for profound uterine relaxation; (2) increased potential for significant maternal or fetal blood loss or fluid shifts; (3) intraoperative fetal monitoring, fetal anesthesia, and the potential need for fetal resuscitation; and (4) postoperative maternal analgesia and prevention of preterm labor. Box 21.2 details specific considerations to be addressed before undertaking open fetal surgery. The majority of these items are also useful when planning for minimally invasive and EXIT procedures.

A non-particulate oral antacid is administered preoperatively for aspiration prophylaxis, indomethacin is administered for tocolysis, and an epidural catheter is placed for postoperative analgesia. Type and cross-matched blood products are obtained for both mother and fetus. Sequential compression devices are placed on the mother's lower extremities to minimize the risk for deep venous thrombosis. Similar to what occurs when any general anesthetic is administered after about 20 weeks of gestation, the patient is positioned with left uterine displacement, adequately preoxygenated, and rapid-sequence induction and tracheal intubation are performed during cricoid pressure. Prior to incision, anesthesia is typically maintained with low concentrations of volatile agent and/or a propofol infusion. During this time, the ultrasonographer determines fetal presentation and placental

Box 21.2: Considerations for open fetal surgery

Preoperative considerations

1. Maternal counseling by multidisciplinary team
2. Complete maternal history and physical examination
3. Imaging studies to define fetal lesion and placental location
4. Complete fetal work-up to exclude other anomalies or karyotype abnormalities
5. Surgical meeting or "time-out" with all team members prior to starting
6. Prophylactic premedication: non-particulate antacid (aspiration) and rectal indomethacin (tocolysis)
7. Blood products typed and cross-matched for potential maternal and fetal transfusion
8. High lumbar epidural catheter placement for postoperative analgesia
9. Sequential compression devices on lower extremities for thrombosis prophylaxis
10. Fetal resuscitation drugs transferred to scrub nurse in unit doses
11. Emergent delivery plan if fetus considered viable for birth

Intraoperative considerations

1. Left uterine displacement and standard monitors
2. Fetal assessment prior to maternal induction
3. Preoxygenation for 3 min prior to induction
4. Rapid-sequence induction and intubation
5. Maintain maternal FiO_2 at ≥50% and end-tidal CO_2 at 28–32 mmHg
6. Ultrasonography to determine fetal and placental positioning
7. Urinary catheter placed and additional large-bore intravenous access obtained
8. Administer prophylactic antibiotics
9. Following incision, initiate high concentrations of volatile anesthetics (2–3 MAC) to achieve uterine relaxation, or an alternate SIVA technique relying on remifentanil and propofol infusions with a reduced volatile anesthetic (1–2 MAC).
10. Consider intravenous nitroglycerine if uterine tone remains increased
11. Maintain blood pressure near baseline with intravenous phenylephrine or ephedrine
12. Intramuscular administration of fetal opioid and paralytic with ultrasound guidance or by direct vision
13. Place fetal pulse oximeter and use periodic ultrasound for fetal monitoring
14. Obtain fetal vascular access if significant fetal blood loss is expected
15. Restrict maternal fluids to <2 L to decrease risk of pulmonary edema
16. Administer loading dose of intravenous magnesium sulfate when uterine closure begins
17. Discontinue halogenated agents after magnesium sulfate bolus complete
18. Activate epidural for conclusion of surgery and postoperative analgesia
19. Administer nitrous oxide and opioids to supplement epidural anesthesia during fascia and skin closure
20. Close monitoring of neuromuscular blockade due to potentiation of magnesium sulfate
21. Extubate trachea when patient is fully awake

Early postoperative considerations

1. Postoperative debrief with team members
2. Continue tocolytic therapy
3. Patient-controlled epidural analgesia
4. Monitor uterine activity and fetal heart rate
5. Ongoing periodic fetal evaluation

MAC, minimum alveolar concentration; SIVA, supplemental intravenous anesthesia.

location, additional large-bore vascular access is obtained, the urinary bladder is catheterized, and prophylactic antibiotics are administered.

For both open and EXIT procedures, 2–3 MAC of volatile anesthetic agent is frequently used to provide maternal and fetal anesthesia and the surgical tocolysis (uterine atony) required for the procedure. Volatile anesthetic agents inhibit myometrial contractility by calcium-sensitive potassium channel modulation [210]. The human uterus has a thick, muscular layer that is sensitive to stimulation or manipulation, and stimulation may produce strong uterine contractions. Complete uterine relaxation is essential because increased uterine tone compromises uterine perfusion and increases the risk for partial placental separation. Because high levels of volatile anesthetic are associated with abnormal fetal cardiac function, some fetal centers use supplemental intravenous anesthesia with a lower MAC of halogenated agent (1–1.5 MAC) combined with propofol and remifentanil infusions [211–213]. High intravenous doses of nitroglycerine may also be used as a supplemental or primary agent for intraoperative uterine relaxation [214].

Prior to hysterotomy, the uterus is assessed for increased tone. If increased uterine tone is noted before or after incision, the halogenated agent can be increased (up to 3 MAC) or additional intravenous nitroglycerin can be given in small boluses (50–200 μg IV) or by continuous infusion. If nitroglycerine is used without high concentrations of volatile anesthetic, an intravenous infusion of up to 20 μg/kg/min may be required [214]. Arterial blood pressure is maintained with intravenous phenylephrine or ephedrine as needed to maintain adequate mean arterial pressures near maternal baseline. Maternal monitoring by arterial line and central venous catheter is not typically required, but may be used at some centers. Cross-matched blood for the mother and O-negative, CMV-negative, leukocyte-reduced, irradiated blood for fetal transfusion should be readily available in the operating room. For open procedures with the potential for significant fetal blood loss (e.g. sacrococcygeal teratoma resection), close attention to fetal monitoring and estimated fetal blood loss is required. It may be necessary to insert a fetal intravenous catheter to transfuse blood. Vascular access is obtained in a fetal hand or arm vein, or by surgical cut-down on the internal jugular vein.

Intraoperative ultrasound is used to determine placental location and fetal position. The uterine incision is made away from the placenta, but in a position that allows for appropriate exposure of the fetal part. A stapling device with absorbable lactomer staples is used to prevent excessive bleeding and seal the membranes to the endometrium [215]. During surgery, the exposed fetus and uterine cavity are bathed with warm fluids.

With ultrasound guidance or direct vision, opioid (e.g. fentanyl 10–20 μg/kg) and muscle relaxant (e.g. rocuronium 2.5 mg/kg) are administered to the fetus intramuscularly before the fetal incision is made [93]. Drugs for fetal resuscitation (atropine 20 μg/kg, epinephrine 1 μg/kg and 10 μg/kg) are transferred to the scrub nurse in sterile fashion for administration by the surgeon (if needed) under the direction of the anesthesiologist. Each syringe is prepared with a single, unit weight-based dose and appropriately labeled.

Maternal and fetal anesthesia, uterine incision, fetal manipulation, and surgical stress may adversely affect uteroplacental and fetoplacental circulation by several mechanisms. Maternal hypotension increases uterine activity and causes maternal hyperventilation and hypocarbia, which impair uteroplacental and/or umbilical blood flow. Manipulation of the fetus may affect cardiac output, regional distribution of cardiac output, and/or umbilical blood flow. Direct compression of the umbilical cord, inferior vena cava, and/or mediastinum adversely affects fetal circulation. Fetal well-being is assessed by continuous fetal pulse oximetry, periodic fetal heart rate (FHR) monitoring by intraoperative ultrasonography, and fetal echocardiography for assessment of ventricular contractility, flow in the ductus arteriosus, and/or umbilical artery flow.

During surgical closure, a loading dose of magnesium sulfate is administered (4–6 g) intravenously over 20 min and is followed by an intravenous infusion of 1–2 g/h to maintain uterine quiescence and prevent postoperative contractions. Intraoperatively, maternal intravenous fluids are restricted to minimize the risk of postoperative pulmonary edema, which is associated with the use of tocolytic agents [12,216,217]. Inspired concentrations of volatile agents are significantly decreased or discontinued once the magnesium sulfate bolus has been administered. Maternal anesthesia can be maintained with a combination of fentanyl, propofol, and/or nitrous oxide, and activation of epidural anesthesia. This regimen facilitates timely tracheal extubation of a fully awake patient and minimizes the likelihood of coughing or straining and jeopardizing the integrity of the uterine closure. If neuromuscular agents are utilized, the absence of neuromuscular blockade should be determined prior to tracheal extubation, since magnesium sulfate potentiates neuromuscular blockade.

Whatever anesthetic technique is used for open fetal surgery, it must ensure adequate uteroplacental perfusion, profound uterine relaxation, maternal hemodynamic stability, fetal anesthesia and immobility, and minimal fetal myocardial depression and compromise.

Postoperative management

Management of postoperative preterm labor has been one of the most difficult aspects of fetal surgery, but prevention and treatment of uterine contractions is essential for optimal fetal outcomes. Postoperative tocolysis has included a variety of agents, including magnesium sulfate, β-adrenergics, indomethacin, and calcium-entry blockers. Magnesium likely competes with calcium at voltage-operated calcium-sensitive potassium channels by an action similar to volatile anesthetics [210]. Indomethacin blocks the synthesis of prostaglandins, and β-adrenergic agents act directly on the uterus by activating adenylate cyclase and thereby reducing intracellular calcium. The relative inefficacy of tocolytic agents and their adverse side-effects have made this aspect of postoperative management challenging. Tocolysis is normally unnecessary after cordocentesis or intrauterine transfusion, but tocolytics are used at most centers for more invasive percutaneous procedures (e.g. shunt catheter placement, endoscopic techniques). With open fetal procedures, early postoperative uterine contractions are expected and tocolysis is provided by a continuous infusion of magnesium sulfate for approximately 24 h. This is supplemented with indomethacin and occasionally with terbutaline or nifedipine as indicated.

Postoperative analgesia can be provided for several days by continuous epidural analgesia or by intravenous opioids by

PCA. Effective analgesia may help prevent preterm labor by decreasing plasma oxytocin levels [218]. Other postoperative concerns include preterm labor, PPROM, infection, and fetal complications that include heart failure, intracranial hemorrhage, chorioamnionitis, indomethacin-induced constriction of the ductus arteriosus, and fetal demise. Uterine activity and FHR are monitored closely during the first few postoperative days. The fetus is typically evaluated daily by ultrasonography and echocardiography looking for ductal narrowing, cardiac valvular function, and oligohydramnios. In rare cases MRI is used to determine the presence of fetal intracranial hemorrhage.

KEY POINTS: PERIOPERATIVE AND PROCEDURAL CONSIDERATIONS

- Thorough preoperative assessment and multidisciplinary planning is necessary for all fetal interventions
- Anesthetic techniques vary from local anesthesia with or without sedation to neuraxial anesthesia to general anesthesia to a combination of these techniques.
- Profound uterine relaxation is necessary for open procedures

Future of fetal therapy and surgery

The future of fetal diagnosis and therapy is bright and provides many opportunities for advances that benefit the fetus and perhaps adults with diseases that originate during fetal development. In the future, prenatal fetal stem cell and gene therapy hold promise for possible treatment of hemophilia disorders, cystic fibrosis, and muscular dystrophy [219].

In the future it is likely that the majority of fetal surgical interventions will be performed percutaneously, using imaging or endoscopic guidance. Although use of minimally invasive techniques will simplify anesthetic management, many issues remain unresolved because research in this area is difficult. The potential neurotoxicity of anesthetic agents in the fetal and neonatal brain, impact of surgical stress on the fetus and/or later in life, prevention of preterm labor, standards of intraoperative fetal monitoring, and optimal anesthetic techniques are among the many issues that require further evaluation. Future advances in fetal therapy and surgery require careful consideration of potential fetal benefit and fetal risk and, most importantly, maternal risk. Maternal safety remains a paramount concern for the anesthesiologist.

CASE STUDY

An ultrasound diagnosis of a large (>6 cm) fetal neck mass, consistent with a cervical teratoma, was made in 25-year-old, gravida 1 woman at 32 weeks' gestation. The mother was otherwise healthy, and no other anatomical abnormality was detected in the fetus. The ultrasound images and patient's history were discussed at the weekly multidisciplinary fetal treatment conference, and it was decided to re-evaluate the fetus in 2 weeks. The planned delivery strategy was by EXIT procedure at 38 weeks' gestation after confirming fetal lung maturity by amniocentesis. Concern was expressed that it would not be possible to intubate the trachea by direct laryngoscopy during the EXIT procedure, given the massive size of the lesion. No significant changes occurred in the mother during the ensuing 2 weeks, and she was admitted at 38 weeks' gestation for amniocentesis. The EXIT procedure was scheduled for the following morning. All team members were notified and their availability confirmed by the perinatologists who performed amniocentesis for fetal lung maturity.

Before entering the operating room, all team members participated in a pre-procedure conference to ensure the availability and readiness of all necessary equipment and personnel, and to discuss the surgical plan, issues specific to the case, and potential complications that might arise. In preparation for the procedure, the anesthesiologists checked maternal and fetal drugs and their doses, and ensured a manometer, sterile manual ventilation system, and separate source of oxygen supply were available for ventilating the fetal lungs once an airway was established. The anesthesiologists had a second pulse oximeter and sterile probe for fetal monitoring. They also prepared a combination of paralytic agent and opioid to administer to the fetus and transferred the sterile drugs in one labeled syringe to the scrub nurse. Similarly, with an estimated fetal weight of 3 kg, two doses of atropine 60 μg each, two doses of epinephrine 30 μg each, and two doses of epinephrine 3 μg each were prepared in labeled syringes for emergent administration to the fetus, if needed. The scrub nurse ensured the appropriate surgical equipment was available, as well as sterile laryngoscopes, bronchoscopes, a Jackson Rees non-rebreathing circuit, endotracheal tubes, cables and sensors for pulse oximetry, including transparent adhesive medical dressing to secure the oximeter and an opaque cover to shield the oximeter sensor from the surgical lights.

The mother was premedicated with 30 mL of sodium citrate before entering the operating room. A preinduction "time-out" was completed, and a high lumbar epidural catheter was placed for postoperative pain control. She was then positioned supine and left uterine displacement was initiated to prevent aortocaval compression by the gravid uterus; 100% oxygen was administered by tight-fitting facemask while pulse oximeter, arterial blood pressure cuff, and electrocardiogram leads were applied. The fetus was evaluated by ultrasonography and was noted to be in a cephalic presentation; the fetal heart rate was 130 beats per minute with appropriate variability. After denitrogenation of the mother's lungs and application of cricoid pressure, rapid-sequence induction of anesthesia was performed with propofol and succinylcholine and the trachea was rapidly intubated. Once tracheal intubation was confirmed by auscultation and by normal-appearing carbon dioxide end-tidal waveform tracings, sevoflurane was

administered. A urinary catheter and a second large-bore intravenous catheter were placed. Prophylactic antibiotics were administered, and her abdomen was prepped and draped. The fetal surgeon, perinatologist, and neonatologist positioned themselves around the surgical table and the equipment was readied. The neonatologist passed the oxygen supply line to the fetal breathing circuit and an additional catheter for connection to the manometer over the drape to the anesthesiologist. Together they ensured the integrity and dynamics of the circuit, with a pop-off valve set for 15 cm water pressure to avoid iatrogenic pneumothorax when fetal ventilation was initiated. The pulse oximeter cable was passed over the drape and connected to the second oximeter. The sensor was tested to ensure all connections were intact.

Following a Pfannenstiel incision, the sevoflurane concentration was increased and was 1.9 MAC at the time of the hysterotomy. No vasopressor support was required to maintain the mean arterial pressures above 65 mmHg (maternal baseline). The uterus was visualized and palpated to assess tone. Since it was not sufficiently relaxed, the inspired concentration of sevoflurane was increased. The ultrasonographer determined the location of the placenta so the surgeons could avoid it during hysterotomy. After 5 min, the end-tidal sevoflurane concentration was 2.6 MAC, the mother's vital signs were stable, the fetal heart rate was 130 beats/min, and the uterus was appropriately relaxed. A purse string suture was placed in the uterine wall and an incision was made that was just large enough to insert a uterine stapler to divide the myometrium and membranes and to apply absorbable staples to seal the edges of the hysterotomy and provide hemostasis. Given the somewhat anterior location of the placenta, the hysterotomy was performed near the uterine fundus using the "classical" uterine incision, which will require all future babies to be delivered by cesarean section without a trial of labor.

Once the uterus was opened, a mixture of 30 μg fentanyl and 7.5 mg rocuronium was administered into the fetus' left triceps muscle. The fetal head and upper thorax were delivered, and the pulse oximeter was placed across the fetus' left palm, secured with a transparent adhesive dressing, and covered with an opaque dressing to shield the sensor from the surgical lights. The pediatric surgeon, neonatologist, and anesthesiologist were unable to visualize airway structures by laryngoscopy and bronchoscopy (Fig. 21.15). Initially, a decision was made to perform a tracheostomy, but this was considered unwise given the enormity of the neck lesion. Instead, during the next 2 h the teratoma was excised while the fetus was maintained on placental support and monitored by pulse oximetry. Peripheral venous access was obtained in the left arm (Fig. 21.16). After the teratoma was resected, it was necessary to perform a tracheostomy. After the airway was secured, positive pressure ventilation was initiated with peak pressures of 15 cmH_2O and a positive end-expiratory pressure of 4 cmH_2O. The fetal oxygen saturation rapidly increased, and when it exceeded 90% the umbilical cord was clamped and cut and the newborn was delivered to the awaiting neonatal resuscitation team for further care. Blood gases from a doubly clamped segment of the umbilical cord were normal and showed no evidence of acidosis.

After cord clamping, sevoflurane was discontinued, an infusion of oxytocin was started, intravenous fentanyl (150 μg) was administered, and a propofol infusion (125 μg/kg/min) was initiated. A test dose was administered through the epidural catheter. Following the negative test dose, epidural bupivacaine (0.125%) with 2 μg/ml fentanyl was administered. Following closure of the uterus and abdomen, the patient awakened, was extubated, and had no significant pain. She received 2 L of crystalloid, no colloid or blood, and had 200 mL of urine output and an estimated blood loss of 650 mL. Over the first 36 postoperative hours, analgesia was provided with epidural analgesia.

The mother did well without any perioperative complications. The pathology confirmed a teratoma, and the neonate had an excellent outcome.

KEY POINTS

- Most fetal malformations diagnosed *in utero* are not appropriate for fetal intervention
- Detailed anatomical information regarding airway mass and placental position is needed for appropriate patient selection and optimal outcome
- Thorough preparation and planning for unanticipated emergent events (e.g. fetal bradycardia, maternal hemorrhage) is critical for a successful outcome
- Maternal safety is a primary consideration and maternal risks must be weighed against potential fetal benefit
- Successful fetal procedures require a multidisciplinary team effort in which detailed preoperative planning and discussion among all team members is crucial
- Preterm PROM and preterm labor remain significant obstacles to ideal outcomes from fetal surgery

In addition, it provides retrospective evidence that this decreased level of volatile anesthetic may better preserve fetal cardiac function.

CHAPTER 22
Anesthesia for Premature Infants

George A. Gregory
Department of Anesthesia and Perioperative Care, University of California San Francisco, San Francisco, CA, USA

Introduction

Preoperative evaluation of premature neonates is the most important part of anesthesia. During this time the anesthetist determines what abnormalities are present, gathers information from the intensive care nursery (ICN) team, and makes plans to care for the infant during the perioperative period. This chapter provides information about premature infants, preoperative evaluation, and provision of anesthesia. This information is the basis for understanding the physiology and pathophysiology of preterm neonates, which is necessary for effective evaluation of these patients for surgery and for providing appropriate care for them.

Background

About 10% of infants are born prematurely, i.e. <37 weeks' gestation [1]. The more immature they are at birth, the more likely they are to die during the neonatal period and to have serious complications, especially neurological complications. Great strides have been made in reducing the mortality rate, even in very small infants. It is now expected that at least 60–70% of infants weighing <750 g at birth will survive [2]. With this increased survival has come a host of complications that often require surgery, including patent ductus arteriosus (PDA), retinopathy of prematurity (ROP), necrotizing enterocolitis (NEC), intraventricular hemorrhage (IVH) with hydrocephalus, and inguinal hernias, to name a few.

Most body organs undergo continuous structural and functional development during the last 3 months of gestation. Infants born prematurely have inadequately developed organs that are required to perform functions that may be beyond their capacity. Consequently, preterm infants are less able to maintain their body temperature, suck, swallow, eat, and sustain breathing. Many of them experience asphyxia at or just before birth, predisposing them to central nervous system injury, IVH, NEC, myocardial dysfunction, and the respiratory distress syndrome (RDS).

Preterm infants can be divided into three groups: borderline premature (34–37 weeks' gestation); moderately premature (32–33 weeks' gestation); and severely premature ("micropremies," 28–31 weeks' gestation). The problems of each group increase in number and severity with decreasing gestational age [3].

Late preterm

Seven percent of all livebirths and 71% of preterm births are late preterm infants (34^0–$36^{6/7}$ weeks' gestation) and can often be cared for in the normal neonatal nursery [1]. However, they do require close observation for the first 12 h of life, because, as a group, they have more difficulty maintaining their body temperature without added external heat, and they may not suck and feed well. Those born at 34 weeks' gestation require neonatal intensive care unit (NICU) admission 50% of the time for maintenance of body temperature, cardiorespiratory monitoring, and management of complications of prematurity (RDS, transient tachypnea of the newborn (TTN), and apnea). If feeding is a problem, gavage feeding may be required for a few days, and these infants may be slow to regain their birthweight, especially if they have RDS. Eight percent of borderline premature infants born by cesarean section have RDS versus 1% of those born vaginally, probably because vaginal birth more effectively removes water from the lungs [4,5].

Because they are predisposed to respiratory distress, the respiratory system of near-term infants must be carefully evaluated during the preoperative visit. Intercostal

Gregory's Pediatric Anesthesia, Sixth Edition. Edited by Dean B. Andropoulos and George A. Gregory.

retractions, tachypnea, grunting respirations, and cyanosis suggest RDS but also may be signs of meconium aspiration, pneumothorax, or pneumonia in these large preterm infants. Temperature instability and hyperbilirubinemia suggest sepsis but are usually just manifestations of prematurity.

Moderate prematurity

Moderately premature infants (32–33 weeks' gestation) account for about 1.2% of all births [1]. The neonatal mortality of infants born at 32 weeks' gestation is below 5%, whereas it is nearly zero at 36 weeks' gestation when there are no congenital anomalies. The major causes of death are intracranial hemorrhage, sepsis, and RDS. As in late preterm infants, the incidence of RDS, TTN, pneumonia, and pulmonary hypertension is higher in moderate prematurity. Apnea of prematurity is significantly increased in this group due to brainstem immaturity and to greater compliance of the upper airway and chest wall that leads them to collapse more easily on inspiration. As a result, maldistribution of ventilation and perfusion are common. Hypoglycemia and jaundice are more common than in larger neonates.

Very and extremely premature infants (micropremies)

Infants of 28–31 weeks' gestation are very preterm, and those less than 28 weeks' gestation are extremely premature infants. Infants of 24–31 weeks' gestation make up about 1.6% of all liveborn infants [1]. However, they account for more than 70% of neonatal mortality. They also account for a major portion of neurologically damaged children later in life. The causes of death include birth asphyxia, acidosis, and respiratory failure (congestive heart failure, PDA, RDS, infections, especially β-streptococcus and listeria), NEC, and intracranial hemorrhage. All the problems of prematurity are exaggerated in these very immature infants who really are fetuses living outside the womb. Studies are underway to develop an artificial womb that may reduce some of these problems.

About one of 200 term infants, one of 20 moderately premature infants, and one of two infants weighing less than 1 kg at birth suffers birth asphyxia. Preterm fetuses are more prone to asphyxia than term fetuses because the preterm infant's blood oxygen content is lower (due to lower hemoglobin concentrations) than that of term infants. Slight degrees of stress lead to anaerobic metabolism and metabolic acidosis, which in turn reduce cardiac output and increase cerebral blood flow. The latter may damage the central nervous system (CNS) if it causes the fragile vessels of the periventricular areas of the brain to bleed [6,7]. Causes of asphyxia include antepartum hemorrhage, intrauterine infections, breech delivery, and RDS. Treatment of birth asphyxia has been described elsewhere [8].

Most extremely premature infants are asphyxiated at birth and often require tracheal intubation and assisted ventilation or nasal continuous positive pressure breathing (nCPAP) as part of delivery room resuscitation. It has been hoped that early application of nCPAP will avoid some of the complications of tracheal intubation and mechanical ventilation, although this is unproven [9]. However, early nCPAP does reduce the number of infants who require mechanical ventilation by approximately 50% [10] and does reduce bronchopulmonary dysplasia and death on meta-analysis [11]. Because these infants frequently have both metabolic and respiratory acidosis, they often require mechanical ventilation, blood volume expansion, and, if necessary, a slow, cautious infusion of enough sodium bicarbonate or tris(hydroxymethyl)aminomethane (THAM) to correct their pH to 7.3.

Ventilation should be controlled during sodium bicarbonate infusion, which should never be infused more rapidly than 1 mEq/kg/min. Rapid infusion of bicarbonate may quickly expand the intravascular volume, raise the arterial blood pressure, and increase the $PaCO_2$, all of which can cause intracranial hemorrhage in premature neonates. Fifty mL of sodium bicarbonate (50 meq) produces 1250 mL of CO_2 when the bicarbonate is fully reacted with hydrogen ions. This is of little consequence if the lungs are normal and can easily excrete the additional CO_2. If the lungs are abnormal, the $PaCO_2$ may rise rapidly and cause IVH or cardiac arrest. Artificial ventilation to increase CO_2 removal can prevent these complications. What is considered an "adequate" $PaCO_2$ has changed over the years. Many preterm neonates now undergo "permissive hypercapnia" with $PaCO_2$ as high as 70 mmHg if the pH is 7.2 or above [12]. However, data supporting the use of hypercapnia are lacking. Allowing hypercapnia has not reduced the incidence of chronic lung disease [13]. Compensation for the hypercapnia includes bicarbonate retention and a positive base excess. In this situation, if the $PaCO_2$ is reduced to normal, the attendant alkalosis decreases cerebral blood flow and may also decrease the ionized calcium concentration, myocardial function, and arterial blood pressure.

In the past, hypoglycemia was partly responsible for the increased incidence of CNS damage in small preterm infants [14]. Fortunately, hypoglycemia is less common today because blood glucose concentrations are maintained between 50 and 90 mg/dL, not 20–40 mg/dL as in the past. Hyperglycemia is also to be avoided because fewer hyperglycemic patients can be resuscitated from a cardiac arrest, and those who are resuscitated have more CNS damage [15]. Hyperglycemia also causes an osmotic diuresis and can cause hypovolemia. Unlike older patients, premature infants spill glucose in their urine with blood sugar concentrations as low as 125 mg/dL.

KEY POINTS: INTRODUCTION AND BACKGROUND: THE PREMATURE INFANT

- Ten percent of infants are born prematurely, i.e. before 37 completed weeks of gestation
- Seven percent of infants are late preterm, born at 34–36 weeks' gestational age
- Some 1.2% of infants are moderately preterm, born at 32–33 weeks' gestational age
- Very preterm (28–31 weeks' gestation) and extremely preterm (less than 28 weeks) comprise about 1.6% of livebirths, but more than 70% of neonatal mortality

Common problems associated with prematurity

The following are some problems associated with prematurity. While they are covered more fully in other chapters, they are presented here to give an overview of the problems and to provide a means of organizing one's thoughts when planning anesthesia for a preterm infant.

In general, anesthesia for premature infants is fraught with problems because they often have multisystem disease and respond poorly to anesthesia. To reduce the risk, it is important to garner as much information preoperatively as possible. A common mistake, especially among novice anesthetists, is to ignore the fact that those caring for the infant in the NICU have considered the patient's problems over an extended period of time and have come to a plan of therapy based on an understanding of these problems. It is neither appropriate nor sensible to alter this plan, unless there is an urgent reason to do so, without thorough discussions with the neonatologists.

Temperature regulation

Hypothermia, or even a short exposure to a cold environment, increases the metabolic rate and oxygen consumption of preterm infants, which can cause hypoxemia, acidosis, apnea, or respiratory distress and is a risk factor for infant mortality [16]. The minimal oxygen consumption of preterm infants is 4.3–5.4 mL/kg/min on day 1 and 8–9 mL/kg/min by 2 weeks of age [17]. As the oxygen consumption increases, so do the ventilation and caloric requirements. Body heat is dissipated by conduction, convection, radiation, and evaporation. During mechanical ventilation, heat and liquid are lost from the lungs, especially when dry gases are used in the operating room. This heat loss can be avoided by using warmed, humidified gases. The surface/volume ratio of preterm infants is high, and their flaccid, open posture tends to increase heat loss rather than conserve it. The preterm neonate's lack of insulating fat allows more heat loss from the core to the surface.

Evaporative heat loss accounts for approximately 25% of the heat lost in term neonates and adults. Brück [18] showed that preterm neonates can vasoconstrict and increase heat production when exposed to cold, but they still lose heat because they lack insulation and their overall heat production is lower. The rise in metabolic rate in preterm neonates is approximately linear between 28° and 36°C [17]. Extremely low birthweight neonates do not have subcutaneous fat nor do they peripherally vasoconstrict appropriately, which is a problem in cold operating rooms [19].

Young infants become agitated and move more in response to cold. Serum norepinephrine concentrations increase, which stimulates brown fat metabolism and heat production. The increased heat produced warms the CNS and vital organs [20]. Primitive brown fat cells begin to differentiate from reticular cells at 26–30 weeks' gestation [21] and increase in size and number for 3–6 weeks after birth. Infants born before the cells fully develop have more difficulty maintaining their body temperature when exposed to cold environments, as do hypoglycemic infants and those with CNS damage.

Because small premature infants lose heat and water through their thin, transparent skin, they easily become dehydrated, especially when cared for under a radiant warmer and are fluid restricted. Covering the premature infant's body with clear plastic film, and the head with a cap, significantly reduces both heat and water loss, as does warming and fully humidifying the inspired gases to 34–37°C [22,23]. The addition of forced air warming systems, circulating water blankets, and room temperature of 30°C provides maximal efficiency in reducing dry heat loss [24].

The clinical consequences of chilling include periodic breathing or apnea, bradycardia, metabolic acidosis, hyperglycemia, and aspiration of gastric contents. Fewer infants nursed in non-neutral thermal environments survive [25]. Those who survive gain weight more slowly. Maternal anesthesia (general) and neonatal fentanyl analgesia cause hypothermia in some infants, while morphine or conduction anesthesia do not [26].

Respiratory manifestations

Respiratory distress

Respiratory distress is common in preterm infants. It occurs three times more often after cesarean section than after a vaginal birth. The less mature the infant, the more severe the disease tends to be, although some very immature infants escape this affliction, especially if given surfactant shortly after birth or if there was chorioamnionitis [27]. Survival of preterm infants depends on their size and gestational age. Moderately premature babies (1500–2500 g) with RDS require more support of ventilation and fewer of them survive than their larger counterparts. Despite their small size, more than 95% of the former should survive. Eighty-five percent of those weighing less than 1000 g and about 80% of those weighing less than 750 g now survive. Administration of exogenous pulmonary surfactant at birth has increased survival and decreased serious complications [28,29]. This rapidly improves lung function, which can lead to pulmonary gas leaks and lung injury if ventilation pressures are not decreased appropriately. The increased lung compliance improves oxygenation, which increases the likelihood of both ROP (see section "Retinopathy of prematurity") and inflammatory lung damage. Thus the FiO_2 must also be rapidly reduced to acceptable levels (SaO_2 of 87–94%).

In addition to surfactant administration, in recent years ventilation strategies have changed in premature infants with RDS in an attempt to reduce the incidence and severity of bronchopulmonary dysplasia (BPD – see section "Bronchopulmonary dysplasia"). Targeting lower SpO_2 of 87–94% instead of 95–98%, employing nCPAP instead of endotracheal intubation, and limiting positive pressure ventilation by allowing permissive hypercapnia have all been shown to reduce the severity of RDS and the incidence of BPD. In contrast, high-frequency oscillatory ventilation does not improve RDS or reduce incidence of BPD. Routine treatment with dexamethasone resulted in a lower severity of lung disease and less BPD; however, it is associated with increased risk of intestinal perforation, cerebral palsy, and neurodevelopmental impairment so its use has greatly diminished in recent years [30]. Finally, inhaled nitric oxide in infants less than 1250 g, when administered for 14 days, resulted in significantly greater BPD-free survival in one large multicenter study, and did not adversely affect long-term neurodevelopmental outcomes [31].

Bronchopulmonary dysplasia

Many preterm infants develop chronic lung disease (BPD) as a result of mechanical ventilation, oxygen administration, infection, inflammation, or a combination of these factors [32]. The number of infants with BPD is increasing because more 500–750 g infants now survive [33,34]. Today's BPD differs from that described by Northway et al [35]. Many of today's preterm infants have no oxygen requirement above that of room air and normal lung function for a few days after birth, probably because of prenatal steroids and/or the administration of surface-active material after birth. Lung function then deteriorates, often in association with pulmonary infections [36], the oxygen requirements increase, and respiratory failure develops. The deterioration is made worse if the child has a PDA [36]. Furthermore, the chronic lung disease (CLD) of today's smaller infants has changed [37]. Today's CLD consists of simplified lungs, increased alveolar size, decreased alveolar number, and dysplastic pulmonary vasculature [38,39]. The end-result of these lung abnormalities is maldistribution of ventilation and perfusion, hypercarbia, hypoxemia, and occasionally the need for prolonged mechanical ventilation. Later in life, if these infants require surgery, their lung function [40] and gas transfer will be reduced [41]. Positive end-expiratory pressure (PEEP) and furosemide 0.5–1 mg/kg every 6–12 h are frequently used to treat pulmonary edema and improve gas exchange. However, furosemide often causes metabolic alkalosis, especially if these babies are not given sufficient potassium and chloride. CO_2 is retained to compensate for the alkalosis. Reducing the $PaCO_2$ may cause severe alkalosis, reduced arterial blood pressure, and reduced cerebral blood flow (Fig. 22.1). Some preterm infants require higher ventilator pressures (tidal volumes) and oxygen concentrations during surgery, but many have improved ventilation and reduced oxygen requirements. During surgery, many infants can be ventilated with room air to maintain appropriate oxygen saturations. Although an oxygen saturation of 87–94% is considered (hoped) to be safe, the infant's PaO_2 would be 30–40 mmHg were they still *in utero*.

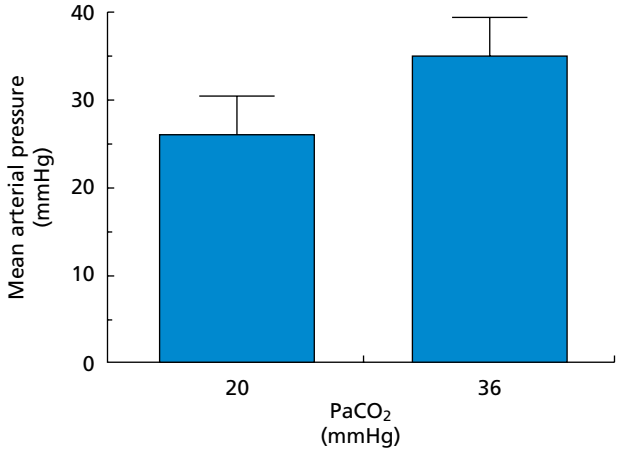

Figure 22.1 The effects of alkalosis on mean arterial pressure in premature infants. Ventilation was maintained constant and CO_2 was added to raise the $PaCO_2$ to normal.

Apnea

Periodic breathing (cessation of breathing for <15 s) and apnea (cessation of breathing for >20 s or <20 s with a decrease in SaO_2 plus bradycardia) are common in preterm infants, especially after the first week of life [42]. The incidence of apnea is inversely related to postconceptual age [43]. Apnea occurs in <2% of preterm infants after they reach 40 weeks of gestation [44]. The causes of apnea are multiple and include anemia (hematocrit <30%), hypo- and hyperthermia, hypo- and hyperglycemia, hypo- and hypercalcemia, hypo- and hypervolemia, decreased functional residual capacity, PDA, constipation, hypothyroidism, poorly developed control of respiration, excessive handling and stimulation, birth trauma, maternal drugs (narcotics), seizures, infections, and congenital heart disease. However, the primary cause of apnea of prematurity is immaturity of the CNS. Repeated apnea increases the likelihood of CNS damage due to repeated episodes of hypoxemia [45]. Infants who had apneic spells in the ICN usually must be ventilated from the time anesthesia is induced. Giving caffeine 5 or 10 mg/kg IV before surgery reduces or prevents postoperative apnea and oxygen desaturation, especially in patients who have had previous apneic spells, a hemoglobin concentration below 10 g/dL, or pre-existing CNS injury [46].

Moderately premature infants, especially those recovering from RDS and those requiring mechanical ventilation, may have chronic lung disease. If they do, the $PaCO_2$ is frequently elevated and the PaO_2 or SaO_2 decreased during room air breathing. (Alveolar oxygen decreases 1 mmHg for each 1 mmHg increase in CO_2.) Overexpansion of the lungs of premature infants should be avoided, as this may injure their lungs [47,48].

Patent ductus arteriosus

Fifty percent of full-term infants close their ductus arteriosus by 24 h of age and almost all of them do so after 72 h [49]. Most preterm infants of 30 weeks' gestation or more close their ductus arteriosus by 96 h of age. However, the ductus arteriosus of 70–80% of smaller preterm infants frequently remains open [50,51] and symptoms of a PDA often appear between the third and fifth day after birth [52]. Infants treated with surfactant at or near birth may have a significant PDA within a few hours of birth as the lungs expand and pulmonary vascular resistance decreases. A PDA murmur is usually heard at the left upper sternal border and is often continuous. It is loudest during exhalation or apnea, and its intensity is increased by hyperventilation. Patients with a PDA have bounding pulses and a widened pulse pressure (Fig. 22.2).

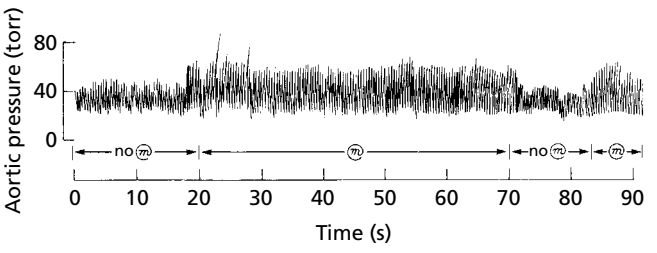

Figure 22.2 Aortic blood pressure of a preterm infant during periods when a patent ductus arteriosus was present and was absent. Note the widening of the pulse pressure and elevated arterial pressure when the murmur was present. *Source*: Courtesy of Dr Joseph A. Kitterman.

A gallop rhythm may be present. Up to 70% of extremely low birthweight infants receive some therapy (drugs, surgery) for their PDA.

As the left-to-right shunt increases, so does the pulmonary blood flow. If the heart cannot keep up with the increased demand for cardiac output, congestive heart failure (CHF), manifested by increased respiratory failure (intercostal retractions, diminished breath sounds, poor air entry, rales), tachycardia, and a gallop rhythm develop. The PaO_2 decreases and the $PaCO_2$ rises. Apnea, increasing requirements for oxygen and mechanical ventilation, and a widened pulse pressure are often the earliest signs of a PDA. Signs of heart failure often appear before a murmur is heard [53] and if the ductus arteriosus is very large, no murmur is heard. In this case, a PDA is usually detected by changes in oxygenation, increased need for mechanical ventilation, and an echocardiogram.

The initial treatment of a PDA is medical, which includes fluid restriction [54,55] (occasionally to the point of dehydration) and administration of cyclo-oxygenase inhibitors, indomethacin and ibuprofen [56,57], and diuretics. Indomethacin has greatly reduced the number of patients requiring surgical closure of a ductus arteriosus, but it has not reduced the incidence of CLD or CNS injury [58].

If fluid restriction prevents adequate calorie intake, surgical ligation of the ductus arteriosus is usually undertaken. Early closure of the ductus arteriosus (either with indomethacin or surgically) allows earlier weaning from mechanical ventilation and initiation of feeding within a few days after surgery. Several studies have demonstrated increased incidence of death and CNS injury in preterm infants who have undergone ligation of a PDA [59–61]. However, these studies failed to account for confounding problems present before surgery. After accounting for these factors, Weisz et al found no evidence of increased morbidity, CNS injury, CLD, or ROP in children who underwent ductus ligation [62].

A second reason to close a patent PDA early is to reduce the incidence of NEC [63]. With large PDA shunts, as much as 80% of the cardiac output is shunted away from the systemic circulation and into the lungs, leaving little blood for the remaining body. Because the gut of neonates is one of the first organs to be deprived of blood during periods of low systemic blood flow, it is the shock organ in neonates. The use of prostaglandin synthetase inhibitors has not decreased the incidence of NEC, but early ligation of the PDA may do so. Early detection and treatment of a PDA was associated with reduced in-hospital mortality and pulmonary hemorrhage. There were no differences in NEC, BPD, or CNS lesions [64].

Central nervous system injury

Premature infants have two predominant forms of CNS injury. The most common in very premature infants is periventricular white matter injury, which is a leading cause of later cerebral palsy. The pathophysiology is incompletely understood, but the immature oligodendrocyte precursors are exquisitely sensitive to a number of common insults, including hypoxemia, hypotension, and inflammation [30]. The arterial supply to these areas is not fully developed, leading to vulnerability to ischemia. In addition, because of the fragile state of the developing vascular supply in the germinal matrix, these vessels are prone to rupture, causing the common complication of IVH. Grade I IVH is confined to the germinal matrix, grade II IVH occurs when bleeding extends to the cerebral ventricles, grade III IVH involves ventricular dilation, and grade IV IVH includes parenchymal extension of the bleed. Grades III and IV IVH may lead to hydrocephalus requiring ventriculoperitoneal shunting, a common procedure in premature neonates. Chapters 8 and 25 discuss pathogenesis and treatment of these disorders in more detail. Recent data suggest that the type of injury has changed from cystic lesions to impaired cerebral growth of neurons and glia, not cell death [65].

Infection

Infections (e.g. pneumonia, sepsis, and meningitis) are common in preterm infants, especially those who are moderately or severely preterm, because both their cellular and tissue immunity are reduced. Although the signs of sepsis are often subtle, sepsis is suspected if the infant is hypo- or hyperthermic (despite a neutral thermal environment), lethargic, mottled, gray, or apneic. If, despite a constant infusion of glucose, the serum glucose concentration increases, sepsis should be suspected. Laboratory examinations may be helpful but preterm infants are often septic without positive blood cultures, elevated white blood cell (WBC) counts, or fevers. In fact, this is more often true than not. The presence of an abnormal WBC count, whether increased or decreased, is diagnostically helpful (Table 22.1). A shift to the left toward neutrophil predominance is also helpful, but this is not always present. Band counts in excess of 15% are abnormal and are a good indicator of infection in preterm infants [66]. Cerebrospinal fluid (CSF) should contain fewer than one WBC per 200 red blood cells (RBCs), although an absolute count of 70 WBC/mm^3 may be normal [67]. The concentration of glucose in the CSF should be at least 50–60% of that in the blood. Urine should contain fewer than five WBCs per high-power field. A bladder tap urine specimen should be devoid of WBCs.

Preterm infants respond appropriately to antibiotics, although the dosage and interval between doses often must be altered (see Appendix A). Aminoglycosides may cause muscle weakness or paralysis and act synergistically with non-depolarizing muscle relaxants to increase their effect. The hearing loss may be worse if the baby is simultaneously exposed to loud noise (as occurs in a busy ICN) [68].

Necrotizing enterocolitis

NEC is a common surgical emergency, especially in tiny preterm infants [63,69]; 20–50% of patients with this problem die [70–72]. The onset of NEC is usually between 27 and 34 weeks' gestation [73], but it can occur in term infants. The most common associations with NEC are prematurity, feeding per os, excessive feeding, and overgrowth of the bowel with non-normal bacterial flora [74,75]. There may also be genetic factors at work [76]. An infant who suddenly develops abdominal distension, vomiting, bloody stools, reducing substances in the stool, and shock should be suspected of having NEC. Shock occurs because large amounts of fluid are translocated into the peritoneal cavity, gut, and other tissues and because of bacterial toxins. Radiographs of the abdomen demonstrate distended loops of bowel, air in the bowel wall and, if the

bowel has perforated (which occurs about one-third of the time), free air in the peritoneal cavity. Such infants are extremely ill (often moribund), hypovolemic, and require fluid resuscitation with blood, colloid, fresh-frozen plasma, platelets, and large volumes of saline or lactated Ringer's solution prior to surgery if they are to survive (sepsis and bleeding are common problems). The volume of fluid required for resuscitation is often enormous. Administering the quantity of fluid needed to accomplish volume resuscitation often worsens any respiratory failure present and increases the need for mechanical ventilation. Infants with NEC should be started on IV broad-spectrum antibiotics preoperatively. Most survive, although about 10% of those who survive have short gut syndrome [77]. Many infants with NEC have cerebral palsy, severe neurological delay, and mental retardation, which may complicate anesthesia later in life [78]. Their treatment with aminoglycosides may cause hearing defects [68].

Hematological manifestations

Preterm infants are frequently anemic because their ability to produce RBCs is reduced and because their caregivers frequently take blood for tests. Compensatory responses include tachycardia, increased cardiac output, and increased extraction of oxygen from blood. If the oxygen demand is unmet, lactic acidosis occurs. Low iron stores and inadequate iron intake worsen the anemia. The amount of transfusion can be reduced by delayed cord clamping at birth, milking (stripping the cord), and drawing all NICU baseline blood studies from the placenta [79]. This may be important because NEC occurs more commonly in very low birthweight infants if they are transfused, as does IVH when they are transfused early [80]. As long as preterm infants have respiratory or cardiovascular problems, their hemoglobin levels should probably be maintained at or above 10 g/dL by blood transfusions from a limited number of units of packed RBCs and by the administration of epoetin alfa. A hemoglobin concentration of 14–15 g/dL is more likely to reduce the number of apneic spells and the CHF associated with a PDA than a hemoglobin of 8–10 g/dL. One study found that limiting transfusion was associated with higher rates of CNS hemorrhage, periventricular leukomalacia, and apnea [81] but another study failed to find these problems [82]. It is probably unwise to begin surgery for preterm infants if their hemoglobin concentration is <10 g/dL unless forced to do so by an absolute emergency. Transfusion of blood with adult hemoglobin, besides raising the hematocrit, shifts the oxygen dissociation curve to the right, which improves oxygen delivery to the tissues.

The WBC count of normal preterm infants is shown in Table 22.1. At birth, the WBC is higher than at later ages; it decreases over the first week of life. Stress can elevate the WBC count to 40,000–50,000/mm^3. Septic neonates either increase or decrease their WBC.

Erythropoietin (EPO) is produced in the kidney and regulates erythropoiesis. Growing fetuses have high levels of erythropoiesis, a relatively high hematocrit, and predominant synthesis of hemoglobin F (fetal hemoglobin). The high concentrations of EPO present at birth decline relatively rapidly. The concentration of hemoglobin decreases over time and causes many preterm infants to be anemic. Phibbs et al [83] showed that giving 100 μg/kg of recombinant human erythropoietin intravenously to anemic preterm infants twice weekly for 6 weeks increased the reticulocyte counts (and RBCs) faster than a placebo and did not suppress subsequent release of endogenous EPO. The need for blood transfusions was reduced.

On rare occasions, premature infants are polycythemic. If the hematocrit exceeds 65%, an exchange transfusion may be required before surgery to prevent occlusion of their renal, portal, or cerebral veins, especially if the patient becomes hypovolemic and/or hypotensive during surgery. If it is necessary to operate on a polycythemic child, sufficient fluid must be administered during surgery to maintain a normal or slightly increased intravascular volume. Hypotension must be treated immediately.

Nutrition and growth

Premature infants frequently have difficulty sucking effectively for some time after birth and require intermittent or continuous gavage feedings. While their gastric capacity and gastrointestinal motility are adequate to accept the

instilled food, they often have difficulty absorbing their feeds. As a result, intravenous fluids and nutrition are commonly required. Infants who will not be fed orally for 3 or 4 days after birth usually receive intravenous feedings with glucose 12.5%, protein (amino acids) 2–3 g/kg/day, and lipids 3 g/kg/day within the first few hours of life [84]. From this diet they derive 80–100 kcal/kg/day, depending on the volume of fluid infused, which is usually sufficient to maintain positive nitrogen balance, prevent tissue breakdown, and allow some growth (albeit inadequate). Attempts to feed asphyxiated infants early are often associated with NEC or abdominal distension and regurgitation of gastric contents. When this occurs, oral feedings are usually discontinued for 5–6 days. While enough free water is required to maintain normal intra- and extravascular fluid volumes, administering more than 130–150 mL/kg/day increases the likelihood of a PDA, congestive heart failure, and the risk for NEC. Electrolytes (3 mEq/kg sodium, 2 mEq/kg potassium, 200–500 mg/kg calcium gluconate) and vitamins (including vitamin E) should be administered in the maintenance fluids. Because antibiotics kill gut flora, vitamin K 0.2 mg is administered twice weekly as long as the patient is receiving antibiotics [85]. Failure to do this increases the risk of bleeding during surgery.

Serum chemistry determinations

Calcium

During the last trimester of pregnancy, fetal concentrations of calcium exceed those of the mother [86]. At birth, the maternal supply of calcium is withdrawn and the baby's serum calcium concentration decreases, often to 7.5–8.5 mg/dL. If the baby takes in sufficient calcium, the levels increase after several days. Despite the low concentrations of total calcium, ionized calcium concentrations are normal (because serum protein concentrations are lower, at 3–4.5 g/dL). Consequently, total serum calcium concentrations above 7 mg/dL are adequate if ionized calcium concentrations are normal [87]. Phosphate and magnesium concentrations are similar to those of term infants.

If the patient has symptoms of hypocalcemia (e.g. twitching, seizures, hypotension), calcium gluconate 10–30 mg/kg is administered slowly intravenously. Hyperventilation (alkalosis) decreases the unbound fraction of calcium, which can lower the seizure threshold. Despite the presence of hypocalcemia, the electrocardiogram (ECG) is usually normal.

Sodium

The serum sodium concentrations of tiny preterm infants are labile. They rise quickly with dehydration and decrease just as quickly with overhydration. Hypernatremia can damage the CNS, and hyponatremia (<120 mEq/L) can cause seizures. Water intoxication is usually associated with persistent hyponatremia. Hypertonic saline is seldom required to correct hyponatremia; fluid restriction usually suffices.

Glucose

Most neonatologists attempt to maintain the postnatal nutrition of preterm infants at or above their requirements during fetal life in the hope of maintaining normal growth. This goal is seldom met for many reasons [88]. Glucose provides most of the energy for many organs, including the brain. Most non-anesthetized larger preterm infants tolerate an infusion of 5–7 mg/kg/min of glucose without developing hyperglycemia, glucosuria, polyuria or dehydration, but many extremely low birthweight infants (23–25 weeks' gestation) require at least 10 mg/kg/min to maintain normoglycemia and growth. The only way to know the serum glucose concentrations is to measure them frequently, especially in the operating room. Excessively high serum glucose concentrations (>200 mg/dL) can cause an osmotic diuresis, hypovolemia, and possibly CNS injury [89,90]. With adequate nutrition, preterm infants gain 25–30 g/day and increase their head circumference by 0.8–1 cm/wk. It may, however, be difficult to provide sufficient nutrition to achieve this growth for myriad reasons. The level of nutrition and weight gain should be determined carefully before surgery because infants with poor preoperative nutritional states often tolerate anesthesia and surgery less well.

The blood glucose concentrations of many preterm infants are below 40 mg/dL, which constitutes hypoglycemia. If present, hypoglycemia should be corrected with 10–20% dextrose 2–5 mL/kg over 5 min and with a continuous infusion of sufficient dextrose to maintain the glucose concentration between 50 and 90 mg/dL. Many preterm infants have an SaO_2 of 80–90%. However, if they are hypoglycemic and anemic in addition to having their SaO_2 at these low levels, their growth rates are often reduced [91]. Care should be taken to avoid inducing hyperglycemia because it may lead to dehydration, reduced ability to resuscitate from cardiac arrest, and increased CNS injury.

Bilirubin

Because they conjugate substances less well, preterm infants often have higher serum bilirubin concentrations, especially infants who are bruised, polycythemic, or have intracranial, gastrointestinal, or pulmonary hemorrhage. The relative hypoproteinemia, the decreased effectiveness of the blood–brain barrier, and the often-present acidemia increase their susceptibility to kernicterus – brain injury secondary to the direct neurotoxic effects of prolonged high serum unconjugated bilirubin concentrations. Even low concentrations of bilirubin (10–15 mg/dL) are sufficient to produce kernicterus in acidotic infants [92–94]. It may be necessary to do a two-volume exchange transfusion before surgery if the patient's indirect bilirubin concentration is elevated and if time permits, because intraoperative hypoxemia and acidosis may prove disastrous (Table 22.2). It is important to determine the neurological status of preterm infants preoperatively because many of them have CNS injury that may later be attributed to anesthesia.

Retinopathy of prematurity

Fifty percent of infants weighing 1000–1500 g at birth have some degree of ROP [95]. Seventy-eight percent of those weighing 750–999 g have ROP, and more than 90% of those weighing less than 750 g have some degree of ROP. ROP is rare in term infants. Of extremely low birthweight infants weighing 500 g or less, 80–85% have some degree of ROP and 40% of them have severe ROP [96]. ROP is divided into five stages [97].

Table 22.2 Serum bilirubin concentrations for exchange transfusion

Birthweight (g)	Serum bilirubin concentrations for exchange transfusion (mg/dL)	
	Normal infants†	Abnormal infants‡
<1000	10.0	10.0§
1001–1250	13.0	10.0§
1251–1500	15.0	13.0
1501–2000	17.0	15.0
2001–2500	18.0	17.0
>2500	20.0	18.0

These guidelines have not been validated.
† There have been case reports of basal ganglion staining at concentrations considerably lower than 10 mg.
‡ Normal infants are defined for this purpose as having none of the problem listed below.
§ Abnormal infants have one or more of the following problems: perinatal asphyxia, prolonged hypoxemia, acidemia, persistent hypothermia, hypoalbuminemia, hemolysis, sepsis, hyperglycemia, elevated free fatty acids or presence of drugs that compete for bilirubin binding, and signs of clinical or central nervous system deterioration.

- Stage 1: a thin white line separates the posterior vascularized portion of the retina from the anterior avascular retina.
- Stage 2: the demarcation line increases in volume and elevates. At this point it is known as the "ridge." The changes found in stage 1 and 2 regress in 80% of patients. Between 5% and 10% of premature infants with stage 1 and 2 disease progress to stage 3 [98].
- Stage 3: tissue proliferation develops from the ridge, usually posteriorly. Stage 3 can be mild, moderate, or severe, depending on the volume of the extraretinal tissue [97].
- Stage 4: partial retinal detachment occurs with the macula still attached (stage 4a). The macula is detached in stage 4b.
- Stage 5: total retinal detachment occurs in stage 5.

ROP begins with retinal blood vessel constriction, reduced vascular endothelial growth factor (VEGF), and retinal hypoxia [99]. The retinal hypoxia stimulates VEGF production and vascular proliferation, hemorrhage, and (in the worst cases) retinal detachment. While oxygen is a major contributing factor to the development of ROP, it is not the only factor. It is unknown what levels of oxygenation cause ROP, but a PaO_2 of 150 mmHg for as little as 1–2 h (the length of many surgical procedures) has done so. It is also possible that ROP might develop at considerably lower PaO_2s because the retinas of preterm infants, were they still *in utero*, would be exposed to a PaO_2 of 25–40 mmHg, not 50 mmHg or more, as often occurs after birth. Preterm infants whose SaO_2 was maintained between 80% and 96% for the first several postnatal weeks had less ROP than those with higher SaO_2 [99]. Interestingly, after 31 weeks' gestation, an SaO_2 of 94–99% was required to reduce the risk of further retinal damage. At this age the lower oxygen concentrations and mild hypoxia were adding to the retinal hypoxia. After discussion with the neonatologist, it may be appropriate to maintain higher oxygen saturations in *this specific group* of patients during surgery.

Hypoxia inducible factor-α (HIF-1α) is important in normal retinal development and is suppressed by increased oxygenation. This allows a decrease in the VEGF concentration and initiates retinal hypoxia and ROP. Increasing HIF-1α prevents ROP in animals [100]. The left-shifted oxygen dissociation curve of fetal hemoglobin (HbF) releases less oxygen to the tissues, which may protect the retina. Transfusion with adult blood may increase the risk of developing ROP because the relatively right-shifted oxygen dissociation curve releases more oxygen. Chorioamnionitis and neonatal systemic inflammatory disease also increase ROP [101].

Vitamin E and omega-3 fish oils may protect against ROP by their membrane-stabilizing and antioxidant actions [102,103]. While vitamin E concentrations normally decrease rapidly after birth, due to inadequate intake and storage of vitamin E, administering more than physiological amounts of vitamin E to premature infants has little beneficial effect and may increase the incidence of NEC and infection [104,105].

Approximately 85% of acute ROP undergoes spontaneous regression [106]. Grades 1 and 2 regress in 2–3 months, while grade 3 regresses in 6 months or more. Grade 4 and 5 ROP results in blindness or limited vision in approximately 25% in infants who were at high risk for retinal detachment [107].

Patients with ROP come to the anesthetist's attention because they require an eye examination, photocoagulation, or scleral buckling under anesthesia. It is unknown if exposure to increased oxygen concentrations during anesthesia worsens pre-existing ROP. Because we do not know, it is better to keep the SaO_2 during anesthesia at the same levels present in the ICN, usually between 87% and 94% [108]. Because many of these patients also have CLD and maldistribution of ventilation and perfusion, their SaO_2 can rapidly decrease with the induction of anesthesia. Adding a small amount of PEEP (2–5 cmH_2O) often improves both the match of ventilation-perfusion and oxygenation. Excessive PEEP may overdistend the ventilated portions of the lung and decrease oxygenation. Aoyama et al and Jiang et al have published sensible plans for anesthetizing patients with ROP [109,110]. They point out that many patients require postoperative mechanical ventilation and ICU care after surgery, even if they did not require them preoperatively. Ulgey et al demonstrated a significant reduction in the need for mechanical ventilation following retinal surgery by using an infusion of propofol plus ketamine [111]. Because the surgeons often inject air into the eye during surgery, it is best to use air as the carrier gas for inhaled anesthetics and avoid using nitrous oxide.

KEY POINTS: COMMON PROBLEMS ASSOCIATED WITH PREMATURITY

- Respiratory distress syndrome and bronchopulmonary dysplasia severity has decreased in recent years with routine surfactant administration, permissive hypercapnia, and non-invasive ventilation strategies
- Patent ductus arteriosus may be seen in up to 70–80% of small preterm infants, but medical therapy (fluid restriction, diuretics, cyclo-oxygenase inhibitors) has significantly reduced the incidence of surgical closure

- Periventricular white matter injury and intraventricular hemorrhage are common causes of CNS injury and long-term neurodevelopment problems in premature infants
- Necrotizing enterocolitis is a significant problem, usually between 27 and 34 weeks' gestation, and carries a 20–50% mortality
- Retinopathy of prematurity is a significant cause of loss of visual acuity; its incidence can be lessened with lower SpO_2 management, i.e. 87–94% in small premature infants

Preoperative preparation

History

During the preoperative visit, the patient's chart must be read, understood, and thoroughly discussed with the physicians and nurses caring for the patient. It is the nurses who stand at the bedside 24 h a day and provide the patient's minute-to-minute care. They know the idiosyncrasies of each patient. For example, the nurses may know that very brief periods of apnea cause severe hypoxemia and cyanosis or that the patient's perfusion decreases when his blood glucose concentration is <40 mg/dL or when the ionized calcium concentration is below 0.9 mmol/L.

Both the fetal and birth histories are important when planning an anesthetic for preterm infants. If the infant was asphyxiated before or at birth, the effects of asphyxia (right ventricular dysfunction, coagulation abnormalities, intracranial hemorrhage, etc.) may still be present. Autoregulation of the cerebral circulation may be absent [7,112,113]; if so, sudden increases in arterial pressure may rupture fragile cerebral vessels and cause intracranial hemorrhage [114].

Myocardial function may still be depressed, and the heart may show signs of hypoxic strain, including insufficiency of the tricuspid valve. Blood flow to the gut may be reduced. Both the blood volume and the hemoglobin concentration may be low if they were not corrected. These abnormalities can persist for several days after birth.

A maternal medication history should be sought in every case because many pregnant women take prescription or nonprescription drugs. A few use illicit drugs, and the baby may be undergoing drug withdrawal at the time of surgery. The symptoms of narcotic withdrawal include agitation, tremors, poor feeding, vomiting, and occasionally seizures. Infants withdrawing from barbiturates, diazepam, or methadone may only do so at 5–10 days of age. Fetuses who are repeatedly exposed to cocaine, which causes premature delivery, may also have pulmonary hypertension and bowel perforation. Infants born after maternal ingestion of large doses of aspirin or acetaminophen may have pulmonary hypertension and persistent fetal circulation (PFC) during the first few days of life [115,116]. PFC must be considered in any severely hypoxemic infant.

Systems review and examination

Head, eyes, ears, nose, and throat

Congenital anomalies of the face and mouth are common, either as part of a syndrome or as a lone entity. A cleft palate may be missed when infants are mechanically ventilated from birth. If the anesthetist must reintubate the patient's trachea, a cleft palate may make this more difficult because the tongue cannot be fixed against the palate and flops over the laryngoscope blade, obstructing the anesthetist's view of the glottis. The small mouth and the relatively large tongue of preterm infants frequently obstruct breathing, especially when pressure is applied to the submental triangle while holding an anesthesia mask on the patient's face. Even slight pressure in this area can completely obstruct the airway. Anesthesia masks with large air-filled cuffs are dangerous if they slip off the bridge of the nose and compress the nares while the mouth is being held closed. Most babies are obligatory nasal breathers for several months after birth [117]. A nasogastric tube (NGT) obstructs half of the unintubated infant's upper airway when the mouth is closed. This often increases respiratory work and leads to apnea during the induction of anesthesia. NGTs should be removed and reinserted orally if necessary. Atropine, if administered to patients with some types of cataracts or with glaucoma, may increase the intraocular pressure and further damage the eye (see Chapter 35).

Pulmonary system

As stated above, pulmonary dysfunction is common in preterm infants. Therefore, the pulmonary system must be evaluated carefully before anesthesia and surgery. Answers should be sought to the following questions.

- Does the patient now have or is he/she recovering from RDS? If so, how much support of breathing is required? What are the ventilator rates, pressures (peak-inspired and end-expiratory), inspired oxygen concentrations, and inspiratory times? Is the patient breathing spontaneously during mechanical ventilation? Is he/she triggering inspiration by the ventilator? What SaO_2, blood gas, and pH values do spontaneous breathing or the ventilator settings occasion? How labile are the blood gases? Do the blood gases and pH change when the patient is moved from side to side or onto the back or abdomen [118], when the trachea is suctioned, or when the chest is percussed [119]? It may be a problem if the patient must be turned into the lateral position for surgery and this position causes deterioration of the blood gases and pH.
- Has the patient had a pulmonary hemorrhage? If so, has the bleeding stopped and are there residual effects of the bleeding?
- Is pneumonia present? Pneumonia may be difficult to differentiate from RDS, pulmonary edema, or CLD on radiograph. A WBC count, a differential WBC count, and a smear of the tracheal secretions may be helpful in making this differentiation. If the infant has pneumonia, the tracheal smear will show both WBCs and bacteria. Either finding alone is seldom significant.
- Is the endotracheal tube (ETT) fixed securely in place? Accidental extubation of the trachea on the way to the operating room is disconcerting. Tape used to hold the ETT in place should not completely encircle the infant's head to avoid causing brainstem hemorrhage [120].
- Does the infant have intercostal retractions? Most preterm infants have grade 1-of-4 to 2-of-4 retractions because their chest walls are not fully developed. Those with pulmonary disease have grade 3-of-4 to 4-of-4 retractions. Retractions indicate increased work of breathing, decreased lung compliance, increased airway resistance or all three.

- Can rales be heard? Most preterm infants have occasional rales. Moist rales indicate intra-alveolar fluid, usually associated with pulmonary edema or infection. Dry rales are usually associated with atelectasis. Rhonchi are also common, especially after several days of tracheal intubation.
- Are there secretions? White or clear secretions seldom contain significant amounts of bacteria. Yellow, green, or brown secretions, on the other hand, often indicate infection. Frothy, pink, or blood-tinged secretions are usually indicative of pulmonary edema or pulmonary hemorrhage.

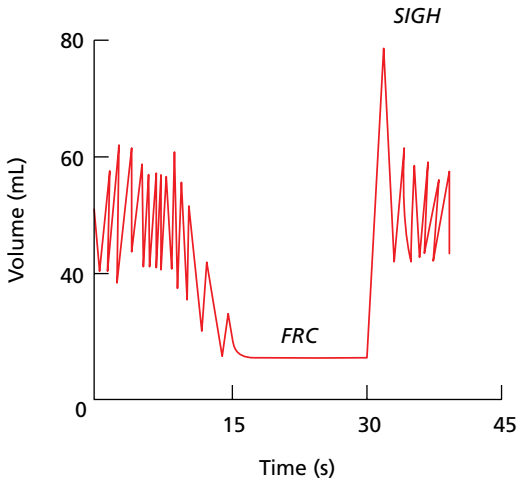

Figure 22.3 Changes in functional residual capacity (FRC) with bradypnea and apnea. *Source*: Reproduced from Gregory [121] with permission from Wolters Kluwer.

Preterm infants normally breathe 30–60 times per minute. However, those with lung disease can have respiratory rates of 150 breaths/min or more, especially when lung compliance is reduced. Babies "choose" to breathe rapidly and shallowly rather than slowly and deeply, probably because the metabolic cost of breathing rapidly and shallowly is less. Rapid respirations help maintain the functional residual capacity by not allowing sufficient time for complete exhalation. Unless PEEP is applied, slow respiratory rates decrease functional residual capacity (Fig. 22.3) [121].

Evaluating blood gas and oxygen saturation data gives important clues to the patient's responses to ventilatory maneuvers. Preterm infants normally have lower PaO_2 than term babies (Tables 22.3 and 22.4). Therefore, small changes in PaO_2 cause large changes in oxygen saturation and in oxygen content [122]. Brief periods of apnea lead to hypoxemia. Is the patient having apneic spells (see section "Retinopathy of prematurity")? Apneic spells are often indicative of other problems. If the infant is having or has had apnea, he/she may have postoperative apnea and require mechanical ventilation for a variable amount of time (see Chapter 23). Figure 22.4 shows the chest radiographs of a normal infant and one with hyaline membrane disease.

Cardiovascular system

Many preterm infants have problems with their cardiovascular systems (including PDA, hypotension, and shock) [123,124] but congenital heart disease is less common. Because the bulk of muscle is laid down in the pulmonary arteries during the third trimester of pregnancy, infants born earlier have less muscle and are prone to develop a PDA and increased

left-to-right shunting of blood through the ductus arteriosus earlier in life (3–5 days of age) than term infants (7–14 days of age). The net result is increased pulmonary blood flow, pulmonary edema, congestive heart failure (CHF), reduced lung compliance, hypoxemia, and CO_2 retention. Surfactant administration establishes the functional residual capacity (FRC) more quickly, which is associated with a PDA and left-to-right shunting of blood within a few hours after birth.

CHF may not be heralded by tachycardia in preterm infants, as it is in older patients. In fact, the heart rate is often monotonously regular and usually within normal limits (120–160 beats/min) (Table 22.5). A third heart sound (gallop) may be present but may be difficult to hear because of the rapid heart rate and environmental noise (e.g. mechanical ventilators, alarms, monitors, people). Murmurs can be difficult to hear for the same reason. Two murmurs are commonly present in preterm infants, that of a PDA and that of tricuspid insufficiency. The PDA murmur is a systolic ejection murmur that is best heard along the upper left sternal border when the ductal flow is small. When it is large, the murmur extends into diastole, is continuous, and is heard throughout the chest. The "machinery murmur" described in older patients is seldom heard. The murmur of tricuspid insufficiency is systolic in nature and is best heard along the right sternal border. It seldom radiates far, and it disappears after several days of life as ventricular function improves.

CHF reduces peripheral perfusion and slows capillary filling. The pulses are decreased, except in patients with a PDA. Peripheral edema is common, in part because serum protein concentrations are low. Edema usually appears first in the eyelids. Pitting edema of the feet and shins is uncommon in other than the sickest babies. Puffiness of the feet, however, is common.

The chest radiographs of preterm infants with CHF are frequently difficult to differentiate from those of infants with RDS. The former usually show central fluffiness and slightly larger markings than those of RDS (Fig. 22.5).

Table 22.5 Heart rate in preterm infants with patent ductus arteriosus

Condition	Heart rate (bpm)
Normal cardiac function	150 ± 18
Congestive heart failure	148 ± 22
Postligation ductus arteriosus	146 ± 18

The liver size is a good indicator of right-sided heart failure and of CHF in preterm infants because their livers are very distensible. The inferior margin is normally sharp and located 1–2 cm below the right costal margin; with CHF, the liver can quickly distend into the pelvis. Just as quickly, it returns to its normal position with appropriate therapy. Applying excessive pressure when examining the abdomen may push the liver up into the thoracic cavity and make the liver appear smaller than it really is. The position of the liver edge can usually be determined by gently running one's fingertips over the right upper abdomen or by percussing the abdomen. Percussion is especially useful when the abdomen is distended. Enlarged livers often extend across the midline, which may make it difficult to differentiate from the spleen, which also is often enlarged during CHF.

Abdomen

The abdomen of preterm infants is normally protuberant and soft. The venous pattern of the abdominal wall is prominent and is exaggerated with liver disease. Intra-abdominal organs are generally easy to palpate. The spleen is usually palpable below the left costal margin in patients who have erythroblastosis fetalis, systemic infections, liver disease, or fluid overload. The ascites of erythroblastotic infants may interfere with ventilation of the lungs and make it necessary to remove some of the fluid by paracentesis to allow adequate ventilation of the infant's lungs. In some cases paracentesis may be required before the induction of anesthesia.

The preterm infant's kidneys are easily palpable as small globular masses in the retroperitoneum. They may be enlarged by renal vein thromboses or by renal, ureteral, or bladder anomalies. The urinary bladder is usually felt as a round mass extending above the pelvic rim. Obstruction of the urethra can cause the bladder to distend above the umbilicus. The ureters are occasionally palpable as cords running longitudinally in the retroperitoneum.

It is often possible to see loops of distended bowel through the abdominal wall. Abdominal distension is seldom a cause of abdominal tenderness unless peritonitis is present. Then the abdomen is tender, rigid, and edematous enough to leave one's fingerprints on the skin. Intraperitoneal fluid often passes through the inguinal canals and distends the scrota. As a consequence, inguinal hernias occur in about 30% of premature male infants. Redness around the umbilicus is often a sign of systemic or intra-abdominal infections.

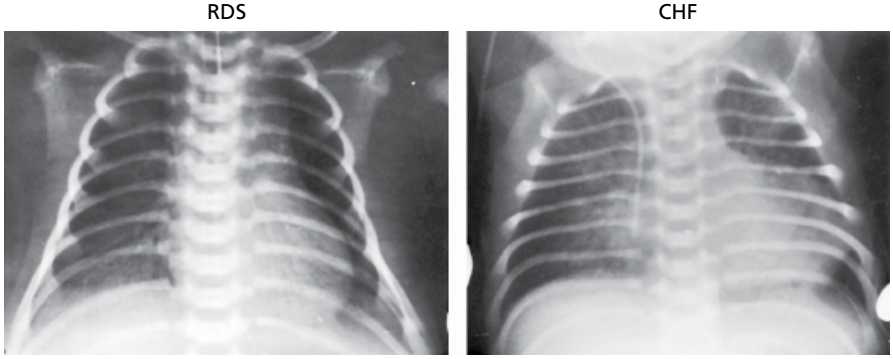

Figure 22.5 Chest x-rays of a normal preterm infant with respiratory distress syndrome (*left*) and one with a patent ductus arteriosus and congestive heart failure (*right*). Note the enlarged heart, the central fluffiness, and the loss of clear vascular shadows in the latter. *Source*: Courtesy of Dr Robert C. Brasch.

One should ascertain patency of the anus before the infant undergoes surgery. Occasionally an imperforate anus is missed in very sick infants. Nothing (including thermometers) should be inserted more than 0.5 cm into the rectum to avoid perforating the bowel.

Central nervous system

The incidence of CNS injury increases with increasing degrees of prematurity and asphyxia (see Chapter 25). CNS injury is usually manifested as flaccidity, hypertonia, hypotonia, or a difference in tone between the upper and lower or between the right and left sides of the body. Deep tendon reflexes and the grasp reflex are often absent. Healthy preterm infants normally have a positive Babinski sign. The back, neck, and sacral area should be examined for evidence of a meningomyelocele. Again, these lesions can be missed preoperatively when very ill infants are placed on their backs and left there for days because of the extent of their illness.

State of hydration

The hydration state of preterm infants should be carefully assessed during the preoperative visit. Their large surface/volume ratio, thin skin, rapid respiratory rates, relatively large minute volumes, and infrared warmers increase water losses [125,126]. Failure to replace these losses adequately leads to dehydration. Covering the baby with clear plastic film significantly reduces water and heat losses. Reducing fluid intake to less than 130 mL/kg/day decreases the incidence of PDA in preterm infants but can also lead to severe fluid and calorie restriction [55]. Restricting fluid and caloric intake may cause infants to be dehydrated and undernourished when they present for surgery. Administration of potent diuretics, such as furosemide, can cause further dehydration. Preterm infants third-space fluids more easily than older patients because the preterm infant's capillaries leak easily, serum protein levels are lower, and the oncotic pressure is reduced [127,128]. As a consequence, infants with sepsis or shock lose large amounts of fluid into the peritoneal cavity. These patients commonly gain 20–50% of their bodyweight, despite being intravascular volume depleted.

Laboratory findings

Most sick preterm infants undergo a multitude of laboratory tests, the results of which must be reviewed and understood before anesthesia is induced.

Hematology

In well infants, a hemoglobin concentration above 7 g/dL is usually adequate. In infants with cardiorespiratory disease, the concentration of hemoglobin should exceed 9 g/dL to ensure adequate oxygen-carrying capacity. As discussed previously, the hemoglobin (Hb) concentration decreases rapidly after birth, frequently because caregivers extract large volumes of blood for tests.

Besides knowing the PaO_2 and SaO_2, it is important to determine the oxygen content of the patient's blood:

$$\left(\left[\left\{1.36\,\text{mL oxygen/g Hgb}\times\text{Hgb g/dL}\right\}\times SaO_2\right]+0.003\times PaO_2\right)$$

0.003 is the solubility coefficient of oxygen in plasma. If the hemoglobin concentration were 10 g, the oxygen content would be about 13.1 mL oxygen/100 mL of blood. The entire body extracts about 5 volumes percent of oxygen from the blood. However, the heart extracts 12 volumes percent from blood passing through it. There is barely enough oxygen present to meet cardiac demands. If the Hb concentration were 5 g, the oxygen content of the arterial blood would be about 6.5 mL/100 mL of blood, which is insufficient to meet cardiac demands, unless coronary blood flow increases and cardiac oxygen requirements remain constant or decrease while the oxygen extraction from blood increases. This is a precarious position in which to begin surgery. Infants with low Hb concentrations should be transfused before surgery if possible to normalize their blood oxygen content.

Electrolytes

The concentrations of the serum electrolytes vary more in preterm infants than in older patients because premature infants are affected more severely by small changes in fluid and electrolyte intake, by fluid and electrolyte losses, and by the infant's environment. A single electrolyte value can be misleading; serial values are much more helpful. A rise in serum sodium is usually a result of either dehydration or excessive sodium administration. The latter is associated with peripheral edema. Although hyperkalemia is common, it seldom affects the ECG. Hypokalemia (<3 mEq/L) is also common, especially when preterm infants are given potent diuretics. Inadvertent hyperventilation and alkalosis further reduce the serum potassium concentration when potassium moves into the cells in exchange for hydrogen ions. The serum concentration of chloride is normally higher in preterm infants (105–115 mEq/L) than in older children, which in part accounts for the commonly present metabolic acidosis.

The total calcium concentration is usually lower than that of term infants (see section "Calcium"), but the ionized calcium concentrations of the two groups are similar. Hyperventilation may reduce the ionized calcium concentration to unacceptable levels. The tendency of most neonatologists is to maintain the total serum calcium concentration above 7 mg/dL if the ionized calcium concentrations are normal for age [86]. Failure to provide sufficient phosphorus in the diet may lead to hypercalcemia [129].

Coagulation status

At birth, the levels of coagulation factors are approximately 50% of adult values (see Chapter 12), although babies seldom bleed because of this [130–132]. Their platelet counts are similar to those of normal adults, but their platelets probably function less well. Does the infant have a bleeding diathesis? Infants who are asphyxiated at birth have depression of factors V, VII, and VIII, which return to normal within 3–4 days if the infant is resuscitated quickly [133]. These levels may not return to normal for a week or more if the hypoxia is prolonged. The latter infants are frequently thrombocytopenic, often below 10,000/mm^3. Even at these levels, bleeding seldom occurs in the absence of surgery or injury. Therefore, it is seldom necessary to transfuse platelets to premature infants unless they require surgery or their platelet count is below 5000/mm^3, especially when their other clotting parameters are normal and there is no evidence of bleeding. When

surgery is required, platelets should be transfused to raise their concentration to 50,000/mm^3 or greater. If the surgical procedure lasts for several hours, another platelet transfusion may be required. If the patient has not received vitamin K after birth, has been nil per os (NPO), and has received IV antibiotics, vitamin K 0.2 mg/kg should be administered preoperatively to preterm infants [132–134].

Bleeding disorders such as disseminated intravascular coagulation (DIC) must be corrected preoperatively with fresh frozen plasma, cryoprecipitate, or factor VIIa. If both the clotting factors and the platelets are decreased, the patient will benefit from fresh whole blood because it contains all of the clotting factors, platelets, proteins, and RBCs required.

Preoperative plan

For very ill preterm infants, it is advisable to have the help of a second anesthetist during surgery. It is difficult for one person to ventilate the patient's lungs, give fluids and blood, watch the surgical field and monitors, and keep the anesthesia record at the same time (although automatic record keeping has made this easier – see Chapter 49). In an attempt to prevent hypothermia, the operating room should be warmed to 35–37°C or above before the patient arrives and a servo-controlled infrared heater should be placed over the operating table. An air-circulated heating pad should be placed under the child and maintained at 35–37°C. Pressure transducers used to monitor arterial and central venous pressure should be set up and calibrated if needed. Intravenous solutions are made up if they differ from those being infused in the nursery. Patients often receive 5% dextrose in 0.2 normal saline in the ICN. *This solution should not be used to replace fluid losses during surgery*. Ringer's lactate or normal saline is used for this purpose; large volumes of normal saline may cause metabolic acidosis. Fluid should be warmed and delivered through an infusion pump when possible. If a drip chamber is used, it should never contain more fluid than is safe to give in 1 h. This avoids accidental overhydration if the IV infusion runs wide open.

Before transport to the operating room, an exchange of information between the ICN physician and nurse and the anesthesiologist should occur, summarizing the patient's current status and any special concerns the team has. Transporting preterm infants to and from the operating room can be dangerous. During transport, the anesthetist should always accompany sick infants to reduce this risk. The patient is connected to battery-operated arterial blood pressure, ECG, and oxygen saturation monitor during transport. Infusion pumps should continue to infuse fluids and drugs, especially vasoactive drugs. Ventilation is supported during transport, usually with a Jackson Rees device, and a portable air–oxygen blender. Sufficient oxygen should be administered to keep the oxygen saturation between 87% and 94% [122].

The inspired oxygen concentration should not be 100% during transport or in the operating room unless that concentration of oxygen is needed to maintain the desired oxygen saturation. Otherwise, the FiO_2 should be kept as low as possible while providing appropriate oxygen saturations. Use of an air–oxygen blender is required during transport to the operating room so the FiO_2 can be properly adjusted.

Table 22.6 Body temperature of preterm infants during transport to and from the operating room

Time	Body temperature (°C)
Preoperative: nursery	36.4 ± 0.5
Preoperative: operating room	35.7 ± 0.7
End of surgery	36.4 ± 1.0
Postoperative: nursery	35.9 ± 1.7

Keeping the patient warm is a major problem during transport. Table 22.6 shows the changes in body temperature of preterm infants being transported 11 floors to and from the operating room for surgery. Note the loss of nearly a degree of body temperature during this short period. Their body temperature increased to normal in the operating room and decreased again during the trip back to the nursery. These heat losses can usually be prevented by covering the baby's body with clear plastic film and warm blankets, covering the infant's head with a cap, and placing a chemical heating pad under the patient (Porta-Warm, Allegiance Health Care Corp.). Elevators should be waiting for the patient, not vice versa. The operating room should be warm, and the infant should go directly into the operating room and be immediately placed under a servo-controlled radiant warmer.

KEY POINTS: PREOPERATIVE PREPARATION

- Preoperative history must be thoroughly understood, not only from review of the medical record, but from discussion with the bedside physicians and nurses
- Review of systems and examination are crucially important; particular attention to respiratory, cardiovascular, CNS, infection, and congenital anomalies is warranted
- Preoperative discussion and planning of location of surgery (bedside versus operating room) and recovery (extubation of trachea, PACU versus direct transfer to nursery) should occur for every case

In most instances, it is better to ligate a PDA, insert a Broviac catheter, or treat NEC in the NICU rather than transport the child to the operating room. This allows the patient's mechanical ventilator and monitors to be used during surgery. The infection rates of patients undergoing surgery in the ICN are the same as those of patients undergoing surgery in an operating room [135].

Induction of anesthesia

Although preterm infants require anesthesia [136,137], their requirements are lower than those of older patients [138,139]. Failure to provide adequate anesthesia predisposes them to hypertension and intracranial hemorrhage if their cerebral vascular autoregulation is absent, which it commonly is [140,141]. When this occurs, increases or decreases in arterial blood pressure increase or decrease cerebral blood flow. Adequate anesthesia prevents or attenuates these changes in pressure. Because deep anesthesia reduces the arterial blood pressure of infants and children more than it does that of adults [140], arterial blood pressure must be supported with

fluid and vasopressors when necessary. Increases in heart rate and arterial blood pressure are usually signs of light anesthesia. However, the heart rate often does not change during hypotension because the baroreceptors of preterm infants are obtunded by even light levels of anesthesia [142–144]. Seventy percent nitrous oxide reduces the baroresponse to the same extent as halothane [143]. Fentanyl 10 μg/kg also depresses the baroreceptor reflex significantly [144] though this does not cause hypotension. Anand and associates showed that inadequate anesthesia induces a stress response in preterm infants [136] and that underanesthetized infants have a 10-fold greater complication rate.

Inserting an ETT without anesthesia or analgesia increases arterial and intracranial pressures [145]. Obviously, some patients are too ill to anesthetize before inserting an ETT, but this is uncommon after the immediate neonatal period.

Anesthesia is often induced with inhaled anesthetics (usually sevoflurane) and sufficient oxygen to maintain the desired SaO_2. If controlled ventilation is required during the induction of anesthesia, the anesthetic concentration must be reduced to prevent sudden, severe hypotension [146]. An alternative anesthetic technique employs propofol 1–2 mg/kg or fentanyl 10–30 μg/kg IV given over 1–2 min [138]. Once the eyelid reflexes are lost, an ETT can be inserted. If an assistant places a finger in the patient's suprasternal notch, the tip of the ETT can be felt as it encounters the finger. At this point the tube tip is in the mid-trachea and advancement of the tube can be stopped and the tube fixed in place. This reduces inadvertent endobronchial intubation. If necessary, the patient can be paralyzed with rocuronium 0.3–1.0 mg/kg. Muscle relaxants that increase the heart rate are preferred for preterm infants because this better maintains cardiac output.

Maintenance of anesthesia

There are few data on the anesthetic requirements of preterm infants, especially extremely premature infants [139]. However, experience suggests that premature infants require less anesthesia than their healthy full-term counterparts. The sevoflurane requirement for infants undergoing ligation of a PDA is approximately 50–80% of that of term infants. At that dosage, no change occurs in either heart rate or arterial blood pressure with skin incision [139].

Preterm infants anesthetized with inhaled anesthetics are more often hypotensive than older patients [147], probably because there is less response of peripheral vessels to catecholamines [142], myocardial depression, and loss of baroresponse [148]. Because preterm infants depend heavily on heart rate for cardiac output, loss of baroresponses makes it difficult for them to respond appropriately to hypotension. Table 22.7 shows the heart rate and arterial blood pressures of preterm infants anesthetized with halothane for ligation of a PDA. Note the heart rate did not increase when the blood pressure decreased or increased, so baroreceptor function was reduced. Similar data are unavailable for sevoflurane, but the changes are almost certainly similar because sevoflurane depresses the baroreceptor responses of adults [149].

Table 22.7 Relation between heart rate and systolic blood pressure in preterm infants anesthetized with halothane for ligation of a patent ductus arteriosus

Condition	Heart rate (bpm)	Systolic pressure (mmHg)
Preinduction	146 ± 20	62 ± 16
Before ductal ligation	143 ± 17	48 ± 16
After ductal ligation	145 ± 16	66 ± 15

To avoid anesthesia-induced hypotension, fentanyl is commonly used to anesthetize preterm infants [138,150]. Administering 10–30 μg/kg of fentanyl prevents changes in both heart rate and arterial blood pressure with a skin incision. When the blood volume is adequate, administration of fentanyl seldom causes hypotension. Patients who are regularly receiving fentanyl in the NICU may require much higher doses of fentanyl for surgery, often more than 50 μg/kg. As with all drugs, fentanyl should be titrated to the desired clinical effect. Muscle relaxants are often used to prevent movement and to reduce anesthetic requirements. Premature infants receiving muscle relaxants must, however, be anesthetized! Nitrous oxide, like other anesthetics, can cause hypotension and cardiac arrest in hypovolemic patients.

The lungs of preterm infants should be mechanically ventilated during anesthesia and surgery. Operating room mechanical ventilators are poor substitutes for those used in the ICN, but ICN ventilators cannot deliver inhaled anesthetics. If an ICN ventilator is used, a narcotic-based anesthetic will provide adequate anesthesia. No ventilator adequately compensates for changes in compliance and resistance of the lungs induced by retractors, surgical packs, and the surgeon's hands. Consequently, the lungs of small preterm infants are often ventilated by hand while observing the surgical field and chest expansion. The lowest pressures and tidal volumes possible should be used to *normally* expand the chest and lungs. If the neonate required PEEP in the NICU, he/she will require it during anesthesia and surgery. The initial ventilator settings used during anesthesia should mimic those used by the physicians, nurses, and respiratory therapists in the NICU to produce the best blood gases and oxygen saturations. These variables can be adjusted as needed. To avoid administering a high oxygen concentration, it must be possible to adjust the FiO_2 between 0.21 and 1.0 during surgery. Administering high oxygen concentrations to preterm infants who do not need them unnecessarily exposes the infants to the risk of ROP (see section "Retinopathy of prematurity").

Actively determining and replacing the premature infant's blood losses with blood and fluid is crucial because the blood volumes of premature infants are small, about 100 mL/kg. Consequently, in a 1 kg infant a loss of 10 mL of blood is equivalent to a 10% loss of blood volume. It is often difficult to accurately determine such small blood losses during surgery. Weighing the used sponges is a more accurate method of doing so than merely looking at them and guessing how much blood is in them. A 1 g increase in sponge weight equals 1 mL of blood. Suctioned blood should be collected in small bottles to more accurately determine blood losses. Volumes of flush solutions must be accurately recorded so they can be subtracted from the amount of fluid in the blood collection bottle. The most difficult part of estimating blood loss is determining how much blood is lost into the surgical drapes and into the tissues. Because of these inadequacies in blood loss determinations, it is often necessary to increase the estimated blood loss by 25–50% and to administer that amount of blood or an

appropriate volume of crystalloid while monitoring intravascular pressures and heart rate and determining serial hematocrits. Low hematocrits are corrected with packed RBCs.

The volume of fluid administered depends in great part on the amount of surgical trauma occurring. Abdominal or thoracic procedures are more traumatic than peripheral procedures and therefore require 8–12 mL/kg/h or more of lactated Ringer's solution. Replacing fluid losses with 0.2 or 0.3 normal saline is dangerous because it leads to hyponatremia, water overload, and occasionally death. Infusing approximately 5–7 mg/kg/min of glucose is a good starting dose under anesthesia, unless the patient was receiving higher concentrations of glucose in the ICN. The blood glucose concentration should be measured frequently and maintained between 50 and 90 mg/dL. Giving more glucose may cause hyperglycemia (Tables 22.8–22.10).

Additional fluid should consist of lactated Ringer's solution (without glucose), 5% albumin, blood, or a combination of these. Blood products and plasma contain dextrose and may increase blood glucose concentrations. Intravenous alimentation fluid is *never* used to replace fluid losses during surgery because doing so causes severe hyperglycemia and possibly CNS damage. Instead, the anesthetist should infuse hyperalimentation fluids at their preoperative rate and provide additional fluid needs with plain lactated Ringer's solution. The blood glucose concentration should be determined during surgery with a glucometer and the infusion rates of dextrose altered as needed.

Adequate replacement of colloid and crystalloid is aided by measuring central venous pressure (CVP), mean arterial pressure (MAP), and urine output. MAP is a good indicator of intravascular volume. An arterial blood pressure that is two standard deviations below normal for that age group [151] indicates hypotension and suggests hypovolemia (Fig. 22.6).

Table 22.8 Serum and urine glucose values and urine volume in a 1 kg infant

Assay	Time (h)			
	Baseline	1	2	Recovery
Serum glucose (mg/dL)	45–90	90	175	130
Urine glucose	1+	2+	4+	4+
Fluid intake (mL/kg/h)	4	7	15	12
Glucose infused (mg/h)	400	700	1500	1200

Table 22.9 Blood and urine glucose concentrations in term and preterm infants during surgery (% of patients)

Age	% of Patients by urine* results				% of Patients by blood† results (mg/dL)		
	Negative	2+	3+	4+	45–90	130–175	≥250
Preterm	50	20	15	15	40	50	10
Term	70	14	10	6	66	20	25

Table 22.10 Effects of adding glucose to intravenous fluid of infants and children during surgery

Age	Glucose concentration (mg/dL)			
	Ringer's lactate		D-5 Ringer's lactate	
	Infants	Children	Infants	Children
Preoperative	78 ± 12	95 ± 13	76 ± 9	87 ± 13
Anesthesia				
20 min	88 ± 20	122 ± 17	143 ± 18	147 ± 38
60 min	78 ± 12	93 ± 18	201 ± 39	186 ± 37
120 min	81 ± 15	93 ± 12	213 ± 41	158 ± 32

* Glucose was added when the intravenous infusion was started in those receiving glucose. Infants were 1 week to I year of age. Children were 1–7 years of age.

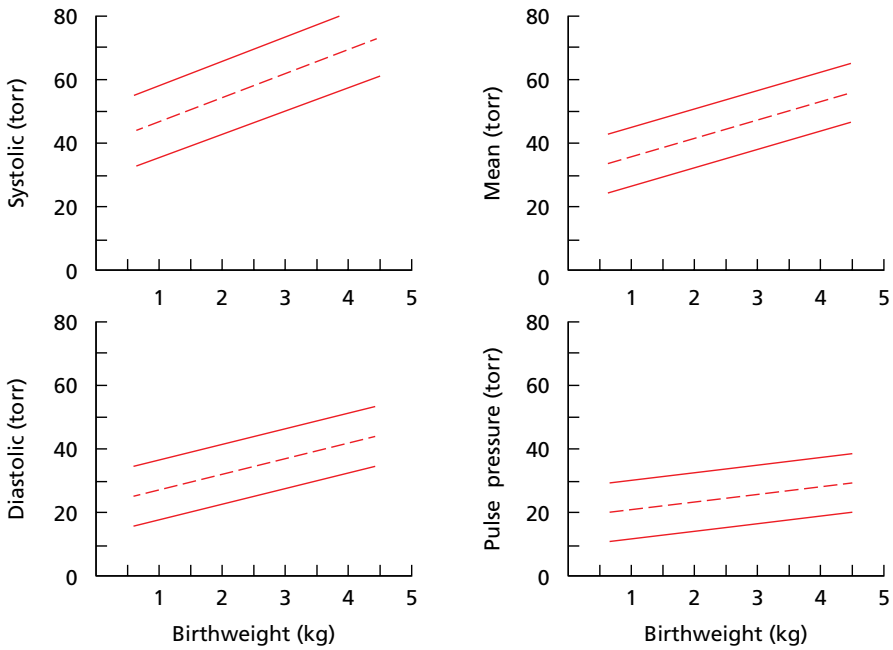

Figure 22.6 Systolic, diastolic, and mean arterial blood pressures and pulse pressures of infants between 610 and 4200 g. *Source*: Reproduced with permission of Gregory, Versmold.

Infusing adequate fluid usually returns the blood pressure to normal. CVP is also a useful measurement of intravascular volume status. A CVP below 3 cmH_2O suggests hypovolemia.

Urine output is also a good indicator of intravascular volume. It should exceed 0.75 mL/kg/h. The urine specific gravity of normal neonates is usually less than 1.005 [152]. A urine specific gravity in excess of 1.009 usually indicates that the patient is conserving fluid. If the skin over the fontanelle is below the inner table of the skull, and the baby is not crying, he is probably hypovolemic.

Body temperature is maintained between 36°C and 37°C to avoid postoperative hypoventilation, delayed awakening from anesthesia, atelectasis, respiratory and metabolic acidosis, infection, poor feeding, and aspiration of gastric contents. The body temperature is maintained in the normal range by warming the operating room and the inspired gases. Intravenous fluids and blood can be warmed using a conventional fluid warmer set to 38–41°C and leaving only a short length of tubing to the patient's IV catheter, so that the fluid will not cool in a long length of tubing. The short segment of tubing must be visible so air bubbles can be detected and removed. Even small air bubbles (0.1 mL) can be lethal if they lodge in a coronary or cerebral artery, which is possible because the foramen ovale is patent in most of these neonates.

Recovery from anesthesia

Emergence from anesthesia can be as dangerous as induction of anesthesia. There is often pressure to quickly remove the patient from the operating room so that the next case can start. This pressure must be resisted while careful preparations are made to transport the patient to the recovery area, usually the ICN. Before the patient leaves the operating room, it must be known that the ICN nurses are available and ready to receive and care for the patient. The ICN should be informed of the FiO_2, ventilator settings, body temperature, and planned postoperative pain therapy before the patient leaves the operating room. After transport to the ICN, a complete verbal exchange of information from the anesthesia team and surgeons to the ICN nursing and physician team is important, to inform them of intraoperative events.

In most instances the lungs of preterm infants should be ventilated on the way to and in the ICN. It can then be decided whether mechanical ventilation is required postoperatively or not. Muscle relaxants must be reversed and adequate spontaneous ventilation established before an ETT is removed.

Many preterm infants who are less than 44 weeks' gestation develop postoperative apnea [153,154]. The incidence of apnea is related inversely to the gestational age at birth [155]. Although the cause of apnea is unknown, it may be due to persistence of small amounts of anesthetic in the CNS that affect the autonomic nervous system [156] or it might be related to an incompletely developed CNS [157]. Most postoperative apnea occurs during the first 4 h after surgery, but apnea may occur 12 or more hours after surgery [158]. Patients who are <46 weeks' gestation are usually monitored for apnea and SaO_2 in hospital for 12–24 h after surgery due to their high risk for apnea. Those with gestational ages of 47–60 weeks are evaluated carefully for 6 h postoperatively. If there is no evidence of apnea, bradycardia, or oxygen desaturation, they can be discharged home, all else being normal. Those older than 60 weeks' gestation can be treated as normal term infants and can be discharged home after surgery if there are no other problems. Infants who develop postoperative apnea may require mechanical ventilation for several hours to several days. This possibility usually precludes outpatient surgery for infants who are less than 50 weeks' postconceptual age, although one study disputes this conclusion [159].

Welborn and associates found that ex-premature infants whose hematocrit was below 30% had an increased incidence of apnea [160]. Eighty-nine percent of the infants with low hematocrits were apneic after surgery while only 21% of those with a hematocrit of greater than 30% were apneic.

The same authors found less apnea in infants treated with spinal anesthesia than in those anesthetized with general anesthesia [161]. No instances of apnea occurred with spinal anesthesia unless the patients were also sedated. Eight of nine infants premedicated with ketamine had significant apnea while five of 16 had postoperative apnea if not given the drug. Although spinal anesthesia caused fewer instances of postoperative apnea [162], apnea and total spinal anesthesia have occurred [163,164]. Kunst et al found no difference in the rate of apnea in patients who received either form of anesthesia [165]. This was also true of recent data [166]. Patients undergoing general anesthesia were more likely to have oxygen desaturation and bradycardia than those undergoing spinal anesthetic. Tashiro and associates [167] found that gestational age, birthweight, postconceptual age, and use of aminophylline preoperatively were associated with a need for postoperative ventilation. Approximately one-third of the infants undergoing hernia repairs had postoperative apnea [168]. Welborn et al found that IV caffeine 5 mg/kg prevented life-threatening postoperative apnea and eliminated the need for mechanical ventilation [169]. It had no effect on lesser degrees of apnea. By delaying surgery until the patient is more than 44 weeks' postconceptual age, most postoperative apnea can be avoided. Patients who require surgery before 44 weeks' gestation should receive IV caffeine.

KEY POINTS: INDUCTION, MAINTENANCE, AND RECOVERY FROM ANESTHESIA

- Failure to provide adequate depth of anesthesia in premature infants predisposes to hypertension and intracranial hemorrhage
- Anesthetic requirements are lower in premature infants than for full-term neonates
- Hypotension is common in premature infants, especially with volatile anesthetics; treatment with fluids or vasopressors is frequently required
- Because the blood volume of premature infants is small, i.e. 100 mL/kg, replacing moderate or significant blood loss is crucial
- Strict attention to body temperature, glucose, and FiO_2 is an important component of anesthesia for premature infants
- Postanesthetic apnea in premature infants less than 46 weeks' gestation is common and monitoring should be used

Anesthesia for micropremies

The marked improvement in the survival of very premature infants ("micropremies," i.e. 400–1000 g at birth) over the past few years has resulted in many surgeries before discharge from hospital. Some of these patients have poor neurological and developmental outcomes. Evidence suggests that only 67–71% of 24–25-week gestation infants are neurologically normal compared to 89% of those born at 26 weeks' gestation (Table 22.11). An additional 22% of 24-week gestation infants have neurological examinations that are suspicious for injury [170,171].

Only 28% of neonates born at 24 weeks' gestation have normal cognitive development at 4.5–7 years of age. Eleven percent of 24–27-week gestation infants had cerebral palsy. The outcome of small infants was significantly improved by delaying their birth until 26 weeks' gestation. Infants with CNS injuries are more likely to have hypotension and bradycardia with anesthesia.

The problems of micropremies are similar to those of larger premature infants, but worse. Because they are so immature, micropremies do not have true alveoli and the distance between their capillaries and their gas exchange units is greater, making oxygenation more difficult. The high surface/volume ratio and the thin fragile skin increase fluid loss and make it more difficult to maintain their body temperature. Removing tape or monitor pads often removes their skin and leaves large weeping abrasions.

To maintain hydration and prevent/treat hypotension, it is often necessary to administer very large volumes of fluid (often >200 mL/kg/day) and vasopressors. Failure to do so results in dehydration and hypotension. However, administering these volumes of fluid may cause a PDA, heart failure, and pulmonary edema.

Table 22.11 Neurological and developmental outcome of micropremies

	24 Weeks	25 Weeks	26 Weeks
No. of infants followed	18	30	38
Neurologically normal	12 (67%)	22 (73%)	34 (89%)
Neurologically suspicious	4 (22%)	2 (7%)	0
Cerebral palsy	2 (11%)	6 (20%)	4 (11%)
Normal cognitive development	5 (28%)	14 (47%)	27 (71%)
Borderline cognitive development	6 (33%)	7 (23%)	7 (18%)
Deficient cognitive development	7 (39%)	9 (30%)	4 (11%)

* Data are presented as n (%).

The normal MAP for infants of 24–26 weeks' gestation is debatable but is grossly the same as the gestational age. Blood pressures measured by non-invasive means are often higher than those measured intravascularly (Table 22.12). Consequently, micropremies may be hypotensive despite having non-invasive MAPs that would be considered normal for gestational age. Determining the state of hydration is more difficult in these patients because they have little or no subcutaneous tissue, their skin is paper thin, and their pulses are frequently difficult to feel. The skin over their fontanelles is level with the outer table of the skull. Their urine output is usually more than 1 mL/kg/h and the specific gravity <1.005.

The anesthesia requirement of micropremies is unknown. However, from previous data it appears that the MAC for halothane is less than 0.55. The dose of sevoflurane is about 60% of that of term infants. Opioids in adequate doses provide anesthesia for these infants; their arterial pressures are more stable than during inhaled anesthesia (Table 22.13). Since these children are often mechanically ventilated after surgery, muscle paralysis with rocuronium 0.3–1.0 mg/kg and anesthesia with fentanyl 10–50 μg/kg provides adequate conditions for any surgery. Although small premature infants have cerebrovascular autoregulation, it is very fragile and easily disrupted. This increases the likelihood of intracranial hemorrhage and CNS injury if the anesthesia is inadequate.

Micropremies have high fluid requirements during surgery. Failure to provide the required amount of fluid results in hypotension and/or shock. All fluid should be administered via calibrated pumps when possible to avoid excess fluid administration.

Where should the surgery for micropremies be performed? Many institutions do it in the NICU because it is easier to take nurses, doctors, and technicians to the NICU than it is to take the patients to the operating room. The infection rate is no different whether the patient undergoes surgery in the ICN or the operating room.

Common surgical problems of micropremies are described elsewhere in this book. PDA is covered in Chapter 27, thoracotomy for pulmonary resection in Chapter 26, hydrocephalus in Chapter 25, and NEC and inguinal hernia in Chapter 31. The following case study illustrates and integrates many of the points discussed above.

Table 22.12 Arterial blood pressures determined non-invasively and from an indwelling arterial catheter: comparison of cuff and intra-arterial pressures

Method	n	MAP	Systolic/diastolic
Cuff	15	32 ± 5	46 ± 5/22 ± 3
Line	15	26 ± 6	38 ± 4/15 ± 3

MAP, mean arterial pressure.

Table 22.13 Vital signs during fentanyl and halothane anesthesia (23–26 weeks' gestation)

	Halothane				Fentanyl		
	HR	MAP	CVP		HR	MAP	CVP
Awake	148 ± 17	31 ± 3	4 ± 1	Awake	152 ± 17	31 ± 3	4 ± 1
0.5 MAC	138 ± 26	28 ± 4	5 ± 1	10 μg/kg	148 ± 26	30 ± 4	4 ± 1
1.0	130 ± 28	27 ± 3	5 ± 2	30 μg/kg	147 ± 13	30 ± 3	3 ± 1

CVP, central venous pressure; HR, heart rate; MAC, minimum alveolar concentration; MAP, mean arterial pressure.

CASE STUDY

The infant was 5 days old at the time we were asked to evaluate him for anesthesia and surgery for NEC. He was born after 29 weeks' gestation and weighed 980 g at birth. On the day of surgery his weight was 840 g, a 15% weight loss from birth. He was severely asphyxiated at birth and required immediate tracheal intubation and assisted ventilation.

His initial blood gas values were pH 7.00, $PaCO_2$ 63 mmHg, and PaO_2 43 mmHg (SaO_2 91%) despite ventilation with 100% oxygen. His mean arterial blood pressure was 16 mmHg at 5 min of age. Ventilation was continued, and 10 mL of whole blood were administered over 5 min, which brought his mean arterial blood pressure to 28 mmHg. His blood gases improved following the transfusion. By 25 min of age the PaO_2 was 165 mmHg (SaO_2 100%), the $PaCO_2$ 33 mmHg, and the pH 7.34. He was transferred to the NICU after the PaO_2 had been reduced to 50 mmHg (SaO_2 97%) by progressively decreasing the FiO_2 to 0.67. A chest radiograph demonstrated classic RDS.

During the next 4 days, the RDS improved and the NICU staff reduced the level of assisted ventilation. On day 1 he received 5% dextrose in water, equal to 50 mL/kg/day, plus electrolytes. This rate was increased to 70 mL/kg/day thereafter. He was covered with clear plastic film to reduce evaporative heat loss and placed under a servo-controlled radiant warmer. He was started on ampicillin and gentamicin shortly after birth because it was uncertain if sepsis was present. When the blood, urine, and CSF cultures failed to demonstrate bacteria on day 3, the antibiotics were discontinued. The initial hemoglobin value was 12.5 g/dL. Because of blood sampling, the hemoglobin concentration decreased to 9.5 g/dL. He was transfused to increase it to 11.2 g/dL on the third day of extrauterine life and started on erythropoietin.

On day 5, he developed abdominal distension, vomiting, and bloody stools following attempts to feed him with breast milk. His RDS, which had been improving, now worsened. He required higher ventilator rates and pressures and a higher FiO_2. An abdominal radiograph showed free air in the peritoneal cavity and a diagnosis of necrotizing enterocolitis was made. At this point, he was scheduled for surgery.

A review of the records and his physical examination demonstrated the following.

Hydration

His skin was pale and mottled and failed to return to its resting position for 8 s after being tented up. The fontanelle was sunken below the inner table of his skull. It took more than 6 s for the skin of his fingers and toes to fill with blood after they were blanched. His extremities were cold from the groins and axillae outward. There were no pulses in his feet or wrists and his groin pulses were markedly diminished. The pulse rate was 150 beats per minute (bpm) and the arterial pressure 40/15 mmHg, with a mean pressure of 23 mmHg. There had been no urine output for 6 h and only 2 mL of urine during the 4 h previous to that. The urine specific gravity of his last sample was 1.028.

Chest findings

He had bilateral rales that did not clear when the ETT was suctioned. Air entry into the upper lobes of the lungs was appropriate but was decreased in the bases. An ETT was in place in the mid-trachea and was fixed securely. The PaO_2 was 72 mmHg (SaO_2 98%), $PaCO_2$ 30 mmHg, and pH 7.21. His base deficit was −15 mEq/L. He was ventilated 20 times per minute with peak pressures of 30 cmH_2O, and PEEP of 5 cmH_2O.

Cardiovascular findings

His heart rate was normal (150 bpm) and there was no murmur or gallop. However, one would expect it to be higher to compensate for the hypotension present. The point of maximal cardiac impulse was in the fourth interspace anteriorly. His pulses were as listed previously.

Abdominal findings

His abdomen was grossly distended. Loops of bowel were visible through the anterior abdominal wall, which was edematous, warm, and tender. Bowel sounds were absent. The liver was not palpable, but it could be percussed 1 cm below the right costal margin.

Laboratory data

His WBC count was 29,300/mm^3 with a shift to the left. Fifteen percent of these cells were bands. His hemoglobin was 14.5 g/dL. His electrolytes showed a sodium concentration of 147 mEq/L, potassium 5.3 mEq/L, chloride 120 mEq/L, and bicarbonate 17 mEq/L. His serum total calcium concentration was 6.3 mg/dL and his ionized calcium was 1.0 mmol/L. The total protein concentration was 4.5 mg/dL.

Discussions with the nurses indicated that the infant would become severely cyanotic and his SaO_2 would abruptly decline to 80–88% when the ETT was disconnected for tracheal suctioning. They also pointed out that his body temperature was labile and that, over the past few hours, he required increasing amounts of exogenous heat to maintain his body temperature in the normal range.

Preoperative preparation

On the basis of this information, it was clear that the infant was severely intravascular volume depleted, although his bodyweight had not changed over the past 12 h, probably because volume had been translocated to the peritoneal cavity and bowel. His peripheral perfusion and arterial blood pressure were decreased. The lack of urine output for 6 h indicated not only that the intravascular volume was decreased but also that he had more than a 70% chance of becoming hypotensive with the induction of anesthesia. The rise in his hemoglobin concentration also indicated intravascular volume depletion. A central venous line was inserted with local anesthesia and was connected to a pressure transducer. The CVP was 0 cmH_2O. Lactated Ringer's solution 10 mL/kg was infused over 15 min which increased his CVP to 2 cmH_2O. Additional lactated Ringer's solution 10 mL/kg raised the CVP to 5 cmH_2O. With this increase, the peripheral perfusion improved and the

mean arterial pressure rose to 32 mmHg. His urine output increased to 2 mL/kg/h, and the urine specific gravity decreased to 1.006. He needed less mechanical ventilation because the PaO_2 rose to 123 mmHg (SaO_2 100%) and the $PaCO_2$ decreased to 18 mmHg. His base deficit rose to −5 meq/L without infusing sodium bicarbonate. His blood glucose concentration was now 128 mg/dL. Calcium gluconate 30 mg/kg was administered to treat the hypocalcemia. Repeat electrolyte determinations showed a calcium concentration of 8.1 mg/dL and ionized calcium of 1.02 mmol/L, a sodium concentration of 140 mEq/L, a potassium concentration of 4.5 mEq/L, and a chloride concentration of 115 mEq/L. His hemoglobin concentration had decreased to 11.0 g/dL after rehydration.

After 90 min of preparation, the patient was transported to the operating room while being manually ventilated at the same pressures, rates, and inspired oxygen concentration used in the nursery.

Surgery

The patient was anesthetized and operated on in his intensive care bed. Anesthesia was induced with fentany 20 μg/kg, and he was paralyzed with pancuronium 0.1 mg/kg. Surgery began within 5 min of his arrival in the operating room. The inspired oxygen was maintained at a level that kept the PaO_2 between 50 and 70 mmHg (SaO_2 91–96%) by using air as the carrier gas and adding oxygen as needed. Oxygen saturation was measured continuously with a pulse oximeter, and the blood gases and pH were measured intermittently, as was the serum glucose. The total calcium concentration was determined once during the 2-h procedure and was found to be 6.9 mg/dL. The concentration of ionized calcium was 1.01 mmol/L. Calcium gluconate 20 mg was given slowly through the central venous line. A blood loss of 15 mL was replaced with packed RBCs, bringing the hemoglobin to 15 g/dL. His IV fluids included 5% dextrose in lactated Ringer's solution 4 mL/h and lactated Ringer's solution without glucose 6 mL/h, which maintained the blood glucose concentration and the arterial and central venous pressures within normal limits. The bowel was resected and an end-to-end anastomosis performed in addition to a diverting colostomy.

His body temperature was maintained within normal limits by wrapping the extremities with sheet wadding, covering his head with a cap, placing a warming pad under him, warming and humidifying the inspired gases to 37°C, warming the infused fluids, and placing him on a forced air warming blanket. At the end of the procedure he was covered with warm blankets and clear plastic film. His ventilation was controlled during transport to the NICU. Mechanical ventilation and paralysis were continued in the postoperative period. Once we were sure that the vital signs and ventilation were adequate, his care was transferred to the NICU staff after a complete report of intraoperative events.

His condition continued to improve over the next week, and he was weaned from mechanical ventilation and fed intravenously through the central venous line. He was discharged from the hospital at 2 months of age neurologically intact and eating well. At 4 months of age, his colostomy was closed, and he has done well since.

Conclusion

This case illustrates how severely dehydrated such premature patients can be and how well they respond to fluid replacement. It also shows how stable they can become once the deficits are replaced.

CHAPTER 23

Anesthesia for the Full-term and Ex-premature Infant

Neil S. Morton, Ross Fairgrieve, Anthony Moores, and Ewan Wallace
Department of Anaesthesia, Royal Hospital for Children, Glasgow, UK

Introduction

More premature babies are surviving and presenting for surgery in early life with residual effects of prematurity, complications of prematurity and neonatal intensive care, and co-morbidities. The risk of perioperative apnea has been elucidated and anesthetic techniques with modern volatile agents or using awake regional anesthesia have been developed and compared, particularly for inguinal hernia repair. For more major congenital abnormalities such as tracheo-esophageal fistula, abdominal wall defects, and congenital diaphragmatic hernia, the principles of neonatal anesthesia are described in general with particular refinements of technique for each of these major lesions described in detail. The dilemma for the anesthesiologist of having to provide anesthesia for a muscle biopsy in an infant is also discussed. The current neonatal resuscitation algorithm is discussed with information from recent trials of techniques aimed at trying to improve outcomes.

Residua and complications of prematurity

With advances in obstetric and neonatal care, a higher proportion of premature babies are surviving and presenting for anesthesia and surgery in early life [1–3]. Often the survivors have one or more residua of prematurity (Box 23.1) or complications of prematurity or neonatal intensive care unit (NICU) management. The incidence and severity of disabilities tend to be in proportion to the degree of prematurity and length of NICU stay [3,4].

Chronic lung disease

Significant chronic lung disease, or bronchopulmonary dysplasia (BPD), persists in up to 10% of ex-premature infants. The severity and incidence have been ameliorated by antenatal maternal steroid therapy, exogenous surfactant treatment, new ventilatory support strategies to minimize barotrauma and volutrauma, and improved monitoring to prevent oxygen toxicity (see Chapter 22). However, because a higher proportion of premature babies are surviving, the number of babies presenting for surgery and anesthesia with some degree of lung disease has tended to increase. The mechanisms leading to chronic lung disease are detailed in Chapter 7, but a useful clinical classification of severity of BPD [5] highlights for the anesthesiologist those at particular risk of perioperative pulmonary complications such as pneumothorax, interstitial emphysema, bronchospasm, hypoxemia, and pulmonary hypertension. For babies born at less than 32 weeks' gestational age who are assessed at hospital discharge or 36 weeks' postconceptional age (PCA) as having needed supplemental oxygen for at least 28 days, the severity of BPD is *mild* if the baby is now breathing room air, *moderate* if the baby is now needing less than 30% oxygen, and *severe* if the baby now needs 30% oxygen or more and/or positive pressure

Gregory's Pediatric Anesthesia, Sixth Edition. Edited by Dean B. Andropoulos and George A. Gregory.

Box 23.1: Residua or complications of prematurity in the young infant of importance to the pediatric anesthesiologist

- Chronic lung disease
- Airway problems: laryngotracheomalacia, subglottic stenosis
- Apnea: spontaneous and post anesthetic
- Cerebral damage: intraventricular hemorrhage, white matter injury
- Eye problems: retinopathy of prematurity
- Anemia
- Patent ductus arteriosus (PDA)
- Difficult vascular access
- Altered pain threshold

ventilation or nasal continuous positive airway pressure (CPAP) [5]. To minimize perioperative deterioration in lung function, strategies for the anesthesiologist include use of awake regional anesthesia techniques where feasible or, for patients who need general anesthesia, tracheal intubation with controlled ventilation is usually recommended with administration of the minimum effective inspired oxygen concentration to maintain arterial oxyhemoglobin saturation between 92% and 96%, use of minimum effective peak inspiratory pressures, application of low levels of positive end-expiratory pressure (PEEP) to minimize airway collapse, permissive hypercapnia, and relatively slow ventilatory frequency with shorter inspiratory:expiratory (I:E) ratio to minimize gas trapping and overinflation of lung segments. Bronchodilator medication should be continued on the day of surgery and postoperatively. For severe BPD cases, elective postoperative ventilatory support may well be required, although with good regional analgesia, early extubation may be possible for certain operative procedures.

Airway problems

Subglottic stenosis, tracheal stenosis, tracheomalacia, and bronchomalacia may occur in up to 10% of ex-premature babies.

Subglottic stenosis at the level of the cricoid ring is most often due to repeated tracheal intubation, use of too large a tracheal tube, or prolonged tracheal intubation. It may also be associated with gastro-esophageal reflux with repeated spillover of acid or bile into the airway. It may well be that in an infant presenting for elective surgery, consideration should be given to therapy for the subglottic stenosis as a higher priority, depending on its severity, but this decision requires careful discussion. Where anesthesia has to be given, a much smaller tracheal tube diameter than expected may be required and elective steroid therapy given prior to extubation to minimize mucosal edema.

Tracheomalacia may be primary or secondary to extrinsic compression (e.g. vascular ring) or prolonged positive pressure ventilation. The tracheal cartilages may be underdeveloped and the membranous part of the trachea posteriorly may be widened. Tracheal collapse typically occurs on expiration giving expiratory stridor, a seal-like cough, and expiratory wheeze. A similar pattern may be seen with *bronchomalacia* which may be primary or secondary to extrinsic compression, for example from a large pulmonary artery or left atrium. Bronchomalacia may lead to unilateral lung collapse or hyperinflation. Care must be exercised on starting positive pressure ventilation to ensure sufficient end-expiratory pressure to splint the collapsible large airways open on expiration to avoid stacking of breaths and gross hyperinflation of the lung. On extubation of the trachea, babies with tracheobronchomalacia benefit from postextubation CPAP or bilevel positive airway pressure (BiPAP) to minimize postoperative lung collapse and respiratory failure.

Apnea

The mechanisms of apnea in the premature and ex-premature infant are described in detail in Chapter 22. Apnea has long been recognized as an issue for such babies [6]; soon after it was reported, the use of xanthine derivatives such as aminophylline [7] or theophylline [8,9] and their active metabolite caffeine [8–14] as therapy was elucidated. Anesthesiologists became aware of this work when the problem of postoperative apnea was highlighted by landmark reports during the 1980s [15–20] and key dose-finding studies of caffeine as prophylaxis [21,22]. Around this time there was also interest in the use of "awake" regional anesthesia as an alternative to general anesthesia for such cases, particularly for inguinal surgery. Comparative trials of general with regional anesthesia were undertaken and risk factors for postoperative apnea were further elucidated [23–28] most notably in a combined analysis by Cote et al [29]. This made clear that the main risk factors are young PCA, anemia (hematocrit <30%), and nature of the surgery [29]. The importance of this analysis for clinical practice has been immeasurable in helping clarify risks for all ex-premature infants up to 60 weeks' PCA, allowing guidance for monitoring and postoperative care to be developed and helping decision making about day care and time of discharge [29]. Recently, a secondary analysis of apnea from the GAS study (a large randomized controlled trial comparing general anesthesia with awake regional anesthesia for hernia repair in 722 infants) reinforced these principles and risk factors, although it did not find an effect of anemia [30]. The incidence and severity of early apneas in the postanesthesia care unit (PACU) (0–30 min) were lower in the regional anesthesia group [30,31]. In summary, the risk to benefit ratio suggests a default position of considering admission for monitoring of all ex-premature infants who are younger than 60 weeks' PCA as the risk is around 1 in 200 for non-anemic infants who have not exhibited apnea in the PACU until around 55 weeks' PCA (Fig. 23.1).

For those with co-morbidities, those scheduled for more major surgery, those who are anemic with hematocrit <30%, or those who become apneic in the PACU, admission for at least 12 h after the last apneic episode is recommended. Caffeine 10 mg/kg intravenously is recommended [32,33]. These guidelines apply whatever anesthetic technique has been used, including awake regional anesthesia, although some authors have questioned this based on their own local expert practice [34,35]. There have been reports of postoperative apnea in full-term neonates [36–39] and it is prudent therefore to admit and monitor full-term infants of less than 44 weeks' PCA who show any respiratory abnormality during recovery from anesthesia for monitoring for at least 12 apnea-free hours.

Cerebral damage

Residual cerebral damage may be present from birth asphyxia, intraventricular hemorrhage, periventricular leukomalacia, hydrocephalus, and seizures. The mechanisms of cerebral

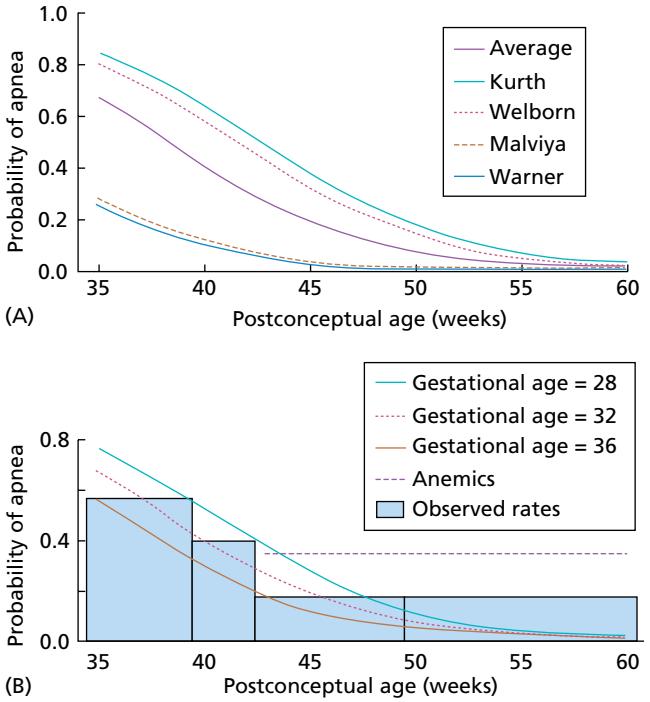

Figure 23.1 Postoperative apnea risk (A) showing variation among centers, (B) by gestational age and postconceptual age and influence of apnea.
Source: Reproduced from Coté et al [29] with permission from Wolters Kluwer.

damage are detailed in Chapter 22. The clinical effects are manifest as cerebral palsy, cognitive and behavioral deficits, hearing loss, and visual impairment. Published longer-term follow-up in 2005 showed that around one in five very premature babies had severe disabilities at age 5 years, and only one in four exhibited normal development [40]. More recent analyses [41] suggest that some centers are achieving much lower prevalence rates of cerebral palsy (as low as 1.9% in very preterm infants born at 20–27 weeks' gestation) and rates of hearing and vision loss as low as 1% [41]. The anesthesiologist should make a detailed preoperative assessment of residual neurological impairment and document this baseline carefully, noting the pathology underlying the deficit, presence of hydrocephalus and/or a ventriculoperitoneal shunt, seizures and their pattern and frequency, and antiseizure medication. These findings may affect choice of anesthetic agent and technique, use of central regional blockade, need for perioperative antibiotics, and decisions about early extubation or elective postoperative ventilatory support. The documentation is also important from a medico-legal perspective to minimize the risk of subsequently being accused of causing neurological damage by anesthetic agents, techniques, or procedures. Anesthetic goals should be to maintain a normal range of blood pressure, carbon dioxide levels, and arterial oxyhemoglobin saturation in the range 92–96%, and in particular to minimize episodes of fluctuation above and below these norms for age.

Eye problems

The mechanisms of retinopathy of prematurity (ROP) are described in Chapter 22. Residual eye problems occur in up to 50% of ex-premature babies [42] and the anesthesiologist needs to be aware of the importance of avoiding hypoxia and hyperoxia and thereby potentially exacerbating the retinal damage. Thus titrating oxygen delivery to maintain stable arterial oxyhemoglobin saturation values of 92–96% and avoiding major fluctuations is recommended [43].

Anemia

The full-term neonate usually has a high hematocrit of 45–55%, depending on the degree of placental autotransfusion at delivery, and this level starts to fall within the first week of life. In response to increased oxygen saturation after birth, the levels of erythropoietin decrease and so replacement of short half-life red blood cells containing fetal hemoglobin with longer half-life cells containing adult hemoglobin is delayed. This results in a low point of hematocrit of 24–30% at around 2–3 months of age. In the premature baby, this low point of hematocrit often occurs earlier (1–2 months of age) and is more profound (21–27%) due to repeated blood sampling and nutritional deficiencies of iron, folic acid, and vitamin E. Many NICUs aim to maintain the hematocrit in the range 36–45%, especially in the sickest infants with severe lung disease, low arterial oxyhemoglobin saturations, and low cardiac output states. A study of preterm babies weighing between 500 and 1300 g showed that restricting blood transfusion resulted in more medical complications (brain hemorrhage, periventricular leukomalacia, and apnea) [44]. Use of exogenous erythropoietin as therapy to increase hematocrit levels in the NICU showed initial promise but resulted in an increased incidence of ROP [45]. For anesthesia, it is important to optimize oxygen delivery. Transfusion with blood containing adult hemoglobin, which releases oxygen to tissues more readily, may be required. There is an important association between the incidence and severity of perioperative apnea and anemia [24,29]. For individual cases transfusion triggers will depend on the starting hematocrit, the likelihood of blood losses, the risk of apnea, and the presence and severity of co-morbidities such as BPD and cardiac disease [46].

Patent ductus arteriosus

PDA is common amongst ex-premature babies and the prevalence has increased with improved survival rates and as a concurrent effect of exogenous surfactant therapy. PDA may still be present when an ex-premature baby presents for other surgery, especially emergency surgery. For elective surgery, consideration should be given to closure of the duct first, by medical therapy (e.g. with indomethacin or ibuprofen [47]), transcatheter device closure, thoracoscopic duct ligation/clipping, or open duct ligation/clipping as appropriate. The presence of a PDA adds risks because of left-to-right shunting with increased lung water, decreased lung compliance, pulmonary hypertension, congestive heart failure, potential for shunt reversal, and increased risk of hypotension, especially diastolic hypotension due to excessive run-off into the pulmonary circuit. Coronary arterial hypoperfusion with myocardial ischemia can occur. The low diastolic blood pressure can also result in splanchnic hypoperfusion. Cardiac output reserves are also diminished for the ill baby (e.g. with necrotizing enterocolitis – NEC) or should bleeding occur during surgery; severe hypotension may occur in such cases.

Difficult vascular access

Ex-premature infants may present serious difficulties with peripheral and central venous access and sometimes also arterial access, particularly if they have had a long and complicated NICU stay. Peripheral veins may have been used repeatedly for blood sampling or cannulated for intravenous fluid and drug administration or for central venous access using a peripherally inserted central catheter (PICC). Central veins may have become thrombosed; this often induces the expansion of collateral venous channels that can be very difficult to cannulate, catheterize, and sustain.

Altered pain perception and responses and tolerance to analgesics and sedatives

Most premature babies are exposed to multiple painful procedures in early life. These can alter sensory perception, including that for pain, and also induce long-term changes in sensory responses and behavior [48–56]. This can manifest clinically as increased sensitivity to pain [56] and increased analgesic requirements or alternatively reduced sensitivity to pain [48]. For the anesthesiologist, this emphasizes the importance of individualizing pain assessment and management [57]. In addition, premature babies may have had considerable exposure to sedative and analgesic drugs during their NICU stay and may have developed tolerance with important effects on their individual dose requirements [58–61].

KEY POINTS: RESIDUA AND COMPLICATIONS OF PREMATURITY

- Chronic lung disease persists in up to 10% of ex-premature infants; incidence and severity have decreased due to modern ventilatory strategies
- Postanesthetic apnea is a risk until approximately 60 weeks' postconceptional age, with young postconceptional age, anemia, and type of surgery as major risk factors
- Cerebral damage, mainly from white matter injury and intraventricular hemorrhage, may manifest as cerebral palsy, cognitive and behavioral deficits, hearing loss, and visual impairment
- Residual eye problems, from retinopathy of prematurity, can occur in up to 50% of ex-premature infants, and avoiding hyperoxia and hypoxia is crucial for those patients at risk

Operating room environment for the neonate

The operating room (OR) environment for the neonate must carry a range of appropriate equipment drugs and fluids and must have appropriate means of maintaining the baby's temperature to minimize heat losses to the environment. The ambient room temperature should be increased to around 23–25°C (80–85°F), anesthetic inspired gases should be warmed and humidified, IV fluids should be delivered via a warming device, and a forced warm air delivery device and/or warming blanket used. Exposure of the baby to the ambient environment should be minimized to avoid heat losses. For awake regional anesthesia, the ambient light level should be lowered and monitor alarm volumes reduced to a minimum. Monitoring equipment should comply with current standards and include electrocardiogram (ECG), precordial/esophageal stethoscope, pulse oximetry, and monitors for blood pressure (BP), temperature, and both inspired and expired anesthetic agent and gas composition. Appropriate sizes of pulse oximeter probes and provision to monitor pre- and postductal saturations should be available. The anesthetic machine should be able to deliver air and oxygen to allow titration of inspired oxygen to avoid hypoxia or hyperoxia and should have a ventilator capable of supporting small infants, including delivery of PEEP if needed. Many pediatric anesthesiologists prefer non-rebreathing circuits but circle systems are now being used more widely. Technological advances allow improved gas monitoring, including accurate tidal volume and pressure measurement, which can be very helpful. Invasive pressure monitoring should be readily available. A full range of airway equipment appropriate for small infants must be immediately available including facemasks, oral airways, laryngeal mask airways (LMAs), suction catheters, stylets, tracheal tubes, and laryngoscope blades. A full range of anesthetic, analgesic, muscle relaxant and resuscitation drugs, and IV fluids (including dextrose 10%) should be immediately available. Peripheral and central venous cannulae of appropriate size and length should be immediately to hand, as should small size intraosseous needles. Many ORs construct a neonatal cart which is checked regularly to ensure all equipment is present in case of an emergency. When difficult intubation is anticipated, an appropriate sized fiberoptic bronchoscope, videolaryngoscope, and intubation aids such as guidewires and airway exchange catheters should be available.

There is a growing acceptance that it may be advantageous for some groups of neonates to undergo surgery outside the OR in the NICU [62,63]. This is not a new concept: for many years surgical ligation of a PDA has been performed in the NICU and found to be safe and cost effective. Repair of congenital diaphragmatic hernias and laparotomies for NEC have also been extensively reported. Ex-premature or low birthweight neonates who are ventilated and/or critically unstable may not tolerate handling and transport to the OR. They may be stable on neonatal ventilators or high-frequency oscillators delivering respiratory parameters that are not possible to achieve on ventilators in the OR. Surgery in the NICU has the advantages of avoiding disruption to ongoing critical care management by maintaining the presence of specialist neonatology input, physiological stability, and a thermoneutral environment, and avoiding the potential risks of inter- or intrahospital transportation such as dislodgement of intravenous or arterial lines or endotracheal tubes.

There are anesthetic and surgical challenges to overcome in facilitating surgery in the NICU. It is an unfamiliar, often hot and poorly lit environment, with minimal space and scavenging for anesthetic machines. Anesthesia is usually delivered intravenously and opioid-based as a result. Access to the neonate in the incubator can be difficult and the lack of space can lead to disruption for the other neonates and their families, and staff on the unit.

The NICU environment must provide the same range of anesthetic equipment, adequate monitoring, and drugs found in the OR. These are often transported from the OR in a prestocked neonatal trolley to minimize delay and avoid the need to retrieve equipment from the OR intraoperatively.

Postoperative extubation versus postoperative ventilation

For the neonate undergoing surgery under endotracheal general anesthesia the question of whether to extubate or not at the end of surgery is a common dilemma. For some infants with major co-morbidity undergoing major surgery the decision may be clear, but for others it may be more difficult. Because of their size and their relative physiological immaturity, neonates and ex-premature infants require careful consideration for postoperative extubation. They are sensitive to many environmental, physiological, and pharmacological factors; before the decision to extubate is taken, the anesthesiologist must take all of these factors into account.

Newborn and ex-premature infants differ physiologically from older children with regard to certain aspects of their respiratory physiology, and this has some bearing on the decision (see Chapters 7 and 22). Minute ventilation and therefore the relative work of breathing in the neonate is three to four times greater than in adults because of much higher oxygen consumption [64]. During normal tidal ventilation, neonatal lungs are close to closing volume [65]. This means more rapid desaturation during apneic episodes. Furthermore respiratory control mechanisms are not fully mature and hypoxia can result in short periods of hyperventilation followed by apnea [66]. An immature respiratory center is also sensitive to the effects of volatile anesthetics and sedative and opioid drugs. These factors mean that, for all but the shortest and non-stimulating procedures, tracheal intubation and controlled ventilation are appropriate.

In general, the attainment of normal physiological parameters is a prerequisite prior to extubation of the ex-premature or term neonate following general anesthesia. The infant should be awake and able to flex the hips and lift the arms. Muscle relaxation should be fully reversed and there should be a regular respiratory pattern with adequate minute ventilation and a satisfactory $PaCO_2$. The infant should also be normothermic as the consequences of hypothermia include delayed drug metabolism, hypoxia, and apnea [6]. Apnea risk is a particularly important factor in those under 44 weeks' PCA) [28] with a lesser but not insignificant risk in those infants born at less than 37 weeks, in whom the risk persists until 60 weeks' PCA [29]. Prophylactic respiratory stimulants such as caffeine or theophylline are highly recommended in these groups, particularly if early extubation is being considered [32,33,67]. Anemia in the immediate postoperative period should be corrected because a hemoglobin level of <10 g/dL has also been shown to significantly increase the risk of postoperative apneic episodes [24], although this was not confirmed in the GAS study [30]. Opioid administration is also a factor that must be considered. The less well developed neonatal blood–brain barrier allows greater penetration of opioids into the cerebrospinal fluid in the newborn [68]. Moreover, an immature respiratory center is more sensitive to the respiratory depressant effects of opioid drugs [69]. The use of shorter acting opioids such as alfentanil or remifentanil may facilitate extubation more easily but transition to ongoing analgesia can be difficult to manage. Care must be exercised with the use of morphine, which has a much longer half-life. Also, its active metabolite morphine-6-glucuronide is excreted renally. Immature renal tubular function in the term and ex-premature infant therefore means there is reduced clearance of morphine and its main metabolites, thus prolonging their effects. For the neonate undergoing surgery, intubation and postoperative ventilation may be mandatory, for example in the case of repair of congenital diaphragmatic hernia or in long-gap esophageal atresia. Significant hypothermia, hypoglycemia, hypocalcemia, or other uncorrected biochemical abnormalities are also indications for postoperative ventilation. Similarly, there is rarely reason to consider extubation in the syndromic infant or in the case of major thoracic, abdominal, or airway surgery. However early extubation, either in the OR or within 3 h, has been found feasible in some neonates undergoing cardiac surgery [70]. The advantages are thought to be reduced postoperative complications, a shorter hospital stay, and reduced costs. This is only achievable in some centers and with a dedicated and highly involved multidisciplinary team approach.

For infants undergoing some abdominal or thoracic procedures, the choice of anesthetic technique can influence the decision to extubate post procedure. Desflurane, with its low blood/gas and tissues/gas solubility coefficients has a very rapid offset and while it may be irritant and unsuitable for spontaneous ventilation it is a very useful agent in the ventilated neonate and is the volatile agent of choice for maintenance of anesthesia when extubation is required. The addition of local anesthetic techniques to supplement general anesthesia may reduce or eliminate the need for opioids. Inguinal hernia repair, for example, can be achieved easily without opioids by either supplemental ilioinguinal nerve blockade or caudal epidural anesthesia. Epidural techniques are appropriate in many scenarios and often allow a reduction in opioid administration. Caudally sited epidural anesthesia is a straightforward procedure and is useful for both abdominal and thoracic surgery depending on level. In esophageal atresia repair it has been shown to reduce the need for postoperative ventilatory support [71].

KEY POINTS: OPERATING ROOM ENVIRONMENT AND POSTOPERATIVE EXTUBATION VERSUS VENTILATION

- The OR environment must be fully prepared with equipment and drugs for small neonates
- Temperature maintenance with a warm OR, forced air warming, and warmed IV fluids is essential
- Careful attention to stability during transport to and from the OR is crucial
- Bedside surgery in the NICU is safe and cost effective for many conditions
- Early tracheal extubation is desirable for many full-term neonates; full reversal of neuromuscular blockade, adequate respiratory effort, and emergence need to be ensured

Inguinal hernia

Inguinal hernias are found in up to one-third of ex-premature neonates [72] and it is recommended that they are repaired surgically in early life because of the risks of incarceration of bowel in the hernia sac (bowel obstruction, bowel infarction) and testicular infarction. The need for early surgery has to be balanced against the risks of anesthesia, perioperative apnea, and medical co-morbidities, including the residual effects of prematurity. The optimal timing of surgery [73] has to be decided on an individual case basis but some hernias need urgent repair, particularly those that are irreducible, those associated with frank signs of bowel obstruction, or those that are very large where the testicular blood supply may be compressed or compromised. The decision-making process has been affected by recent concerns about developmental neurotoxicity of general anesthetic and sedative agents [74–76]. This has led to renewed interest in awake regional anesthesia techniques [77–92]. The GAS study [76] reported no difference in neurodevelopmental outcome at 2 years of age (a secondary outcome milestone) when comparing sevoflurane anesthesia with awake regional anesthesia [93]. Some units now favor delaying repair but the risks of leaving hernias unrepaired are significant in an already vulnerable population [73]. Surgical techniques and attitudes to prophylactic repair of the contralateral side are evolving with the advent of laparoscopy [94,95]. Many centers now undertake these procedures entirely laparoscopically, while others use the technology to inspect the contralateral side. Open repair is still widely practiced and gives good results [96]. All surgical repair techniques have complications (infection, bleeding, testicular infarction, bowel perforation, hernia recurrence) and opinion is still divided as to whether open surgery or laparoscopy has a lower incidence of these various problems [94]. Often the hernia repair is scheduled toward the end of the baby's hospital stay prior to discharge home from NICU or the specialist children's center, although some babies go home first and are then readmitted at a slightly later stage if the hernias are deemed to be low risk.

The baby should be assessed for residual effects or complications of prematurity or NICU care as noted previously and in particular for the known risk factors related to PCA, anemia, co-morbidities [29] and nature of the hernia (elective, emergency, unilateral, bilateral, very large, incarcerated, or complex) and surgical technique (open, laparoscopic, open with contralateral inspection) [94]. Whichever anesthetic technique is used, general anesthesia or awake regional anesthesia, the earlier guidance about monitoring and aftercare should be used. Consider the use of caffeine 10 mg/kg IV if the baby is not already receiving it. The choice of anesthetic technique should be discussed in detail with the surgical team and with the parents and informed consent obtained.

Anesthetic and analgesic techniques

There are two main groups of techniques, both with a considerable evidence base behind them, namely awake regional anesthesia and general endotracheal anesthesia (usually with a regional analgesic component).

Awake regional anesthesia

This may be provided by a single-shot spinal (subarachnoid) injection of local anesthetic [35,78–80,83,84,87,88,90,97–108], a single-shot caudal (epidural) injection of local anesthetic [20,79,85,87,88,109,110], a combination of these (see Case study at the end of this chapter), or a catheter-based caudal anesthetic (single or multiple shots and/or continuous infusion of local anesthetic) [77, 91]. Plain local anesthetic solutions are preferred for ex-premature and term neonates because additives such as clonidine can produce an increased apnea risk [111–115]. However, epinephrine has been shown to prolong spinal anesthesia with tetracaine by about one-third. The local anesthetic agents used include tetracaine [100], bupivacaine [78,80,116], ropivacaine [108,116], and levobupivacaine [116] (see Table 23.1).

Spinal anesthesia has the advantage of quicker onset than a caudal but duration may be shorter and the institution of the block can be technically challenging with a failure rate of up to 15%. In the GAS study, the only predictor of failure was a bloody tap on first attempt at lumbar puncture [117]. The doses in Table 23.1 typically give a block adequate for inguinal surgery lasting around 1 h but a tetracaine spinal may extend this by a further hour [79]. Additionally, even with a successful block, the conversion rate to general anesthesia because of inadequate surgical conditions is as high as 20% [117]. Supplementation of the spinal block with any sedative or anesthetic agent results in loss of the benefits in terms of reduced apnea. Sucrose analgesia is a useful adjunct and often helps settle a restless baby [118]. Some authors feel that a caudal is more likely to succeed, and more anesthesiologists are familiar with caudal blocks so the disadvantage of slow onset is countered by improved reliability and longer duration of action [79].

Table 23.1 Recommended doses of local anesthetic agents for awake regional anesthesia for inguinal hernia repair in neonates

Local anesthetic	Concentration	Dose (mg/kg)	Reference
Spinal anesthesia			
Tetracaine	10 mg/mL hyperbaric	1	[100]
Bupivacaine	5 mg/mL hyperbaric	0.3	[78]
Bupivacaine	5 mg/mL isobaric	1	[116]
Levobupivacaine	5 mg/mL isobaric	1.2	[116]
Ropivacaine	5 mg/mL	1	[108,116]
Caudal anesthesia			
Bupivacaine	2.5 mg/mL	2	[79]
Levobupivacaine	2.5 mg/mL	2	[214]
Ropivacaine	2 mg/mL	2	[214]

General anesthesia

General endotracheal anesthesia could be regarded as the standard technique but early study results were confounded by use of older volatile agents such as halothane [100]. With newer volatile agents such as sevoflurane and desflurane showing promise for infant anesthesia in terms of speed of recovery and low incidence of postoperative respiratory complications [119–121], a head-to-head study of spinal versus sevoflurane anesthesia for hernia repair in ex-premature infants [104] favored spinal anesthesia in terms of reduced early respiratory adverse events but there were a number of failures to secure a spinal block which gave cause for concern. The GAS study results confirmed these findings [30,31,93]. General anesthesia with modern volatile agents, supplemented by local anesthetic infiltration, peripheral nerve block, or a caudal is therefore a more reliable and flexible technique and may be essential in certain cases, in particular incarcerated, complex, or very large bilateral hernias. With an increasing trend toward laparoscopic repair, it may well be that general anesthesia for such cases will be needed more often in the future. A number of initiatives to improve the quality and safety of general anesthesia in infants are recommended, such as Safetots (www.safetots.org), which focuses on maintaining physiological norms for age throughout the perioperative period and ensuring appropriate facilities and trained staff [122]. The importance of this approach is emphasized by the GAS study secondary results showing significantly more hypotension and interventions to treat hypotension in the general anesthesia group compared with the regional anesthesia group [123].

KEY POINTS: INGUINAL HERNIA

- Each baby should be assessed for residual effects or complications of prematurity or NICU care and for the known risk factors related to postconceptual age, anemia, co-morbidities and nature of the hernia (elective, emergency, unilateral, bilateral, very large, incarcerated, or complex) and surgical technique (open, laparoscopic, open with contralateral inspection)
- Awake regional anesthesia has advantages in some cases but should only be used by experts with adequate training and ongoing experience in the technique
- If awake regional anesthesia is used, there should be a clear plan in case of failure of the technique and should surgery become more complex or extensive
- For cases under general anesthesia, an appropriate regional block should be used as part of the technique unless specifically contraindicated

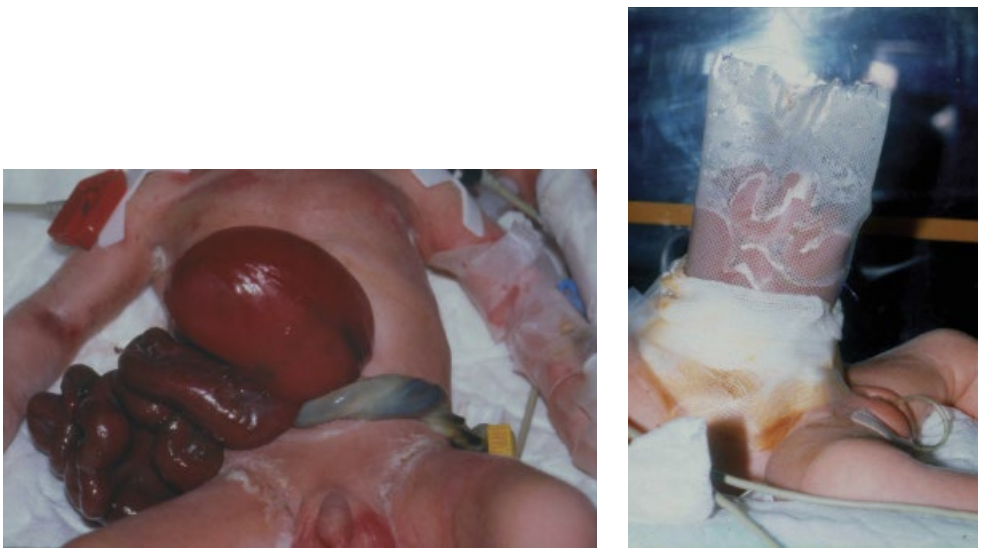
Abdominal wall defects

Abdominal wall defects are congenital abnormalities that are usually detected antenatally by fetal ultrasonography. Gastroschisis and omphalocele are the most common defects, resulting in herniation of viscera through a defect in the upper or lower abdominal wall [124,125]. Although the anesthetic management of these conditions is essentially the same, the two conditions have significant embryological and clinical differences [126].

Gastroschisis

The incidence of gastroschisis is approximately 1 in 3000–8000 livebirths. It is more common in mothers aged <20 years, the infant tends to be born prematurely with a low birthweight, and in recent years the incidence has been rising for reasons unknown [127–129]. Specialist antenatal and postnatal care results in a survival rate of over 90%. Gastroschisis is a congenital defect of the abdominal wall resulting in herniation of the abdominal contents, most commonly the small and large intestine (Fig. 23.2).

The defect is usually on the right side of a normally developed and positioned umbilical cord, and the viscera are not enclosed in a peritoneal sac. The vertical opening is approximately 2–5 cm in length making herniation of other organs,



(A) (B)

Figure 23.2 (A) Gastroschisis. (B) Silo for gastroschisis.

such as the liver, unusual. The herniated intestine often appears dilated, foreshortened, and edematous, and is covered in a thick inflammatory fibrin peel, likely due to exposure to amniotic fluid *in utero*. The intestine is often functionally abnormal and this may be complicated by the presence of intestinal atresia, stenosis, or malrotation [130]. Associated congenital anomalies are uncommon in gastroschisis, however initial routine investigations should aim to exclude potential cardiac abnormalities. The etiology of gastroschisis is not certain but is thought to involve vascular disruption of either the right umbilical vein or right omphalomesenteric artery. The result is paraumbilical ischemia and atrophy of the layers that form the anterior abdominal wall at the base of the umbilicus [131].

Following delivery the initial priorities for gastroschisis must focus on ensuring the newborn has a safe and patent airway, ventilation and oxygenation are not compromised by the defect, the exposed bowel is protected, and fluid and heat loss are minimized and adequately managed. Reduction of the abdominal contents should take place urgently within hours of delivery to minimize the risk of volvulus, ischemia, and infection. A nasogastric tube should be inserted to decompress the bowel, minimizing any splinting of the diaphragm, and reducing the risk of regurgitation and aspiration. If signs of respiratory distress are evident or the newborn requires large volumes of fluid resuscitation then endotracheal intubation and ventilation are necessary.

The exposed bowel should be covered and supported using a sterile plastic wrap or a clear polythene bag to cover the lower limbs and abdomen to minimize fluid and heat loss.

The newborn should be dried and then placed under a radiant heater or in a heated incubator. Patients with gastroschisis should be nursed on their right side in a lateral decubitus position to enhance venous return from the gut and avoid vascular compromise. Intravenous access is required early to allow fluid resuscitation, administration of broad-spectrum antibiotics, blood sampling, and cross-match if going to surgery. Umbilical vessel catheterization is contraindicated. Third space losses in gastroschisis can be substantial and require fluid resuscitation with isotonic solutions: 0.9% normal saline, Hartmann's solution, PlasmaLyte®, 5% albumin, blood, or blood products. Boluses of 20 mL/kg should be given and the adequacy of resuscitation regularly monitored. Regular assessment of capillary refill, core–peripheral temperature gradients, heart rate, urine output, and evidence of correction of acid–base disturbance will help guide the resuscitation efforts. Insertion of a peripheral arterial line is invaluable for repeated sampling to detect acid–base or electrolyte changes during the resuscitation and perioperative period.

Surgical management of the newborn depends on the size of the defect. Small defects can be closed by primary closure in the OR under general anesthesia or in the NICU without an anesthetic. If the defect is large, concerns arise about the effects of returning the abdominal viscera into a relatively small abdominal cavity, resulting in raised intra-abdominal pressure and abdominal compartment syndrome (ACS). Raised intra-abdominal pressure reduces venous return from compression of the inferior vena cava, decreasing cardiac output. Perfusion of the renal and splanchnic circulation is impaired, potentially leading to renal failure and bowel ischemia causing intestinal perforation, NEC, and a metabolic acidosis. Raised intra-abdominal pressure increases tension on the wound, causing dehiscence, and also results in splinting of the diaphragm, causing respiratory failure. The safety of primary closure can be assessed intraoperatively by measurement of intragastric, bladder, and central venous pressures or changes in ventilatory pressures as an indirect way of measuring intra-abdominal pressure. Intragastric or intravesical pressures less than 20 mmHg were found to result in successful primary closure and no ACS in neonates with gastroschisis [132,133]. Peak plateau respiratory pressures should be kept below 25 cmH_2O [134]. Gastric tonometry and pulse oximetry have also been used to help predict the onset of ACS [135,136]. If the surgeon is unable to perform a primary closure then a staged reduction is undertaken. The neonate may initially be taken to the OR and fitted with a protective Silastic® silo, or in some cases the silo may be applied in the NICU without general anesthesia. The silo is suspended above the incubator, allowing gravity to ease the viscera back into the abdominal cavity over the next 5–7 days. Each day the silo is gradually reduced in size, minimizing the risk of ACS. Once reduced, the neonate is returned to the OR for surgical closure of the abdominal wall defect.

Important anesthetic considerations include the following.

1. Ensure the baby is adequately resuscitated and preoperative tests are performed before coming to the OR.
2. Actively warm the neonate during transfer to the OR in their incubator and on arrival in the OR with overhead radiant heaters, warm air blankets on the OR table, intravenous fluid warmers, and humidified and warmed anesthetic gases. Monitor core and peripheral temperature perioperatively.
3. Aspirate the nasogastric tube before induction in left lateral, right lateral, prone, and supine positions.
4. Induction may be a rapid-sequence induction (RSI) or modified RSI. Sevoflurane induction may be performed and atracurium, vecuronium or rocuronium used for muscle relaxation prior to intubation.
5. Nitrous oxide should be avoided to prevent further intestinal distension.
6. Provide analgesia using morphine or fentanyl; for smaller defects where early extubation is anticipated, a regional block technique may be used.
7. Maintenance fluids (containing 10% dextrose) supplemented with boluses of albumin 5% or other isotonic solutions should be titrated according to the cardiovascular status of the neonate.
8. In addition to routine monitoring of intragastric or intravesical pressures, urine output and lower limb oxygen saturations may be measured to assist in deciding whether a primary closure is possible.
9. An intra-arterial cannula is useful for regular blood sampling and acid–base monitoring. Central venous cannulation, either conventional via internal jugular or subclavian routes, or PICC lines, is necessary for large defects where repeat procedures or prolonged total parenteral nutrition (TPN) are required.
10. The majority of neonates are returned to NICU intubated, ventilated, paralyzed, and sedated for further monitoring and ongoing management. They are ventilated until the bowel has settled back into the abdomen. TPN feeds, antibiotics, and muscle relaxants are given.

In some centers reduction may take place in the NICU without general anesthesia. NICU reduction is carried out in newborns who are stable and uncomplicated, i.e. absence of perforations, volvulus, atresias, and obstruction [137,138]. The introduction of a spring-loaded silo that can be fitted at the bedside without any sutures or anesthesia has permitted staged closure in the NICU. When the reduction is complete the umbilicus is often used to plug the defect.

Spinal anesthesia has been described as a technique suitable for primary surgical closure of gastroschisis, however its short duration of action and unpredictable block level was less than ideal [139]. Similarly, a combined spinal–epidural technique has also been described but was found to be time-consuming and often technically difficult [140]. A recent small case series has advocated the use of caudal anesthesia as an alternative to general anesthesia [141]. The authors suggest it may be useful in high-risk cases to avoid general anesthesia and the subsequent requirement for postoperative mechanical ventilation. They also suggest it may be a useful technique in areas of limited resources.

Outcome in gastroschisis is generally good unless complicated by intestinal atresia, stenosis, perforation, NEC, volvulus, sepsis, rare associated cardiac abnormalities, or problems relating to prematurity (respiratory distress syndrome, intraventricular hemorrhages) [130].

Omphalocele

Omphalocele has an incidence of 1in 5000 livebirths. It is an abdominal wall defect where the abdominal viscera herniate into the base of the umbilical cord through the umbilical ring. It is thought to result from failure of the midgut to return to the abdominal cavity around week 10 of gestation causing incomplete closure of the anterior abdominal wall around the umbilicus. Unlike gastroschisis, the viscera are covered by a membrane and the bowel looks normal. Occasionally the peritoneal sac may rupture and can resemble gastroschisis although examination of the intestine helps differentiate these two conditions. The herniation may be a small defect 2–5cm in diameter (exomphalos minor) or may be large (greater than 10 cm) involving liver and spleen, with poorly developed abdominal and thoracic cavities and pulmonary hypoplasia (exomphalos major) (Fig. 23.3). In patients with a large omphalocele, the position of the viscera and liver may compress the inferior vena cava in the supine position and so preferentially these infants require to be nursed on their left side. A ruptured omphalocele can result in considerable third space fluid loss.

Associated congenital abnormalities are much more common than in gastroschisis with at least 60% of infants born with omphalocele having at least one associated anomaly. These may be cardiac in origin (30–40%), chromosomal abnormalities (trisomy 13, 18, or 21), cloacal or bladder extrophy, or Beckwith–Wiedemann syndrome (macroglossia, organomegaly, hypoglycemia, gigantism, and congenital heart disease) [142]. Rarely, omphalocele may be part of the thoraco-abdominal pentalogy of Cantrell with a cleft sternum, anterior diaphragmatic hernia, heart defects, and an absent pericardium [143]. Given that associated anomalies are more common in this condition, a thorough preoperative examination with appropriate investigations (chest x-ray, cardiac echo, renal ultrasound, and routine blood investigations) should be performed before surgical correction.

Anesthetic management of omphalocele is very similar to that for gastroschisis. Unless the membrane is ruptured, omphalocele repair is less urgent. Defects without rupture of the membranous sac may be allowed to epithelialize on the ward using topical agents (silver sulfadiazine or antibiotic preparations) and a silo, avoiding any surgical intervention in the initial stages. This may take several weeks to months, after which the infant will return to surgery for repair of the ventral hernia defect [144]. Care must be taken for cases that come to the OR for reduction or silo fitting if the liver is herniated. Damage to the liver parenchyma or compression of the hepatic veins can result in dramatic periods of cardiovascular instability. Outcome in omphalocele is mainly dependent on the severity of additional abnormalities and chromosomal defects. Infection, surgical complications, low birthweight, hernia rupture, and intestinal obstruction also contribute to mortality rates.

Figure 23.3 Omphalocele (exomphalos major).

Many centers are now utilizing non-operative delayed closure of giant omphaloceles, consisting of gradual intra-abdominal reduction followed by delayed epithelialization of the defect, facilitated by silver sulfadiazine or povidone–iodine ointment. A systematic review of this approach versus standard operative treatment revealed similar mortality rates with non-operative closure (21.8% versus 23.4% in the surgical group) and shorter time to full enteric feedings (14.6 versus 23.5 days). This approach has reduced the number of these infants undergoing primary surgical closure [145].

KEY POINTS: GASTROSCHISIS AND OMPHALOCELE

- Gastroschisis is usually right-sided, the umbilical cord is not involved, the intestines are not covered by peritoneum, and the patient usually has no other congenital anomalies except that prematurity is common
- Omphalocele herniates into the base of the umbilical cord, intestines are covered by a membrane, and 60% of patients have at least one associated anomaly, including cardiac in 30–40%
- Delayed closure and use of silo techniques are becoming the norm for management of abdominal wall defects
- In addition to routine monitoring of intragastric or intravesical pressures, urine output and lower limb oxygen saturations may be measured to assist in deciding whether a primary closure is possible

Esophageal atresia and tracheo-esophageal fistula

Esophageal atresia (EA) encompasses a group of congenital anomalies in which there is interruption of the continuity of the esophagus. In 86% of cases this coexists with a distal tracheo-esophageal fistula (TEF), while in 7% there is no fistulous connection. In 4% of cases there is a TEF but no EA. EA occurs in around 1 in 2500–3000 livebirths. In less than half of these the condition exists in isolation while more than 50% occur in the presence of other congenital anomalies, the commonest being one or more of those associated with the VACTERL group of anomalies (vertebral, anal, cardiac, tracheo-esophageal, renal and limb defects). The presence of a major cardiac anomaly reduces an almost complete survival rate to around 80%. Low birthweight is also associated with a survival rate of around 80%, while the presence of both of these risk factors together reduces survival to 30–50% [146]. Respiratory insufficiency, however, is the single most significant risk factor affecting outcome [147]. Together these factors provide a significant challenge to the anesthesiologist [148,149].

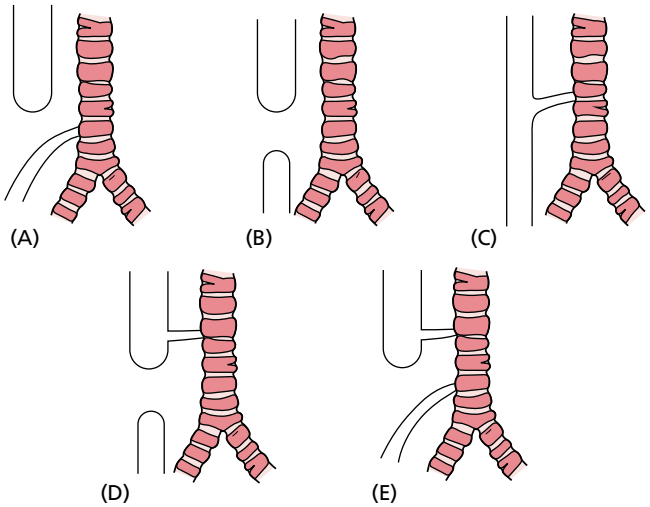


Figure 23.4 Esophageal atresia and tracheo-esophageal fistula variants. (A) The commonest arrangement with a blind upper esophageal pouch and a distal tracheo-esophageal fistula (Gross type C, Vogt type 3B). (B) Proximal and distal esophageal stumps with a missing segment and no TEF (Gross type A, Vogt type 2). (C) H-type fistula (Gross type E). (D) Proximal esophagus meets distal trachea with distal esophageal stump (Gross type B, Vogt type 3A). (E) Proximal esophagus terminates on lower trachea with distal esophagus arising from carina (Gross type D, Vogt type 3C).

Clinical features

Two classification systems are in use today, the first being that proposed by Vogt in 1929, later modified by Gross in 1953. These are summarized in Table 23.2.

The most commonly occurring defect is Gross type C (Vogt 3B), which accounts for 86% of EAs (Fig. 23.4). These classification systems are, however, not comprehensive, and variations other than those described can occur.

Diagnosis

Suspicion may be raised by antenatal ultrasound scan at around 18 weeks' gestation. This may show an absent or small gastric bubble. The incidence of EA is also increased in the presence of polyhydramnios. The diagnosis may be confirmed at birth in these babies by failure to pass a nasogastric tube beyond 9–10 cm from the mouth. This is usually confirmed by a plain abdominal and chest radiograph that may reveal other associated anomalies such as vertebral or rib abnormalities or the "double bubble" associated with duodenal atresia. However, if not suspected prenatally, EA may not manifest itself until feeding begins, whereupon the baby may cough, choke, and become cyanosed. Failure to recognize the condition swiftly can result in the development of aspiration pneumonitis, and dehydration can result due to accumulation of saliva and disturbed swallowing. Initial preoperative surgical management involves the passage of a suction catheter, often a radio-opaque double-lumen tube (Replogle tube) into the blind-ending pouch for continuous irrigation and suction.

Table 23.2 Classification of esophageal atresia and tracheo-esophageal fistula

Gross	Vogt	Description
	Type I	Esophageal agenesis (not included by Gross). No fistula present
Type A	Type 2	Proximal and distal esophageal stumps with a missing mid segment. No fistula present
Type B	Type 3A	Proximal esophagus meets lower trachea with distal esophageal stump
Type C	Type 3B	Proximal esophageal atresia. Esophagus ends in blind loop superior to sternal angle with the distal esophagus arising from the lower trachea or carina
Type D	Type 3C	Proximal esophagus terminates on lower trachea or carina with distal esophagus arising from carina
Type E (or Type H)	–	Type D variant where the esophagus is continuous but the presence of a fistula creates the appearance of the letter H
Type F	–	Esophageal stenosis

Preoperative evaluation

The baby presenting with EA/TEF presents many challenges for the anesthesiologist. First, due to the large variation in the anatomy of these lesions, correct placement of the endotracheal tube may be difficult. Furthermore, prematurity of 34 weeks' gestation or less is present in 12% of babies presenting with esophageal atresia [150] and may result in moderate to severe neonatal respiratory distress syndrome. Associated anomalies may also impact significantly on both the difficulty of the anesthetic and the outcome for the patient. Cardiovascular anomalies account for 29% [151] and have been shown to be the single most common mortality-related association in EA [152]. Of the other associated anomalies, anorectal defects comprise 14%, genitourinary 14%, gastrointestinal 13%, vertebral/skeletal 10%, respiratory 6%, genetic 4%, and others 11% [151]. Preoperative evaluation of infants with EA should include a detailed history of the neonatal course including delivery. A history of polyhydramnios may also indicate possible renal anomalies and is more common where there are associated chromosomal abnormalities such

as Down syndrome or Edwards syndrome. Major neurological anomalies may impair fetal swallowing, also resulting in polyhydramnios. If there is no antenatal suspicion and the infant presents later, a feeding history should be obtained with special attention being paid to episodes of cyanosis or choking that may indicate aspiration and the possible development of aspiration pneumonia. Preoperative preparation by this time will have established a blind-ending esophagus with continual suction and irrigation of the pouch being provided, preferably by a Replogle tube. A full anesthetic history should also be obtained from the parents regarding any significant family reactions to anesthesia. A plain radiograph of the chest and abdomen will confirm the tip of the suction catheter proceeding no further than the upper mediastinum while gas in the stomach is significant in that it confirms the presence of a TEF. Absence of gas suggests an isolated atresia. A clinical examination of the neonate should have established any dysmorphic features and indicated the presence of any major cardiac anomaly. However, cardiac echo is required routinely as a preoperative investigation in these cases. This will define any structural abnormality of the heart but may also reveal a right-sided aortic arch, which occurs in 2.5%. This has implications for patient positioning and surgical approach [153] and may also significantly affect ventilation. A congenital cardiac lesion producing high pulmonary blood flow is unlikely to pose significant physiological problems during the first few days after birth as pulmonary vascular resistance remains high initially. These patients can usually proceed safely for surgical correction. However, patients who have lesions with significant right- or left-sided obstructive components may have either a systemic or pulmonary circulation that is ductus arteriosus dependent. Babies with duct-dependent circulation have been shown to have a significantly increased risk of mortality [154]. In these cases the duct can be kept open with an infusion of prostaglandin E_1 and if the baby remains stable and in good condition, surgery may proceed. A small number of patients will present in poor condition with a closed or closing duct. In these cases resuscitation is often required and surgery needs to be delayed. Rarely, such babies will require a palliative shunting procedure or cardiac repair prior to surgery for EA [155]. A renal tract ultrasound scan is required due to the associated incidence of genitourinary anomalies. Blood biochemistry and hematology should be ascertained and blood should be cross-matched for surgery. Assessment of the respiratory system is paramount. The presence of respiratory distress is a significant prognostic indicator [147] and has an important bearing on the conduct of anesthesia in particular with regard to the principle of maintaining low airway pressures. Preoperative oxygen saturation should be measured and increased oxygen requirement noted.

Conduct of general anesthesia

Preparation of the operating environment is as for any other small baby. However, particular attention needs to be paid to the ambient temperature. This may need to be increased in the case of the premature infant. A heated warming mattress, heated and humidified breathing circuit, and warmed intravenous and irrigation fluids will help to prevent heat loss. Intravenous access would ordinarily have been established prior to surgery as these babies are unable to feed. This can be used for maintenance fluids with 5–10% glucose where required. A second IV line is required for replacement therapy, and this should be of sufficient caliber to allow for rapid replacement of blood loss if required. In addition to the application of standard monitoring, invasive arterial pressure monitoring is invaluable as it allows for real-time measurement. This is especially so in the case of aberrant cardiac or great vessel anatomy where surgical access may cause hemodynamic compromise. It also allows for easy blood sampling intraoperatively. This can be particularly useful where significant respiratory compromise exists and allows for rapid and accurate assessment of gas exchange and acid–base status. Central venous access is not usually required but may be necessary in the event of failure to establish adequate peripheral intravenous access.

The major consideration of both anesthetic and surgical management of the neonate with EA and TEF is ventilation of the lungs without ventilation of the fistula (Fig. 23.5). Endotracheal tube misplacement can result in undesirable consequences such as massive gastric distension and resulting respiratory and cardiovascular compromise. Even with a correctly placed endotracheal tube, poorly compliant lungs and a large distal fistula can result in selective passage of anesthetic gases into the gastrointestinal tract resulting in hypoventilation, hypercarbia, and a respiratory acidosis [156]. The interplay between the variable anatomy of the defect, pre-existing co-morbidity, and anesthetic technique may be unpredictable. As a result, techniques have focused on the avoidance of muscle relaxants and positive pressure ventilation until ligation of the fistula is achieved [157]. Traditionally, intubation may have been performed awake but in the preterm neonate this is associated with an increased risk of intraventricular hemorrhage [158].

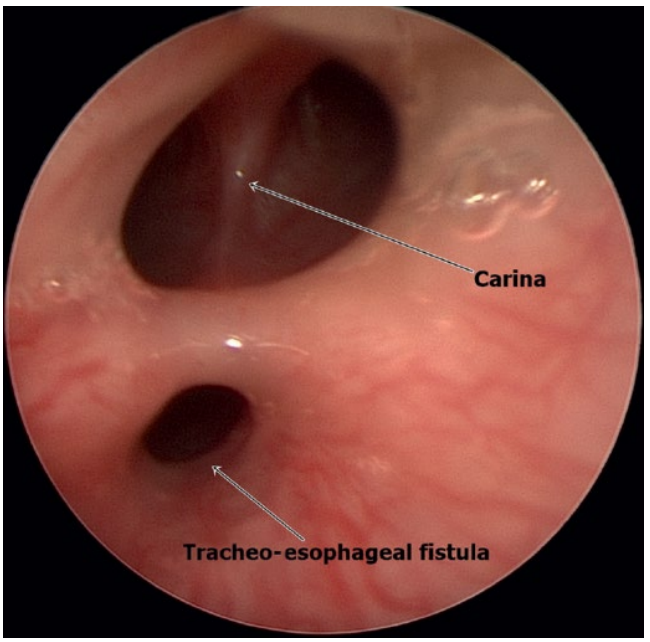

Figure 23.5 Bronchoscopic view of a large tracheo-esophageal fistula (TEF) at the level of the carina. This size and position of the TEF is associated with a higher incidence of ventilation difficulties. See text for further details. *Source*: Reproduced from Teague and Karpelowsky [167] with permission from Elsevier.

One recognized technique is induction of general anesthesia by inhalation with the patient in a semi-supine position. Once adequate depth of anesthesia is achieved, and with the patient spontaneously ventilating, laryngoscopy should be performed and the vocal cords sprayed with no more than 3 mg/kg of lidocaine. An appropriately sized endotracheal tube is then passed through the cords and beyond the carina, aiming for endobronchial intubation. This is then confirmed by auscultation and the tube is withdrawn until ventilation is just heard on both sides. At this point it is possible to confirm the position of the endotracheal tube by passage of a flexible bronchoscope through it. If all is well then a muscle relaxant may be administered and the patient positioned for surgical repair. This technique is limited, however, by the assumption that the fistula is proximal enough to allow passage of the endotracheal tube beyond it. It also may not be an adequate technique where there is a large fistula. In one series, 11% of fistulae were at or below the carina, with a further 22% being within 1 cm of it [159]. Even with such a lesion it may be possible to achieve adequate ventilation initially, with problems only being encountered on repositioning of the patient or during surgical manipulation, particularly compression of the right lung. Additionally the patient's condition may preclude spontaneous ventilation, requiring that muscle relaxation be instituted followed by gentle positive pressure ventilation. It is, however, in the preterm neonate with respiratory distress that this is most problematic. Poorly compliant lungs and a large distal fistula can mean an easy egress of ventilator gases into the stomach with resultant compromise in ventilation [156]. With progressively increasing gastric distension the stomach may rupture, resulting in a tension pneumoperitoneum which further impairs ventilation [160]. The traditional approach in this instance would be to perform an emergency gastrostomy. However this often worsens the situation as the sudden reduction in intragastric pressure further facilitates escape of ventilator gas through the fistula. Resuscitation in this instance is often ineffective until leakage of gas through the esophagus is controlled [161]. Placement of a 2 Fr or 3 Fr Fogarty embolectomy catheter (Baxter Healthcare Corporation, Irvin, CA, USA) through a rigid bronchoscope to occlude the fistula in a neonate with severe respiratory compromise was first described in 1982 [162]. Since then, routine rigid bronchoscopy has become standard practice for some institutions as part of the airway management in TEF, with 18% of patients in a retrospective review requiring the insertion of a Fogarty catheter [157]. In this same series, ventilation difficulty was only encountered with a fistula >3 mm in diameter at or near the carina. Smaller fistulae or those greater than 5 mm above the carina were not associated with ventilation problems. Routine preoperative rigid bronchoscopy has also been found to be useful in the diagnosis of abnormal variants and unsuspected findings [147,163]. However rigid bronchoscopy in the newborn can be technically difficult, often resulting in arterial desaturation; it may be impossible altogether in preterm neonates weighing less than 1500 g who have severe respiratory compromise. Tracheoscopy-assisted repair of TEF has also been reported [164]. The technique described involves passage of a narrow-diameter fiberoptic bronchoscope through the endotracheal tube in a neonate who is intubated with established muscle paralysis and low-pressure intermittent positive pressure ventilation (IPPV). The aim is for gentle ventilation with the tip of the endotracheal tube sitting above the fistula so that identification and repair of the fistula take place under direct visual control. In 47 cases over a 10-year period, no adverse events related to the tube being positioned above the fistula occurred. The authors suggest that mandatory positive pressure ventilation with their technique avoids hypercapnia, hypoxia, and respiratory acidosis that can result in a potentially disastrous return to fetal circulation. With this technique, unlike rigid bronchoscopy, visualization of the airway can take place at any point during the surgical repair.

In the past, the infant with TEF/EA often underwent an initial surgical gastrostomy, sometimes under local anesthesia, with the thought that this would decompress the stomach and minimize ventilation problems. The thoracotomy was then performed several days later. However, as noted previously, a gastrostomy may allow egress of ventilator volume through the fistula and out the gastrostomy. In modern practice the gastrostomy is rarely performed primarily, and usually not at all except in cases of long-gap EA where prolonged healing is required.

An alternative surgical option to prevent the egress of gas through a large type C fistula just above the carina into the stomach has been described. A bulldog clamp is placed on the lower end of the oesophagus just above the stomach to prevent gastric dilatation while the fistula is identified and ligated [165].

Thoracoscopic repair of EA with or without TEF has also been accomplished. McKinlay described a series of 26 neonates, 20 with TEF/EA and six with isolated EA [166]. Anesthetic technique is described as standard tracheal intubation without bronchial blocker or other special technique. Three thoracoscopic ports are inserted in the right hemithorax with insufflation of CO_2 to a pressure of 6 mmHg, which is often accompanied by hypercarbia and arterial desaturation, requiring adjustment of ventilation, as the lung collapses to afford the surgeon a view of the field. The TEF is suture ligated and the esophageal pouches dissected, mobilized, and anastomosed with 5-0 vicryl sutures (Fig. 23.6). The anesthetic techniques were not described in detail, but no severe ventilation problems were apparently encountered. Patient weights were 1.4–3.9 kg and gestational ages 31–41 weeks. There were two early deaths (one patient with trisomy 18 and another with associated congenital diaphragmatic hernia), and one late death from congenital heart disease. There were seven minor esophageal anastomotic leaks managed conservatively, one recurrent TEF managed thoracoscopically, and nine anastomotic strictures. Further details on the anesthetic management of thoracoscopic surgery are discussed in Chapter 26. The advantages of a thoracoscopic technique over an open technique are said to be a lower incidence of musculocutaneous sequelae (winged scapula, chest wall asymmetry, thoracic scoliosis), a smaller scar, better visualization of the fistula and a reduction in postoperative pain [167] (Fig. 23.7). Both in open and thoracoscopic techniques the anesthesiologist must be vigilant to changes in airway pressures, tidal volumes, and end-tidal CO_2 that may occur as a result of surgical compression or kinking of the trachea or bronchi in order to improve surgical access. Accumulating evidence in the literature suggests that both short- and longer-term outcomes with thoracoscopic repairs are equivalent to open surgery [167].

Because of the numerous different approaches to TEF/EA repair, and even variation within institutions, a thorough preoperative discussion with the surgeon, focusing on airway and ventilation management strategies and a contingency plan in case of severe ventilatory compromise, must be held when approaching these patients.

Postoperative anesthetic care

Postoperative ventilation is mandatory in neonates weighing less than 2000 g [64] and in those with respiratory distress or significant cardiac pathology. Repair of the esophageal anastomosis under tension is also an indication for postoperative ventilation, usually for a period of 5 days [146,168]. Furthermore, it has been proposed that safe awake extubation may affect every anastomosis to some degree, whether or not it is a long-gap anastomosis under tension, and that emergent reintubation may have catastrophic consequences for an anastomosis [169]. This latter problem leads some institutions to routinely leave the trachea intubated in all of these patients until it is clear that the threat of respiratory insufficiency has passed. Tension at the anastomotic site is recognized to be the most important factor contributing to anastomotic complications, however it is very difficult to assess and measure and should therefore be assumed [170]. Analgesia both intra- and postoperatively can be provided by a long-acting opioid such as morphine. This can be given by intravenous bolus at surgery and continued by infusion in the intensive care unit.

Although postoperative ventilation should be the norm where staffing and facilities exist to provide this, there may be occasions when extubation is planned at the end of surgery. Avoidance of opioids or minimizing their use is desirable although it may be necessary to use a short-acting opioid such as alfentanil or remifentanil. Regional anesthesia may be provided by a caudal catheter technique with insertion to T6/7 level or a thoracic epidural catheter; alternatively, supplementary local anesthetic can be injected by the surgeon. If morphine is required postoperatively, it must be used with extreme vigilance.

KEY POINTS: ESOPHAGEAL ATRESIA AND TRACHEO-ESOPHAGEAL FISTULA

- The major consideration of both anesthetic and surgical management of the neonate with esophageal atresia and tracheo-esophageal fistula is ventilation of the lungs without ventilation of the fistula
- Both in open and thoracoscopic techniques the anesthesiologist must be vigilant to changes in airway pressures, tidal volumes, and end-tidal CO_2 that may occur as a result of surgical compression or kinking of the trachea or bronchi in order to improve surgical access
- Preoperative and intraoperative bronchoscopy is now often used to evaluate and manage the fistula and its closure

Congenital diaphragmatic hernia

Congenital diaphragmatic hernia (CDH) occurs with an incidence of approximately 1 in 3000 births and was described by Bochdalek in 1848. The commonest left-sided form bears his name and accounts for approximately 80% of CDH. The embryological development of CDH is incompletely understood but it is thought that the defect may result from failure of closure of the pleuroperitoneal canals. Animal studies using rats exposed to the teratogenic herbicide nitrofen showed that the defect is formed very early in the embryonic period with early ingrowth of the liver through the defect [171]. At a cellular level there may be abnormalities of epithelial and mesenchymal growth and differentiation that may also have implications for lung development [172]. Further rat studies have suggested that lung hypoplasia as a result of fibroblast growth factor deficiency may precede the development of CDH and lend support to the theory of a global mesenchymal embryopathy [173]. Infants presenting with the condition are often born at full term and weigh in excess of 3 kg [174]. Around half of infants with CDH will have other congenital anomalies, with the heart being commonly affected. Some 4–16% will have chromosomal abnormalities. Survival is often severely affected by the presence of associated anomalies. In the infant with CDH, abdominal viscera, most commonly bowel, herniate through the defect into the thoracic cavity, effectively acting as a space-occupying mass. This is accompanied by abnormal pulmonary development, particularly on the affected side, but mediastinal shift can prevent normal growth and development of the contralateral lung. Despite the apparent simplicity of the anatomical defect, the pathophysiology of the condition is complex. The lungs show a decreased number of bronchopulmonary segments, decreased alveolar surface area, and abnormal pulmonary vasculature [175]. There is also a thickening of arteriolar smooth muscle that extends to affect the alveolar capillaries. This impairs pulmonary function further by increasing pulmonary artery pressure that can lead to right-to-left shunting.

Diagnosis

In the majority of affected infants, CDH is discovered at prenatal maternal ultrasound scan. This provides both an opportunity to arrange for delivery of the infant in an appropriate center for management and to arrange prenatal counseling for the parents and family. It may also allow fetuses with poor outcome to be identified. Ultrasound is, however, dependent on equipment, expertise, and experience and may fail to detect the condition prenatally in up to 50% of cases [176]. Two parameters have been shown to be of some prognostic value. First, if there is herniation of the liver into the thoracic cavity, the likelihood of survival is halved [177]. Second, at 24–26 weeks' gestation it is possible to measure the cross-sectional area of the contralateral lung and to compare it with the head circumference. A lung to head ratio (LHR) of >1.4 is associated with no mortality, compared to a LHR of <0.8 which carries a 100% mortality rate [178]. With the advent of three-dimensional ultrasound some centres are now able to assess LHR usefully from 24 to 34 weeks' gestation. Furthermore, fetal MRI scanning has also been found to be a useful modality in the prenatal assessment of CDH [179] including measurements that can be predictive of CDH pulmonary morbidity such as observed versus expected total fetal lung volumes and the percentage of liver herniation [180]. For left-sided CDH with poor prognosis, prenatal intervention consisting of fetoscopic tracheal occlusion (FETO) with a detachable balloon has been reported [181]. This intervention can promote lung growth by preventing amniotic fluid egress and expanding the lungs. The balloon is placed at 27–29 weeks' gestation and removed at 34–35 weeks, and delivery is at term where possible. Belfort and colleagues reported lower extracorporeal membrane oxygenation (ECMO) rates (30% versus 78%, p = 0.05) and greater 6-month survival (80% versus 11%, p = 0.01) with FETO versus conventional treatment in a small series of 19 patients. See Chapter 21 for further details of fetal intervention and surgery.

Following prenatal diagnosis, a birth at or as close to term as possible is preferred because preterm delivery is associated with a poorer outcome [182]. The infant born with CDH usually presents with a scaphoid abdomen and an unusually prominent ipsilateral chest with an increased anteroposterior diameter. Breath sounds are diminished on the side of the lesion and heart sounds may be deviated towards the contralateral side. Diagnosis may be confirmed with a plain chest radiograph that demonstrates air-filled intestinal loops in the affected side of the thorax and a paucity of intestine in the abdominal cavity. There can also be mediastinal shift with a resultant deviation of heart sounds (Fig. 23.8).

Figure 23.8 Chest radiograph of left congenital diaphragmatic hernia. Note liver and intestines in left hemithorax with heart displaced to right.

Postnatal management

At or shortly after birth, the majority of infants will develop signs of respiratory distress. If the defect is large then severe hypoxia and respiratory acidosis will be present and the infant will require immediate resuscitation including endotracheal intubation and mechanical ventilatory assistance. A naso- or orogastric tube is passed to decompress the gut. Pulmonary hypertension may worsen the situation and can result in a persistent fetal circulation with shunting of blood from right to left through the ductus arteriosus and foramen ovale. This further exacerbates hypoxia and hypercarbia, and a decrease in systemic oxygenation results in a metabolic acidosis. However, a small minority of infants are born asymptomatic and remain so for the first day of life. In these cases the defect is small and physiologically much less significant. This group usually has an uneventful course following surgical repair.

In the past CDH was considered a surgical emergency and infants were rushed to the operating room but the last decade has seen a change to preoperative stabilization of the infant prior to surgery [183,184]. In particular, stabilization strategies have been aimed at preserving extrapartum circulation and minimizing acidosis with avoidance of further damage to the lungs. Current practice involves transfer of the infant to an intensive care unit and institution of gentle ventilation aimed at minimizing barotrauma [185,186]. Strategies include permissive hypercapnia to a pCO_2 of no greater than 7.8 kPa (60 mmHg). However, with the frequent association of pulmonary hypertension, this level of hypercarbia is sometimes not tolerated. An oxygen saturation of no less than 80% on 60% inspired oxygen is considered an indication for alternative forms of ventilation or respiratory support [187]. Typically the stabilization period may range from 24 h to a number of days depending on the condition of the child. Current practice may allow for stabilization of the sick infant, thus allowing a potentially less fraught perioperative course. However in a large multistudy review, no difference in outcome was demonstrated when delayed repair after stabilization was compared to both repair within 24 h and repair immediately after birth [188]. The availability of ECMO has become widespread in line with the advent of delayed surgery in these infants. It has been shown that the overall survival rate for infants requiring ECMO is 52.9% versus 77.3% (p <0.001) for non-ECMO infants. However, in those who were deemed to have a mortality risk of 80% or more, ECMO is associated with improved outcome. Furthermore, in infants with additional risk factors, ECMO may worsen outcome [189,190]. High-frequency oscillatory ventilation (HFOV) and inhaled nitric

oxide (iNO) are also frequently used when failure of conventional ventilatory support occurs. HFOV and iNO are both aimed at improving oxygenation. HFOV achieves improved ventilation with a reduction in barotrauma [191] while iNO is used as a selective pulmonary vasodilator aimed at reducing pulmonary vascular resistance. Neither modality has been shown to have any conclusive effect on outcome in infants with CDH [188]. Recently, the detailed protocol for a long-term trial of the selective phosphodiesterase 5 (PDE5) inhibitor sildenafil has been agreed [219]. Sildenafil can be given orally or intravenously and inhibition of PDE5 results in an increase in cGMP and nitric oxide-mediated vasodilatation. There is some evidence of the efficacy of sildenafil in CDH cases and it is easier to administer than iNO, but improvement in outcome has not yet been proven. Surfactant and prenatal steroids have found vogue in recent years. Although steroids are a recognized and valuable treatment for immature lungs, they are of unproven benefit in CDH. Similarly, surfactant has been found to be of little value [188].

Overall conclusions of a recent systematic review of six management issues for CDH revealed very little high-quality evidence [192]. Using available lower quality of evidence, conclusions were that gentle ventilation with permissive hypercapnia provides the best outcomes, with initial HFOV of unproven benefit. Routine iNO or other medical treatment for pulmonary hypertension does not provide benefit. There was no evidence for routine corticosteroid administration. Mode of ECMO (veno-venous versus arteriovenous) does not appear to affect outcomes. Early repair on ECMO may have outcome benefits. Open repair has significantly fewer recurrences than laparoscopic repair.

Anesthetic care for congenital diaphragmatic hernia repair

Immediately after birth, the infant with CDH may be in acute respiratory distress and will require emergent tracheal intubation. Where possible, bag and mask ventilation should be avoided to prevent gaseous distension of the stomach. A naso- or orogastric tube should then be placed to provide intestinal decompression. The infant will need to be transferred to a neonatal intensive care unit for assessment and stabilization. When it is deemed appropriate to undertake repair, there are several anesthetic concerns. First, pulmonary hypoplasia and the resulting pulmonary hypertension can make the maintenance of adequate oxygenation challenging. Hypoxia, hypercarbia, and acidosis all act to increase the pulmonary vascular resistance further [193,194]. Instrumentation of the airway may also result in a dangerous increase in pulmonary vascular resistance [195] and so an opioid such as fentanyl should be given at the beginning of the procedure and can be repeated as necessary. A dose of 25 μg/kg has been shown to abolish the stress response to airway instrumentation [196]. The OR should be prepared as for any neonate requiring major surgery. Standard monitoring is applied. Good venous access is mandatory, and central venous access is highly desirable for both the measurement of central venous pressure and for the administration of inotropes such as dopamine. Invasive arterial blood pressure monitoring is also required as it provides real-time measurement of intra-arterial pressure. Umbilical artery and vein catheterization is achieved preoperatively in most CDH patients. This is particularly useful as surgical access (Fig. 23.9) may result in acute compression of the great vessels resulting in sudden acute hypotension. The surgical approach usually involves a left thoracoabdominal incision, reduction of the intrathoracic intestinal viscera and liver, and repair of the diaphragm, often with a patch made of synthetic material.

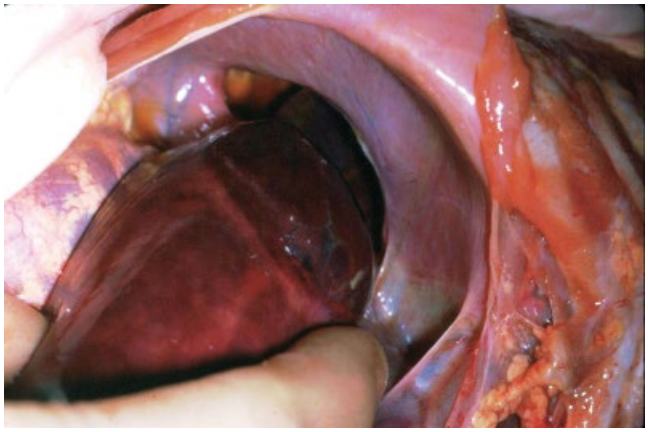

Figure 23.9 Operative appearance of congenital diaphragmatic hernia via left thoracoabdominal incision. Liver is being reduced through large diaphragmatic defect.

Furthermore, the changes in pressure that may be seen during the cycling of ventilation can indicate hypovolemia. A urinary catheter is useful to monitor urine output. The goals of anesthetic management are to provide adequate analgesia and depth of anesthesia with minimal impact on pulmonary vascular resistance and myocardial function. Therefore great care must be exercised with the maintenance of anesthesia. Volatile anesthetic agents are known to attenuate hypoxic pulmonary vasoconstriction [196]. However, they may cause systemic hypotension if not used carefully. For this reason a fentanyl-based anesthetic may be preferable. Nitrous oxide has been shown to have little effect on pulmonary vasculature in infants [197], however it should be avoided because of its effect on alveolar PaO_2 and its propensity to worsen bowel distension. Muscle relaxation may be provided by competitive neuromuscular blockade. Vecuronium and rocuronium are appropriate. Pancuronium is best avoided because of its intrinsic sympathomimetic activity. Mechanical ventilatory parameters should be set to allow for adequate oxygenation. A degree of hypercarbia is acceptable as high inflation pressures should be avoided, again being mindful of pulmonary hypertension. If the infant has been stabilized prior to surgery, preoperative PaO_2 and $PaCO_2$ levels serve as reasonable targets. Throughout the procedure the anesthesiologist must be prepared to treat a sudden pulmonary hypertensive crisis. In the event of this, moderate hyperventilation, often manual, may be required with 100% oxygen. The cardiac output may require support and adequate preload should be ensured. Selective pulmonary vasodilators such as inhaled nitric oxide should be available in addition to appropriate inotropic support that may include drugs such as phenylephrine, epinephrine, dopamine, and milrinone. On occasion it is necessary to repair CDH with the patient supported either by HFOV or ECMO. This makes patient transfer hazardous, and in this situation repair is usually undertaken in the neonatal intensive care unit.

KEY POINTS: CONGENITAL DIAPHRAGMATIC HERNIA

- Fetal MRI can be important in prenatal assessment and give an indication of morbidity and outcome
- About half of infants with CDH have other congenital anomalies including congenital heart disease
- Awareness of pulmonary hypertension and its modern management is vitally important
- Modern management of CDH includes preoperative stabilization with ECMO or HFOV; bedside repair may be necessary with these modalities

Meningomyelocele

Meningomyelocele is a form of neural tube defect that occurs in 0.5–1 per 1000 livebirths and is usually diagnosed antenatally. The spinal cord and meninges are exposed to the intrauterine environment and this results in a central sac filled with cerebrospinal fluid and damaged spinal cord and nerve roots. Invariably this defect is associated with the Arnold–Chiari malformation and hydrocephalus. The cerebellar vermis, fourth ventricle, and lower brainstem are herniated downwards below the level of the foramen magnum. Primary closure is usual within the first 2 days to minimize infection. Treatment of hydrocephalus is individualized but a concurrent ventriculoperitoneal shunt placement may be needed.

Fetal repair has been described with reduced need for ventriculoperitoneal shunting at age 1 year, but no improvement in neurological deficits was demonstrated [198]. A recent review has suggested that prenatal repair of fetal myelomeningocele may be preferable when compared to postnatal repair [199]. Specifically it has now been shown in a randomized trial of 183 patients that as well as reducing the need for ventriculoperitoneal shunting, fetal repair improves motor outcomes at age 30 months [200]. This will have an impact on future practice and the requirement for postnatal repair may decline over time as the prenatal repair technique becomes more widespread. See Chapter 21 for further details.

For postnatal repair, problems for the anesthesiologist are: positioning for induction solved by use of pads or a circular gel ring to protect the fragile sac; prone positioning for surgery; awareness of preventing latex allergy by use of a latex-free environment and equipment; the potential for large intraoperative blood losses due to dissection of skin flaps to gain coverage of the defect; and postoperative respiratory problems associated with Arnold–Chiari malformation. These babies may have reduced or absent response to hypoxia and hypercarbia and may have impaired swallowing and gag reflexes [201–203]. See Chapter 25 for further discussion of anesthetic care for patients with this lesion.

Muscle biopsy

Muscle biopsy in an infant usually requires a general anesthetic supplemented by local anesthetic infiltration at the biopsy site. This presents a dilemma for the pediatric anesthesiologist who is being asked to provide anesthesia in a child without a definitive diagnosis and therefore a degree of uncertainty about the individual's response to anesthetic and other drugs. A muscle biopsy is often required for definitive diagnosis of a wide range of disorders (Box 23.2) and supplements information from family history, symptoms and signs, biochemistry, genetic tests, and electromyography.

Box 23.2: Indications for muscle biopsy in infants

- Benign congenital hypotonia
- Perinatal asphyxia
- Hypotonic cerebral palsy
- Metabolic disorders
- Spinal cord injury
- Spinal muscular atrophy
- Peripheral nerve disorders
- Congenital myasthenia
- Neonatal myasthenia
- Infantile botulism
- Congenital myopathies
- Muscular dystrophies
- Mitochondrial myopathies
- Glycogen storage disorders

Clinically the infant will usually present with hypotonia or floppiness which may be associated with swallowing difficulties, gastroesophageal reflux, and failure to thrive. If reflux is significant, episodes of aspiration may have caused significant lung damage. Try to assess the degree and extent of muscle weakness and any evidence of respiratory compromise as these infants often have reduced respiratory reserve and may need postoperative respiratory support even for a short procedure such as muscle biopsy. Avoid sedative premedication and opioids if at all possible. A preoperative ECG and echocardiogram are recommended to check for cardiac involvement, for example in Duchenne muscular dystrophy or mitochondrial myopathy. Avoid prolonged fasting as infants with hypotonia often are prone to hypoglycemia, and consider giving IV dextrose from the start of the fluid fast period and continuing intra- and post-operatively. Inhalational anesthesia with sevoflurane with or without tracheal intubation and ventilatory support as appropriate to the individual child is indicated along with local anesthesia of the biopsy site by the surgeon and simple analgesia thereafter with acetaminophen and or non-steroidal anti-inflammatory drugs (NSAIDs). If possible, avoid muscle relaxants and certainly succinylcholine, which can cause dangerous hyperkalemia in some of these disorders. If a non-depolarizing neuromuscular blocking agent is needed, titrate carefully against neuromuscular monitoring and ensure complete reversal at the end of the procedure. Rocuronium would be an appropriate choice of muscle relaxant as reversal is predictable and complete with administration of sugammadex. The possibility of malignant hyperthermia is a concern, and for this reason some anesthesiologists avoid volatile agents. Dantrolene should be available but not administered prophylactically as it can itself exacerbate muscle weakness in some of these disorders. Even after a short procedure, postoperative monitoring should be extended and ventilatory support must be available as required. This may be best carried out in an intensive care setting. In a large series of 877 pediatric muscle biopsy patients, regional anesthesia was utilized in 15.6% of patients and consisted of spinal anesthesia in 80 patients, caudal in five, and

peripheral nerve block in 27. Volatile agents were utilized in only 16% of patients, non-depolarizing muscle relaxants in 46%, and succinylcholine in two cases. Interestingly, no incidences of malignant hyperthermia, hyperkalemia, rhabdomyolysis, cardiac dysfunction, or intensive care admission were observed [204]. See Chapter 33 for further discussion of neuromuscular diseases.

KEY POINTS: MENINGOMYELOCELE AND MUSCLE BIOPSY

- Postnatal myelomeningocele repair is a surgical emergency, and prone positioning to protect the sac from rupture, a latex-free environment, and postoperative prone positioning are principles of anesthetic care
- Prenatal myelomeningocele repair reduces the need for ventriculoperitoneal shunting and improves longer-term motor outcomes
- Muscle biopsy in infants presents the problem of a hypotonic infant without a diagnosis; a variety of techniques including general anesthetic with or without volatile agents, and spinal anesthesia have been safe and effective

Resuscitation of the newborn

During the transition from intrauterine to extrauterine life, the neonate will undergo a significant and complex physiological change from the fetal circulation to the adult circulation, with a period of time in a transitional circulation. At birth, the neonatal systemic blood pressure increases after the cord is clamped. The first breath of air needs to expand fluid-filled alveoli and for this may require negative intrapleural pressures of up to 70 cmH_2O. Oxygen causes the pulmonary vascular resistance to fall because of a reduction in hypoxic pulmonary vasoconstriction and also causes the ductus arteriosus to constrict, thus making the pulmonary artery the route of least resistance from the right ventricle. Flow through the foramen ovale ceases due to the rise in pressures in the left side of the heart. The left ventricle, which is of a similar size at birth, will gradually increase in its function of compliance and contractility.

The World Health Organization estimates that 19% of neonatal deaths worldwide are caused by birth asphyxia [4]. That equates to nearly 1 million deaths annually. The vast majority of newborn infants, however, do not require any form of resuscitation other than drying and being kept warm by being given to their mother, often skin to skin. Approximately 10% of newborns require some assistance to begin breathing at birth, with 1% needing extensive resuscitation [205]. Other studies have estimated that between 5% and 10% of neonates need resuscitation at birth, from simple stimulation to assisted ventilation [206]. Resuscitation of the newborn is commonly managed by the obstetrician or midwife; however, if there is an anticipated sick neonate, cesarean section, or preterm delivery, neonatologists and occasionally anesthesiologists are involved.

The following is based on current practice and evidence as well as guidelines produced by the Neonatal Resuscitation Program (NRP) in association with the American Heart Association (AHA) for Cardiopulmonary Resuscitation (CPR) and Emergency Cardiovascular Care (ECC) of Pediatric and Neonatal Patients [205]. Although neonatologists and pediatricians generally manage newborn resuscitation, the techniques that are set out in the neonatal resuscitation algorithm could be extrapolated to form competencies relevant for any neonatal resuscitation, especially for those patients in their first few weeks of life and those that are preterm. Important trials and studies looking at aspects of neonatal resuscitation caused significant changes in the therapeutic algorithm in the 2010 resuscitation guidelines. These studies include discussion on the use of supplemental oxygen as part of initial resuscitation and therapeutic cooling which aims to decrease the neurological damage caused by asphyxia at birth. The 2015 guidelines (updated in 2017 [220]) expand on and define these issues, as discussed in the following.

It is important to note that anticipating the need for resuscitation as well as the preparation of appropriate equipment, environment, and trained staff are all crucial to a successful outcome. Cardiac arrest at birth remains predominantly due to asphyxia so the resuscitation guidelines have a heavy focus on delivering good initial ventilation.

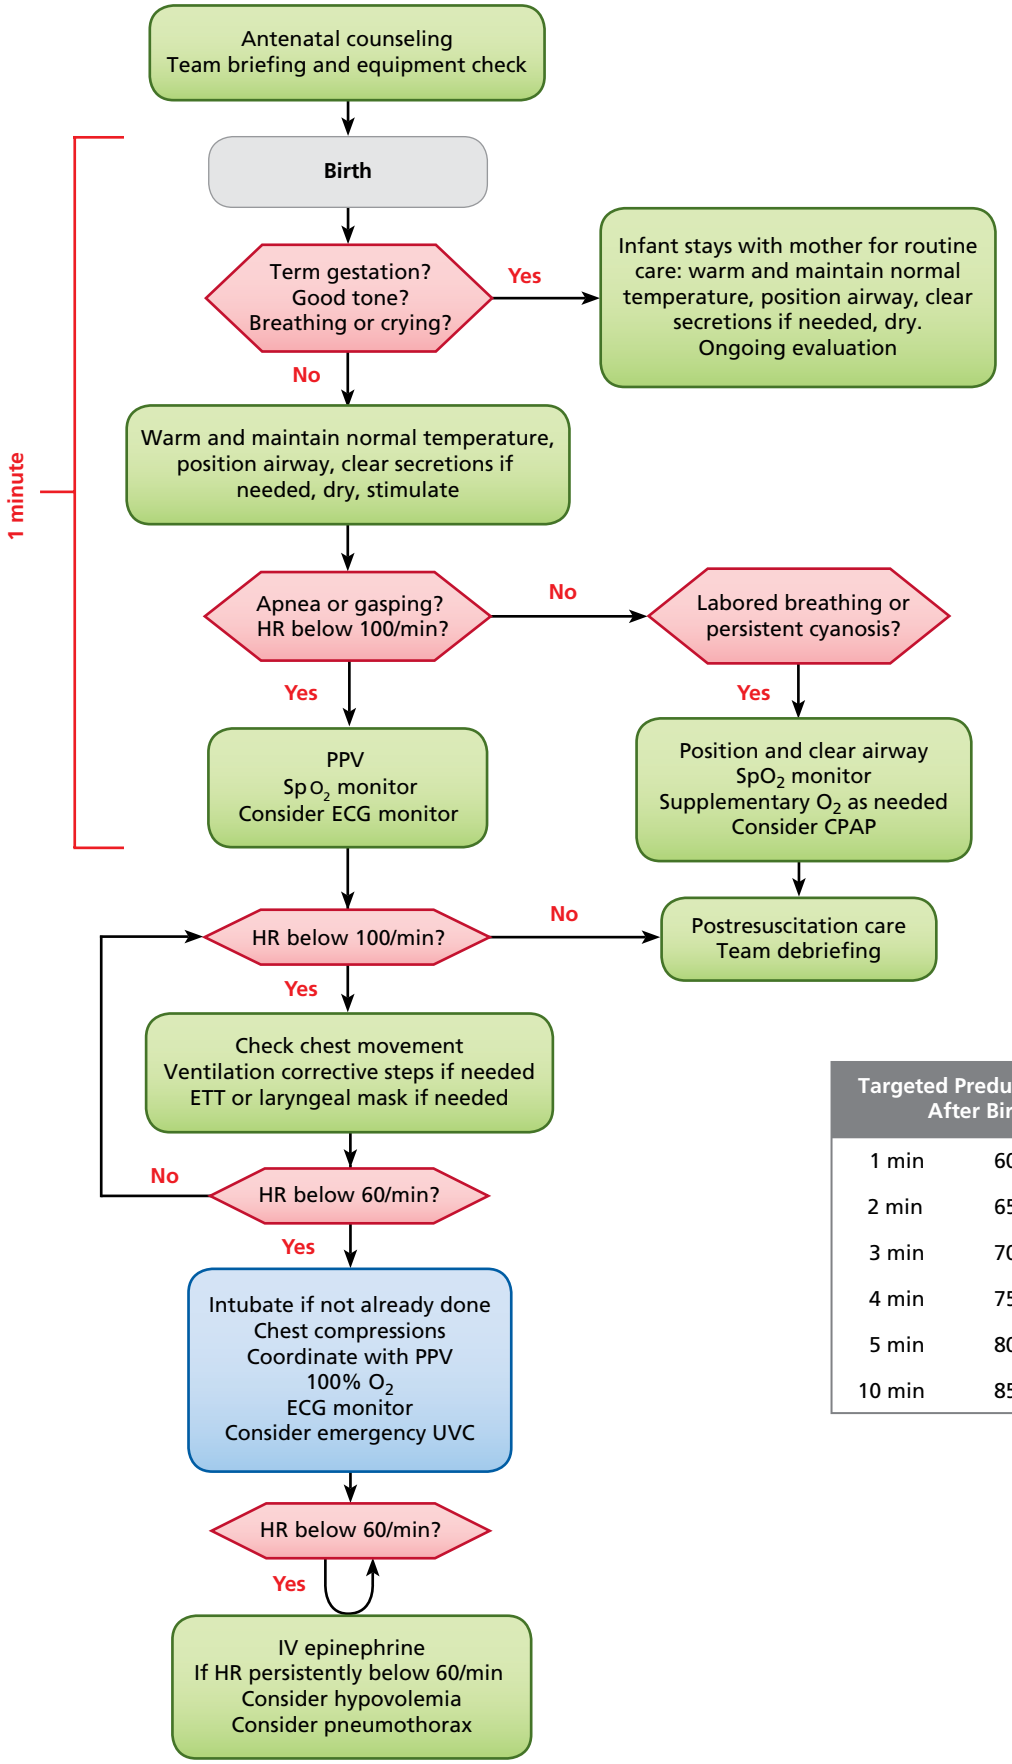
The algorithm in Figure 23.10 is taken from the 2015 guidelines [205] and remains unchanged in the 2017 update. The guidelines are still divided mainly into four broad categories of: (1) assessment, initial care, and observations; (2) ventilation and monitoring; (3) chest compressions; and (4) drug and fluid administration. These areas will be discussed with the emphasis on current significant evidence and recent trials. The first "golden" minute of assessment with progression to ventilation is emphasized to help reduce unnecessary delays. "Start the clock!" is the very first directive during newborn resuscitation.

Assessment and initial care

Immediate assessment and initial care includes drying and stimulating the baby and clearing and positioning the airway, which includes suctioning with a soft suction catheter and positioning the head in the "sniffing" position. The 2015 guidelines have changed the *order* of the three initial assessment questions. These now read: (1) Term gestation?; (2) Good muscle tone?; and (3) Breathing or crying? Tracheal suction of meconium has been shown not to improve outcome, so this is no longer recommended by the NRP. Evidence suggests that the resuscitation procedures should follow the same principles for meconium-stained aspiration as for clear fluid. There should always be some way of providing a source of warmth during resuscitation, and this is normally done under a radiant heat source or with a warming mat. Preterm infants and neonates with a very low birthweight (<1500 g) are recommended to have the additional warming technique of being placed in a plastic wrapping with a hat, as well as being placed under a radiant heat source or on a warming mat. This has been shown to decrease heat loss without hindering ongoing resuscitative measures [205,207,208]. Delayed umbilical cord clamping is recommended for all vigorous term and preterm newborns.

The immediate assessment is of respiratory effort, muscle tone, heart rate, and color. This in practice also includes

Neonatal Resuscitation Algorithm—2015 Update



Targeted Preductal SpO_2 After Birth	
1 min	60%–65%
2 min	65%–70%
3 min	70%–75%
4 min	75%–80%
5 min	80%–85%
10 min	85%–95%

Figure 23.10 Neonatal resuscitation algorithm. *Source*: Reproduced from Wyckoff et al [205] with permission of Wolters Kluwers.

saturation monitoring. The use of three-lead ECG monitoring of heart rate is also now suggested because clinical assessment of heart rate has been found to be unreliable in the resuscitation environment. The first major sign of tissue hypoxia in newborns is bradycardia (heart rate <100 as per the guidelines). Bradycardic episodes normally respond well to a brief period of positive pressure ventilation. This is done via a bag and mask, T-piece, or manually operated, gas-powered, pressure-regulated resuscitator (Neo-puff™, Fisher and Paykel Healthcare, Auckland, New Zealand). According to the NRP guidelines, it is then recommended to give supplemental oxygen. There are many studies comparing the risks and benefits of using oxygen to resuscitate neonates.

Oxygen versus air

First, there is evidence linking ventilation of neonates on high concentrations of oxygen, even for short periods of time, to ROP, chronic lung disease, oxygen free radical disease of the neonate, infection, and leukemia. Studies comparing initial resuscitation with air and varying concentrations of oxygen are beginning to show some evidence that using air alone can have outcomes comparable to using oxygen supplementation, thereby preventing the risks associated with oxygen therapy, but there is as yet insufficient evidence to resolve all questions [209].

Some studies have shown that room air may be superior to 100% oxygen as the initial choice for resuscitation [210]. The resuscitation algorithm recommends step-wise targeting of preductal saturations using supplemental oxygen as needed during the first 10 min after birth (see Fig. 23.10). It also further recommends starting resuscitation of *preterm* (under 35 weeks) neonates with low inspired oxygen concentrations of 21–30%. Standard practice would include decreasing the oxygen concentration as saturations rise to over 95%. It is also reasonable practice to start resuscitation of a term newborn with room air. The AHA guidelines recommend supplemental oxygen when giving positive pressure ventilation and free-flow oxygen to those spontaneously breathing with central cyanosis. Some studies suggest a compromise, aiming for 30–40% oxygen [211]. The use of oxygen blenders with either T-pieces or Neo-puff apparatus is recommended.

Temperature control – therapeutic hypothermia

A review of the literature looking at hypoxic ischemic encephalopathy of newborn infants found that there is evidence from trials to show that induced hypothermia helps to improve survival and development at 18 months for, specifically, term babies at risk of brain damage [212]. A great deal more research is needed into methods of cooling, whether it is isolated to the head or whole-body therapeutic hypothermia. There is also the difficulty of patient selection. It is unclear which patients would benefit from cooling and also to what temperature and for how long. This technique is only recommended in institutions with the appropriate expert personnel and equipment.

Ventilation

Improving bradycardia is the first sign that effective ventilation is being conducted during resuscitation. Improving color and muscle tone, with a return to spontaneous and regular breathing, normally follows this. Effective ventilation is achieved using a T-piece or self-inflating Ambu-bag®, however many centres now use the Neo-puff as it has an oxygen blender as part of its design. CO_2 monitoring is the gold standard method of confirming correct placement of the endotracheal tube. The use of a LMA may be considered in term neonates as an alternative to intubation in those that have had failed endotracheal intubation attempts who are requiring ongoing resuscitation.

Studies looking at resuscitation of asphyxiated neonates at birth have shown that term babies often require around 30 cmH_2O as initial inflation pressures [213] with preterm and low birthweight babies needing higher inflation pressures due to their underdeveloped lungs. Large-volume inflations can cause injury [214], however the inclusion of PEEP has been shown to have a protective effect against lung injury as well as improving lung compliance and gas exchange [215,216].

Chest compressions

Good ventilation strategies are the most effective way of successfully resuscitating a neonate. Chest compressions are only indicated if there is a continuing bradycardia <60 beats/min in the face of adequate ventilation and oxygenation. Chest compressions should be started after approximately 1 min of resuscitation as per the algorithm. There should be at least a period of 30 s where adequate assisted ventilation is delivered before starting chest compressions. The two thumb–encircling hands technique is the one recommended by the AHA for chest compressions as this should generate higher peak systolic and coronary artery perfusion pressures [205]. If access to the umbilicus is needed for umbilical catheter insertion during resuscitation, chest compressions can be continued with the two-thumb technique from the head of the cot.

Drugs

If bradycardia persists despite good ventilatory resuscitation with poor perfusion and no improvement in color, muscle tone, or saturations then volume expansion and administration of specific drugs, especially epinephrine, are indicated. Emergency umbilical vein access, where the catheter is inserted only 3–5 cm until blood return is obtained, is the preferred route for administration of emergency drugs and fluids [217]. The concentration of epinephrine used is 1:10,000 (0.1 mg/mL). The intraosseous route can be considered if umbilical access fails or is not possible.

Although there is a lack of data on the effectiveness of endotracheal epinephrine, it can be used as a route of administration while IV access is being obtained. The dose used for endotracheal epinephrine is 0.1 mg/kg. This is a 10-fold increase in concentration of the recommended dose for IV administration. The recommended IV dose is 0.01–0.03 mg/kg per dose. Higher doses are not used as they can cause a paradoxical decrease in myocardial function due to exaggerated hypertensive responses with subsequent poorer neurological outcome [218]. Other drugs are used during resuscitation but rarely.

Naloxone and other narcotic antagonists are not recommended due to a lack of clinical evidence during initial resuscitation and also because they may precipitate withdrawal seizures in newborns of mothers taking regular opioids.

The Resuscitation Council (UK) does recommend the administration of sodium bicarbonate when there is no effective cardiac output, or virtually none, prior to a second dose of epinephrine. There are no well-powered studies to support the potentially beneficial effects of sodium bicarbonate use and the NRP no longer recommends its use.

KEY POINTS: NEONATAL RESUSCITATION

- The golden minute for assessment and implementation of appropriate resuscitation is vital
- Good ventilation strategies are the most successful way of resuscitating a neonate
- Preductal oxyhemoglobin saturation targets are helpful during the first 10 min of neonatal resuscitation
- FiO_2 is targeted to oxyhemoglobin saturation and excessive inspired oxygen levels avoided whenever possible

CASE STUDY

This case study illustrates the principles of anesthetic management of the ex-premature infant as detailed in this chapter and Chapter 22.

A 44-week ex-premature boy weighing 2 kg presented for surgical repair of a unilateral large but easily reducible inguinal hernia at 44 weeks' postconceptual age having been born at 28 weeks' postconceptional age by cesarean section after his mother went into premature labor with premature rupture of membranes. The mother had been given predelivery steroids to encourage lung maturation and surfactant production in the baby's lungs but the baby showed signs of *in utero* fetal distress and a decision was made to deliver early. The birthweight was 1 kg and the baby required exogenous surfactant therapy, intubation, and ventilatory support for 2 weeks using high-frequency oscillation for severe neonatal respiratory distress syndrome complicated by group B streptococcal septicemia. Weaning from ventilatory support was slow and it became evident that the baby had a patent ductus arteriosus. Medical treatment with nasogastric ibuprofen was unsuccessful. The PDA was clipped via a left mini-thoracotomy performed in the NICU and the baby's lung function improved but he continued to require oxygen therapy for several weeks. A right inguinal hernia was noted but was easily reducible. After discussion with the surgical team and parents, and because the baby lived locally, it was agreed to allow him home and readmit at around 44 weeks' postconceptual age when he had grown a bit more and been weaned from oxygen therapy for a number of weeks. He had no residual cerebral damage and echocardiography revealed normal cardiac anatomy with no residual ductal flow. His blood work-up prior to the hernia repair was normal except for a hemoglobin level of 9 g/dL. Thus this baby presents as an ex-preterm infant of 44 weeks' PCA with mild bronchopulmonary dysplasia and preoperative anemia. He does have a significant risk of postoperative apnea and arrangements are therefore made to admit him after his inguinal herniotomy to the high-dependency area adjacent to the NICU for monitoring overnight even though he was being considered as suitable for an awake regional block technique. The anesthetic options, benefits and risks, and postoperative monitoring and analgesia management were discussed with the parents who were concerned about potential adverse effects of anesthetic drugs on their baby's future development. It was mutually agreed to use a spinal anesthetic supplemented by a single-shot caudal block. The parents were initially concerned that their baby would be upset by being awake in the OR environment but were reassured by the discussion about the use of oral sucrose, topical local anesthesia for the spinal injection and IV cannula sites, and the use of a quiet, warm OR environment. The possibilities of failure of the technique or the need to supplement with or convert to general anesthesia were discussed and the anesthesiologist discussed his personal results for this technique, which were a failure rate of around 5% overall. The parents agreed to this option and to the postoperative plan for overnight admission for monitoring and ongoing pain control with intravenous or oral acetaminophen. The anemia was also discussed as it is an added risk factor for apnea but the parents were not keen on further blood transfusion if this could possibly be avoided. On balance it was felt that leaving this untreated was an acceptable risk. The anesthesiologist recommended that the baby should be given caffeine intravenously to help further reduce the propensity for apneic spells, and this was agreed. The anesthesiologist discussed this plan with the surgeon who was used to operating on these babies under regional blockade and preferred to do open rather than laparoscopic repairs in small infants. The baby was scheduled as the first case of the morning and the OR was prepared for a neonate with appropriate equipment, drugs, and fluids available for a full general anesthetic as well as regional block in case of block failure. The ambient temperature was set to 23°C. A warm air system and warming mattress were set up and the baby was given a breast feed 4 h in advance of the scheduled time and a clear fluid drink 2 h in advance. Tetracaine gel was applied to the back of each hand and to the lumbar region 30 min in advance of the procedure. The baby was brought in to the OR, an IV cannula was sited, and maintenance fluids were commenced at a rate of 8 mL/h. Caffeine 10 mg/kg was administered slowly IV. A neonatal pulse

oximetry probe was placed on the right hand and ECG leads applied. The local anesthesia tray was then prepared for a spinal and caudal block and the anesthetic machine and equipment were also made ready for a 2 kg baby including facemask, oropharyngeal airways, tracheal tubes, anesthetic and muscle relaxant drugs, atropine, and intravenous acetaminophen 7.5 mg/kg. For the spinal/caudal block, full aseptic technique was used including surgical scrub, gown, gloves and mask, skin prep and sterile drapes, equipment, and drugs. The local anesthetic used was isobaric levobupivacaine 5 mg/mL concentration at a dose of 1 mg/kg (0.2 mL/kg). An additional 0.1 mL was added to allow for the deadspace of the needle and its hub. For this 2 kg baby, that was a volume of 0.4 + 0.1 mL = 0.5 mL drawn into a 1 mL syringe. A 25 G neonatal lumbar puncture needle was used at the L5/S1 interspace with the baby sitting supported by a trained assistant who paid particular attention to supporting the baby's chin to avoid flexion of the head and neck on the trunk which can cause airway obstruction (this baby is too young to have head control) (Fig. 23.11A and B). After the spinal injection the baby was immediately placed in the left lateral position and a caudal cannula inserted (22 G) via the sacral hiatus (Fig 23.11C–F). Levobupivacaine at a concentration of 2.5 mg/mL was slowly injected to a dose of 2 mg/kg (0.8 mL/kg) via the sacral hiatus, which was a volume of 1.6 mL for this baby. The caudal cannula was then removed, small dressings applied to the spinal and caudal puncture sites, and the electrocautery grounding plate was applied to the baby's back. The baby was then turned supine and a blood pressure cuff applied to a lower limb and skin temperature probe applied to a toe. A pacifier with dextrose was given to the baby (50% dextrose via a pinhole made in the nipple) who fell asleep (Fig. 23.11G). The legs were straightened out and stayed straight. Gentle skin pinch testing showed a block to just above the umbilical level. The room lights were dimmed, noise levels were kept to a minimum, and monitor alarm volumes were minimized. After surgical prep and draping of the operation field, an open herniotomy was performed in conventional fashion via a 1.5 cm skin incision. The baby did not respond to the incision; he showed slight signs of arousal during dissection of the hernia sac but settled after sucking further on the pacifier. Oxygen saturation, respiratory rate, pulse, and blood pressure were stable throughout. The operation lasted a total of 20 min from prep to dressing. The spinal/caudal took a total of 20 min from patient arrival in the OR to start of skin prep for surgery. The baby was taken straight to the high-dependency unit and monitoring applied. No apneic episodes were observed overnight and the baby resumed breast feeding 1 h postoperatively. Acetaminophen was administered orally twice before discharge the following day after surgical review. The parents were delighted and felt this had been a very good option for their baby.

Introduction

Adolescence, defined as the time between puberty and adulthood, roughly ages 13–19, is a time of significant change for the child, even without significant health problems. Chronic diseases beginning in infancy and childhood may further complicate the transition to adulthood. The pediatric anesthesiologist cares for patients in both categories and may face a number of challenges in patients in this age group. This chapter first reviews developmental and behavioral issues in the adolescent, and then addresses the reproductive issues of the adolescent as they relate to anesthesia care. Then, common chronic adolescent and young adult illnesses are reviewed including cystic fibrosis, congenital heart disease, cancer, sickle cell anemia, diabetes, inflammatory bowel disease, and developmental disabilities and autism, emphasizing anesthetic care. Finally, obesity and bariatric surgery in the adolescent are reviewed, as is thyroid surgery.

Developmental/behavioral issues in the adolescent

Adolescence is a transitional period between childhood and adulthood that is generally characterized by ongoing cognitive development, greater emotional lability, increased risk-taking behavior, and inconsistencies in behavior modulation [1,2]. Non-compliance with medication administration, and other medical treatment regimens including subspecialty follow-up, is a form of risk-taking behavior. From an evolutionary perspective, this period is designed to prepare the person for independent survival, but it is also is a period of vulnerability. The social environment is changing so that more time is often spent with peers rather than adult family members; peer influence is greater, and may also influence emotional reactivity. Most of the time these changes are positive; however, of the more than 25,000 adolescent and young adult (ages 10–24) deaths in the USA annually, about 70% result from risk-taking behavior including automobile accidents, unintentional trauma, homicide, and suicide [3]. Several neurobiological hypotheses have been advanced to explain these changes; many have cited increased growth and activity in the prefrontal regions of the brain as the reason for progressively greater cognitive control and affective modulation as a person grows into adulthood. Newer theories based on functional brain magnetic resonance imaging (MRI) studies implicate the subcortical limbic areas (nucleus accumbens and amygdala) in the likelihood of engaging in risky behavior as teenagers, versus adults or younger children. Recent reviews emphasize that adolescents are more sensitive to this risk–reward behavior than adults, and, combined with reduced inhibitory control, this behavior is maximal in the early to mid-adolescent periods [4]. In addition, there are significant gender differences. For example, females have an earlier and lower magnitude peak in sensation seeking during mid-adolescence that is followed by a more rapid decline to stability by early adulthood. It has also been demonstrated that impulse control improved steadily in females following early adolescence, but males remained more impulsive than females through their mid-20s.

The dopaminergic (DA) system has been linked to reinforcement learning and to high-level cognitive processes and control. The DA system, including levels of the neurotransmitter and receptors, is undergoing rapid changes during adolescence, and some theories postulate that DA activity is greater in the frontal cortex of adolescents, which may result in greater propensity toward riskier (and perceived greater

Gregory's Pediatric Anesthesia, Sixth Edition. Edited by Dean B. Andropoulos and George A. Gregory.

reward) behavior. This neurobiological underpinning substantiates the clinical knowledge that despite their physical size and physiological (i.e. cardiac and pulmonary physiology) similarity to a mature adult, and tendency for healthcare providers to treat them like adults, adolescents indeed have substantial emotional and behavioral differences that may affect anesthetic care [5] (Fig. 24.1).

The ubiquitous presence of electronic devices, particularly smartphones, has become a major developmental influence for adolescents worldwide in the past few years. A recent report on media use of adolescents in the USA documented that they spend an average of 7.5 h per day engaged with electronic media, and 29% of that time is spent in media multitasking [6]. Social media use comprises a significant portion of this time, and the benefits have been documented, including use of social media in the service of critical adolescent developmental tasks, such as peer engagement and identity and aspirational development [7]. As adolescents strive for autonomy and seek intimacy with their peers, their online environments frequently reflect their offline lives. A number of negative effects of social media use have been reported, including cyberbullying, depression, social anxiety, and exposure to developmentally inappropriate content. Heavy users of media have been found to have lower performance on tests of sustained, goal-directed attention, relational reasoning, inhibition control, and long-term memory. Smartphone addiction in adolescents now has formal diagnostic criteria, and the same dopaminergic reward circuits involved in other addictions are active in this disorder [8].

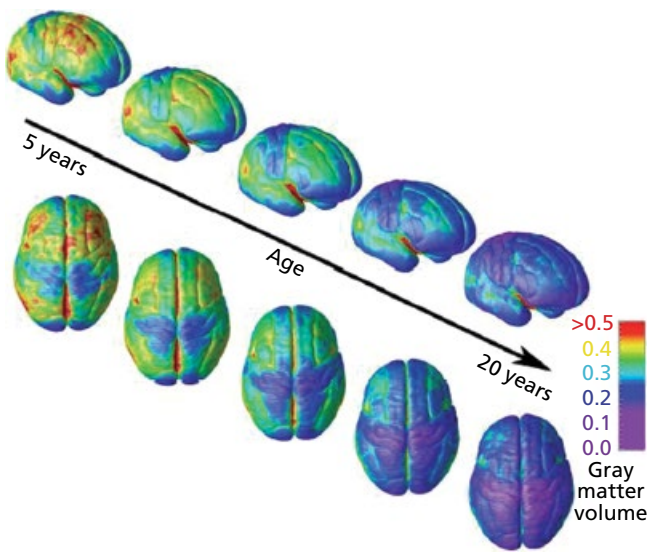

Figure 24.1 Structural changes in gray matter over time derived from serial MRI studies in children, adolescents, and young adults. Right lateral and top views of the dynamic sequence of gray matter maturation over the cortical surface. The side bar shows a color representation in units of gray matter volume. Fifty-two scans from 13 subjects each scanned four times at approximately 2-year intervals. The developmental trajectory of cortical gray matter follows a regionally specific pattern with areas subserving primary functions, such as motor and sensory systems, maturing earliest, and higher order association areas, which integrate those primary functions, maturing later. For example, in the temporal lobes the last part to reach adult levels is the superior temporal gyrus/sulcus, which integrates memory, audio-visual input, and object recognition functions. *Source:* Reproduced from Lenroot and Giedd [5] with permission of Elsevier.

Substance abuse and "recreational" use of alcohol and drugs (both legal and illegal) is one area of difference between the adolescent and mature adult. Annual surveys in the USA have generally reported a decline in the use of drugs (except marijuana) and alcohol over the past 5–10 years. Prevalence of alcohol use (any lifetime use) among 10th graders in the USA (age 15–16) was estimated at 42.2% in 2017, and any use of illicit drugs such as marijuana, cocaine, or methamphetamines was 34.3% [9]. Substance misuse is defined as a maladaptive pattern of use leading to clinically important impairment or distress, manifested by persistent or recurrent use of the substance despite interference with important functions such as school, home life, and interpersonal relationships, and issues such as legal problems and use in physically hazardous situations [10]. Substance dependence is much more limited, with daily use of alcohol reported by 0.7%, and of marijuana by 3.1% of 8th, 10th, and 12th graders [9]. Substance dependence is equivalent to addiction and usually is accompanied by physiological changes related to chronic drug administration, including tolerance, withdrawal, unsuccessful efforts to stop using the drug, interference with important daily activities, and spending a great deal of time and effort obtaining the drug. Alcohol and drug use and misuse in adolescence have important neurodevelopmental consequences. Functional MRI studies of adults dependent on cocaine have shown abnormal responses in the prefrontal cortex and basal ganglia, including the nucleus accumbens and related structures, and that the clinical effect of cocaine ingestion coincides with rapid saturation of dopamine transporters in the basal ganglia [10]. Other neuroimaging studies have found a smaller prefrontal cortex and hippocampus in young adults who had been dependent on alcohol during adolescence. Large epidemiological studies of US adults found that those who had their first alcoholic drink before age 14 or first drug use before age 15 were three times more likely to develop alcohol or drug dependence than those whose first use was at an older age. Regular use of marijuana before age 15 may be linked with increased risk of subsequent psychosis [10]. As noted previously, executive functions are developing in the adolescent, and recent research has confirmed associations between poor development of these functions and adolescents who are at high risk of developing alcohol/substance abuse problems. In addition, there is a familial or genetic component to substance abuse behaviors [11].

There is concern that the opioid use and overdose epidemic in recent years can have its origin for some of those affected in first-time use of medication prescribed for postoperative pain or for other people, either family members or diverted from other sources. A major US annual survey indicated that the annual incidence of non-medical use of hydrocodone decreased significantly in 2017 among 12th graders to about 2%, down from a high of 10% in 2002–2009 [9]. However, the overall tripling of overdose deaths in the USA from 1999 to 2014 has also been observed in late adolescence and early adulthood, with a combined rate of heroin and prescription opioid overdose mortality of about 10 per 10,000 in 20- to 21-year-olds in 2014 [12]. In a survey of 343 inpatients (two-thirds of whom were 8–21 years of age) prescribed opioid pain medication on postsurgical discharge, the median number of doses dispensed was 43, but 58% of doses were not consumed [13]. Only 4% of families disposed of leftover opioid.

This survey has brought attention to the potential for overprescribing of postoperative opioids to adolescent patients, and the risk that they could be diverted or misused.

Where there is concern that alcohol or substance use may affect the course of the anesthetic, the best solution is often to ask the parent or guardian if the anesthesiologist can ask the patient a few questions in private, and then take a history of drug or alcohol use by asking direct questions in a non-threatening, non-accusatory manner, emphasizing that this is necessary to provide the best possible care. In urgent or emergent surgery where the patient is suspected to be under the influence of alcohol or drugs, it is important to ascertain as far as possible what drugs were ingested. Acutely, central nervous system depressants will decrease minimum alveolar concentration (MAC) and other anesthetic requirements, whereas central nervous system (CNS) stimulants often have sympathomimetic effects and anesthetic requirements are usually increased and hemodynamic responses exaggerated, i.e. dangerous hypertension and tachycardia are possible. Chronic use of opioids will increase requirements for these drugs, and chronic use of alcohol and other CNS depressants will increase MAC [13–16].

Teen cigarette smoking

Recent US national surveys show that about 10% of 12th graders (17- to 18-year-olds) currently smoke cigarettes, defined as smoking on at least 1 day in the last month; of these, 4.2% smoke frequently, defined as smoking on at least 20 days in the last month. This represents a decline of over 75% since the late 1990s [9,17]. In the adolescent undergoing anesthesia and surgery, several potential adverse effects of smoking are possible. Airway and respiratory events after general anesthesia are more common in smokers. In a large prospective data collection in over 26,000 anesthetics, adverse events were compared in 7100 smokers and 19,000 non-smokers, patients being as young as 16. Respiratory events, including bronchospasm (the most frequent), laryngospasm, hypoxemia, and others, were 2.3 times more common in young smokers [18]. It is well known that carbon monoxide levels in the blood of heavy smokers may exceed 10%, impairing oxygen-carrying capacity and delivery. Cigarettes function as a means to deliver nicotine rapidly to the CNS. Nicotine activates several types of acetylcholine receptors, predominantly in the CNS, and is postulated to modulate neurotransmitter release, including dopamine. Despite its potential effects on pain modulation, and acute withdrawal of nicotine in the postoperative period, several studies in adults have demonstrated that nicotine withdrawal symptoms are minimal, and thus perhaps this is an opportunity to achieve sustained abstinence from tobacco [19]. An important effect of tobacco smoke exposure is to exacerbate asthma symptoms and precipitate bronchospasm; since asthma incidence is at its peak during adolescence, any teenager with asthma who smokes should be strongly encouraged to quit [20].

A recent trend among adolescents and young adults is use of electronic cigarettes, known as e-cigarettes. This practice is also termed "vaping," or using a device that results in the vaporizing of a liquid and gives the sensation of cigarette smoking. The majority of toxic chemicals present in tobacco smoke are not present; however, most of these liquids contain nicotine, and other substances can be incorporated, such as marijuana or hashish. Symptoms of chronic bronchitis or wheezing are increased 2-fold in adolescent e-cigarette users [21]. In 2017, about 28% of US 12th graders reported vaping, more than double the incidence of cigarette smoking [9]. A recent meta-analysis of over 17,000 adolescents and young adults aged 14–30 documented that use of e-cigarettes increased the risk of initiating and maintaining cigarette smoking 3- to 4-fold [22].

KEY POINTS: DEVELOPMENTAL/BEHAVIORAL ISSUES IN THE ADOLESCENT

- Adolescence (age 13–19) is a period between childhood and adulthood that is characterized by ongoing cognitive development, greater emotional lability, and increased risk-taking behavior
- Substance abuse has generally declined in recent years during adolescence
- Electronic device use, and electronic cigarette use, have increased dramatically in recent years

Pregnancy/reproductive issues in the adolescent and young adult

Teenage pregnancy testing before anesthesia is a controversial topic, but recent data and publications offer some guidance for pediatric anesthesiologists [23,24]. In the USA in 2013, 456,000 women younger than 20 became pregnant. The pregnancy rate was 43.4 pregnancies per 1000 women aged 15–19, meaning pregnancies occurred in about 4% of women in this age group. In general, the teen pregnancy rate has been declining for the past 30 years; in 2013, the US teenage pregnancy rate reached its lowest point in at least 80 years (43.3 per 1000), down 64% since its peak in 1990 (116.9) [25,26]. The teenage birthrate in 2013 was 26.7 births per 1000 women, a total of over 455,000 births. This was 57% lower than the peak rate of 61.8, reached in 1991. From 1986 to 2013, the proportion of teenage pregnancies ending in abortion declined over one-third, from 46% to 29% of pregnancies among 15- to 19-year-olds. These interesting data make the point that although the teenage pregnancy rate has declined, it is not a rare condition, and the anesthesiologist must consider the possibility when caring for adolescent females. Taking a history about possible pregnancy and missed menstrual periods is known to be inaccurate, thus many pediatric anesthesia departments have instituted policies for routine urine human chorionic gonadotropin (HCG) testing in menstruating females before anesthesia [27] (Table 24.1). At Texas Children's Hospital (TCH), parents are told that this urine pregnancy testing at age 12 or older, or in females who begin menstruation earlier than 12, is routine, and are asked to give consent, but exceptions can be made at the discretion of the anesthesiologist based on medical or cultural grounds. In practice, positive tests are rare, but, after confirmation by serum HCG testing, the policy is to have the surgeon, anesthesiologist, and social worker inform the parent with the patient, after permission has been obtained from the patient. Elective surgery is cancelled because of the potential effects of anesthetics, including benzodiazepines,

Table 24.1 Considerations in preoperative urine pregnancy testing in adolescents

Is it important to identify pregnancy before anesthesia or sedation?	Concerns include risk of congenital malformation, spontaneous abortion, medicolegal risk
What is the risk?	American Society of Anesthesiologists (ASA) Task Force on Preanesthesia Evaluation: the literature is inadequate to inform patients or physicians on whether anesthesia causes harmful effects on early pregnancy
	Pregnancy testing may be offered to female patients of childbearing age and for whom the result would alter the patient's management
What is the incidence of undiagnosed pregnancy?	Kahn et al [110]: five positive tests per 2588; three unrecognized pregnancies, one asymptomatic ectopic, one false positive
	Wheeler and Cote [23]: three positive tests per 235 (two were adults); all denied possibility
	Malviya et al [111]: test results correlated with history (*n* ~500)
What constitutes adequate informed consent?	ASA Committee on Ethics: routine pregnancy testing of all women and/or testing in the absence of informed consent is inconsistent with the privacy and autonomy rights of women making healthcare decisions about these sensitive issues
	"Mature minor" status may apply if patient believes herself to be pregnant
	Generally, parents need to consent for routine testing
Who can be informed if the test is positive?	Varies by state; essential to know local law
	Law may either require or prohibit informing parents
	Support structure (social work) and referral ability should be available if testing is performed
Logistical questions	Accuracy of test, turnaround time, cost, point-of-care credentialing requirements
	Most centers use urine testing unless unable to obtain sample
	Laboratory medicine notes lack of sensitivity early

Source: Reproduced from August and Everett [27] with permission of Elsevier.

halogenated anesthetic agents, and nitrous oxide, on early fetal development. Emergent surgery proceeds, avoiding agents that may be implicated in fetal malformations. At TCH, in 2008–2010, of over 91,000 anesthetics, approximately 9% were performed in menstruating females. During this period, only four of more than 6000 urine HCG tests were positive. Before implementing a policy concerning preoperative urine pregnancy testing, institutional, local, and state laws and regulations must be consulted. In general, reproductive confidentiality laws mandate that the pregnant teen under the age of 18 has the right to be informed first of a positive test, and to decide whether her parents are notified. In practice, this situation is rare, and the involvement of experts in social work, behavioral health, and adolescent medicine is highly desirable in this complicated situation.

Chronic diseases in the adolescent and young adult, and transition to adult care

Pediatric anesthesiologists care for a large number of patients for procedures caused by chronic diseases that are congenital or start in infancy or early childhood and continue through adolescence and into adulthood. Very often these patients and parents are very attached to their caregivers in the pediatric environment and have developed great trust and confidence in them. Expertise in a specialized pediatric field such as congenital heart disease is not widely available in the adult care environment, and many of these patients are understandably anxious about changing to a set of adult providers in an adult setting. Over 90% of children with chronic diseases now survive into adolescence and early adulthood, and so the concept of transition of care to the adult environment has assumed increasing importance in recent years. In a study of 283 patients aged 14–25 years with chronic conditions across a range of subspecialties who had not yet been transferred to adult healthcare, 50% of patients thought the best age to transfer care was 18–19 years; however, 14% felt that age 20 years or older was best. Some 39% of respondents felt that chronological age was the most important factor in deciding when to transfer care, and 34% said that feeling too old to see a pediatric specialist was the most important factor. Only 11% believed that their relationship with the pediatric specialist was a factor, and 3.5% felt that the severity of the chronic disease was important. Barriers to transition included: feeling at ease with the pediatric specialist, cited by 45%; anxiety because of not knowing the adult specialist (20%); and lack of information about adult services (18%) [28]. This ambivalence on the part of patients, parents, and pediatric caregivers leads to many young adults being cared for in the pediatric setting, and to variable policies about age limits for pediatric care, which are often different in different services in the same institution. In a study of 73 pediatric emergency departments (ED) in the USA, 79% had age limits for treatment, with 18 and 21 years the most often cited cutoffs. Those EDs with age limits over 21 years were most often associated with freestanding children's hospitals. There were many subspecialty-specific exceptions to the age policy allowing older patients to be cared for, with cystic fibrosis (64%), congenital heart disease (56%), and sickle cell disease (53%) the most common. Interestingly, underage exceptions, allowing care in the adult environment for patients less than 18 years, were made most frequently for teen pregnancy (79%), burn patients (50%), and psychiatric patients (40%). Only 18% of institutions had a specific transition of care policy [29]. Recommendations for transition of care plans for pediatric systems include starting education of the patient and family about transition several years in advance and having the patient acquire increasing age-appropriate information about the disease, taking increasing responsibility for their own care, i.e. medication administration and insurance information, and understanding the differences between the adult and pediatric systems [30–33]. It should also be noted that the mentally competent young adult patient (18 years in the USA) legally must sign their own consent for treatments.

Several of the most common chronic disease states presenting for anesthesia care in the transition period from adolescence to adulthood will be discussed.

Cystic fibrosis

Cystic fibrosis (CF) is an autosomal recessive disease that affects primarily the respiratory and gastrointestinal systems. Historically, CF was a uniformly fatal disease of childhood; however, it has become more a disease of adolescents and adulthood, with the median age of patients who die now at 28 years, and median predicted survival of 45.1 years [34]. In the United Kingdom, 60% of the people in the CF registry are over 16 years of age. This improvement in mortality is the direct result of more aggressive, standardized treatment involving many disciplines [35–38].

In the past, CF was considered a disease of the Caucasian population. Now the incidence in Caucasian, Hispanic, and African American births is 1 in 2500, 1 in 12,000, and 1 in 15,000 respectively. One thousand patients are newly diagnosed each year in the USA. The prevalence is growing quickly due to the increase in median survival age.

The fundamental defect in CF is a gene mutation on the long arm of chromosome 7 that encodes a protein, cystic fibrosis transmembrane receptor (CFTR), in the apical membrane of epithelial cells in submucosal glands. CFTR is important in the regulation of airway surface liquid. The CFTR mutation causes defective chloride secretion and excessive sodium reabsorption that results in loss of airway surface liquid [39,40]. Beyond the problems of regulation of surface liquid, a profound inflammatory response is present in patients with CF that is only partially explained by ongoing infection. The cumulative effect is persistent progressive symptoms and irreversible lung damage.

More than 2000 known mutations of the CFTR gene have been identified, but genotype and phenotype correlate poorly, especially regarding the severity of lung disease. Only about 200 of these mutations lead to the CF phenotype [34]. Certain genotypes are closely tied to the development of CF liver disease and portal hypertension (SERPINA1 A allele), while other genotypes increase the risk of developing type 2 diabetes with CF (TCF7L2) or of pancreatic insufficiency [41,42].

Pulmonary disease is the source of 90% of the morbidity and mortality. Pulmonary goblet cells exude a thick tenacious mucus that overwhelms mucociliary clearance. Patients develop a severe unremitting cough of secretions that are difficult to clear. The accumulation of secretions leads to airway occlusion, atelectasis, and hypoxemia. The retained viscid mucus is a fertile growth medium for bacteria, especially *Pseudomonas aeruginosa* and *Staphylococcus aureus*. Pulmonary disease begins at a very early age with evidence of lower tract respiratory infections, neutrophilic inflammation, elevated IL-8, and elevated elastase present in infants (median age 3.6 months). Cough is a poor indicator of the presence of *Pseudomonas*, which can be cultured from over 50% of asymptomatic children. Left undetected or untreated, *P. aeruginosa* leads to an increased inflammatory cytokine response and poorer clinical status, made worse by the concomitant presence of *S. aureus*. In older patients, airway contamination with the fungus *Aspergillus fumigatus* and *Stenotrophomonas maltophilia*, an aerobic motile gram-negative rod of low virulence, develops as a consequence of recurrent use of antibiotics [40]. The infections trigger a neutrophilic inflammatory response that damages airways and culminates in bronchiectasis and later bronchomalacia.

The chest roentgenogram may show hyperinflation and flattened diaphragms, bronchiectasis, and cyst formation. Tram-track radiodensities are parallel lines from advanced peribronchial cuffing and bronchial wall thickening. Computed tomography (CT) scans reveal the extent of pulmonary involvement but may overestimate severity of disease as assessed by exercise tolerance.

Airway reactivity is common and may worsen in adolescence. The response to β-agonist bronchodilators may worsen expiratory flow due to progressive loss of airway cartilaginous support. The airway becomes more dependent on muscle tone for patency, and the airways become floppy similar to bronchomalacia. Further smooth muscle relaxation by bronchodilators increases airway obstruction.

Pulmonary function tests (PFT) reveal severe airway obstruction that may be poorly responsive to, or worsen with, bronchodilators. While PFT typically demonstrate increased residual volume/total lung volume (RV/TLV) ratios and decreased forced expiratory volume during 25–75% of expiration ($FEV_{25–75}$), the reduction in forced expiratory volume in 1 s (FEV_1) correlates with reduced survival [35]. Outcome predictors are rapid loss of pulmonary function, poor nutritional status, presence of *Pseudomonas*, persistent rales on pulmonary examination, and frequent clinical illness from infections [43].

Progressive bronchiectasis and airflow obstruction ultimately lead to hypoxemia and finally to hypercarbia. Destruction of pulmonary architecture and chronic hypoxia cause pulmonary hypertension, right ventricular hypertrophy, and eventually cor pulmonale. Patients may feel better with home oxygen and non-invasive ventilation support with continuous positive airway pressure or bilevel positive airway pressure (CPAP, BiPAP). These adjuvants may be very helpful during postoperative care.

All mucosal cells are affected by the defective CFTR, causing generalized mucosal hypertrophy. Nasal mucosal hyperplasia causes chronic sinusitis. Pedunculated nasal polyps are found in nearly half of patients and are most common during adolescence. Although surgical removal of polyps may be necessary, the use of rehydration therapy with hypertonic saline irrigation, topical or inhaled nasal rhDNase (dornase alfa; Pulmozyme®, Genentech Inc., San Francisco, CA, USA), and glucocorticoids may be helpful. The presence of nasal polyposis makes the use of nasopharyngeal airways or nasal tracheal tubes a higher risk than normal.

Pancreatic exocrine function is reduced in 90% of patients. Absent CFTR impairs bicarbonate secretion due to a dysfunctional chloride–bicarbonate exchanger. The volume and pH of pancreatic secretions are reduced. Pancreatic enzymes plug the pancreatic duct, and the retention of those enzymes causes inflammation and autodigestion of the pancreas.

Antenatal accumulation of viscid secretions from the intestinal mucosa glands causes meconium ileus, a bowel obstruction in neonates. Adolescents and adults may have recurrent gastrointestinal obstruction, a meconium ileus equivalent, caused by a similar mechanism. This condition is better termed distal intestinal obstruction syndrome because it may occur in the colon or the ileum. Advanced pancreatic disease,

dehydration, irregular use of pancreatic enzyme supplements, and use of medications that slow intestinal transport are precipitating factors of this condition.

Tenacious secretions obstruct pancreatic exocrine ducts, reducing overall pancreatic secretion of lipase, an enzyme necessary for the hydrolysis and subsequent absorption of fat. Inadequate absorption of fat-soluble vitamins (vitamins A, D, E, and K) worsens the patient's nutritional state and overall quality of life. Vitamin D deficiency leads to fractures from inadequate calcification of bones. Coagulopathy occurs due to reduced vitamin K supplies because of malabsorption and secondary to the effects of chronic antibiotics that reduce enteral bacterial synthesis of vitamin K. Vitamin E deficiency results in ataxia, decreased sensation to vibration, lack of reflexes, and paralysis of eye muscles. A decline in cognitive function is an early sign of vitamin E deficiency, particularly in the pre-teen years. Vitamin A deficiency causes predominantly eye and skin problems while excessive supplementation of vitamin A may cause harm to the respiratory and skeletal systems in children. A Cochrane review found no studies to show that giving vitamin A regularly to people with CF is beneficial [44].

Enteric-coated pancreatic enzyme supplements (Creon® (a delayed-release form of pancrelipase), Pancrease™ (lipase, amylase, and protease)) and fat-soluble vitamin supplements are essential elements of supportive care.

Pancreatic endocrine dysfunction gradually develops from the progressive autodigestion of the pancreas. The loss of islet cell function may become severe enough to trigger diabetes. Curiously, insulin resistance may be concurrent with insulin deficiency and complicate glucose homeostasis. Preparation for intraoperative care requires skilled management of both hyperglycemia and hypoglycemia. Microvascular deterioration of retina, kidney, and peripheral nerves becomes more frequent with prolonged poor glucose management.

The younger the age at diagnosis, the greater is the liver and pancreatic compromise. One-third of patients will have liver dysfunction with fatty infiltration, cirrhosis, and portal hypertension. Cirrhosis is the second most common cause of death in patients with CF. This progression typically occurs in specific histocompatibility complex genotypes, with male gender, or when nutrition is poor. If liver disease is suspected from function tests, preoperative evaluations for biliary fibrosis and cirrhosis may be necessary since they may cause coagulopathy and altered drug metabolism.

Bone demineralization is common in patients with CF. Poor nutritional status with malabsorption of vitamin D and the administration of steroids are precipitating factors for fractures and scoliosis. In addition, chronic pulmonary infections increase serum cytokines and stimulate bone resorption. Scoliosis and/or kyphosis in patients older than 15 years is seen in 75% of females and over 30% of males. Prevention of skeletal degeneration includes aggressive nutritional support with pancreatic enzyme supplements and fat-soluble vitamins, and treatment with growth hormone, calcium, and sex steroids.

Congenital absence of vas deferens with obstructive azoospermia causes infertility in 95% of males. Menstrual irregularity from chronic disease and thick cervical secretions reduce fertility in females. The natural history of CF is one of progressive deterioration. It is important to monitor carefully the quality of life indicators, the presence of depression, and the patient's ability to cope, as it will directly affect their compliance with treatment [45].

Treatment of cystic fibrosis

Inhaled hypertonic saline acutely increases mucociliary clearance and is a safe, inexpensive means of improving clearance of secretions. Chest physiotherapy, employing percussion via exhalation flutter valves or direct chest compression, serves to improve the efficacy of the patient's cough.

Although it has been used clinically for decades, the effectiveness of inhaled N-acetylcysteine (NAC) (Mucomyst® Bristol-Myers Squibb and others) has been questioned. NAC is thought to reduce mucus viscosity by splitting disulfide bonds that link proteins present in the mucus (mucoproteins), but evidence that this results in improved mucus clearance is absent [46]. However, high-dose oral NAC is thought to modulate inflammation in CF and may counter the intertwined redox and inflammatory imbalances [47].

Aerosolized antibiotics (i.e. tobramycin, aztreonam) decrease the population of *P. aeruginosa*, thereby reducing hospitalization and the rate of pulmonary deterioration. Even short-term use of inhaled aztreonam is effective in improving lung function [48] and quality of life indicators.

Oral azithromycin, an acid-stable derivative of the macrolide antibiotic erythromycin, is a component of standardized maintenance therapy for patients with CF. The drug's principal effects appear to be unrelated to its antibiotic effect, acting through modulation of proinflammatory effects of bacterial infection and alteration of the virulence of *Pseudomonas*. Azithromycin interferes with neutrophil recruitment, chemotaxis, and oxidative bursts, all of which injure airways during infections. With protracted use, azithromycin is associated with gradual improvements in FEV_1 and forced vital capacity (FVC). It appears especially useful in patients with persistent *Pseudomonas* infection, but this may not be due to its antibiotic potential. Subinhibitory concentration of azithromycin can be bactericidal to *P. aeruginosa* when exposed for protracted periods [49].

Bacterial growth in biofilms is associated with reduced sensitivity to antibiotics. Formation of biofilms is an iron-dependent process, and iron chelation therapy, when combined with antibiotics, reduces biofilm formation and leads to enhanced antibiotic susceptibility of *P. aeruginosa* [50].

Deoxyribonuclease I (DNase), a bovine recombinant enzyme, and its recombinant twin, rhDNase (dornase alfa, Pulmozyme®) catalyzes the hydrolytic cleavage of phosphodiester linkages in the DNA in white blood cells that accumulate in the mucus. When white cell DNA is hydrolyzed, the "stickiness" of the mucus is reduced, and it is much easier to clear from the lungs. The net effect is to reduce air trapping, improve FEV_1, and reduce the frequency of clinical infections. Although rhDNase is efficacious at reducing atelectasis, hyperinflation, and mediastinal shift over a period of 3 days, its use in the hyperacute setting of the operating room has not been demonstrated. Prolonged use of rhDNase does not reduce pulmonary colonization, and the timing of its administration to chest percussion is a subject of considerable debate. A recent meta-analysis of 19 randomized trials of dornase alfa in over 2500 CF patients demonstrated clear benefit of dornase alfa over placebo or hypertonic saline on FEV_{1at} 1, 3, and

6 months, and 2 years, and a decrease in pulmonary exacerbations. Daily dornase alfa is one of the newer treatments in recent years that is believed to be responsible for improved CF outcomes [51].

A new treatment option is to increase the amount of functioning CFTR at the cell surface. Phe508del is the most common CFTR mutation; approximately 45% of patients with CF are homozygous for this allele. A two-step process is felt to be ideal at restoring CFTR function: correction of cellular misprocessing to increase the amount of functional mutated CFTR, and potentiation to further increase channel opening. Ivacaftor is an approved oral CFTR potentiator that increases the probability that CFTR channels will be open *in vitro* and improves clinical outcomes in patients 6 years of age or older who have CF and at least one copy of most CFTR mutations [52]. Lumacaftor is an investigational agent that corrects CFTR misprocessing, increases the amount of the transporter protein, and increases chloride transport when used together with ivacaftor to a greater extent than either agent alone. In two phase III randomized trials, 1100 subjects were assigned to either both drugs, or lumacaftor, or ivacaftor alone, with placebo, for 24 weeks. Twenty-five percent of the patients were 12–18 years of age, and average age in the study was 24–25 years. The combination of both drugs resulted in a mean relative improvement in FEV_1 of 4.3–6.7% ($p < 0.001$). Pooled analyses showed that the rate of pulmonary exacerbations was 30–39% lower in the lumacaftor–ivacaftor groups than in the placebo group; the rate of events leading to hospitalization or the use of intravenous antibiotics was also lower in the lumacaftor–ivacaftor groups [53].

Gene therapy is another novel treatment approach, considered experimental at this writing but showing promise in improving the chronic course of CF. A randomized, blinded, placebo-controlled trial of a nebulized plasmid DNA encoding the CFTR gene in a liposome complex on a monthly basis for 12 months was recently reported [54]. There was a significant improvement in FEV_{1in} the CFTR gene group (3.7%, $p = 0.046$), proving the concept that this therapy can be delivered safely and improve lung function.

Sinus surgery in cystic fibrosis

The paranasal sinuses become infected before pulmonary contamination and infections begin. As patients age, they are more likely to have infection in both upper and lower airways. Bacteria spread from the sinuses to the lungs in CF [55]. Because the upper and lower respiratory tracts have the same mucosal lining, improvements in sinus health reduce the frequency and severity of lower tract infections.

Nasal obstruction and chronic rhinosinusitis are common otorhinological manifestations of CF. The altered viscoelastic properties of mucus result in impaired ciliary function and obstruction of sinus ostia. Chronic sinusitis and mucosal edema lead to sinonasal polyposis and nasal obstruction in nearly all adolescent and adult patients. The sinonasal disease increases the risks of pneumonia, the bacterial origin of which lies in the paranasal sinuses [56].

The prevalence of nasal polyposis in children with CF is 6–48% [56]. Nasal polyps begin as an edematous growth of mucosa as a consequence of an inflammatory mucosal reaction in the paranasal sinuses. They are commonly found bilaterally and lead to septal deviation, bulging of the nasal dorsum, and even hypertelorism [57].

Almost all CF patients have abnormalities on CT; the findings do not correlate well with symptom severity. Surgical intervention for sinus disease is based on symptom management, pulmonary status, and frequency of infection. Endoscopic sinus surgery is safe and at least temporarily effective at reducing these complications. Grading the severity of nasal polyposis can help predict the need for future sinus surgery [58]. A recent review reported that about 2–3% of pediatric CF patients undergo sinus surgery annually; indications and frequency of surgery vary widely by institution and short-term improvement is usually seen but there is a paucity of data about long-term outcomes [59].

Chronic high-dose ibuprofen in pediatric patients with CF appears to be effective in management of nasal polyposis in young adults [60]. Hypertonic saline lavages improve clearance of viscid secretions. Despite aggressive medical management, approximately one-quarter of patients with CF require sinus surgery. Paranasal sinus surgery in children and young adults with CF can be safely performed, resulting in symptom reduction and improving rhinosinusitis symptoms (less facial pain, headache, nasal obstruction, postnasal drip, and rhinorrhea). Although combined medical and surgical management may yield symptomatic relief, the infections, obstruction, and nasal polyposis can recur because CF is a chronic, unremitting disease.

Intraoperative management of CF patients undergoing open or endoscopic sinus surgery includes appreciation of the degree of nasal airway obstruction, avoiding instrumentation of the nares with tracheal tubes and nasal airways, management of vitamin K-deficient coagulopathy, and readily available equipment for suctioning tenacious mucus from the lungs.

Portosystemic shunts

Liver disease is the second most common death of patients with CF, occurring in over one-quarter of the patients [61]. The purported pathophysiological mechanism of liver injury is focal inspissation of bile due to its abnormal viscosity, decreased flow, and high concentrations in the liver tissue. The decreased bile flow obstructs small biliary ductules and induces collagen deposition in the portal tracts [62]. The spectrum of clinical liver disease in patients with CF runs from cholestasis to focal biliary cirrhosis to multilobular cirrhosis and, finally, to portal hypertension. Portal hypertension occurs in 7% of the most severely affected patients, with a preponderance of male gender. It causes massive splenomegaly, hypersplenism, ascites, and esophageal bleeding from varices [63]. Initial management of variceal bleeding may include sclerotherapy, while a portosystemic shunt in its various forms (Fig. 24.2) provides more definitive relief of the complications of portal hypertension [64]. Increasingly, liver transplantation is an option for CF patients with significant liver disease. See Chapter 30 for more detail about this approach.

Pulmonary surgery in cystic fibrosis

Pulmonary surgery in patients with CF requires special comment. Surgical treatment of bronchiectasis, whether segmental or diffuse, may be indicated to reduce cough sputum production and decrease the rate at which new areas of

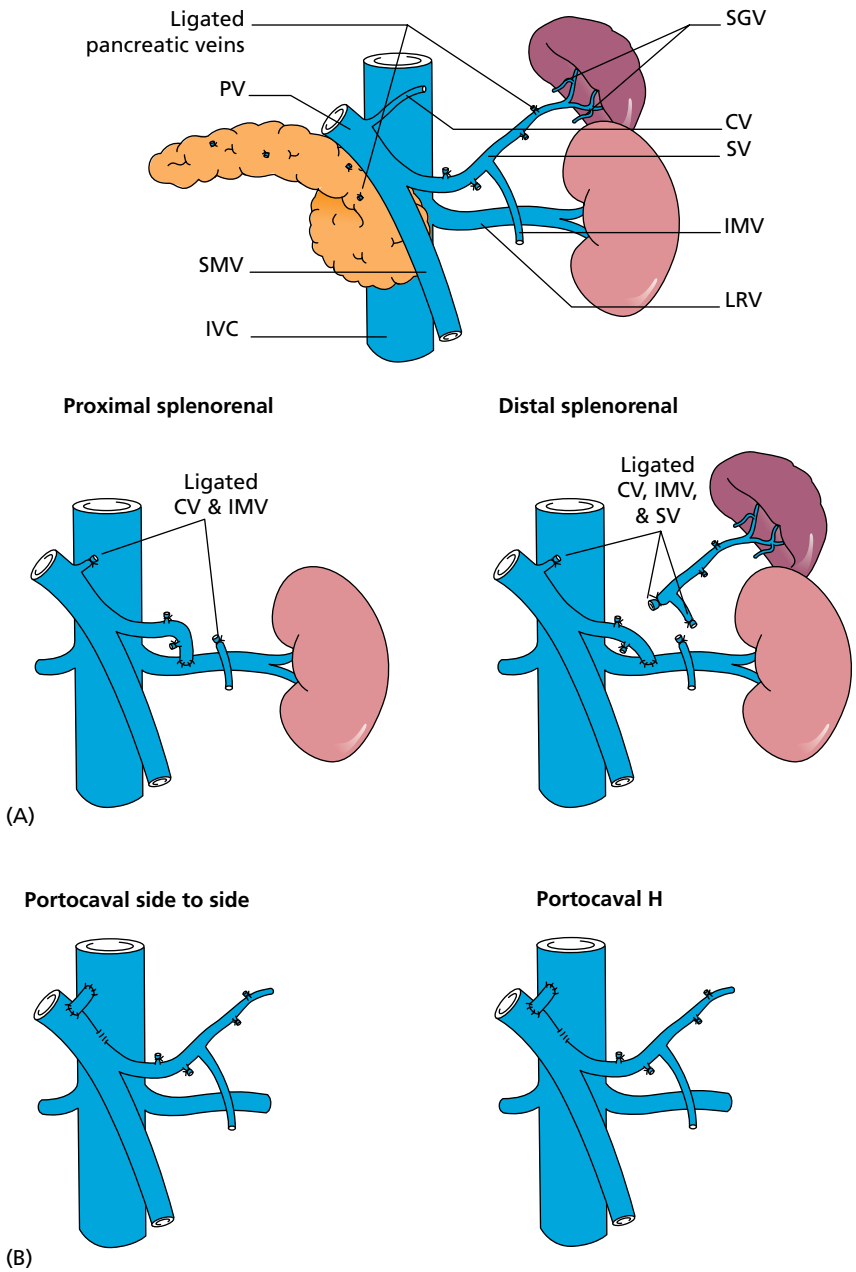

Figure 24.2 The four types of shunts. CV, cardiac vein; IMV, inferior mesenteric vein; IVC, inferior vena cava; LRV, left renal vein; PV, portal vein; SMV, superior mesenteric vein; SGV, short gastric veins; SV, splenic vein. *Source:* Reproduced from Lillegard [64] https://www.hindawi.com/journals/hpb/2010/964597/abs/. Licensed under CC BY.

bronchiectasis form. Pulmonary function is affected very little by the resection since the area of diseased lung contributes little to respiratory function. Resection may reduce the severity of symptoms and improve oxygenation. Even larger resections may be tolerated.

In severe or recurring cases of pneumothorax, bleb resection and/or multiple treatments with talc pleurodesis may be necessary. Talc creates an enhanced pleural reaction and causes the parietal and visceral pleural surfaces to adhere, thereby reducing the frequency of pneumothorax. This technique is particularly helpful in patients with bleb formation. Unfortunately, future surgical procedures (i.e. lobe resections, lung transplants) become extremely difficult.

CF is the third most common indication for pulmonary transplantation in adolescents and adults. The calculated survival must be less than 50%, or life expectancy <2 years, typically marked by FEV_1 <30%, PaO_2 <50 mmHg, and $PaCO_2$ >55 mmHg. The most common precipitating conditions for transplantation are progressive loss of FEV_1 <30%, severe hypoxemia and hypercarbia, increasing frequency of hospitalization, and hemoptysis. When transplantation is a consideration, bilateral lung transplants are usually required due to cross-contamination of the good lung. A review of 9 years of pulmonary transplantation revealed that older patients have improved cumulative survival when compared to younger patients [65]. Older patients have less infections, bronchiolitis obliterans, and graft rejection. Patients 6–10 years of age receiving transplants for CF have similar overall survival to patients of the same age being transplanted for other reasons. Evidence-based decision aids

help to improve expectations of lung transplantation and prepare patients for the post-transplantation experience [66]. See Chapter 30 for a detailed discussion of the anesthetic management of lung transplantation.

Anesthetic management in cystic fibrosis

The perioperative evaluation should be designed in accordance with the severity of clinical disease and the extent of the operative intervention planned. Routine chemistries, liver profile, and coagulation assessments are warranted. Exercise tolerance is a good prognostic indicator that may determine the risk for postoperative pulmonary complications. Pre-operative arterial blood gases are helpful to determine stage of disease and may help in guiding postoperative care.

The anesthetic should be designed to facilitate early extubation and avoid prolonged mechanical ventilation. Volatile agent anesthetics may be of benefit in patients with bronchospastic disease that is known to improve with bronchodilators. Total intravenous anesthesia may be best for patients whose degree of airway obstruction becomes more severe with bronchodilators or when vapor diffusion is severely affected by the extent of pulmonary disease.

Propofol normally has 30% first-pass metabolism in the lungs. Its clearance may be substantially increased in the presence of active inflammatory lung disease like CF and much larger doses may be required to achieve adequate anesthesia. Inadequate insulin supply, along with the presence of insulin resistance, makes intraoperative glucose monitoring imperative. The tracheal tube selected should be as large as possible to facilitate suctioning. Because of nasal mucosa hypertrophy and the potential for nasal polyps, nasal airway devices should be avoided if possible. Inspired anesthetic gases should be humidified, and frequent suctioning with or without bronchodilators may be required.

Use of neuromuscular blocking drugs (NMB) may complicate ventilation in patients who rely on muscle tone for airway patency. Avoiding prolonged administration of NMB, particularly in combination with adrenocorticosteroids, is essential to avoiding muscle weakness, prolonged ventilation support, and additional pulmonary infections.

Prior to extubation, tracheal suctioning, with or without aerosolized hypertonic saline treatment, and lung recruitment maneuvers are helpful to restore pulmonary function. Patients may need longer periods of observation postoperatively, until effective analgesia is balanced against the need for additional oxygen support.

Non-invasive ventilation support (CPAP, BiPAP) is helpful postoperatively. Aggressive pulmonary toilet including percussion postural drainage and flutter valve therapy is beneficial to improve postoperative function. Inhaled hypertonic saline or rhDNase may facilitate secretion clearance and be efficacious at treating atelectasis.

Postoperative pain control should not be provided exclusively with opioids because of their effect on intestinal transit and its potential to initiate distal intestinal obstruction syndrome. Acceptable analgesic adjuvants include non-steroidal anti-inflammatory drugs, continuous IV infusion of lidocaine (because of its ability to reduce inflammation), and low-dose ketamine (for modulation of pain via N-methyl-D-aspartate (NMDA) receptors). If the procedure and parameters permit, regional or neuraxial anesthetic techniques may lower the risks of altered drug metabolism and excretion.

KEY POINTS: CYSTIC FIBROSIS

- CF results from an autosomal recessive gene mutation on the long arm of chromosome 7 that encodes cystic fibrosis transmembrane receptor in the apical membrane of epithelial cells in submucosal glands, affecting primarily the lungs but with multiorgan effects
- Survival and lung function in CF have dramatically improved in recent years due to a standardized multisystem approach and new therapies such as dornase alfa and ivacaftor
- Endoscopic sinus surgery, portosystemic shunts, thoracic surgery, lung transplant, and liver transplant are performed in CF patients

Congenital heart disease

Congenital heart disease (CHD) is the most common birth defect requiring treatment, being present in 8 per 1000 births in the USA and Europe. Because of improved survival rates (now above 90%) for neonatal and infant cardiac surgery for complex lesions, the vast majority of these patients survive into adolescence and adulthood and present both for cardiac surgery and non-cardiac surgery for a range of procedures similar to patients without CHD. In the USA there are approximately 1 million children and 1 million adults over the age of 18 living with CHD. Of these survivors, 55% have simple disease, 30% moderately complex, and 15% complex lesions [67]. For patients with CHD it is crucial to have current, accurate information about the status of their cardiac condition and repair. Patients with complex and moderately complex lesions must have an evaluation by a cardiologist with expertise in CHD that is recent, and have their medical condition optimized for the surgery and anesthetic [68]. Patients with significant potential for instability and need for specialized care should undergo anesthesia only in facilities where such expertise is readily available whenever possible. Infective endocarditis prophylaxis guidelines must be followed [69]. For more detail about the preanesthetic evaluation and anesthetic management of patients with CHD for both cardiac and non-cardiac surgery, see Chapters 27 and 28.

Cancer

The most common new cancers diagnosed in the adolescent population in 2010–2014, in the 10–14-year and 15–19-year age groups, and their incidences per 1 million population, are: (1) leukemias (33 and 32 per million); (2) lymphomas (25 and 49 per million); (3) brain and spinal neoplasms (27 and 23 per million); (4) malignant bone tumors (13 and 14 per million); and (5) soft tissue and other extraosseous sarcomas (13 and 17 per million) [70]. Testicular cancer in 15- to 19-year-old males is - the most prevalent malignancy in that age/gender group at 40 per million [70]. Five-year survival for all cancers in childhood is improving, and in 2007–2013 was 84.8%, with leukemias and lymphomas having the best

survival at 85–97%, and malignant bone and CNS cancer the lowest survival at 74–75% [70]. These adolescent cancer patients will present for anesthesia for a wide variety of procedures, including primary and secondary resection of tumors (sometimes after initial chemotherapy) and metastatic lesions, vascular access procedures, bone marrow aspirations, and many others. The reader is referred to chapters elsewhere in this text for a discussion of anesthetic management of procedures in specific organ systems. Radiation therapy is common in these patients. Emergency radiation therapy in the patient with lymphoma or leukemia and an anterior mediastinal mass and airway obstruction is a rare occurrence, but fraught with the dangers of managing the airway coupled with transport to a remote location. See Chapter 26 for a discussion of the anesthetic management of the patient with a mediastinal mass. Many patients will require a number of follow-up imaging procedures, including MRI, CT, positron emission tomography/CT (PET/CT), and ultrasounds, but sedation is not needed for the vast majority of adolescent patients.

As with many other congenital and acquired conditions in childhood, survival for childhood cancers has increased dramatically over the past several decades. Many of these patients present for anesthetic care, either for procedures for follow-up or treatment of their cancer, or for completely unrelated issues. The residual medical and psychological problems that may be present in these adolescents are important for the pediatric anesthesiologist to understand [71]. When evaluating these patients, knowledge of their past treatments is important, particularly chemotherapy and radiation therapy, which can affect cardiac and pulmonary function (Table 24.2). For example, anthracycline chemotherapy may cause cardiomyopathy, and routine follow-up with echocardiography is performed on all these patients. Pulmonary and renal toxicity should also be sought out and the anesthetic planned accordingly. Cranial irradiation is used commonly to treat leukemia and CNS tumors and leads to a significant incidence of neurodevelopmental disability.

As with many chronic illnesses, survivors of childhood cancer have an increased incidence of psychological problems. In a review of psychological and quality of life studies in over 7000 adolescent and young adult cancer survivors, the cancer survivors were 80% more likely than the general population to report clinically relevant impairments in mental health, and twice as likely to report emotional distress [72]. Those with particularly high levels of anxiety and depression include patients with CNS tumors, bone tumors, leukemia, and lymphoma, and those who have undergone cranial irradiation. Chronic pain may also be an important component of the residual medical problems for cancer survivors.

Sickle cell disease

Sickle cell disease (SCD) is an autosomal dominant condition caused by a substitution of the normal glutamate by valine at the sixth position of the β-globin chain of

Table 24.2 Long-term effects of childhood cancer

System	Risk factor	Potential effect
Cardiac	Radiation therapy Anthracyclines	Valvular disease Pericarditis Myocardial infarction Congestive heart failure Sudden death
Pulmonary	Radiation therapy Carmustine/lomustine Bleomycin	Restrictive lung disease Exercise intolerance
Renal/urological	Radiation therapy Platinums Ifosfamide and cyclophosphamide Cyclosporin A Nephrectomy	Atrophy or hypertrophy Renal insufficiency or failure Hydronephrosis Chronic cystitis
Endocrine	Radiation therapy Alkylating agents	Growth failure Pituitary, thyroid, and adrenal disease Ovarian or testicular failure Delayed secondary sex characteristics Infertility
Central nervous system	Radiation therapy Intrathecal chemotherapy	Learning disabilities
Psychosocial	Childhood cancer	Post-traumatic stress disorder Employment and educational difficulties Insurance discrimination Adaptation and problem-solving difficulties Difficulties with transition to independence
Second malignancies	Radiation therapy Alkylating agents Epipodophyllotoxins Type of primary malignancy	Solid tumors Leukemia Lymphoma Brain tumors

hemoglobin, producing hemoglobin S instead of the normal hemoglobin A. Sickle cell anemia is most common in populations whose origins are from Africa, South or Central America (especially Panama), the Caribbean islands, Mediterranean countries (Turkey, Greece, and Italy), India, and Saudi Arabia. In the USA, an estimated 70,000–100,000 children and adults have a diagnosis of sickle cell anemia, mainly African Americans. The disease occurs in about 1 of every 500 African American births, and also occurs in more than 1 of every 36,000 Hispanic American births. More than 2 million Americans have sickle cell trait (heterozygous hemoglobin AS); this condition occurs in about 1 in 12 African Americans [73]. Worldwide, an estimated 300,000 babies are born with SCD annually, the majority in three countries: Nigeria, the Democratic Republic of the Congo, and India [74]. Homozygous hemoglobin SS causes abnormal aggregation of hemoglobin under conditions of low oxygen tension or acidosis, resulting in reduced red cell elasticity and causing the characteristic sickle shape of erythrocytes with homozygous SCD. This in turn leads to impedence of passage of deformed erythrocytes through capillaries in all organ systems, resulting in the myriad problems seen in this disease (Fig. 24.3). Red cell survival is shortened, leading to hemolysis and anemia, with most patients maintaining hemoglobin levels between 7 and 9 g/dL. Homozygous SS patients are usually significantly affected and have hemoglobin S concentrations that exceed 80%. In the USA, about two-thirds of SCD patients have this genotype. Other variants, such as hemoglobin SC disease, or hemoglobin S β-thalassemia, are also frequently encountered. In terms of severity of disease, hemoglobin SS and S-β° thalassemia genotypes generally are most affected, although symptoms vary. Heterozygous carriers with one copy of the hemoglobin S gene are usually relatively asymptomatic [75].

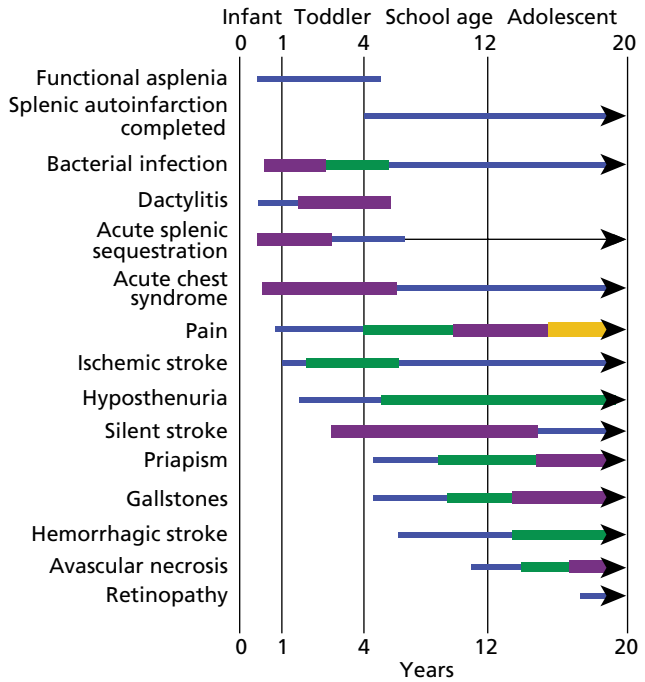

Figure 24.3 Sickle cell disease complications by age. Width and color of the arrow shaft signify the relative incidence of the complication. *Source:* Reproduced from Redding-Lallinger and Knoll [75] with permission of Elsevier.

Problems of particular importance for the adolescent with SCD are acute painful crises and chronic pain, strokes, priapism, cholelithiasis, and avascular necrosis of the hip and other joints [74] (Fig. 24.4). Acute chest syndrome episodes, resulting in pulmonary hypertension, are also seen in this age group. Current therapy for SCD often involves chronic transfusion therapy to maintain higher levels of hemoglobin A and lower levels of hemoglobin S. This therapy has been demonstrated to reduce episodes of painful crisis, stroke, priapism, and acute chest syndrome, and reduce risk for chronic pain and pulmonary hypertension. In recent years hydroxyurea treatment has been demonstrated to increase the percentage of hemoglobin F (fetal hemoglobin) and decrease the percentage of hemoglobin S, resulting in reductions in episodes of painful crises and acute chest syndrome. Leukopenia and thrombocytopenia are possible side-effects of hydroxyurea treatment. Packed red blood cell transfusion or exchange transfusion is used for acute problems such as acute chest syndrome, painful crises, priapism, and acute stroke. Erythrocytes for transfusion should be sickle negative, leukocyte-poor and matched for C, E, c, e, and Kell antigens as well as Rh D and ABO (extended cross-matching or partial phenotypic matching). This will reduce the risk of alloantibody sensitization against the many antigens the patient is likely to be exposed to during future transfusion therapy. Hematopoietic stem cell transplantation in children with SCD is 85% effective in curing the disease. Matched sibling donors are associated with a survival rate of >90%, with the lowest rates of rejection and graft versus host disease; unfortunately, only 20% of SCD patients have a matched donor sibling. Gene modification or replacement therapies are experimental and have shown some promise in SCD [76]. Gene therapy strategies include replacing the defective β-globin gene utilizing viral vectors, inserting γ-globin genes (increasing HbF production), and genome editing to reactivate silenced γ-globin genes. A summary of current approaches to treatment of sickle cell disease is presented in Table 24.3 [74].

The goal of perioperative anesthetic management in SCD is the prevention of excessive sickling of abnormal cells and thus significant complications such as acute chest syndrome, painful crises, stroke, and other major problems. The cornerstones of management are to avoid known precipitating factors for sickling, including hypoxemia, hypovolemia, acidosis, and hypothermia, which then set off a vicious circle of red cell adherence to endothelium, causing vaso-occlusion, further tissue hypoxia and ischemia, inflammation, activation of coagulation, and further vasoconstriction (Fig. 24.5). Among the most common surgical procedures that adolescents with SCD present for are cholecystectomy for cholelithiasis caused by chronic hemolysis, tonsillectomy, orthopedic procedures for avascular necrosis, and priapism. Case reports and case series of other major procedures, including cardiac surgery with cardiopulmonary bypass, have also been published [77–79]. The most recent consensus guidelines about perioperative management of SCD patients were published in 2014 by the US National Institutes of Health National Heart, Lung, and Blood Institute [80] (Box 24.1). Besides strict attention to preoperative hydration, oxygenation, temperature maintenance with warmed IV fluids and other warming measures such as forced air warming, and avoidance of acidosis and

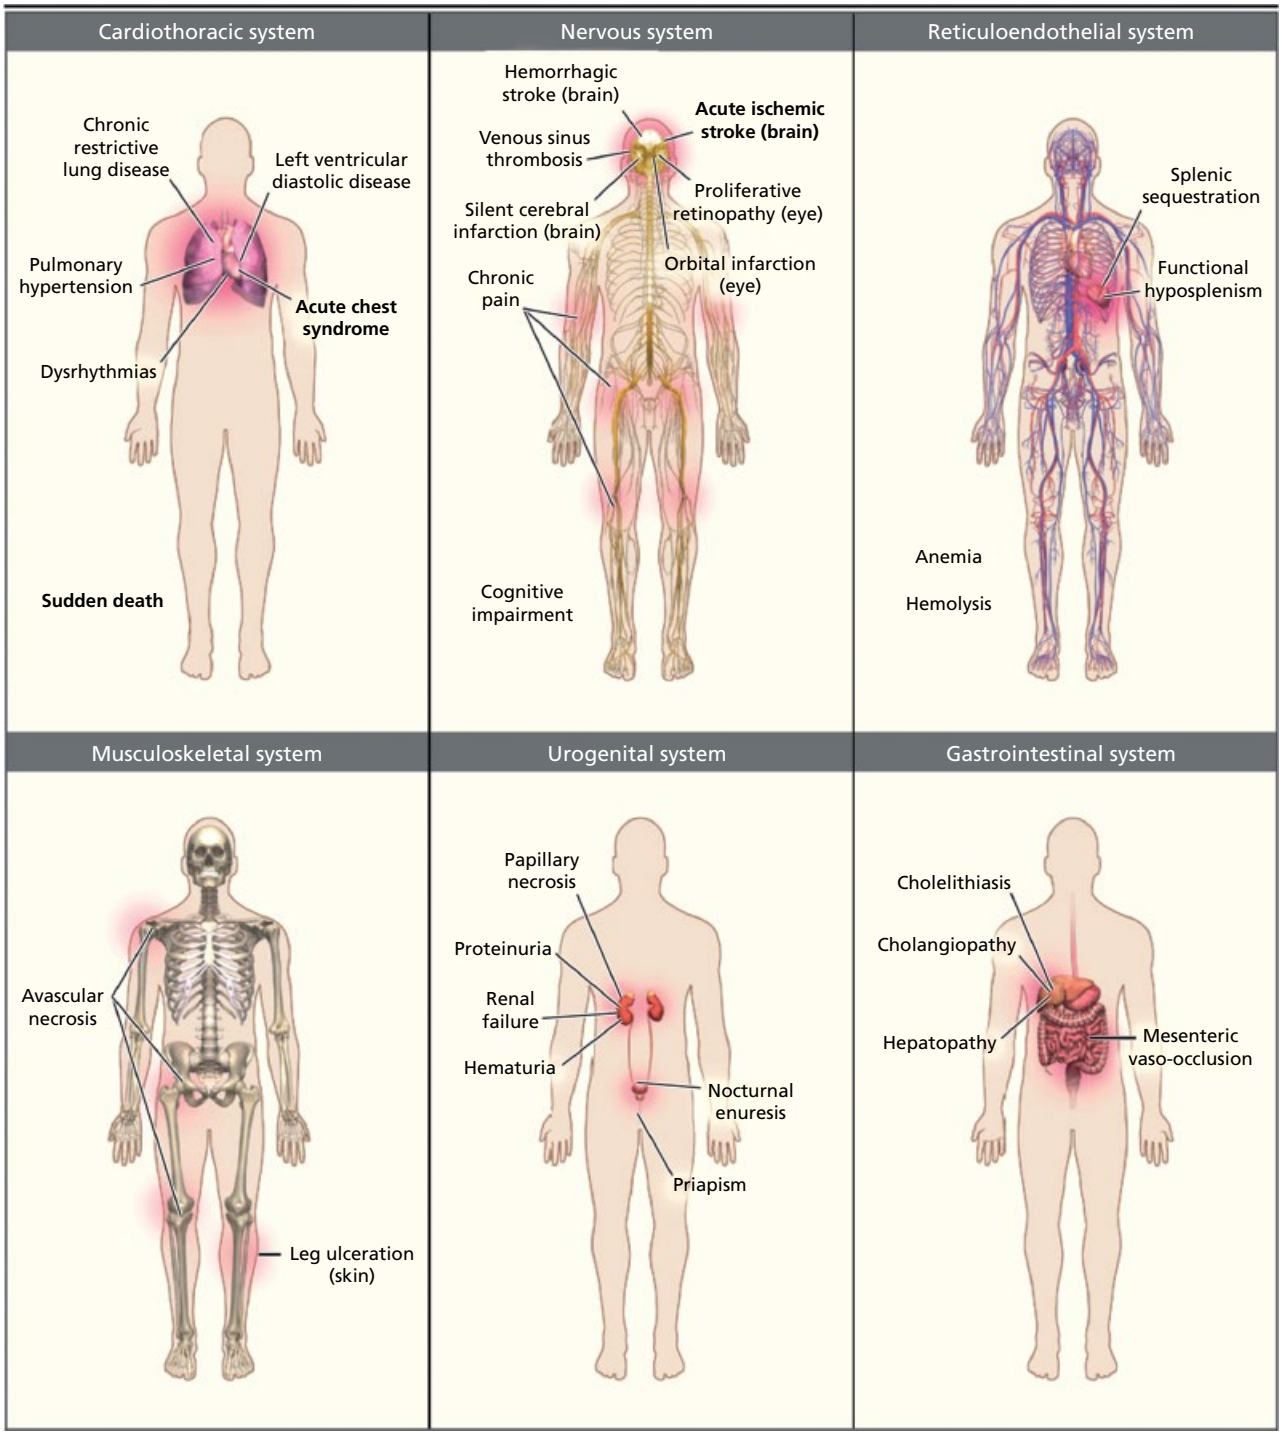

Figure 24.4 Common clinical complications of sickle cell disease. Acute complications are shown in boldface type. *Source:* Reproduced from Meier and Rampersad [76] with permission of Springer Nature.

hypovolemia, simple transfusion to a minimum hemoglobin of 10 g/dL is recommended for all but the simplest procedures. This includes tonsillectomy, open cholecystectomy, major orthopedic procedures, and other major surgery (see Box 24.1). Exchange transfusion is indicated only for very severely affected patients, or for open heart surgery. Perioperative analgesia is critically important to prevent severe pain, stress, catecholamine release, and the precipitation of further acute events. Attention to preoperative opioid and other pain regimens is important, and provision of intraoperative and postoperative pain relief must be carefully considered. Patient-controlled analgesia is often very effective in adolescents with SCD. Supplemental oxygen to maintain high oxygen saturations is important in the recovery period. For any sickle cell patient undergoing anesthesia and surgery, consultation with the patient's hematologist for perioperative recommendations is key in providing optimal care and outcomes. See Chapter 12 for more discussion of the perioperative management of patients with SCD.

Table 24.3 Summary of recommended treatment approaches for sickle cell disease

Treatment approach	Dose and frequency	Duration	Recommendation	Evidence quality
Prevention of infection				
Penicillin V	62.5–250 mg, twice daily	At least until 5 years of age	Strong	Moderate
Pneumococcal vaccines	Every 5 years, starting at 2 years of age	Lifelong	Strong	Moderate
Malarial prophylaxis when appropriate	Daily (e.g. proguanil), weekly (e.g. pyrimethamine), or intermittent (e.g. mefloquine–artesunate or sulfadoxine–pyrimethamine plus amodiaquine)	Lifelong (in malarial area)	Strong	Low
Blood transfusion				
Acute care				
Treatment of anemia	Simple transfusion; target hemoglobin level, 10 g/dL	Limited	Strong	Low
Preoperative transfusion (if hemoglobin <8.5 g/dL)	Simple transfusion, performed once; target hemoglobin level, 10 g/dL		Strong	Moderate
Ongoing care				
Primary stroke prevention	Target HbS, <30%; transfusions every 3–6 weeks	Indefinite	Strong	High
Secondary stroke prevention	Target HbS, <30% or <50%; transfusions every 3–6 weeks	Indefinite	Moderate	Low
Prevention of additional silent cerebral infarctions	Target HbS, <30%; transfusions every 3–6 weeks	Indefinite	Moderate	Moderate
Hydroxyurea				
Universal use	20–35 mg/kg/day	Indefinite	Moderate	Moderate
Prevention of acute complications	15–35 mg/kg/day	Indefinite	Strong	High
Primary stroke prevention	15–35 mg/kg/day	Indefinite	Strong	Moderate

Box 24.1: Perioperative transfusion recommendations for sickle cell disease

- In adults and children with SCA, transfuse RBCs to bring the hemoglobin level to 10 g/dL prior to undergoing a surgical procedure involving general anesthesia (*strong recommendation, moderate-quality evidence*)
- In patients with HbSS disease who require surgery and who already have a hemoglobin level higher than 8.5 g/dL without transfusion, are on chronic hydroxyurea therapy, or who require high-risk surgery (e.g. neurosurgery, prolonged anesthesia, cardiac bypass), consult a sickle cell expert for guidance as to the appropriate transfusion method (*strong recommendation, low-quality evidence*)
- In adults and children with HbSC or $HbS\beta^+$ thalassemia, consult a sickle cell expert to determine if full or partial exchange transfusion is indicated before a surgical procedure involving general anesthesia *(moderate recommendation, low-quality evidence)*

RBC, red blood cell; SCA, sickle cell anemia.

KEY POINTS: SICKLE CELL DISEASE

- Sickle cell disease (SCD) is an autosomal dominant condition caused by a substitution of the glutamate by valine at the sixth position of the β-globin chain, producing hemoglobin S instead of the normal hemoglobin A
- Multiorgan effects include painful crises, acute chest syndrome, strokes, cholelithiasis, avascular necrosis of the hip, pulmonary hypertension, and priapism
- Survival and quality of life have improved recently due to chronic transfusions and hydroxyurea
- Simple transfusion to hemoglobin of 10 g/dL, along with hydration, oxygenation, temperature maintenance, and avoidance of acidosis are important intraoperative principles

Diabetes mellitus

In the adolescent population, diabetes mellitus is usually type 1, although the incidence of type 2 diabetes is increasing in this population (see section "Obesity in the adolescent"). Approximately 183,000 children age 0–19 had a diagnosis of diabetes in 2015 in the USA, or 0.24% of this population; 65% was type 1. In the 10- to 19-year age group, 85% of new diabetes in the non-Hispanic white population in the USA was type 1, while in the African American and Hispanic populations, the proportion of new type 1 versus type 2 cases was 37:63 and 45:55. In the Asian Pacific Islander (43:57) and Native American populations, new cases are predominantly type 2 (88%) [81]. The onset of type 1 diabetes usually occurs during childhood or adolescence, and it arises from T-cell-mediated autoimmune destruction of pancreatic β cells, resulting in failure of insulin production and hyperglycemia. The incidence of type 1 diabetes is also increasing in many parts of the world. Associated risk factors include genetics, diet, lifestyle, and immune responses to viral infection, with enterovirus most frequently implicated. Insulin therapy is the cornerstone of treatment for type 1 diabetes [82]. Type 2 diabetes results from resistance to the effects of insulin, causing hyperglycemia. Obesity, particularly adipose tissue deposits in the abdomen, and non-alcoholic fatty liver disease, are associated with this disease in adolescents. Treatment is primarily by diet, exercise, and in some cases, oral hypoglycemic drugs such as metformin, sulfonylureas or thiazolidinediones; insulin is rarely necessary in adolescence [83].

The secondary complications of diabetes, e.g. nephropathy, are rare in adolescents; most diabetics present for anesthesia for the standard surgical procedures seen in patients in this age group. In the insulin-dependent diabetic, there are myriad forms of insulin therapy, ranging from short, medium, to long acting insulin; dosing one, two, or more times per day; or sliding scales. Insulin pumps with continuous basal rates of subcutaneous insulin infusion, superimposed on programmable boluses at mealtimes, or in response to hyperglycemia, are also used [84]. The diabetic patient should have a preanesthetic visit, where gaining an understanding of the insulin regimen, history of diabetic ketoacidosis or hospitalization, and degree of glycemic control (hemoglobin A1C <7.5%) is important, as is coordination with the patient's endocrinologist [85]. Whenever possible, an insulin-dependent diabetic patient should be scheduled as the first case of the day. Generally, the night before surgery, the patient's normal meal and insulin regimen should be followed. Fasting guidelines are not different from non-diabetics for a morning case, i.e. nil per os (NPO) for solid food and non-clear liquids for 6 h preoperatively, and clear liquids allowed up to 2 h preoperatively. For insulin-dependent diabetics who are afternoon cases, a light early breakfast may be preferable. For patients on twice daily or more frequent insulin doses, the current recommendations are to omit short-acting insulin, and to give only 50% of the intermediate insulin dose in the morning. After measuring a baseline blood glucose, an infusion of 5% dextrose in ½ normal saline is started at maintenance rates 2 h preoperatively, or as soon as the patient arrives if an early morning case (1500 mL/ 24 h, plus an additional 20 mL/kg/24 h for each kg over 20 kg, maximum 2000 mL/24 h, i.e. 83 mL/h for a 50 kg patient). Also start an insulin infusion made with 1 unit regular insulin per 1 mL normal saline, at 0.025–0.1 unit/kg/h, depending on the baseline glucose. Glucose must be measured every hour while the patient is on an insulin infusion, and the insulin rate adjusted accordingly, with the goal of maintaining blood glucose 90–180 mg/dL. Additional boluses of IV regular insulin, 0.025–0.1 unit/kg, are given for glucose values above 180 mg/dL. Serum electrolytes, i.e. sodium and potassium, are measured at regular intervals and potassium replaced if needed. After surgery, the glucose and insulin infusion is continued, with the addition of potassium chloride at 20 mEq/L in the IV fluid, if the patient is maintained NPO. If oral intake is allowed, IV dextrose and insulin can be weaned, and the patient's normal evening meal and insulin regimen resumed, if glycemic control is adequate. Patients with infusion pumps must be managed in close consultation with the endocrinologist; pump use may be continued during anesthesia. These recommendations are summarized in Box 24.2. For type 2 diabetes patients on insulin the guidelines are the same. If the type 2 patient is taking metformin, it should be discontinued 24 h before elective surgery. If the patient is taking sulfonylureas or thiazolidinediones, these are stopped on the day of surgery.

Adolescent gynecological surgery

Adolescent gynecology is a growing field, and more of these patients are presenting for surgery. In recent years, most of these procedures have been done laparoscopically. Indications for laparoscopic surgery in females in this age group include congenital anomalies such as Mullerian anomalies and disorders of sex development that may require diagnosis and treatment. Adnexal masses such as ovarian torsion, tumors, or tubo-ovarian abscess are also diagnosed and treated with laparoscopy [86,87]. Other less frequent indications include diagnosis and treatment of endometriosis or pelvic inflammatory disease, and procedures to preserve ovarian function before pelvic irradiation [88,89]. See Chapter 31 for a discussion of the anesthetic management of patients undergoing laparoscopy.

Inflammatory bowel disease

Inflammatory bowel disease (IBD) is classified as either Crohn's disease or ulcerative colitis, and the overlapping clinical features of these diseases often lead to lack of clarity in diagnosis in adolescents [90]. Of patients with IBD, 20–30% are less than 20 years of age, and the prevalence in this age group worldwide has recently been estimated to be 2–13 per 100,000 [91,92]. Crohn's disease is a transmural inflammatory disease of the mucosa with episodic progression. It can involve any part of the gastrointestinal tract from the mouth to the anus, but often is concentrated in the small bowel. Ulcerative colitis is a non-transmural inflammatory disease with episodic progression that is limited to the colon. The clinical features of the IBD depend on its localization and often include diarrhea, abdominal pain, fever, clinical signs of ileus, and the passage of blood and mucus per rectum. Patients with Crohn's disease often do not have bloody diarrhea but rather abdominal pain or non-specific abdominal symptoms, and about 25% have perianal disease on presentation. Table 24.4 summarizes the major features of Crohn's disease versus ulcerative colitis [92]. Growth failure is common in children and adolescents. IBD are autoimmune diseases, associated with susceptibility regions on at least 12 different chromosomes. Other associations include ethnic origin, with Northern European descent predominant, lifestyle, and geographical factors. Extraintestinal manifestations can also be observed, including joint and skin involvement (15–25% in Crohn's disease; 2–16% in ulcerative colitis) [93]. Medical treatment is similar for both Crohn's disease and ulcerative

Box 24.2: Guidelines for perioperative management of patients with insulin-dependent diabetes

NPO guidelines	**6 h preoperatively for solid food, non-clear liquids** **2 h preoperatively for clear liquids**
IV fluids	D5 ½ normal saline 2 h preoperatively at 1500 mL/24 h plus 20 mL/kg for every kg over 20 kg, maximum 2000 mL/24 h
Insulin regimen	No change the evening before surgery Omit short-acting AM insulin, give 50% of usual medium-acting insulin dose
Insulin infusion	Start at 0.025–0.1 unit/kg/h depending on baseline glucose
Glucose measurement	Q 1 h during insulin infusion
Glycemic control	Goal: 90–180 mg/dL; increase or decrease insulin infusion accordingly; may give regular insulin IV 0.025–0.1 unit/kg bolus for values >180 mg/dL, or stop insulin infusion briefly for values below 60 mg/dL
Insulin pump patients	Consult endocrinologist for plan
Postoperative treatment	Continue insulin and glucose infusion if NPO; add KCl 20 mEq/L to IV fluids Wean insulin and glucose and resume normal evening meal and insulin regimen if taking food

IV, intravenous; NPO, nil per os.

Table 24.4 Characteristics of Crohn's disease and ulcerative colitis

Clinical features	Crohn's disease	Ulcerative colitis
Sex distribution	Male > female	Male = female
Symptoms and signs	Abdominal pain, diarrhea, weight loss, anorexia, growth failure	Bloody diarrhea, abdominal pain
Location	Mouth to anus; involves all layers of gut: mucosa to serosa; most common: ileocolonic	Colon; involves only mucosa; most common: pancolonic
Endoscopic findings	Segmental distribution, aphthous ulcers, deep fissuring ulcers, cobblestoning, perianal disease, strictures, fistulas	Diffuse and continuous erythema, friability, granularity, loss of vascular pattern from rectum to variable extent
Histological findings	Pathognomonic non-caseating granulomas; patchy cryptitis, crypt abscesses, ileitis	Cryptitis, crypt abscesses, crypt architectural distortion, basal lymphocytosis, distal Paneth cell metaplasia
Radiological findings	Rigid stenotic segments, skip areas, and sinus tracts or fistulas	Dilatation of colon in toxic megacolon

Source: Adapted from Oliveira SB, Monteiro IM. Diagnosis and management of inflammatory bowel disease in children. BMJ 2017; 357: j2083; Conrad MA, Rosh JR. Pediatric inflammatory bowel disease. Pediatr Clin North Am 2017; 64(3): 577–91.

colitis: oral or rectal mesalamine, corticosteroids, purine analogs (6-mercaptopurine, azathioprine), and methotrexate, in varying combinations depending on severity of disease and acute relapse status. Newer treatments include anti-tumor necrosis factor (TNF)-α antibody drugs (infliximab, adalimumab) or, in severe cases, cyclosporine. In addition, Crohn's disease patients are usually receiving antibiotics (metronidazole, ciprofloxacin). A summary of current drug treatment approaches is presented in Table 24.5 [92].

Adolescents with IBD often present for surgery for complications of the disease or failed medical management. Indications include bowel perforation/abscess, obstruction, stricture, perianal fistula, toxic megacolon, or malignancy. Over 50% of IBD patients will ultimately require bowel resection. Recurrence of disease and reoperation are frequent (in Crohn's disease 50% at 1 year and 77% at 10 years [92]), and so bowel conservation is very important to avoid the complications associated with short bowel syndrome and long-term dependence on total parenteral nutrition. Ostomy formation may be necessary for more severe cases. Complications after surgery for IBD include wound infection, anastomotic leak, anastomotic stricture, fistula, recurrence of disease, small bowel obstruction, and bleeding; these complications are seen particularly in Crohn's disease surgery. For ulcerative colitis, total proctocolectomy is curative; 8–26% of children with UC will require colectomy in the first 5 years from diagnosis [92]. The procedure used depends on the clinical status of the patient but usually involves a total colectomy with or without an ileostomy. Creation of a reservoir in the small bowel with an ileoanal anastomosis is the definitive procedure. These patients also present frequently for upper and lower gastrointestinal endoscopy for diagnosis and treatment, and for cancer surveillance, and may require sedation or anesthesia provided by the pediatric anesthesiologist.

Preanesthetic evaluation and care must consider nutritional status, chronic pain, medications including corticosteroids and other immunosuppressant drugs, and history of anesthesia and surgery. The extraintestinal manifestations of the disease must be carefully sought out. As with any chronic disease in the teenage population, psychosocial distress is common in patients with IBD, and anesthetic care must take this into consideration.

Developmental disabilities/autism

Chapter 43 contains an extensive listing of the genetic causes of developmental delay, including autism spectrum disorder. Acquired causes of developmental delay may include hypoxic-ischemic brain injury from cardiac or respiratory arrest secondary to a disease state, hypoxemic insults from cardiopulmonary bypass or the perioperative period for congenital heart surgery, trauma, near-drowning, cranial irradiation, toxic exposures, and many other etiologies. Clearly it is important to understand fully the patient's history and level of functioning and communication; the parent or other caregiver is essential in the preoperative evaluation and preparation and approach to the anesthetic. Developmentally delayed adolescents present for a variety of procedures including dental care, orthopedic procedures, brain imaging, and many others. Involving the parent by having them present for IV placement or mask induction of anesthesia may be extremely helpful. Premedication, either oral (benzodiazepines, barbiturates) or intramuscular (ketamine or midazolam), may be necessary to accomplish induction of anesthesia in the large, uncooperative, developmentally delayed adolescent.

Obesity in the adolescent

Obesity in children and adolescents is defined in a variety of ways, but one commonly used definition is that of the US Centers for Disease Control: a body mass index (BMI) above the 95th percentile for age as defined by the 2000 CDC growth charts for normal children [94].

Using this definition, the prevalence of adolescent obesity has increased dramatically in the USA between 1976–1980 and 2011–2014, from 5.0% to 20.5% in children aged 12–19 years [95] (Fig. 24.6). For boys and girls, respectively, this corresponds to a BMI of 24–25 at age 12, 27–28 at age 15, and 29–30 at age 18. Morbid obesity is often defined in the adult population as BMI >40. Epidemiological studies suggest that over 90% of cases of adolescent obesity are not accompanied by an underlying medical condition or syndrome, but primarily represent excess intake of calories, accompanied by relative lack of physical activity and often social/psychological inputs, genetic and environmental factors, as well as possibly

Table 24.5 Dosing for commonly used drugs in pediatric inflammatory bowel disease

Drug	Dose	Side-effects
Prednisone (oral) or methylprednisolone (intravenous)	1–2 mg/kg daily, maximum 40–60 mg/day	Growth suppression, adrenal suppression, immunosuppression
Budesonide	9 mg orally daily	Same as above but lower
5-aminosalicylate	50–80 mg/kg/day orally up to 4 g daily	May mimic acute exacerbation, interstitial nephritis
Azathioprine	2–3 mg/kg/day orally	Immunosuppression, myelosuppression, pancreatitis, lymphoma
6-mercaptopurine	1–1.5 mg/kg/day orally	
Methotrexate	15 mg/m^2/day to maximum 25 mg/day	Nausea, hepatic fibrosis
Infliximab	5 mg/kg intravenously at 0, 2, and 6 weeks, then every 8 weeks; dose can be increased to 10 mg/kg and interval be shortened to every 4–6 weeks	Immunosuppression, psoriasis, lymphoma
Adalimumab	Induction: 2.4 mg/kg (maximum 160 mg) at baseline, 1.2 mg/kg (maximum 80 mg) at week 2; maintenance: 0.6 mg/kg every other week	

Source: Adapted from Oliveira SB, Monteiro IM. Diagnosis and management of inflammatory bowel disease in children. BMJ 2017; 357: j2083; Conrad MA, Rosh JR. Pediatric inflammatory bowel disease. Pediatr Clin North Am 2017; 64(3): 577–91.

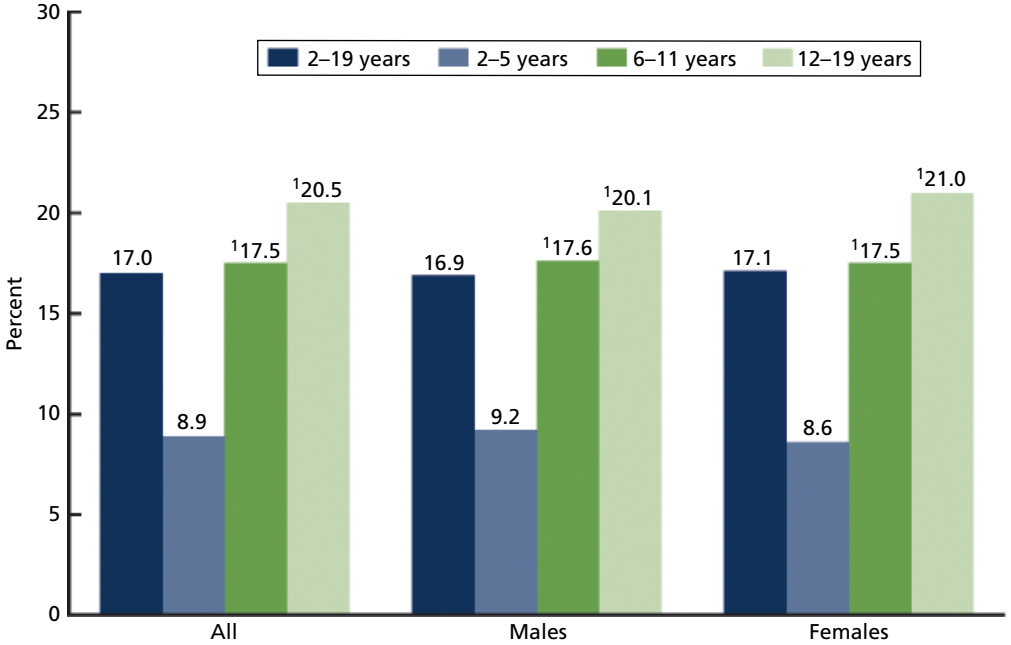

Figure 24.6 Prevalence of obesity among youth age 2–19 years, by sex and age: United States 2011–2014. *Source:* Reproduced with permission from US Centers for Disease Control: National Center for Health Statistics [95].

a deficiency of the hormone leptin in some cases. However, in about 5% of cases in adolescence there is an accompanying genetic syndrome, including Prader–Willi and Laurence–Moon–Biedl syndromes, a glycogen storage disease, medical cause such as chronic corticosteroid administration, or physical inactivity such as accompanies severe muscular dystrophy [96]. Obesity is a complex endocrine state in which the adipose tissue communicates with the brain and peripheral tissues by releasing hormones and cytokines such as leptin, C-reactive protein (CRP), interleukin (IL)-6, TNF-α, lipoprotein lipase, renin, and adiponectin. Significant obesity leads first to insulin resistance and then, if well established, to the metabolic syndrome, consisting of central obesity, hyperinsulinemia, systemic hypertension, and hypertriglyceridemia. Obesity can be considered a chronic inflammatory state. It can lead to multisystem complications including respiratory (asthma, obstructive sleep apnea (OSA), atelectasis, hypoxemia), cardiovascular (systemic hypertension, left ventricular hypertrophy, pulmonary hypertension), endocrine (insulin resistance and type 2 diabetes, polycystic ovary syndrome), gastrointestinal (delayed gastric emptying, gastroesophageal reflux, non-alcoholic fatty liver disease), and psychological (depression, poor body image, loss of self-esteem) [97]. Table 24.6 summarizes the pathophysiology of obesity in adolescents. Diet and behavioral therapy are always attempted, but achieve variable success rates. Drug therapy is sometimes attempted (orlistat to reduce fat absorption). Bariatric surgery is increasingly recommended for morbid obesity in older adolescents when other measures have failed.

Overweight adolescents present for surgery and anesthesia for a range of disorders, including orthopedic (Blount disease or tibia vara, slipped capital femoral epiphysis) [98], cholecystectomy from cholesterol-induced cholelithiasis, tonsillectomy for OSA, and bariatric surgery. Preoperative evaluation must carefully search for co-morbid disease, especially OSA. Some adolescents may require bilevel continuous positive airway pressure (BiPAP), most often at night. Obesity is a known significant risk factor for OSA. See Chapter 34 for a detailed discussion of the perioperative patient with OSA. If the patient is managed with BiPAP, this therapy should be reinstituted in the postanesthesia recovery area if the trachea is extubated, until the patient is awake and demonstrates ability to maintain a patent airway. The obese teen with moderate or severe OSA should most often be admitted after anesthesia, even for a minor procedure, and may require observation in the intensive care unit (ICU) [99,100]. Severe pulmonary hypertension merits very careful planning of the anesthetic, in consultation with the patient's cardiologist or pulmonologist; ICU admission should be arranged for patients with this condition. See Chapter 27 for anesthetic management of patients with pulmonary hypertension. In addition, airway management may be complicated by adipose tissue in the tongue, pharynx, and neck that collapses with decreased muscle tone, causing airway obstruction. Most often this can be managed with an oral airway to assist mask ventilation. In the vast majority of obese teens, mask ventilation, direct laryngoscopy, and tracheal intubation are not difficult. See Chapter 16 for a discussion of management of the difficult airway. Vascular access may be difficult in the obese adolescent: often it is possible to place a small peripheral intravenous catheter preoperatively; larger intravenous access can be secured after induction of anesthesia. Gastroesophageal reflux disease is common in obese teenagers; if the patient is not already on therapy, consideration can be given to prophylaxis for reflux including oral clear antacids, IV histamine-2 blocking agents, and gastrointestinal motility agents. Intravenous drug dosing is problematic, but there are now some data and recommendations that offer more definitive guidance on administering doses based on actual versus ideal bodyweight; this may be different for

Table 24.6 Pathophysiological changes in organ systems associated with obesity and concerns from an anesthesia perspective

System	Effects of obesity	Concerns
Respiratory system	• In children, there is no clear relationship between measures of obesity such as BMI and waist circumference and the presence of restrictive pulmonary function • Fat accumulation on the chest wall produces decreased lung and chest wall compliance • Increased work of breathing • Increased risk of upper airway infections • Increased prevalence of asthma	• Decreased time to desaturation during apnea • Increased risk for hypoxemia and atelectasis • Hypoventilation, especially in the supine spontaneously ventilating patient • General anesthesia and muscle relaxation in obese children leads to atelectasis, severe respiratory mechanics alterations, and increased hypoxemia risk. Atelectasis formation correlates with bodyweight and may be sustained into the postoperative period
	Obstructive sleep apnea (OSA) • The prevalence of OSA in obese children is 13–59%, compared with 2–3% in normal-weight children. Obesity increases soft tissue surrounding the pharyngeal airway and for each increase of 1 kg/m^2 of BMI above the mean in children, the risk of OSA increases by 12% • Factors responsible for increased risk of OSA include airway narrowing, increased critical airway closing pressures, decreased chest wall compliance and abnormal ventilatory control	• Careful history of sleep-disordered breathing and use of oxygen or pressure support ventilation • Overnight oximetry or polysomnography • CBC (for polycythemia due to hypoxemia); increased serum bicarbonate levels (compensation for respiratory acidosis) • Airway concerns • Evaluation for right heart disease • Disposition concerns
Cardiovascular system	• Increased risk for coronary artery disease, carotid intima–media thickening, hypertension and dyslipidemia • Increased left ventricular mass • Pulmonary hypertension in those with OSA	• Increased risk for biventricular failure in patients with OSA • Cardiology evaluation in the presence of history of multiple episodes of desaturation <70%, systemic hypertension or signs of right ventricular dysfunction
Endocrine system	• Excess fat accumulated in muscle cells and hepatocytes secretes bioactive molecules (adipokines), interfering with insulin signaling and increasing risk of type 2 diabetes mellitus (incidence of 1–2%) and impaired glucose tolerance (incidence of 7–25%). Excess body fat accumulation also predisposes obese children to growth and thyroid hormone deficiency as well as pseudohypoparathyroidism	• Perioperative glucose control • Increased risk for infection
Hepatic system	• With every 5-cm increase in waist circumference, the odds of liver steatosis are increased 1.4- fold • Pediatric non-alcoholic fatty liver disease (NAFLD) has a prevalence between 3% and 10% in obese children. When associated with inflammation and cellular hepatocyte damage, it is called non-alcoholic steatohepatitis (NASH)	• NAFLD is usually asymptomatic • NASH may lead to cirrhosis and hepatocellular carcinoma, with the consequent need for liver transplantation
Renal system	• Larger kidney size, an independent predictor of chronic kidney disease progression	• Drug clearance may be increased or unchanged
Metabolic syndrome	• The odds of developing metabolic syndrome in children are 1.55 times more for every half-unit increase in BMI z score. The two most commonly used definitions include the presence of at least three out of five criteria (elevated triglycerides, low high-density lipoprotein, central obesity/abdominal circumference by sex, elevated fasting glucose, and high blood pressure). Since metabolic syndrome predisposes to coronary artery disease, congestive heart failure, obstructive sleep apnea, pulmonary dysfunction, and deep venous thrombosis, its presence carries increased perioperative morbidity	

BMI, body mass index; CBC, complete blood count.
Source: Reproduced from Chidambaran et al [97] with permission of Elsevier.

lipophilic drugs, such as propofol, and ionized drugs such as non-depolarizing muscle relaxants [97]. Pharmacokinetic effects on different drug classes resulting from obesity are summarized in Table 24.7. Current recommendations for common anesthetic drug dosing in the obese adolescent are shown in Table 24.8 [97]. Often the best practice is to start with doses based on ideal bodyweight and to titrate additional doses based on the individual patient's pharmacodynamic response.

Bariatric surgery in the adolescent

In the mature adolescent who is morbidly obese, when diet, exercise programs, and behavioral interventions have failed, there is increasing evidence that bariatric surgery effectively brings about weight loss and reverses significant co-morbidities, including type 2 diabetes, OSA, non-alcoholic fatty liver disease, pseudotumor cerebri, quality of life, and depression [101]. Selection criteria are very important, and all must be met before bariatric surgery can be offered to the adolescent

Table 24.7 Effect of the pathophysiological changes in childhood obesity on drug pharmacokinetics

Physiological change in obese children	Effect on drug pharmacokinetics
Increases in lean body mass (LBM) accounting for 20–40% of the increase in total bodyweight	Increased clearance (CL) of lipophilic drugs: increased V_d for especially lipophilic drugs Saturation of tissue and possible accumulation with prolonged administration
Increase in blood volume, cardiac output, and capillary networks to nourish the excess body fat	Increased volume of distribution – need for higher initial dose
Increase in α1-acid glycoprotein	Decreased free form of drugs that are highly protein bound
Increase in liver volume, fatty infiltration, and non-alcoholic steatohepatitis lead to sinusoidal narrowing; compensated by increase in cardiac output and blood flow	Affects clearance of drugs that have high hepatic extraction ratio depending on extent of contrasting changes
Expression and function of cytochrome P enzymes are largely not affected except CYP3A which has decreased and CYP2E1 which shows increased activity	Affects clearance of drugs metabolized by CYP3A and CYP2E1

General dosing recommendations based on drug solubility:
- Loading doses should be based on IBW when drug distribution is restricted to lean tissues.
- Loading doses based on IBW + % of TBW or LBM when distribution to lean tissue and partially to fat tissue.
- Loading doses based on TBW when distributed to lean and fat tissues or markedly in fat tissue.
- Maintenance doses depend on ability to clear medications. If CL is decreased, dose based on IBW.

IBW, ideal bodyweight; TBW, total bodyweight.

Table 24.8 Recommendations for dosing of commonly used drugs for obese patients in pediatric anesthesia

Drug	Recommended scalar for dosing	Comments
Propofol		
Induction dose	?LBM	Titrate to clinical effect for induction
Maintenance infusion	TBW (allometric)	Allometric weight = 70 × (TBW/70)^x where exponents (x) of 0.72–0.8 have been proposed
Fentanyl	LBM/PK	Lipophilic, elevated V_d in obese; clearance linearly related to PK mass
Remifentanil	LBM/IBW	Pharmacokinetics unaffected in obese, but more side-effects if dosed by TBW
Morphine	IBW	Hydrophilic, V_d does not change with obesity, does not accumulate in body fat
Sufentanil	TBW	Lipophilic; increased V_d in body fat, but risk for accumulation. Loading dose based on TBW, decrease maintenance doses
Alfentanil	LBM/TBW	
Succinylcholine	TBW	May max out dose at 150 mg
Non-depolarizing muscle relaxants (vecuronium, rocuronium, cisatracurium)	IBW	No differences in pharmacokinetic parameters between lean and obese patients. However, prolonged duration of action when dosed by TBW
Benzodiazepines	Loading: ABW/LBM Maintenance: IBW	Lipophilic; CYP3A4 metabolism decreased in obese; higher than IBW, less than TBW – no particular scalar has been studied. Daily clinical retitration recommended
Lidocaine		
Initial dose	TBW	Intermittent doses may be preferable to infusions.
Maintenance infusion	IBW	Monitor clinically
Ketamine	—	Lipophilic; limited pharmacokinetic studies in obese
Acetaminophen (oral)	—	Similar plasma levels with normal doses as non-obese
Acetaminophen (intravenous)	—	Lower levels achieved with usual doses in obese, but higher CYP2E1-mediated metabolite production may preclude dose adjustment. Check liver enzymes
Ibuprofen	—	V_d increased in obese; increase dose without changing dosing intervals
Neostigmine	TBW	Maximum dose 5 mg

ABW, actual bodyweight; IBW, ideal bodyweight; LBM, lean body mass; PK mass, pharmacokinetic mass; –, no recommended scalar; TBW: total bodyweight; V_d, volume of distribution.
Source: Reproduced from Chidambaran et al [97] with permission of Elsevier.

(Table 24.9). The most important criteria are BMI >35 with serious co-morbidities, or >40 with milder co-morbidities, skeletal maturity, and stable and mature psychosocial evaluation, with parental support and high likelihood of compliance with diet and medical follow-up regimens. Evaluation by a multidisciplinary team consisting of gastroenterologists, dieticians, nurse specialists, surgeons, psychologists, and social workers is the standard of care.

Several forms of bariatric surgery have evidence of positive outcomes and low complication rates in adolescents [102] (Fig. 24.7). The first was the Roux-en-Y gastric bypass (RYGB), initially performed as an open procedure but now performed laparoscopically through five or six small incisions by experienced surgeons. This operation involves the creation of a small gastric pouch of 10–30 mL, division of the small intestine and creation of a jejunojejunostomy, and finally connection of

the gastric pouch to the Roux limb (gastrojejunostomy). This operation has the effect of bypassing most of the stomach, and weight loss occurs mostly through restriction of caloric intake from the small gastric pouch. It is intended as a one-time intervention. In recent adolescent case series there were no perioperative deaths and a low complication rate comparable to adult series. The second operation is the adjustable gastric band (AGB; performed in less than 5% of adolescents), also placed laparoscopically, which involves the placement of an inflatable silicone band with an inner inflatable balloon that encircles the top of the stomach, thus creating a virtual gastric pouch 1–2 cm below the gastroesophageal junction. A catheter leads from the balloon to a subcutaneous pouch where a port is implanted, allowing adjustment of balloon size by adding or removing saline. The US Food and Drug Administration has not approved this device in patients under the age of 18; any use of the device in adolescent patients should therefore be in the context of Investigational Device Exemption studies for the purposes of reporting clinical safety and outcomes [103]. In recent adolescent series, complication rates were 6–10%, with no deaths. Reoperation rates, including band removal, were 8–10%. Laparoscopic sleeve gastrectomy has also been performed in adolescents. In terms of weight loss outcomes, RYGB leads to the most significant weight loss, with average BMI reduction around 17 kg/m^2. Clinically significant reduction in BMI is also seen for sleeve gastrectomy and AGB (average reductions of 15 and 11 kg/m^2, respectively) [104]. Other operations, such as biliopancreatic diversion with or without duodenal switch, are not recommended in adolescents.

Table 24.9 Selection criteria for bariatric surgery in adolescents

BMI (kg/m^2)	Co-morbidities
>35	*Serious:* type 2 diabetes mellitus, moderate or severe obstructive sleep apnea (AHI >15 events/h), pseudotumor cerebri, and severe steatohepatitis
>40	*Other:* mild obstructive sleep apnea (AHI ≥5 events/h); hypertension, insulin resistance, glucose intolerance, dyslipidemia, impaired quality of life or activities of daily living, among others
Eligibility criteria[a]	
Tanner stage	IV or V (unless severe co-morbidities indicate WLS earlier)
Skeletal maturity	Completed at least 95% of estimated growth (only if planning a diversional or malabsorptive operation, including RYGB)
Lifestyle changes	Demonstrates ability to understand what dietary and physical activity changes will be required for optimal postoperative outcomes
Psychosocial	Evidence for mature decision making, with appropriate understanding of potential risks and benefits of surgery
	Evidence for appropriate social support without evidence of abuse or neglect
	If psychiatric condition (e.g. depression, anxiety, or binge eating disorder) is present, it is under treatment
	Evidence that family and patient have the ability and motivation to comply with recommended treatments pre- and postoperatively, including consistent use of micronutrient supplements. Evidence may include a history of reliable attendance at office visits for weight management and compliance with other medical needs

AHI, apnea-hypopnea index; RYGB, Roux-en-Y gastric bypass; WLS, weight loss surgery.
[a] All of the eligibility criteria must be fulfilled.
Source: Reproduced from Pratt et al [101] with permission of John Wiley and Sons.

KEY POINTS: OBESITY AND BARIATRIC SURGERY

- Obesity prevalence has increased to 20% of children aged 12–19
- Obesity can lead to the metabolic syndrome and insulin resistance/type 2 diabetes, obstructive sleep apnea, non-alcoholic fatty liver, and depression
- Bariatric surgery consisting of laparoscopic Roux-en-Y gastric bypass, sleeve gastrectomy, or adjustable gastric band can be performed with low complication rates and successful weight loss

Thyroid surgery in the adolescent

Thyroid surgery is infrequently performed in adolescents, but the pediatric anesthesiologist will encounter patients having thyroid lobectomy or total thyroidectomy. The two broad categories of diseases in which thyroid surgery is indicated are thyroid nodules and carcinoma, and hyperthyroidism. Characteristics of 91 total thyroidectomies at Texas Children's Hospital are displayed in Table 24.10 [105]. The risk of a thyroid nodule being malignant is 5–15%, depending on age, gender,

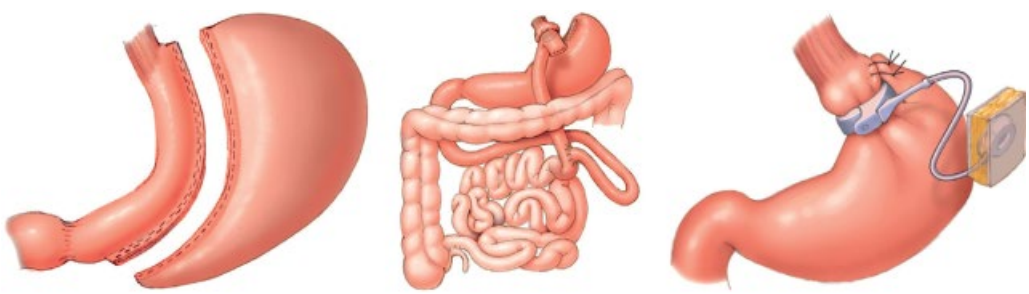

Figure 24.7 Bariatric surgery procedures for adolescents. (A) Sleeve gastrectomy. (B) Roux-en-Y gastric bypass. (C) Adjustable gastric band. *Source:* Reproduced from Kumar and Kelly [102] with permission of Elsevier.

Table 24.10 Demographic and clinical characteristics of pediatric patients undergoing total thyroidectomy

Variable	Total patients (*n* = 91)
Gender	
Female	70 (77%)
Male	21 (23%)
Age (mean)	13.7 ± 4.4 years
Diagnosis	
Malignancy	47 (52%)
Graves' disease	24 (26%)
Hashimoto's thyroiditis	3 (3%)
Multiple endocrine neoplasia (MEN) 2A/2B	6 (7%)
McCune–Albright Syndrome	2 (2%)
PTEN hamartoma syndrome	1 (1%)
Enlarging goiter/mass	5 (5%)
Refractory hyperthyroidism	3 (3%)
Ultrasound	72 (79%)
Biopsy	54 (59%)
Lymphadenectomy	31 (34%)

Source: Reproduced from Yu et al [105] with permission of Elsevier.

family history, radiation exposure, and other risk factors [106]. The risk of malignancy in the adolescent is equal to or higher than that in adults. The approach to a thyroid nodule is to confirm the diagnosis by ultrasound, measure thyroid function tests, and perform fine needle aspiration. If the resulting pathology is suspicious or confirmed to have malignant features, surgery is performed – either lobectomy or total thyroidectomy with possible lymph node dissection depending on other characteristics such as size and suspected lymph node involvement. There are approximately 300–400 new cases of thyroid cancer in children and adolescents annually in the USA. Of 1753 total cases in children reported to the major US cancer registry, 83% were papillary thyroid cancer, 10% follicular thyroid cancer, 5% medullary thyroid cancer, and 2% other types [106].

Hyperthyroidism in adolescents is most commonly caused by Graves' disease, an autoimmune thyroiditis that results from autoimmune binding to the thyroid stimulating hormone (TSH) receptor on follicular cells, elevation of T3 and T4, and signs of hyperthyroidism including weight loss, fatigue, palpitations, tremor, goiter, and changes in behavior. Hashimoto's thyroiditis is a similar autoimmune condition, caused by antibodies against thyroglobulin or thyroid peroxidase and accompanied by invasion of thyroid tissue by T-lymphocytes. A female preponderance of autoimmune thyroiditis of about 7:1 exists in adolescents. Medical treatment consists of antithyroid drugs such as methimazole (propylthiouracil should no longer be used in children because of the risk of liver failure), radioactive iodine, or, in refractory cases, thyroidectomy [107]. Thyroid storm results from uncontrolled secretion of thyroid hormones and results in hypertension, tachycardia, and potentially cardiovascular collapse. Treatment is with antithyroid drugs, radioactive iodine, and β-blockers to control hemodynamic changes until thyroid function is normalized.

Preoperative evaluation of the adolescent undergoing thyroid surgery should elicit any symptoms of current hyper- or hypothyroidism and review thyroid function tests (TSH, T4, T3 (free and total)) and any thyroid medications. Baseline evidence of tachycardia or hypertension should be ascertained. Examination of the neck and airway for large nodules or goiter is important to determine any potential difficulty with airway management. Most adolescent thyroid surgery patients do not present airway concerns. It is important to discuss the surgical plan with the surgeon to ascertain whether the procedure will be a partial or total thyroidectomy, and whether neck dissection is planned. In addition, because of the risk of injury to the superior laryngeal and recurrent laryngeal nerves, discussion about whether intraoperative neuromonitoring is planned is important.

Because of the need to monitor the recurrent laryngeal and superior laryngeal nerves, muscle relaxation beyond initial tracheal intubation is often avoided in thyroid surgery. In addition to direct nerve stimulation, neuromonitoring via a specialized endotracheal tube with implanted electrodes (NIM® Trivantage EMG tube, Medtronic Corp., Minneapolis, MN, USA) can be utilized to monitor vocal cord function during surgery (Fig. 24.8) [108]. The tube must be placed correctly so that the electrodes are in contact with the vocal cords. A meta-analysis of over 9000 patients demonstrated a 20% reduction, both short- and long-term, in recurrent laryngeal nerve palsy with intraoperative neuromonitoring. The overall incidence of short-term injury was 1.82%, and long-term injury 0.67% [109]. Besides avoiding neuromuscular blockade, there are no other specialized anesthetic drug requirements. Another method to check the integrity of the recurrent laryngeal nerve is to observe bilateral vocal cord movement with a videolaryngoscope after extubation of the trachea with deep anesthesia. Intraoperative and postoperative analgesia can be provided with a superficial cervical plexus block or local anesthetic wound infiltration by the surgeon.

Other than recurrent laryngeal nerve injury, acute complications of thyroid surgery include airway and neck swelling from extensive dissection or hematoma, and hypocalcemia if the parathyroid glands are also removed. In the series from

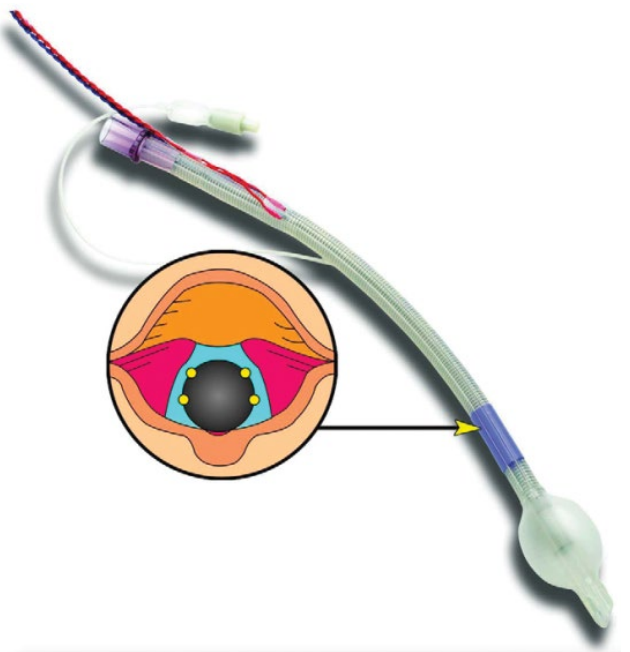

Figure 24.8 Endotracheal tube equipped with two pairs of electrodes (NIM® Trivantage EMG tube, Medtronic Corp., Minneapolis, MN, USA) with a diagram illustrating the contact points between the electrodes and the vocal folds. *Source:* Reproduced from Julien et al [108] with permission.

Texas Children's Hospital, 31 of 91 (34%) total thyroidectomy patients developed transient hypocalcemia (ionized calcium <1.0 mmol/L or total calcium <8.0 mg/dL) [105]. Ten patients were symptomatic, and 13 received IV calcium gluconate supplementation. Signs and symptoms of hypocalcemia include paresthesias, wheezing, dysphagia, voice changes, tetany, and seizures. Pre- and perioperative calcium supplementation reduces the risk of this complication, and these patients should have serum calcium monitored in the immediate postoperative period.

Conclusion

Adolescence is a time of rapid growth and change, and a number of anesthetic challenges occur that are unique to this age group. Knowledge of physiological and psychosocial development and the disease processes and procedures common in these patients is important to providing anesthesia care to maximize favorable outcomes. A direct, honest, positive approach that is distinct from that toward the younger child, empathetic to the adolescent's developmental stage and disease process, is usually greatly appreciated by these patients and their parents. This approach also facilitates the establishment of trust with the anesthesiologist in the often brief time for preoperative evaluation and preparation. Transition to adult care of patients with chronic pediatric diseases such as congenital heart disease and cystic fibrosis is variable, and the pediatric anesthesiologist should be prepared to care for young adults with these conditions.

CASE STUDY

The patient was a 16-year-old girl presenting for laparoscopic Roux-en-Y gastrojejunostomy. Current BMI was 47.8 (height 165 cm, weight 130 kg). Review of her growth charts revealed that the patient had been above the 99th percentile on the US Centers for Disease Control 2000 growth charts since age 10. She had attempted diet and behavioral therapy for the past 4 years without success. Co-morbidities included type 2 diabetes treated with metformin, gastroesophageal reflux disease treated with pantoprazole, and OSA with apnea-hypopnea index of 9 (moderately severe OSA) on sleep study that was treated with BiPAP 10 cm at night by nasal mask. She also had early polycystic ovary syndrome with facial acne and mild hirsutism. After a full evaluation by the bariatric surgery team, including a psychological evaluation, full explanation of the procedure and follow-up required, and contract signed by the patient and parents to adhere to the follow-up guidelines, the patient was accepted for surgery. She had not had anesthesia or surgery previously, there was no family history of anesthetic problems, and she had no medication allergies. She did not smoke, drink alcohol, or use illegal drugs. Menses were irregular, with last menstrual period 6 weeks previously.

Physical examination revealed an alert, anxious, morbidly obese teenager. Room air SpO_2 was 94% without BiPAP, heart rate 80 beats per minute, respiratory rate 16, and blood pressure 145/86. Airway examination revealed a Mallampati Class II examination, full range of neck motion, and intact dentition. Lung examination revealed no respiratory distress, distant clear breath sounds, and decreased breath sounds at both bases. Cardiac examination revealed regular rate and rhythm, with no murmurs. Peripheral veins were difficult to identify. Preoperative laboratory values included hemoglobin 14 g/dL, hematocrit 42%, and white blood cell count 8500/mm^3 with normal differential. Electrolytes were normal, blood urea nitrogen 18 mg/dL, creatinine 1.0 mg/dL, and blood glucose 125 mg/dL. Urine human chorionic gonadotropin test was negative. Chest radiograph revealed mild cardiomegaly and clear lung fields with the exception of some volume loss at both bases. The patient was informed of the anesthetic procedures, that the plan would be to extubate her trachea in the operating room when she was awake and able to follow commands, that she would have her BiPAP reinstituted in the postanesthesia care unit (PACU), and that she would have patient-controlled analgesia (PCA).

A 20 ga peripheral IV was started in the dorsum of the left hand on the second attempt. Metformin had been stopped 2 days preoperatively. Oral sodium citrate and IV metoclopramide and pantoprazole were given in the holding area, along with IV midazolam, 2 mg, which provided anxiolysis. The patient was transported to the operating room (OR) where she was positioned on the OR table with a foam wedge under the back and shoulders to optimize airway alignment. Difficult airway adjuncts were in the OR, including a videolaryngoscope, large adult intubating laryngeal mask airway, and fiberoptic bronchoscope. After application of standard monitors and preoxygenation for a full 5 min, IV induction was achieved with fentanyl 100 μg and propofol 150 mg IV, which was 2 mg/kg based on ideal bodyweight of 75 kg. Eyelash reflex was lost in 45 s. Mask ventilation was easy once an oral airway was inserted, and rocuronium 80 mg was given to facilitate tracheal intubation, which was accomplished easily with a MacIntosh 3 blade achieving a grade I Cormack and Lehane view of the larynx. Anesthesia was maintained with desflurane, 6–12% end-tidal concentration. Positive end-expiratory pressure of 8 cmH_2O was used to prevent atelectasis, and the patient was ventilated with tidal volumes of 750 mL, and FiO_2 50% with an air–oxygen mixture, achieving an SpO_2 of 95–98% during the surgery. A second 18 ga IV was placed after induction. Laparoscopic Roux-en-Y-gastrojejunostomy proceeded via five separate incisions for ports and instruments, and CO_2 insufflation to achieve a pressure of 15–20 cmH_2O was used. The patient was hemodynamically stable throughout the procedure; minute ventilation had to be increased during the insufflation to achieve end-tidal CO_2 of 35–40 mmHg by increasing the rate. After 3 h and 15 min of operating time, estimated blood loss 15 mL, and achieving an excellent surgical result and hemostasis, the incisions were closed after infiltrating

the fascia, subcutaneous tissue, and skin with a total of 30 mL of 0.25% bupivacaine. Ketorolac 30 mg IV, morphine 6 mg IV, and ondansetron 4 mg IV were given during the last hour of the procedure. Neuromuscular blockade was reversed, the patient's respirations were at first assisted with pressure support ventilation of 15 cmH_2O, and when she was awake, following commands, and taking unassisted tidal volume breaths of 500 mL or more, the trachea was extubated, with the patient in semi-Fowler position with head elevated 45°. She was assisted with facemask CPAP, achieving good tidal volumes and SpO_2 94–96% without distress, and was transported to the PACU where her BiPAP was instituted at end-expiratory pressure of 10 cmH_2O and inspiratory pressures of 15 cmH_2O. Patient-controlled analgesia with morphine was instituted in PACU, with no basal rate, and a PCA dose of 1.5 mg morphine with 10 min lockout interval. Ketorolac 30 mg IV Q 6 h × five additional doses and ondansetron were also ordered. Pneumatic sequential compression stockings for deep vein thrombosis prophylaxis were fitted in PACU. After 2 h of monitoring in PACU with several visits by the anesthesiologist to ensure satisfactory airway, pulmonary, and pain control status, the patient was transferred to an intermediate-care monitored unit. She was mobilized out of bed and into a chair the night of surgery, and every 4 h during the first postoperative day. Incentive spirometry exercises commenced the first night after surgery. On the second postoperative day she was out of bed walking around her room every 4 h. Pain control was adequate, with visual analog scale scores 3–5 on a 10-point scale, with a total of 22.5 mg morphine used during the first 24 h. Respiratory status was adequate, with no episodes of OSA or desaturation below SpO_2 90%, and she was able to discontinue the BiPAP while awake after 24 h, thereafter using it only while sleeping. Clear liquid intake and metformin and pantoprazole orally commenced on postoperative day 1. Serum glucose was adequately controlled at 120–200 mg/dL. She was discharged to the surgical ward on postoperative day 3, transitioned to oral pain medication with acetaminophen/hydrocodone oral solution, and discharged home on postoperative day 4.

At 6-month follow-up the patient was doing well, had lost 25 kg, and was compliant with her diet regimen and clinic follow-up visits. Her blood pressure had decreased to 130/80 mmHg. Her endocrinologist was considering discontinuing the metformin.

This case illustrates the principles of preanesthetic evaluation of morbidly obese teenage patients, and the comorbidities they suffer, including OSA and type 2 diabetes. Careful preoperative preparation for a possible difficult airway, gastrointestinal prophylaxis preoperatively to prevent aspiration of acid gastric contents, and proper positioning to facilitate laryngoscopy, allowed appropriate airway management. Dosing lipid-soluble induction agents (propofol) based initially on ideal bodyweight, maintaining functional residual capacity with positive end-expiratory pressure during laparoscopy with CO_2 insufflation, using an insoluble anesthetic gas (desflurane) to minimize uptake by adipose tissue that would delay emergence, minimizing intraoperative opioids, using local anesthesia and non-steroidal anti-inflammatory agent, extubating the trachea with the patient awake, and directly instituting BiPAP immediately after extubation, helped avoid obstructive apnea and hypoxemia. A pain management regimen of PCA without basal rate, continued ketorolac administration, and early mobilization and ambulation all aided in avoiding pulmonary and airway morbidity in this patient.

Introduction

As with many areas of surgery and anesthesiology, the specialized care of patients with neurological and neurosurgical conditions presents an interesting challenge to the anesthesiologist [1]. As in the patient in the case study at the end of this chapter, neurological conditions may be dynamic, and recognition of perioperative events, selection of specific anesthetic agents, and a collaborative approach with intensivist, surgeons, and neurologists may profoundly reduce or prevent significant morbidity. Contemporary neuroanesthetic practice is based on the understanding of cerebral physiology and how it can be manipulated in the presence of intracranial pathology (see Chapter 8). In addition to managing common problems of administering anesthesia to a diverse general pediatric population, the neuroanesthesiologist must give special consideration to the effects of anesthesia on the central nervous system (CNS) of children with neurological diseases. This chapter reviews the fundamentals of clinical management in neurosurgical patients. Discussion of specific neurosurgical conditions and their respective anesthetic management is designed to highlight the common and sometimes unique problems encountered by the pediatric neuroanesthesiologist.

Neuropharmacology

General principles

Evidence from animals suggests that the lethal dose in 50% of the animals (LD50) for many medications is significantly lower in the neonatal and infancy periods than in adults [2]. The sensitivity of the developing human newborn to most of the sedatives, hypnotics, and opioids is increased, probably owing to brain immaturity (incomplete myelination and blood–brain barrier) and to increased permeability for some medications (i.e. the lipid-soluble drugs used in anesthesia) [3]. In addition, the effect of volatile anesthetic agents is influenced by the age of the patient. The minimal alveolar concentration (MAC) in the neonate (0–30 days) is much lower than in infants aged 31–180 days [4]. Although there is an increase in anesthetic requirements in infancy, it must be emphasized that there is a smaller margin of safety between adequate anesthesia and severe cardiopulmonary depression in the infant and child compared with the adult [5]. Therefore, dosages must be appropriately calculated and therapeutic effects must be monitored to avoid inadvertent adverse clinical consequences and prolonged effects.

Gregory's Pediatric Anesthesia, Sixth Edition. Edited by Dean B. Andropoulos and George A. Gregory.

Inhalational anesthetic agents

All modern, volatile anesthetic agents have variable degrees of cerebrovascular effects, primarily vasodilatation and increased cerebral blood flow (CBF). The increase in intracranial pressure (ICP) observed with volatile anesthetics can be partially mitigated by mild hyperventilation and lower inhaled concentrations. Historically used agents are not discussed; instead the focus of this section is on those inhalational agents most widely used in contemporary clinical practice.

Isoflurane

Isoflurane is the most commonly used volatile anesthetic for neuroanesthesia. Its widespread use is based on the fact that it affects CBF less than other inhaled anesthetics at equivalent MAC doses [6] and on the belief that it may provide neuroprotection [7,8]. Compared to other volatile anesthetics, isoflurane has a minimal effect on cerebral autoregulation [6] and reduces cerebrospinal fluid (CSF) through increased resorption [9]. Studies in children suggest that an end-tidal concentration of isoflurane between 0.5 MAC and 1.5 MAC did not change CBF velocity and had minimal effects on the cerebrovascular reactivity to CO_2 [10]. Furthermore, there were no time-response effects of 1 MAC isoflurane on CBF velocity in anesthetized children [11–13]. Of note, the net impact of most volatile anesthetics (like isoflurane) is greatest on CBF, and increased ICP can be mitigated by increased ventilation [14]. Table 25.1 compares the different effects of various anesthetic agents on neurophysiology.

Sevoflurane

Sevoflurane is similar to isoflurane with regard to its effects on CBF, cerebral metabolic rate of O_2 ($CMRO_2$), and ICP in adults (see Table 25.1) [15]. In children, there appears to be no effect on CBF during hypo- and normocapnia under 1 MAC concentrations of sevoflurane [16]. Comparison between isoflurane and sevoflurane showed no difference on elevation in ICP and reduction in arterial blood pressure resulting in clinically similar reduction in cerebral perfusion pressure [17]. Also, sevoflurane has a similar neuroprotective effect as isoflurane during incomplete ischemia, compared with fentanyl and nitrous oxide techniques in rodents [18].

Desflurane

Desflurane increases CBF and decreases $CMRO_2$ in animals. One MAC desflurane has been shown to increase ICP significantly in neurosurgical patients with supratentorial mass lesions, despite hypocapnia [19], although larger studies have not demonstrated this finding [20]. Data in children are limited, though Sponheim et al demonstrated only a modest rise in ICP and a greater reduction in blood pressure which resulted in a decrease in calculated cerebral perfusion pressure compared to isoflurane and sevoflurane. This reduction in mean arterial pressure is perhaps most problematic for managing neurosurgical patients with obvious and subtle issues of increased ICP. When quicker emergence is desired, the use of desflurane with elevated ICP and reduction in perfusion pressure makes intravenous anesthesia a potentially safer option, though this remains a subject of debate [17].

Table 25.1 Effects of volatile anesthetic agents on cerebral metabolic rate for oxygen ($CMRO_2$), cerebral blood flow (CBF), cerebrospinal fluid (CSF) dynamics, and intracranial pressure (ICP)

Volatile agent	$CMRO_2$	CBF	CSF	ICP
Isoflurane	Decrease	Increase	Decrease	Increased
Sevoflurane	Decrease	Increase	No change	Increased
Desflurane	Decrease	Increase	No change	Increased
Nitrous oxide	Increase	Increase	No change	Increased

Nitrous oxide

The effect of nitrous oxide (N_2O) on cerebral circulation and its use in neuroanesthesia remain controversial. The reported variability of its effects on CBF and ICP is probably due to differences in experimental species, background anesthesia, and control of respiration. Subanesthetic doses of N_2O (60–70%) cause excitement, cerebral metabolic stimulation, and increased CBF [21]. Leon and Bissonnette showed that in infants and children 70% N_2O in oxygen with fentanyl–diazepam caudal epidural anesthesia increased CBF significantly compared with an air/O_2 mixture [22]. This increase in CBF was not associated with significant changes in mean arterial pressure (MAP), heart rate, or cerebrovascular resistance. However, other studies have suggested a direct effect of N_2O on increasing $CMRO_2$ in both animals and humans. Clinically, N_2O has been shown to increase CBF and ICP in adults and children [23–25], although the co-administration of intravenous agents (with or without induced hypocapnia) can mitigate these N_2O induced increases in CBF [26,27]. In contrast, volatile agents can further increase CBF [28]. Although N_2O is commonly used, it remains a controversial agent that is best avoided in the clinical scenarios of a brain that is tight or when cerebral ischemia is known to be present.

Intravenous anesthetic agents

There is increased interest in total intravenous anesthesia for some neurological procedures such as awake craniotomy, and the anesthesiologist must be familiar with and utilize the nuanced differences in effect between various intravenous anesthetic agents on neurophysiological parameters (Table 25.2) to provide adequate anesthetic effects.

Table 25.2 Effect of intravenous anesthetic agents on cerebral metabolic rate for oxygen ($CMRO_2$), cerebral blood flow (CBF), cerebrospinal fluid (CSF) dynamics, and intracranial pressure (ICP)

Intravenous agent	$CMRO_2$	CBF	CSF	ICP
Barbiturates	Decrease	Decrease	No change	Decreased*
Etomidate	Decrease	Decrease	No change	Decreased
Propofol	Decrease	Decrease	No change	Decreased*
Benzodiazepines	Decrease	Decrease	No change	Decreased
Opioids	No change	No change	No change	No change
Ketamine	Increased+	No change	No change	Increased
Dexmedetomidine	No change	Increase	No change	No change

* Decreased ICP is a summation on lowering of $CMRO_2$ and reduction in CBF; +, intermittently observed depending on degree of neuronal excitation.

Barbiturates

Barbiturates are a broad class of drugs that bind to the γ-aminobutyric acid (GABA) receptor on the α subunit, creating sedation and amnesia. In addition, barbiturates reduce epileptiform and EEG activity, lower ICP, lower CBF, and reduce $CMRO_2$ in a dose-dependent manner [29,30]. A major problem with barbiturates is that they can significantly reduce myocardial contractility, systemic arterial blood pressure, and cerebral perfusion pressure (CPP) [31]. In non-clinical doses (10–55 mg/kg), thiopental produces an isoelectric EEG and decreases the $CMRO_2$ by 50% [31]. Barbiturates can prevent an increase in ICP [32] during laryngoscopy and tracheal intubation owing to their ability to decrease CBF. Cerebral autoregulation and cerebrovascular reactivity to CO_2 are preserved with barbiturates. Production and reabsorption of CSF are not altered [33]. As mentioned, barbiturates are effective in controlling epileptiform activity, apart from methohexital, which may activate seizure foci in patients [34].

Etomidate

Etomidate is a carboxylated imidazole that binds to the GABA receptors, resulting in hypnosis and amnesia with a reduction of CBF (34%) and $CMRO_2$ (45%) [35]. Etomidate appears to directly vasoconstrict the cerebral vasculature, even before the metabolism is suppressed [36]. Thus, administration of etomidate can potentially lower ICP by reducing cerebral blood volume (CBV) while augmenting or maintaining CPP. Studies of etomidate administration have been primarily in adults; studies in children are limited. However, the clinical applicability of etomidate was perhaps best illustrated in a small clinical study of intubated pediatric patients with traumatic brain injury with elevated ICP (>20 mmHg for over 5 min). After intravenous etomidate administration, all patients had an increase in MAP from baseline, with a significant lowering of measured ICP and improvement in CPP [37]. Other studies have demonstrated that cerebrovascular reactivity to CO_2 is maintained following administration of etomidate [35]. Although etomidate has a great advantage over other intravenous agents, like barbiturates, because of minimal cardiovascular depression, it has two significant disadvantages that limit its use outside airway management: suppression of the adrenocortical response to stress, and increased myoclonic activity, especially after prolonged infusion [38].

Propofol

Propofol is a rapidly acting GABA agent that reduces CBF and $CMRO_2$ [39]. Although administration of propofol either by bolus or infusion can reduce ICP, the cardiovascular effects of a dose-dependent reduction in MAP may have the net result of lowering CPP in the patient with brain trauma [40]. CO_2 cerebrovascular responsiveness is maintained during propofol anesthesia, but the observed reduction in CBF and CBV is not augmented by hyperventilation (end-tidal CO_2 <30 mmHg) in normal children [41]. Although it is routinely a part of neuroanesthetic management in children and adults, the use of propofol outside the operating room in critically ill pediatric patients is limited by concerns about morbidity and mortality related to propofol infusion syndrome [42].

Benzodiazepines

Benzodiazepines bind to the GABA receptor, resulting in amnesia and anxiolysis. In addition, benzodiazepine administration has been reported to decrease CBF by a 25% decrease in $CMRO_2$, reduce ICP, and slow seizure foci [43–45]. However, the sedating effects and relatively short duration of action (compared to barbiturates) have led to their widespread use in patients in both the operating room and intensive care unit (ICU). The benzodiazepine antagonist, flumazenil, has been demonstrated to reverse the beneficial effects of benzodiazepines on CBF, $CMRO_2$, and ICP. Consequently, administration of flumazenil should be undertaken with caution in neurological patients with high ICP, abnormal intracranial elastance, and/or a predisposition to seizure [46].

Opioid analgesics

The opioid agents have little or no effect on CBF, $CMRO_2$, and ICP [47]. However, if patients are experiencing pain, opioids cause a modest reduction in these variables through indirect effects on the sympathetic nervous system [48]. Fentanyl combined with N_2O decreases CBF and $CMRO_2$ by 47% and 18%, respectively [30]. Cerebrovascular reactivity to CO_2 and cerebral autoregulation are preserved with opioids. Fentanyl has no effect on CSF production, but it reduces CSF reabsorption by at least 50% [49]. Fentanyl has no effects on the cerebral circulation of neonatal animals, but alfentanil increases CSF pressure in patients with brain tumors [50]. This effect was less than that observed with sufentanil, but greater than that observed with fentanyl. Alfentanil has the greatest effect on MAP and CPP [51]. Some studies reported a decrease in CBF and $CMRO_2$ [52], whereas others suggested an increase in CBF and ICP [53]. Remifentanil, with an ultrashort elimination half-life, offers the advantage over other opioids of not delaying perioperative neurological assessment [54]. Equipotent infusions of remifentanil and fentanyl were studied in patients undergoing supratentorial tumor surgery in combination with a balanced inhalational anesthetic. Remifentanil appeared to have the same preservative effects as fentanyl on CBF and cerebrovascular reactivity [55,56].

Ketamine

Ketamine is a mixed N-methyl-D-aspartate (NMDA) receptor agonist/antagonist that results in a dissociative anesthetic state [57]. Ketamine appears to be a potent cerebral vasodilator capable of increasing CBF by 60% in normocapnic humans, and thus an increase in ICP [58]. Studies have reported clinical deterioration in patients with increased ICP after ketamine administration [32]. Despite alterations in cerebral tone and CBF, ketamine has a negligible effect on the $CMRO_2$. Although it is suggested that ketamine may have some cerebral protective effects, studies in animal models of brain development have shown it to increase neuronal apoptosis even in the absence of brain injury [59]. The use of ketamine is generally contraindicated in neuroanesthesia.

Dexmedetomidine

Dexmedetomidine, an α_2-adrenergic agonist, causes a unique kind of sedation, acting on the subcortical areas, which resembles natural sleep without respiratory depression. The most common cardiovascular effects are bradycardia and

transient hypotension [60]. All effects are typically responsive to slowing the infusion and/or giving fluid boluses with or without a vagolytic (i.e. atropine). Experimental data demonstrate both cerebral vasoconstriction and vasodilatation, depending on the model and dose studied [61]. In clinically relevant dosages that produce sedation, dexmedetomidine has been shown to reduce CBF in humans and animals, unrelated to hemodynamic changes. In early animal investigations, $CMRO_2$ was unchanged, suggesting the possibility of increasing cerebral vascular resistance [62]. However, additional studies in humans and animals demonstrate that dexmedetomidine maintains a decrease in CBF proportional to its effect on decreasing $CMRO_2$. Further, it appears that CO_2 reactivity of the cerebral vasculature is unaffected by dexmedetomidine. In a study of healthy adults, the relative middle cerebral artery blood flow velocity to CBF and $CMRO_2$ relationship was unchanged following dexmedetomidine administration [63]. Using clinically relevant doses, the researchers confirmed that dexmedetomidine decreases CBF and $CMRO_2$ proportionally in healthy humans. In adult patients with brain injury, it appears that dexmedetomidine is more effective than propofol in providing sedation while preserving functionality [64]. Clinical experience with dexmedetomidine use in functional neurosurgery is limited to small case series [65]. However, these reports suggest that use of dexmedetomidine does not appear to interfere with electrophysiological monitoring, and has permitted brain mapping during awake craniotomy and microelectrode recording during implantation of deep brain stimulators in adults [66] and children [67]. Studies are underway to investigate the pharmacokinetics and pharmacodynamics of dexmedetomidine in infants and children.

Muscle relaxants

Muscle relaxants have little effect on cerebral circulation.

Succinylcholine

Succinylcholine produces an initial fall in ICP followed by a rise, especially in patients with decreased intracranial compliance resulting from increased CBF [68,69]. The increase in ICP is probably related to cerebral stimulation caused by increases in afferent muscle spindle activity [70]. The increase in ICP and CBF with succinylcholine is reduced by prior administration of deep general anesthesia or by precurarization [71]. However, the benefits to pediatric patients with increased ICP from rapid control of the airway and hyperventilation offset the slight increase in ICP caused by succinylcholine. It is important to remember that life-threatening hyperkalemia may occur after administration of succinylcholine to patients with closed head injury even though they do not have conditions classically associated with this adverse effect, including motor deficits, severe cerebral hypoxia [72], subarachnoid hemorrhage [73], cerebrovascular accident with loss of brain substance [74], and paraplegia [75].

Rocuronium

Rocuronium offers an alternative to succinylcholine for rapid-sequence intubation, but it does delay the return of spontaneous respiration and neurological assessment provided by succinylcholine [76,77]. However, with the availability of sugammadex in some countries including the European Union, Japan, and now the USA for reversal of neuromuscular blockade by non-depolarizing agents, this issue may be less relevant [78,79]. Like the other neuromuscular blocking agents, rocuronium has no effect on CBF or hemodynamics [80].

Pancuronium, atracurium, and cis-atracurium

These agents have no effect on CBV, ICP, or $CMRO_2$ in the presence of volatile anesthetics [81]. Large doses of *d*-tubocurarine, atracurium, or metocurine may release histamine and cause transient cerebrovascular dilation, which could account for a slight increase in ICP. However, a slight decrease in MAP may offset any change in intracerebral blood volume [82]. Use of *cis*-atracurium should not result in histamine release and has demonstrated improved cardiovascular stability. In addition, the metabolism of the agent by Hoffman degradation allows for its rapid clearance in patients with impaired renal and hepatic function [83]. Studies in healthy adults have shown rocuronium and *cis*-atracurium to have no effect on CBF [80].

Vecuronium

Vecuronium is known for its cardiovascular stability and its relatively short duration of action. In patients with reduced intracranial compliance, vecuronium slightly decreased ICP, probably because there was a concomitant decrease in central venous pressure (CVP) [84].

Reversal of neuromuscular blockade

Historically, reversal of neuromuscular blockade (NMB) by non-depolarizing agents has been primarily with train-of-four monitoring, timed to see an optimal effect with neostigmine administration. Neostigmine (an acetylcholinesterase inhibitor) has minimal effects on $CMRO_2$ and CBF, however cerebral vascular resistance and CPP are lowered, suggesting a central cholinergic influence of cerebrovascular dilation. Notably, these findings were from higher-concentration infusions into the cerebral vasculature via the carotid or intervertebral artery in non-human primates [85]. That said, early reversal of paralysis after rapid-sequence intubation is preferable to neurological monitoring. Sugammadex is a novel pharmacological agent that was approved for clinical use in December 2015 by the US Food and Drug Administration. It reverses NMB with a mechanism that differs completely from acetylcholinesterase inhibitors by encapsulating rocuronium or vecuronium and thereby may provide complete recovery even when there is a profound degree of NMB [86]. Although experience in children is limited to case series and reports, initial experience suggests the medication to be relatively safe with only minimal side-effects of nausea, hypotension, bradycardia, and anaphylaxis in <1% of patients. In these case reports, sugammadex was able to reverse dense NMB with vecuronium and rocuronium in children without any response on the train-of-four. This has implications for use in neurological patients to facilitate neurological examination and to improve neuromonitoring (as with motor-evoked potentials) [86].

KEY POINTS: NEUROPHARMACOLOGY

- Isoflurane, sevoflurane, and desflurane all decrease $CMRO_2$, increase CBF, and increase ICP; increasing minute ventilation and producing mild hypocapnea can overcome the effects on ICP
- N_2O use is controversial; it is best avoided in clinical scenarios of "tight brain" or when cerebral ischemia is a risk
- Barbiturates, etomidate, propofol, and benzodiazepines all decrease $CMRO_2$, CBF, and ICP; opioids and dexmedetomidine do not effect these parameters; ketamine increases $CMRO_2$ and ICP
- Depolarizing and non-depolarizing neuromuscular blocking agents have little effect on cerebral circulation or metabolism

General anesthetic considerations

The following sections discuss the anesthetic management of pediatric neurosurgical procedures. Topics common to most procedures are reviewed first, followed by discussion of specific considerations and surgical procedures.

Preoperative assessment of the neurosurgical patient

Ongoing developments in neuroimaging and neuromonitoring have increased understanding of cerebral pathophysiology and improved the preoperative assessment of neurosurgical patients. However, the cornerstone of assessment of neurological function is still the history and physical examination. The preoperative anesthetic work-up of the neurosurgical patient includes a complete baseline neurological examination, an assessment of ICP, assessment of the function of vital respiratory and cardiovascular centers that can be affected by neuropathological processes, either in the brainstem or in the spinal cord, and assessment of specific disturbances in neurological function [87]. Important to many neurological procedures is to assess and document preoperative recognition of intracranial hypertension and major neurological deficits. Notably, the history, symptoms, and physical findings of intracranial hypertension differ somewhat according to the age group. In general, the clinical presentation of patients with intracranial hypertension varies with the duration of increased ICP (Table 25.3). Sudden massive increases in ICP often cause coma. In a less acute case, however, there may be a history of headache on awakening, suggestive of vasodilation caused by sleep-induced hypercapnia and reduced intracranial compliance. Vomiting is a common sign. Neonates and infants often present with a history of increased irritability, poor feeding, or lethargy. A bulging anterior fontanelle, dilated scalp veins, cranial enlargement or deformity, and lower extremity motor deficits are also common signs of increased ICP in this age group [88]. Increased ICP in children is frequently caused by a tumor. As ICP reaches critical levels, vomiting, decreased level of consciousness, and evidence of herniation may develop. Other symptoms include diplopia due to oculomotor or gaze palsies (sunset sign), dysphonia, dysphagia, and/or gait disturbances. Injury to the third cranial nerve may result in ptosis. Injury to the sixth cranial nerve produces a strabismus caused by loss of abduction. Nausea and vomiting usually occur, and older children complain of morning headache. Papilledema and lack of venous pulsation of the retinal vessels may be seen on funduscopy.

Neurogenic pulmonary edema is a syndrome that includes acute hypoxia, pulmonary congestion, pink, frothy, protein-rich pulmonary edema, and radiological evidence of pulmonary infiltrates [89], and is associated with a variety of intracranial pathological occurrences, including hemorrhage [90], head trauma [91], and seizures [92]. The mechanisms responsible for activating the sympathetic nervous system and the vagal centers, which lead to pulmonary edema, are related to ischemia of the medulla and distortion of the brainstem [93]. Cranial nerve function and the patient's ability to protect the airway must be evaluated. During the preoperative assessment, the possibility of spinal cord dysfunction must be determined. Neurological dysfunction arising from cervical spinal cord injury may affect the respiratory and cardiovascular centers. Some coexisting conditions may warrant additional anesthetic considerations if neurological problems occur (see Table 25.4).

Laboratory tests may yield evidence of the syndrome of inappropriate secretion of antidiuretic hormone (SIADH) and of electrolyte abnormalities or volume contraction from protracted vomiting. Diabetes insipidus may result in hypernatremia [94]. Disturbances in metabolism, such as hypo- or hyperglycemia, may be present. The preoperative history and chart review may reveal that the patient is receiving steroids to reduce tumor edema. If so, steroids will be required during surgery. Neurosurgical patients may be receiving anticonvulsant medication, either to treat seizures or to prevent them. These drugs may have profound effects on the metabolism of other drugs (e.g. barbiturates, narcotics). Patients with suprasellar tumors, such as craniopharyngioma, frequently have pituitary dysfunction and should have a complete endocrine evaluation before surgery.

Table 25.3 Signs and symptoms of increased intracranial pressure (ICP) in infants and children

	Infants	Children	Infants and children
Symptoms	Irritability Poor feeding	Headache Vomiting	Lethargy
Physical examination	Bulging fontanelle Separated sutures Large head circumference	Diplopia Papilledema	Decreased level of consciousness Cushing's triad Pupillary enlargement Absent upward gaze Cranial nerve III and VI palsies

Table 25.4 Perioperative concerns for infants and children with neurological disease

Condition	Anesthetic implications
Congenital heart disease	Hypoxia and cardiovascular collapse
Prematurity	Postoperative apnea
Upper respiratory tract infection	Laryngospasm and postoperative hypoxia/pneumonia
Craniofacial abnormality	Difficulty with airway management
Denervation injuries	Hyperkalemia after succinylcholine Resistance to non-depolarizing muscle relaxants
Chronic anticonvulsant therapy for epilepsy	Hepatic and hematological abnormalities Increased metabolism of anesthetic agents
Arteriovenous malformation	Potential congestive heart failure
Neuromuscular disease	Malignant hyperthermia Respiratory failure Sudden cardiac death
Chiari malformation	Apnea Aspiration pneumonitis

Skull radiographs, ultrasonography, computed tomography (CT), and magnetic resonance imaging (MRI) aid in the assessment of intracranial hypertension. Skull radiographs may show the "beaten copper sign" and widening of the sagittal sutures in response to chronic increased ICP and universal suture stenosis. In infants and young children, the width of the cranial sutures should not exceed 2 mm, and they should not have bridges or closures [95]. Ultrasonography of the brain is useful in premature infants and neonates because it is relatively inexpensive, does not require sedation, and can be performed at the bedside through the fontanelle. However, the CT scanner can visualize virtually all parts of the brain and is the preferred method for imaging for hydrocephalus [96]. Development of CT scanning and MRI has revolutionized the investigation of brain disease.

Given their complexity and potential need for optimization and integration of both the evaluation and treatment by multiple services, neurosurgical diseases have become a focus in the pediatric perioperative surgical home (PPSH, see Chapter 15). At Texas Children's Hospital we have used this for perioperative care planning for scoliosis surgery and craniosynostosis, with a future focus on epilepsy, arteriovenous malformation (AVM), and glioma surgery [97,98].

Premedication

Most anesthesiologists avoid sedation in pediatric neurosurgical patients. If sedatives and opioids are given as part of premedication for surgery, the patient must be closely monitored because the drugs may precipitate respiratory depression, hypercarbia, loss of airway integrity, and increased ICP. Exceptions to this rule include patients with intracranial vascular lesions (with no increase in ICP) who may benefit from sedation to reduce the likelihood of precipitating increased blood pressure from anxiety or crying that could potentially precipitate a preoperative hemorrhage. Sedation can be accomplished in small children with midazolam (0.5 mg/kg), pentobarbital (4 mg/kg), or chloral hydrate (50 mg/kg) administered orally or rectally 1 h before surgery. Emotional preparation is essential and is accomplished by the anesthesiologist and the parents working together. In older children, a simple explanation of what to expect before induction of anesthesia will reduce the element of surprise and the incidence of hemodynamic instability in a threatening environment.

Patient positioning

Planning of a successful anesthetic includes the preparation of the operating table with proper equipment to protect the patient after positioning. The anesthesiologist's preoperative visit should provide information on patient positioning during surgery.

Although patient positioning varies according to the neurosurgical procedure, the general principles remain the same. The eyes must be securely taped closed and, if the patient is prone, the face and other vulnerable areas must be padded to prevent localized pressure. Since ventilation may be compromised by incorrect positioning, it is mandatory to ensure that chest excursion remains adequate, especially when the patient is prone. This can be achieved by using suitable bolsters or a frame that allows the abdomen to be pendulous and facilitates respiratory movement during intermittent positive pressure ventilation. The endotracheal tube (ETT) should be taped securely in place, most notably in the prone position as secretions may loosen the tape. A 10° head-up position is usually advisable to improve cerebral venous return and reduce venous congestion. Rotation of the head to one side may kink the jugular veins and reduce venous return. This kinking can be avoided by rotating the trunk to maintain the axial position. During any surgical procedure, it is important for the anesthesiologist to be able to inspect the ETT and circuit connection and to have access to the ETT for possible endotracheal suctioning. In addition, it is desirable to have a body part, such as a hand or foot, visible during surgery so that peripheral perfusion and color can be readily assessed. General effects of patient positioning are listed in Table 25.5.

Monitoring

Basic monitoring consists of a precordial/esophageal stethoscope, electrocardiography (ECG), a non-invasive blood pressure measuring device, a temperature probe, a pulse oximeter, and capnometry. In addition, an arterial catheter allows continuous monitoring of peripheral perfusion on a beat-to-beat basis and provides an accurate measurement of blood pressure. A peripheral nerve stimulator for monitoring NMB is desirable. A urinary catheter is required for long surgical procedures and is mandatory if osmotic diuretics are administered.

Induction of anesthesia

The anesthetic technique chosen and recognition of perioperative events may have profound effects on morbidity and approach to induction [17]. Consideration of the developmental, anatomical, and physiological differences of pediatric patients who range from premature neonates to 16- to 18-year-old young adults is critical. Knowledge of normal physiology in these differing age groups is essential. Neonatal anesthesia differs from that in the older child and adult,

Table 25.5 Physiological effects of patient positioning for neurosurgical procedures

Position	Physiological effect	Risks
Supine	Easiest position Typical pulmonary and cardiac mechanics	Axial rotation of the head can cause jugular venous compression Peripheral nerve padding of ulnar with arms tucked
Head-elevated	Enhanced cerebral venous drainage	Increased venous air embolism (VAE) risk
	Decreased cerebral blood flow	Increased hypotension
	Increased venous pooling in lower extremities Postural hypotension	Increased pneumocephalus
Head-down	Increased cerebral venous and intracranial pressure	Increased bleeding
	Decreased functional residual capacity (lung function) Decreased lung compliance	Increased desaturation
Prone	Venous congestion of face, tongue, and neck Decreased lung compliance	Increased risk of eye injury Increased risk of skin injury
	Increased abdominal pressure can lead to venocaval compression	Difficult airway access
Lateral decubitus	Decreased compliance of down-side lung	Brachial plexus injury Decreased perfusion dependent arm

particularly with regard to the respiratory system, the cardiovascular system, and thermoregulation.

Most important is to recognize the neurological status of the patient and modify the induction accordingly. Anesthesia for patients with elevated ICP is fraught with danger. In patients with altered mental status secondary to elevation in ICP, the goal is to safely control the airway, with minimal effect on increasing ICP. As with other patients with lethargy or increased somnolence, a rapid-sequence technique for induction and intubation is preferred to minimize aspiration risk and allow for endotracheal intubation and controlled ventilation (such as hyperventilation) to help control and lower the ICP. The systemic hypertension associated with laryngoscopy may be avoided by giving IV lidocaine at induction of anesthesia. Rapid-sequence induction of anesthesia with propofol, atropine, lidocaine, and succinylcholine, followed by carefully applied cricoid pressure and manual hyperventilation, is recommended [99]. When succinylcholine is contraindicated (i.e. pre-existing spinal cord, stroke injury, congenital myopathy), large-dose rocuronium or vecuronium can be administered as an alternative neuromuscular blocking agent in conjunction with a modified rapid-sequence technique. With appropriate cricoid pressure, manual ventilation can be performed without distention of the stomach. Cricoid pressure reduces the likelihood of aspirating gastric contents; delayed gastric emptying is often associated with increased ICP. Historically, succinylcholine has been used to produce satisfactory intubation conditions because the speed of onset and offset outweighs the small increase in ICP that it causes. Rocuronium (1–1.2 mg/kg) produces intubation conditions comparable to succinylcholine [76]. In patients without ready IV access, anesthesia can be induced via a small butterfly needle that can be inserted with minimal patient stress or hemodynamic fluctuation. Failing this, it is probably less injurious to children with raised ICP to perform a skillful inhalation induction of anesthesia than it is to subject them to a difficult IV placement. Anesthesia is best maintained with air in oxygen, isoflurane, and a suitable muscle relaxant. Intermittent positive pressure mechanical ventilation is provided. Hypoventilation and hypercarbia are best avoided. An IV opioid can be used in children. Most importantly, deep levels of anesthesia are not needed and are relatively contraindicated for achieving the best neurophysiological conditions and the best neurological examination after the procedure.

Fluid management and intracranial pressure control

Fluid management

Fluid administration to neurosurgical patients depends on the pathology or brain insult being treated. A frequent result of these insults is the development of brain edema, with a resultant increase in ICP. It is essential for the neuroanesthesiologist to understand the principles of fluid movement in the injured brain to administer the proper fluid regimen. Edema formation occurs when there is inequality of net movement of fluid between the intra- and extracellular compartments. The blood–brain barrier (BBB) is composed of capillary endothelial cells, which are connected in continuous fashion by tight junctions. The BBB also excludes polar hydrophilic molecules. Thus, the BBB has tight endothelial junctions of 7 angstroms, as opposed to 65 angstroms in other tissues of the body. This junction is small enough in the brain to prevent sodium from moving into the cells. Essential molecules, such as glucose and amino acids, cross the BBB by energy-mediated transport systems. Only water molecules freely communicate with both sides of the membrane. This passive movement of water is regulated by oncotic, osmotic, and hydrostatic pressure changes across the barrier. The colloid oncotic pressure is a relatively weak driving force. A reduction of 50% of the colloid oncotic pressure (normal 20 mmHg) results in a pressure gradient across the membrane, which is less than that caused by a transcapillary osmolarity difference of 1 mOsm/L. As an example, reduction in the colloid oncotic pressure of the brain does not have the same impact as that observed in the bowel. This is because the brain's extracellular space is poorly compliant, due to its network of glial cells, and discourages edema formation, even in the presence of a severe colloid oncotic pressure gradient. Administration of Ringer's lactate alone will lead eventually to hemodilution and reduced plasma osmolarity (osmolarity 273 mOsm/L), which would encourage cerebral edema [100].

The choice of fluid must be dictated by the neuropathological process involved, and there is no formulaic solution for volume replacement in these cases. The goal should be to maintain an isovolemic, iso-osmolar, and relatively iso-oncotic intravascular volume. For example, a patient with increased ICP and/or a brain mass requires a fluid regimen that balances adequate intravascular volume against efforts to dehydrate the brain mass. In a patient undergoing insertion of a ventricular shunt and/or repair of myelomeningocele, fluid management should replace third-space losses.

An osmolar gradient can be maintained only in areas where the BBB is intact. Under normal circumstances, osmotic diuretics and plasma expanders, such as albumin, are excluded. Unfortunately, areas that might benefit the most from dehydration therapy, such as tumor edema, exhibit BBB incompetence. Agents of high osmolality move into these tissues and increase the edema.

Efforts to dehydrate the brain are complicated by the need to maintain adequate circulating blood volume. In many neurosurgical procedures, a substantial portion of the blood loss is onto the drapes and is difficult to measure. Furthermore, the use of large amounts of irrigation solution makes it difficult to assess blood loss accurately. The initial phase of any neurosurgical procedure produces blood loss, especially scalp incisions. Infiltration of the scalp with bupivacaine 0.125% with 1:200,000 epinephrine reduces blood loss and reduces hemodynamic responses (increased heart rate and blood pressure) during incision. In all cases, bupivacaine blood levels were within the therapeutic range [101]. Resection of a vascular malformation may require massive volume replacement. Placing large-bore IV catheters and having available sufficient blood products are part of appropriate planning for anesthesia and surgery. Urine output in the face of aggressive diuresis is a misleading indicator of adequate volume replacement. In this instance, CVP monitoring is very useful.

There is no perfect protocol for fluid replacement in neurosurgical patients with increased ICP. However, maintenance of cerebral perfusion pressure should represent the optimal goal of fluid therapy. Most anesthesiologists start osmotic diuretic therapy at the beginning of anesthesia and measure the resulting urine output. As surgery and blood loss progress, volume replacement usually consists of a mixture of crystalloid and colloid solutions to maintain an isovolemic, iso-osmolar, and iso-oncotic intravascular volume. After an initial 20 mL/kg of crystalloid solution, normal saline or hypertonic saline can be given. Lactated Ringer's and hypotonic fluids should be avoided. Administration of albumin remains controversial. A recent study in adults found that administration of albumin in the resuscitation of patients with traumatic brain injury was associated with a higher mortality than crystalloid-only resuscitation [102]. As described earlier, the brain that has sustained a recent insult (primary lesion) is vulnerable to so-called "secondary insult" (penumbra area) by a minor episode of hypotension, hypoxia, or ischemia related to mechanical insult [103] (retraction [104]) or ischemia (hemodynamic instability) [105]. Although rapid administration of normal saline (10 mL/kg) has little effect on CBV and ICP, it may reinstitute hemodynamic stability. Blood products should be administered only on the basis of hemodynamic instability and diminished oxygen-carrying capacity.

Dextrose-containing solutions are associated with a poorer neurological outcome and are best avoided unless hypoglycemia has been confirmed [106]. Stressed neonates have reduced glycogen stores, and patients from the ICU may have high glucose loads in their parenteral nutrition. Abrupt cessation of high-dextrose solutions can precipitate an insulin-induced hypoglycemia. In these patients, blood glucose levels should be sampled frequently and normoglycemia maintained.

Osmotic and diuretic therapy to reduce intracranial pressure

Hypertonic saline

Some investigators have suggested that extracellular volume dehydration can be accomplished by raising serum osmolality with hypertonic saline (3% saline) [107]. Hypertonic saline solution (typically 3 mL/kg bolus) has been shown to be effective for volume resuscitation, while resulting in less cerebral edema and/or ICP elevation [108]. In children with severe traumatic brain injury, resuscitation with hypertonic saline (sodium 268 mmol/L, 598 mOsm/L) was superior to resuscitation with lactated Ringer's solution (sodium 131 mmol/L, 277 mOsm/L) [109]. Although children treated with the hypertonic saline solution had shorter ICU stay and fewer ICP interventions, the overall survival rate and duration of hospitalization were no different between groups. In another study of children after traumatic brain injury, 3% hypertonic saline significantly reduced ICP when compared to normal saline resuscitation [110]. Based on these findings and others, there is no difference in recommendation between hypertonic saline or mannitol in the current pediatric brain trauma guidelines [111].

Mannitol

Mannitol (20% solution) remains the most popular diuretic for reducing ICP and providing brain relaxation. Small doses, such as 0.25–0.5 mg/kg, will raise osmolality by 10 mOsm and reduce cerebral edema and ICP [112]. The effects of mannitol begin within 10–15 min of its administration and persist for at least 2 h. Mannitol-induced vasodilation affects intracranial and extracranial vessels and transiently increases CBV and ICP while simultaneously reducing systemic blood pressure. In particular, some children may show transient hemodynamic instability (during the first 1–2 min) after rapid administration of mannitol [113]. Therefore, the drug should be given at a rate not exceeding 0.5 g/kg over 20–30 min. The initial period of hypotension will be followed by increases in cardiac index, blood volume, and pulmonary capillary wedge pressure, all of which reach peak values 15 min after infusion [114]. The changes in intravascular volume last for about 30 min before a return to normal levels. Administration of furosemide before giving mannitol may increase venous capacitance, reduce transient increases in intravascular volume, and provide more effective dehydration. There is, however, a danger of producing profound dehydration and severe electrolyte imbalance [115]. Larger doses of mannitol produce a longer duration of action, but there is no scientific evidence that they reduce ICP further. In animal studies, larger doses of mannitol have significantly decreased the rate of CSF formation [116]. In the presence of cerebral ischemia, larger doses of mannitol 2 g/kg can be used with a presumed added benefit of free radical scavenging. In addition, higher mannitol

dosages have been shown to increase CBF [117] and cardiac output [118] probably by reducing blood viscosity (rheology) [119] or acutely increasing intravascular volume. Through the combination of these effects, it has been suggested that mannitol may cause cerebrovascular vasoconstriction and further reduce CBV. Regardless, the net effect is a multifactorial reduction in ICP from mannitol administration that most directly correlates with a reduction in CBV [120].

Loop diuretics

The loop diuretics, such as furosemide and ethacrynic acid, may reduce brain edema by inducing a systemic diuresis, decreasing CSF production [121], and improving cellular water transport [122]. Although furosemide can reduce ICP without increasing CBV or blood osmolality, it is not as effective as mannitol [123]. The initial dose of furosemide should be 0.6–1 mg/kg if administered alone, or 0.3–0.4 mg/kg if administered with mannitol to children [124]. In the setting of co-administration with mannitol, it is thought to mitigate rebound cerebral edema [125,126]. It has been suggested that ethacrynic acid reduces secondary brain injury by decreasing glial swelling [127]. Raising serum osmolality above 320 mOsm may precipitate acute renal failure and water retention, and create a scenario with the negative consequences that follow from a declining serum osmolality during recovery. Periods of aggressive dehydration may be followed by rebound intracranial hypertension during the recovery or normalization period.

Corticosteroids

Corticosteroids are an important part of the therapeutic regimen in neurosurgical patients with raised ICP. They reduce edema around brain tumors, but hours or days may be required before effects are seen. However, the administration of dexamethasone preoperatively or at the induction of anesthesia frequently improves neurological status before the ICP decreases. It has been suggested that this is in response to a partial restoration of BBB function [128].

Temperature homeostasis

In general, extremes of temperature should be avoided and situations of hypothermia and hyperthermia managed aggressively. Often, a normothermic temperature goal of 35.5–36.5°C should be used, with warming measures started below and cooling measures started above these temperature margins. Although hypothermia reduces the $CMRO_2$, it frequently delays drug clearance, slows reversal of neuromuscular blocking agents, decreases cardiac output, causes conduction abnormalities, attenuates hypoxic pulmonary vasoconstriction, alters platelet function, causes electrolyte abnormalities, and can induce postoperative shivering [129]. In addition, the intraoperative vasoconstriction produced by hypothermia reverts to vasodilation and redistribution of body heat upon rewarming, causing a redistribution of heat and a transient fall in core temperature [130].

Neonates and infants are at greatest risk of hypothermia because of their large surface area relative to body mass. Despite a warm operating room, body temperature falls immediately after induction of anesthesia owing to internal redistribution of body heat from the central compartment to the periphery [131]. As heat loss continues, pediatric patients trigger non-shivering thermogenesis in an attempt to rewarm themselves [132]. In the paralyzed and ventilated patient, body temperature and end-tidal CO_2 ($ETCO_2$) concentration may increase at constant minute ventilation [133]. This phenomenon may not be readily apparent because of cold fluid administration. Temperature monitoring is essential, but the actual site of the probe placement is less important than probe reliability. For this reason, we usually place the probe in the esophagus or rectum. During induction of anesthesia and placement of IV lines and monitors, a large body surface area is exposed, and premature infants and small infants should be placed under a radiant heat lamp. Extremities can be covered with plastic wrap or sheet wadding. Dry inspired gases should be warmed and moisturized with a heat exchanger [134,135]. Although the usefulness of warming blankets has been questioned, they appear to work well as long as they are positioned below the patient. Forced air warming blankets that are placed underneath the patient are now available and can be very useful to maintain temperature. Blood warmers should always be used if substantial fluid replacement is required. Rewarming measures such as a forced warm air system can be used in the postoperative period.

Hyperthermia (>38.5°C) in the setting of pediatric traumatic brain injury has been associated with poor outcomes. Studies in both animal models and in patients have shown that during and immediately after brain trauma or ischemia, temperature powerfully influences neurological recovery and increases $CMRO_2$ [136]. The association between the development of hyperthermia and increased morbidity and mortality has been described in adult and pediatric patients with ischemic stroke and closed head injury [137]. Based on these data, aggressive cooling strategies with forced air systems at ambient air temperature, circulating cooling blankets, and cold gastric lavage combined with antipyretic therapy with acetaminophen and non-steroidal anti-inflammatory agents (NSAIDs) may be required to treat and prevent hyperthermia [138]. Further, some institutions have hypothermia protocols to maintain patient temperature in the range 32–34°C in the setting of severe brain injuries or refractory elevation of ICP [139,140]. The current (4th edition) of the Brain Trauma Foundation guidelines does not recommend prophylactic cooling, specifically citing two negative pediatric trials [138]. At our institution, the main thermostasis goal is avoidance of hyperthermia with acetaminophen, forced air cooling, and cooling blankets to targeted temperature of 36°C.

Venous air embolism

Venous air embolism (VAE) is one of the most serious complications of anesthesia and surgery. In neurosurgical cases, various positions place the operative site above the heart, creating increased risk of VAE. This risk increases as the height difference increases. Classically, VAE is associated with posterior fossa surgery in the sitting position, but it is not confined to this procedure. VAE has been reported in infants and children during procedures involving the skull, such as morcellation of the cranial vault, craniectomy for craniosynostosis, and spinal cord procedures [141]. It has also occurred with the patient in the lateral position [142]. The incidence of VAE has been reduced considerably by use of the prone position for

Table 25.6 Relative risk for venous air embolism (VAE) in neurosurgical procedures

Neurosurgical procedure	Relative risk
Craniotomy – sitting position	High
Posterior fossa/neck surgery	High
Craniosynostosis repair	High
Spinal fusion	Medium
Cervical laminectomy	Medium
PRBC infusion	Medium
Peripheral nerve surgery	Low
Anterior neck surgery	Low
Burr hole/ICP monitor placement	Low

Approximate expected reported incidence: high >25%, medium 5–35%, and low <5%.

posterior fossa surgery [143] and by use of mechanical ventilation. Table 25.6 presents the relative risk for air embolization based on various surgical procedures [144].

Air entrainment occurs when a number of conditions are met, including (1) venous pressure at the operative site that is below atmospheric pressure, (2) a vein that is open to the atmosphere, and (3) a vein that is prevented from collapsing. It most commonly occurs during the first hour of surgery, and the most frequent sites of air entrainment are the cranial diploic veins, the emissary veins, and the intracranial venous sinuses, which are kept open by their dural attachment. VAE can also occur from veins in muscles and from the puncture site of the multipoint head-holder used in children over 3 years of age [145]. Detection of VAE depends entirely on the sensitivity of the monitors used (Fig. 25.1). The reported incidence of air emboli varies widely [146]. Using highly sensitive precordial Doppler, the reported incidence of air embolus is as high as 58% in adult patients undergoing posterior fossa surgery in a sitting position [147]. Less than half of the cases of detected emboli produce systemic hypotension [148]. In pediatric neurosurgery the incidence of detectable air emboli is about 33% [149] but systemic complications occur in more than half of the cases. Although children are not more prone to air emboli than adults, they are more susceptible to them. For example, the incidence of air embolism during craniosynostosis repair in supine infants may be as high as 67% [150].

This may explain why, without any obvious reason, some patients experience periods of hypotension. In addition, the increased right-sided pressure may cause air to pass from the right side of the heart to the left via an atrial septal defect, causing paradoxical air embolus. Anatomically, some 27% of patients have a patent foramen ovale and are potentially at risk for embolization to the left heart. Air also may reach the systemic circulation without the presence of an intracardiac septal defect [151] and may result in cerebral or myocardial infarction.

It is essential to take measures to avoid this potentially disastrous complication. Meticulous avoidance of a pressure gradient between the open tissue and the heart and the routine use of positive pressure ventilation are mandatory. On detecting air entrainment, the anesthesiologist must: (1) advise the neurosurgeon to discontinue surgery, flood the surgical field with fluid, compress the jugular veins, and position the operative field lower than the heart to prevent further ingress of air; (2) ventilate the lungs with 100% oxygen; (3) attempt to withdraw air through the central venous catheter; (4) treat any hemodynamic consequences; and (5) if hemodynamic instability persists, turn the patient into a left-side-down position. When venous air is detected during craniotomy in children, air can be successfully aspirated from veins 38–60% of the time [149] (Fig. 25.2).

Intravenous fluids [152], appropriate antiarrhythmic and inotropic agents, or vasopressors may be necessary and should be administered as needed. Nitrous oxide must be discontinued because it increases the size of the embolus several-fold, causing further physiological compromise. Some authors have proposed that a positive end-expiratory pressure (PEEP) of 10 cmH_2O might decrease the rate of air entry by increasing venous pressure, but less than 10 cmH_2O pressure is not adequate to do so [153]. It is possible that the

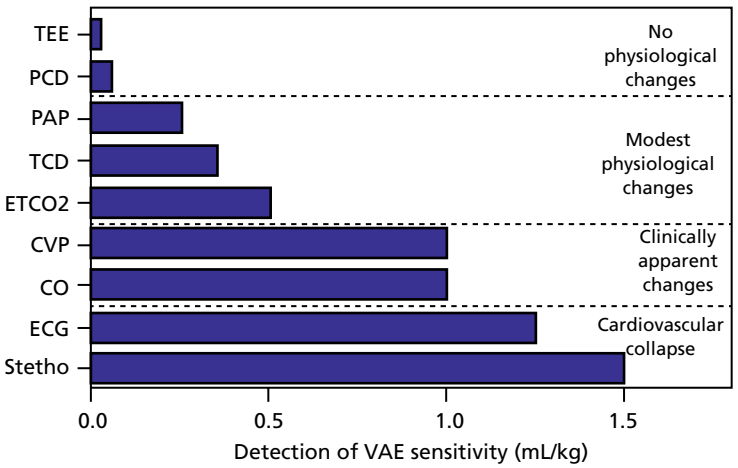

Figure 25.1 Methods of venous air embolism (VAE) detection listed from highest to lowest sensitivity based on smallest detectable volume of air. Those techniques with the highest sensitivity may detect VAE prior to clinical or physiological instability, while those with the lowest sensitivity may only detect VAE when hemodynamic changes and physiological instability are present. Clinical availability of VAE monitoring techniques is low for intraoperative transesophageal echo (TEE) and moderate for precordial Doppler (PCD), pulmonary artery pressure by catheter (PAP), and transcranial Doppler (TCD). Routine clinical monitors such as electrocardiography (ECG) and auscultation with a stethoscope (Stetho) are late detectors and unable to prevent decompensation. use of PEEP may cause paradoxical air embolism and decrease venous return to the heart, resulting in additional hemodynamic instability and necessitating additional fluid and vasopressor support [154].

KEY POINTS: GENERAL ANESTHETIC CONSIDERATIONS

- Preoperative assessment should focus on neurological examination, detecting increased ICP, reviewing neuroimaging studies, and understanding co-morbid conditions such as seizure disorder
- Premedication, if given, should be administered judiciously and patients with elevated ICP monitored carefully until anesthetic induction
- Careful positioning with attention to all pressure points and securing the endotracheal tube is essential; prone positioning is common; avoiding sitting position and head more than 10° elevated are important to avoid VAE
- Careful fluid administration, arterial monitoring, airway and ventilation management to avoid hypercapnia, and osmotic diuresis with hypertonic saline or mannitol are integral approaches to intracranial neurosurgery

Specific anesthetic considerations

Neuroradiology

Children and infants, unlike adults, frequently require general anesthesia or sedation for neuroradiological diagnostic or interventional therapeutic procedures. Several special problems are related to the administration of anesthesia in this context. Among these are the delivery of care in a remote area away from skilled help, the limitations imposed by cumbersome equipment, the need to be at a distance from the patient during the procedure, and the occasional adverse effects of contrast agents. The principal indication for anesthesia in these circumstances is to provide total immobility for extended periods for young patients who cannot cooperate. The most common procedures are CT scanning, cerebral angiography, lumbar myelography, radiation therapy, and MRI. Specific anesthetic considerations for these procedures depend on the patient's condition and the radiological demands. Chapter 41 presents further discussion of neuroradiology procedures.

Skull abnormalities: craniosynostosis

Craniosynostosis is the most common skull anomaly encountered by the pediatric anesthetist. The condition consists of premature fusion of one or more cranial sutures. The incidence is about 1 in 2000 livebirths with a male predominance. While it can be an isolated anomaly, it may be associated with a variety of genetic syndromes. Special considerations for patients with craniosynostosis include increased ICP and blood loss. Children and infants undergoing craniectomy may have increased ICP, and induction of anesthesia should proceed as discussed previously. The degree of blood loss is increased in patients with multiple suture synostoses and in those more than 6 months old with thicker bone tables. Most craniosynostosis surgery is performed between 2 and 6 months of age, a period that coincides with physiological anemia. Transfusion may therefore be required to maintain an acceptable hemoglobin level. Simple suture craniectomy in the young child with normal ICP seldom requires arterial line placement. However, adequate IV access for fluid and blood replacement is essential. Children with elevated ICP and those undergoing extensive multiple suture procedures usually require arterial line placement. Endoscopic craniosynostosis repairs are increasingly undertaken and usually reduce blood loss substantially. See Chapter 36 for a more detailed discussion of these procedures.

Hydrocephalus

Hydrocephalus is a congenital or acquired pathological condition with many variations but always characterized by an increase in the amount of CSF that is now, or has been, under increased pressure (Fig. 25.3). It can occur at any age. It is caused by one of four basic disease processes: congenital anomalies (e.g. Arnold–Chiari malformation), neoplasms, inflammatory conditions, and overproduction of CSF (e.g. choroid plexus papillomas). Hydrocephalus is the most common neurosurgical condition requiring intervention. Besides the underlying etiology, it can be further classified into obstructive/non-communicating (CSF cannot flow around the spinal cord) or non-obstructive/communicating forms (CSF can flow normally). Patients who cannot be medically managed require an external ventricular drain and/or internalized ventricular shunt, or endoscopic third ventriculostomy.

Ventricular shunts

Three types of internalized ventricular shunts are in current use: ventriculoperitoneal, ventriculoatrial, and ventriculopleural. Each has its indications and anesthetic implications. Often, as the pediatric patient grows, the shunt must be revised. It must be replaced if it malfunctions or becomes infected. Placement or revision of shunts is common in both severely neurologically impaired children and in otherwise healthy patients. These children may present to the operating room multiple times and may request a specific anesthesia induction technique. Patients who present for CSF shunting procedures may exhibit a broad spectrum of symptoms and clinical signs, ranging from an apparently healthy child with minimal disability to a seriously ill, comatose patient for whom surgery is urgent.

Figure 25.3 This 12-year-old boy was noted to have increasing headache and vomiting. This axial CT scan reveals severe supratentorial hydrocephalus. This was due to the presence of a posterior fossa mass (pilocytic astrocytoma) obstructing the fourth ventricle and cerebral aqueduct (not shown).

Endoscopic third ventriculostomy

Endoscopic third ventriculostomy (ETV) has emerged in recent years as an effective alternative treatment for hydrocephalus, especially in patients with non-communicating hydrocephalus. This procedure is performed by placing a flexible endoscope into the frontal horn of the lateral ventricle, through the foramen of Monro, into the third ventricle [155]. A ventriculostomy is then created in the floor of the third ventricle, creating a direct communication into the prepontine cistern for CSF drainage (Figs 25.4, 25.5). Choroid plexus cauterization is now usually added to the procedure, particularly in young infants. The obvious advantage to this approach is that a shunt is not used, eliminating a mechanical device that can fail or become infected. However, long-term follow-up studies of standard CSF shunts versus ETV have not consistently demonstrated a clear advantage, and a recent prospective study of ETV with a matched historical control group undergoing shunt in infant hydrocephalus demonstrated a worse intervention-free success rate with ETV in the first 6 months (36% versus 80%, $p < 0.001$) [156]. A recent randomized controlled trial in Uganda demonstrated similar treatment success rates at 12 months (65% for ETV versus 76% for shunting, $p = 0.28$), and similar neurodevelopmental outcome scores between groups [157].

Anesthetic considerations

Preanesthetic assessment must include the following:

- *Level of consciousness*. Patients presenting for primary shunting, shunt revision, or malfunction may exhibit severe elevations in ICP that require aggressive treatment.
- *Full stomach*. Evidence of vomiting or delayed gastric emptying is an indication to take precautions against aspiration of gastric contents (e.g. a rapid-sequence induction).
- *Coexisting pathology*. Does the child have evidence of other significant organ system compromise, such as the cerebral palsied child who frequently aspirates?
- *Age-related pathophysiology*. Is the patient likely to have apnea, poor pulmonary compliance, or immature renal function?

Monitoring

Routine monitoring has been discussed previously. Arterial line placement is usually reserved for the patient with uncontrolled ICP and hemodynamic instability.

Preinduction

Typically, a CT scan to assess the degree of hydrocephalus and a radiographic shunt series to look at the course of the shunt will be performed by the neurosurgeon to evaluate shunt integrity and function. Accessing the shunt (also called a "shunt tap") can help to determine the site of malfunction. In some cases, the increased ICP caused by shunt malfunction can be reduced acutely by tapping the proximal reservoir. Infiltration of the skin with local anesthetic allows the tap to proceed with minimal trauma to the patient. The needle can be left in place to monitor ICP during induction. In the patient at risk for emesis during induction of anesthesia, placement of a nasogastric tube may precipitate coughing and bucking and increase ICP. Severely neurologically compromised children often have gastrostomy tubes, and opening these tubes before induction of

anesthesia is recommended. However, this does not guarantee that the patient will not vomit and aspirate gastric contents.

Induction and intubation

Many patients with hydrocephalus have undergone multiple surgical procedures. If there is no clinical evidence of elevated ICP, anesthesia can be induced by mask or with IV drugs; we usually allow children their preference. On the other hand, children with increased ICP and delayed gastric emptying usually have anesthesia induced with thiopental, atropine, lidocaine, a narcotic, and a non-depolarizing muscle relaxant after preoxygenation. Cricoid pressure is applied and the patient is hyperventilated at low peak inspiratory pressures. Since laryngoscopy is a potent stimulus for increasing ICP, an oral tracheal tube is placed as smoothly as possible.

Maintenance

Patients are placed in a supine position with the head turned, or in a slightly lateral position. Patients with increased ICP should be placed in a 30° head-up position with minimal neck rotation or flexion to improve cerebral venous drainage. Patients whose shunt tubing is placed posteriorly and those

who are placed in a lateral position should have an axillary roll placed and all extremities padded.

After the airway is secured, patients with increased ICP are hyperventilated to a $PaCO_2$ of between 25 and 30 mmHg. Patients with normal ICP are maintained at normocapnia. Spontaneous ventilation should be avoided in patients with ventriculopleural shunts to reduce the risk of pneumothorax, and in those with ventriculoatrial shunts to avoid air embolism. Also, spontaneous ventilation should be avoided when the cranium is opened. Patients with poor pulmonary compliance and those at risk for apnea should be mechanically ventilated during anesthesia.

Anesthesia is usually maintained with nitrous oxide in oxygen, low concentrations of isoflurane, and minimal narcotic supplementation. Although nitrous oxide increases CBF in anesthetized pediatric patients, increases in CBF and $CMRO_2$ are effectively blunted by hyperventilation and pretreatment with propofol. Halogenated anesthetics increase CBF, CBV, and ICP in a dose-dependent manner, with isoflurane having a less adverse effect than halothane. These agents are therefore either used in low concentrations in patients with elevated ICP or avoided entirely until the CSF is drained. Muscle relaxation is usually maintained with vecuronium or atracurium if the procedure is expected to last a short time.

Ventricular shunt procedures usually are not associated with significant blood loss or third-space losses, and fluid management centers around replacement of intravascular volume associated with emesis or drug-induced diuresis.

The body temperature may decrease during shunt procedures, despite their relatively short duration. Exposure of a large body surface area and cold preparation solution, particularly for ventriculoperitoneal shunting, may cause infants to cool rapidly.

Emergence

Adequate time for elimination of the anesthetic agents and adequate reversal of NMB should be ensured before extubation of the trachea. Although it does not provide absolute insurance against regurgitation, the stomach should be suctioned before extubation of the trachea in patients suspected of having increased gastric contents. The patient should be fully awake and have an appropriate gag reflex to protect the airway against emesis. Many patients coming for shunt procedures are severely neurologically impaired and have poor airway control.

Postoperative management

As with any postsurgical patient, supplemental oxygen should be given and the respiratory pattern and adequacy assessed. Neurosurgical patients in general, and preterm infants who are less than 50 weeks' postconceptual age in particular, are likely to have abnormal respiratory patterns or apnea after surgery. Hypothermic patients should be rewarmed before extubation of the trachea.

Analgesics should be used judiciously in neurologically impaired patients. Infiltration of the skin with local anesthetic at the time of surgery substantially reduces the requirement for postoperative analgesia. Patients without preoperative neurological impairment can be given routine postoperative opioids.

KEY POINTS: SPECIFIC ANESTHETIC CONSIDERATIONS FOR NEURORADIOLOGY, SKULL ABNORMALITIES, AND SHUNT PROCEDURES

- Neuroradiology studies are the cornerstone of pediatric neurosurgical procedures; challenges include delivering anesthetic care in remote locations for patients with unrepaired intracranial pathology
- Craniosynostosis surgery is usually a combined neurosurgery–plastic surgery procedure; large blood loss in small infants is a challenge although recent minimally invasive procedures often minimize this issue

- Hydrocephalus is one of the most common neurosurgical conditions; determination of the level of ICP and emergent nature of some hydrocephalus procedures is crucial to maximize outcomes
- CSF shunting procedures and endoscopic third ventriculostomy with choroid plexus cauterization are both now utilized in hydrocephalus

Intracranial tumors

Neoplasms of the CNS account for the major proportion of all solid tumors in children younger than 15 years of age and constitute the second most common cancer in childhood after leukemia. Primary brain tumors are responsible for 20% of all cancers in children and for 20% of childhood cancer deaths. For 2010–2014, the incidence of brain tumors in the USA was 5.54 per 100,000 children less than 15 years of age. An estimated 3560 new cases of childhood **primary malignant and non-malignant** brain and other CNS tumors are expected to be diagnosed in the USA in 2018 [158]. Unfortunately, treatment of primary malignant brain tumors has not resulted in the same dramatic increase in survival seen with childhood leukemia. However, the survival of children with tumors of the CNS has improved significantly over the last several decades. Despite this improvement, much remains to be accomplished, especially in children less than 2–3 years of age at the time of diagnosis. From the anesthesiologist's point of view, intracranial brain tumors are divided according to the site of the tumor. The following section describes an anesthetic approach for supratentorial and posterior fossa craniotomies and for surgical excision of craniopharyngiomas.

Supratentorial craniotomy

Supratentorial lesions account for about half of all pediatric brain neoplasms. For reasons related to embryogenesis, pediatric brain tumors often arise from midline structures, including the hypothalamus, epithalamus, thalamus, and the basal ganglia. These tumors tend to impinge on the ventricular system and cause obstructive hydrocephalus. Hemispheric masses are more common during the first year of life. Their frequency in infants is approximately twice as high as in children (i.e. 37% compared with 16–24%). The relative incidence of hemispheric tumors also increases after 8–10 years of age.

Anesthetic considerations

- *Increased intracranial pressure*. The ICP should be estimated. The CT and MRI images should be reviewed.
- *Full stomach*. Delayed gastric emptying occurs in the patient with raised ICP.
- *Electrolytes and fluid*. Hydration state and electrolyte balance may be altered in the child with intracranial pathology and SIADH.
- *Age-related pathophysiology*. Anesthetic considerations are identical to those discussed previously.
- *Positioning*. The head should be elevated not more than 10° from level. It should be confirmed that venous return is not obstructed.

Monitoring

To the routine monitoring previously described, we add an arterial line for hemodynamic monitoring and blood sampling. In patients in whom significant blood loss, hemodynamic instability, or air embolism, is expected we insert a central venous catheter. A urinary catheter is inserted because of the duration of the surgical procedure and the use of osmotic diuretics.

Preinduction

Detection of preoperative elevation of ICP in patients undergoing craniotomy is essential. Most patients with large mass lesions, significant tumor edema, or obstruction to CSF outflow require an anesthetic approach that aims to reduce ICP. Some children undergo external ventriculostomy drain (EVD) placement before their definitive surgical procedure. Preoperative neurological deficits should be detected and documented. Many patients with intracranial pathology present with SIADH. Such children have evidence of hyponatremia, low serum osmolality, high urine osmolality, and oliguria. Peripheral edema is rarely present. Preoperative treatment of SIADH usually includes fluid restriction.

Induction and intubation

Unlike children with normal ICP, rapid induction of anesthesia, followed by rapid securing of the airway and hyperventilation, is of paramount importance in patients with significantly elevated ICP. Induction of anesthesia generally proceeds as discussed for a modified rapid-sequence intubation. Cricoid pressure is applied and the patient hyperventilated with low peak inspiratory pressures to avoid inflation of the stomach. Laryngoscopy should proceed as smoothly as possible. Some anesthesiologists prefer nasotracheal intubation for patients in whom postoperative ventilation is expected or to better stabilize the ETT in small infants.

Maintenance

Patients with increased ICP are generally ventilated to a $PaCO_2$ of 25–30 mmHg. Occasionally, lower levels of $PaCO_2$ are required if the brain is very "tight" and there is uncontrollable intracranial hypertension. Caution must be exercised because extreme hyperventilation may decrease CPP and either induce cerebral ischemia or shift blood flow from areas of the brain with low flow to areas with impaired autoregulation and high flow (also called the "Robin Hood" phenomenon). Excessive PEEP (>8 cmH_2O) is generally avoided to facilitate cerebral venous drainage and avoid hemodynamic issues such as decreased arterial blood pressure. In patients with impaired oxygenation, low levels of PEEP (3–5 cmH_2O) may correct hypoxia without obstructing venous return.

Pediatric patients are usually placed supine for supratentorial procedures, with the head elevated slightly to facilitate venous drainage. Extremities should be well padded and the eyes protected from injury. Care must be taken to avoid undue flexion, extension, or rotation of the neck.

Fluid management can be a problem. Patients with increased ICP are usually dehydrated after receiving mannitol. This increases the potential for hypovolemia and hypotension, especially when there is significant blood loss. CVP monitoring allows early detection of hypovolemia and volume expansion with isotonic crystalloid and colloid solutions

(such as 5% albumin). Simple craniotomy in patients without significantly increased ICP and in procedures with little blood loss frequently requires crystalloid replacement only.

Emergence

The decision to extubate the trachea at the end of the procedure is made on the basis of the success of the surgical intervention, smoothness of the intraoperative course, normalization of ICP, age of the patient, degree of residual neurological deficit, and presence of factors that affect respiration and airway protection. Patients with inadequate respiratory efforts retain CO_2 and their ICP may therefore be increased. Those without a gag reflex cannot protect their airway. Children who remain sedated and who hyperventilate during the postoperative period should be suspected of having increased ICP. Neonates with poor pulmonary compliance or an immature respiratory drive may require postoperative mechanical ventilation. Barring any of these complications, a child's trachea can be extubated after awakening and after reversal of the NMB and elimination of anesthetic agents.

Postoperative management

As with any postsurgical patient, supplemental oxygen should be administered and the adequacy of respiration assessed. Patients who require postoperative ventilation also require sedation and possibly muscle relaxation to prevent agitation and increased ICP. Infiltration of local anesthetics into the wound intraoperatively or performance of a cervical superficial plexus block at the end of the procedure can reduce the requirement for postoperative analgesics. A balance between patient comfort and the ability to follow the patient's neurological status must be sought. An obtunded patient must be investigated for increased ICP or other surgically correctible pathology, such as intracranial bleeding. Body temperature should be maintained at a normal level.

The most common cause of increased ICP after surgery is uncontrolled systemic hypertension. When postoperative pain control has been achieved, blood pressure can be controlled with vasodilators. Beta-blocking drugs have been used successfully, particularly labetalol, which normally does not cross the BBB.

Seizures frequently occur during the immediate postoperative period. Therefore, many surgeons place their patients on anticonvulsants before surgery and continue these drugs postoperatively. Historically, phenobarbital was the most commonly used drug, with other medications (e.g. fosphenytoin and valproic acid) added if the seizures were refractory to treatment [159]. Nowadays, levetiracetam is more often used, with fewer side-effects than previous prophylactic regimens [160].

Craniopharyngioma

Craniopharyngioma is a benign encapsulated tumor of the hypophysis cerebri (Fig. 25.6). Children with this tumor often present with symptoms of endocrine failure, visual disturbances, or hydrocephalus, as the tumor grows beyond the sella turcica and compresses the optic chiasm or other midline structures. The trans-sphenoidal approach to this tumor is rarely used in pediatric patients, and most resections are therefore performed through a frontal craniotomy. Anesthesia for craniopharyngioma and hypothalamic tumor surgery is similar to that for supratentorial craniotomy.

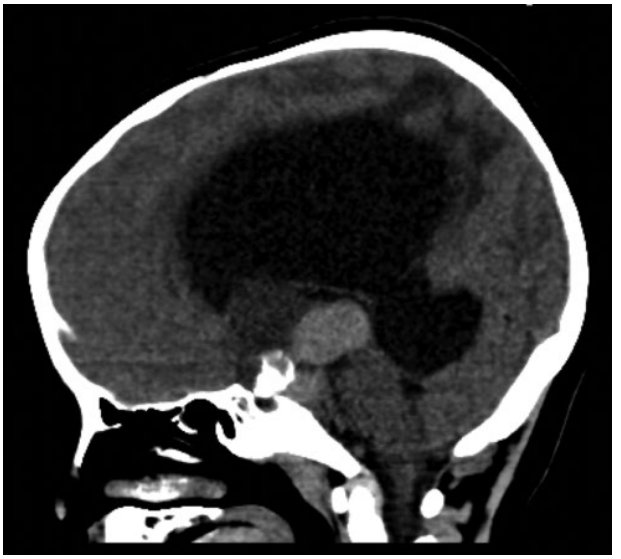

Figure 25.6 Sagittal gadolinium-enhanced T1-weighted MR image showing a 5-year-old girl with a large craniopharyngioma filing the suprasellar cistern and elevating and distorting the third ventricle. A heterogeneous mass is centered in the suprasellar cistern, most compatible with craniopharyngioma. There is obstruction at the third ventricle and cerebral aqueduct with resulting severe hydrocephalus and generalized mass effect/increased intracranial pressure.

Preoperative evaluation of the child with craniopharyngioma focuses on determining the presence of hydrocephalus and the types of endocrine dysfunction that could affect anesthetic management. Children may present with symptoms of hypothyroidism, growth hormone deficiency, adrenocorticotropic hormone (ACTH) deficiency, or diabetes insipidus (DI). Hormone replacement, including thyroid hormone and corticosteroids, may be necessary pre- and postoperatively.

DI is a complication of pituitary surgery and of head injury. It is caused by disruption of antidiuretic hormone (ADH)-secreting cells. It is rarely present preoperatively, but usually begins 4–6 h after surgery, although it occasionally becomes evident intraoperatively. Characteristically, patients produce a large quantity of dilute urine. Their serum osmolality increases, and their urine osmolality is low (less than 200 mOsm/L). The urine specific gravity is below 1.002. The patient becomes hypernatremic and hypovolemic. Treatment of DI requires careful determination of the patient's hourly urine output and administration of maintenance fluids plus 75% of the previous hour's urine output. The type of fluid to be administered is determined by the patient's serum electrolyte concentrations. Urine is low in sodium content and should be replaced with hypotonic solutions, such as 5% dextrose in 0.5 normal saline. Hyperglycemia and osmotic diuresis may occur if a large volume of D5W is used. Vasopressin or one of its analogs, such as DDAVP (1-deamino-8-D-arginine vasopressin), should be administered at an early stage of DI. When administered intraoperatively, aqueous DDAVP occasionally produces hypertension. Postoperatively, DDAVP is divided into two doses (5–30 μg/day) and given transnasally. If DDAVP is given IV, the dose is one-tenth the intranasal dose, divided into two doses. Alternatively, vasopressin can

be administered by constant infusion at 0.5 mU/kg/h. The rate must be adjusted to achieve the desired degree of antidiuresis, typically with monitoring of serum sodium and reduction of urine output to under 2 mL/kg/h.

Postoperative management should include administration of steroids, thyroid, mineralocorticoid, and sex hormone supplements. Insulin-dependent diabetic patients may have reduced insulin requirements after surgery. Therefore, the amount of glucose in their blood must be closely monitored and their insulin regimens altered as necessary.

Other problems that arise postoperatively include seizures and hyperthermia. Surgical exposure often requires significant retraction of the frontal lobes. Consequently, anticonvulsant prophylaxis may be necessary intraoperatively and should be continued postoperatively. Injury to the hypothalamic thermoregulatory mechanisms may result in hyperthermia. Efforts should be made to maintain normothermia and reduce the risk of hypermetabolic cell injury.

Posterior fossa tumor surgery

Posterior fossa tumors (Fig. 25.7) are more frequent in children than in adults and account for about half of all pediatric brain tumors. The four most common tumors are medulloblastoma (30%), cerebellar astrocytoma (30%), brainstem glioma (30%), and ependymoma (7%). The remaining 3% include acoustic neuroma, meningioma, ganglioglioma, and other much rarer tumors. Cerebellar astrocytomas have no gender predilection, but medulloblastomas occur more frequently in males. Hydrocephalus occurs in 90% of children with medulloblastoma and in virtually all children with cerebellar astrocytoma [161].

The most frequent posterior fossa neurosurgical procedure, other than for tumors, is decompression for Arnold–Chiari malformation. The Arnold–Chiari malformation is a complex developmental anomaly that characteristically presents with downward displacement of the inferior cerebellar vermis into the upper cervical spinal canal and elongation of the medulla oblongata and the fourth ventricle. Preoperatively, the anesthesiologist should pay particular attention to the neurological symptoms, such as cerebellar dysfunction, upper airway obstruction (inspiratory stridor), cardiovascular instability, and increased intracranial pressure.

Anesthetic considerations

- *Age-related pathophysiology*.
- *Intracranial pressure*. Symptomatic hydrocephalus may require placement of an EVD after induction of anesthesia. Maintenance of cerebral perfusion is essential. Mannitol, furosemide, and corticosteroids may be required.
- *Full stomach*. Pathology in the posterior fossa decreases gastric emptying in children and makes them prone to regurgitation and aspiration of gastric contents with induction of anesthesia.
- *Associated pre-existing problems:*
  - cardiovascular: some patients may be hypertensive in response to brainstem compression
  - pulmonary: recurrent aspiration pneumonia is a common occurrence
  - nervous system: central sleep apnea occurs and may persist postoperatively.
- *Air embolism*. See previous sections.
- *Airway management*. Arnold–Chiari malformation or brainstem compression may cause upper airway dysfunction and inspiratory stridor.
- *Fluid and electrolytes*. Preoperative attempts to reduce ICP may cause electrolyte imbalance and contraction of the intravascular volume.
- *Premedication*.

Preoperative evaluation and induction of anesthesia

Preoperative assessment of these patients is similar to that described previously.

During the induction of anesthesia, attempts must be made to preserve CPP, to avoid ICP elevations, and to provide an appropriate depth of anesthesia. The choice of anesthetic is not as crucial as the manner in which it is administered. A combination of propofol, atropine, and a non-depolarizing muscle relaxant associated with an opioid, such as fentanyl, is common. Succinylcholine can be used safely unless the patient

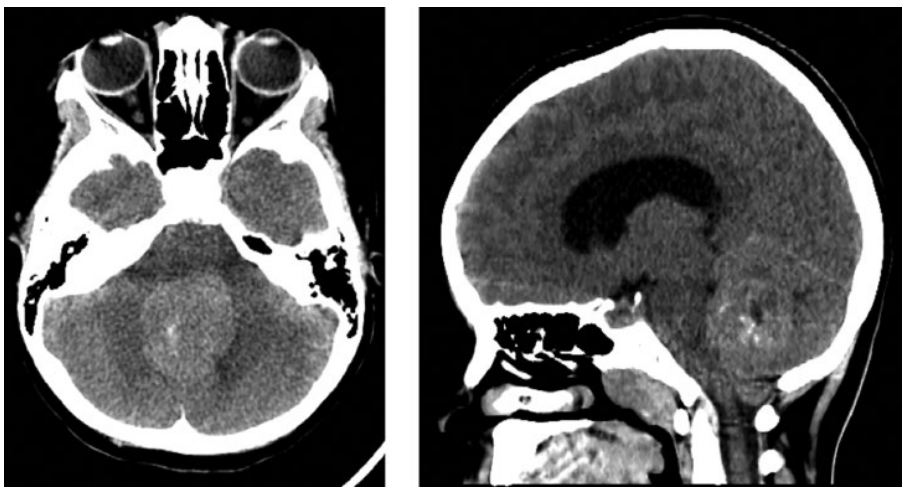

Figure 25.7 Axial and sagittal unenhanced T1-weighted MR image of a 9-year-old boy who presented with ataxia, headache, and morning vomiting showing probable medulloblastoma within the fourth ventricle resulting in brainstem compression, mild obstructive hydrocephalus, tonsillar herniation, and increased intracranial pressure.

shows signs of severe increased ICP with hemodynamic instability. To minimize the possibility of kinking and obstructing the ETT during positioning, a wire-reinforced armored orotracheal tube can be used. Many neuroanesthesiologists, however, prefer to use a nasotracheal tube for better stability and fixation. Use of an oral tracheal tube with a soft bite block reduces epistaxis and avoids possible nasal mucosal injury and infection.

Maintenance

As with induction of anesthesia, no single anesthetic technique has been shown to be superior, and the maintenance regimen must be tailored to the needs of the patient and the requirements of the surgical procedure. After skin preparation, local anesthetic (bupivacaine 0.125% with epinephrine 1:200,000) should be infiltrated along the incision line and anesthesia depth should be increased with fentanyl and/or isoflurane. The aim is to provide a "slack brain," which will reduce the amount of pressure caused by retractors and allow adequate cerebral perfusion. Muscle paralysis is provided by a non-depolarizing muscle relaxant, and the ICP is reduced by mannitol and furosemide. The intermittent positive pressure ventilation is adjusted to maintain the $PaCO_2$ between 25 and 28 mmHg.

Patient positioning

Three patient positions are commonly used for posterior fossa tumor operations. Older literature reported that the prone position is used in 55% of cases, the sitting position in 30%, and the lateral position in 15% [162,163]. In recent years, the sitting position has rarely been used in pediatrics because of the increased risk of VAE. It is the anesthesiologist's responsibility to ensure that during positioning the ETT is not advanced into or withdrawn from the trachea, that ventilation is adequate, that pressure points are well padded, and that the neck is not flexed enough to occlude jugular venous drainage. The method of head fixation depends on the age of the patient, the skull thickness, and the surgeon's needs. Horseshoe head rests are useful, but the patient's face must be padded carefully and the eyes must be free of compression. After 3 years of age, the multipin head-holder is preferable. Infiltration of the pin sites with local anesthetic reduces nociceptive responses.

Monitoring

Monitoring for posterior fossa surgery is basically the same as for supratentorial craniotomy, with one important exception. The precordial Doppler should be used to detect air embolism). Occasionally, sensory-evoked potentials should be obtained during resection of intramedullary or brainstem tumors.

Emergence and recovery

Prompt awakening is mandatory, but it is important to keep the patient hemodynamically stable and unstimulated during tracheal extubation. The pathological process often dictates the appropriate postoperative airway management (e.g. postoperative tracheal intubation is essential after resection of intramedullary tumor). When early tracheal extubation is appropriate, intraoperative administration of opioids plus lidocaine 0.5–1 mg/kg to infants and children will allow emergence from anesthesia without coughing and straining, which might otherwise lead to a hypertensive episode and intracerebral bleeding. Postoperative pain can usually be managed with morphine 50 μg/kg, with or without acetaminophen. Avoidance of medications that affect the sensorium or the pupils is important.

Intraoperative magnetic resonance imaging

Postoperative imaging for intracranial tumors by MRI or CT, either immediately after surgery or within 12–24 h of the end of surgery, has become common practice to assess the extent of resection and residual tumor, and complications such as intracranial bleeding. With the advent of MRI scanners within the operating room suite, a number of institutions are now performing an intraoperative MRI scan before the end of surgery to determine whether additional resection is indicated, and to rule out complications before the craniotomy is closed [164,165]. In addition, traditional stereotactic planning methods rely on imaging obtained preoperatively, or at the beginning of the procedure with images obtained on a remote scanner. This approach does not account for the brain shift that occurs intraoperatively during open craniotomy. Intraoperative MRI allows the stereotactic planning process to occur after the craniotomy begins, saving time and also potentially increasing the accuracy of the surgical plan.

There are two basic configurations for intraoperative MRI (iMRI) scanning: (1) mobile iMRI scanner, fixed OR table and patient position; and (2) fixed iMRI scanner, and mobile OR table and patient. The first configuration is displayed in Figures 25.8 and 25.9, and the second in Figure 25.10. MRI safety is an integral consideration for the planning of iMRI suites, and obviously any equipment that is near or in the iMRI field must be MRI compatible. Extensive planning for MRI compatible anesthesia machines, monitors, laryngoscopes, infusion pumps, OR tables, instruments, and other equipment must occur. In addition, there are certain patients with implanted devices, i.e. pacemaker–defibrillators, in whom iMRI is contraindicated unless the device itself is certified to be MRI safe. Thorough MRI safety training for all personnel, including support personnel such as anesthesia technicians and housekeeping staff, must occur. Detailed preoperative planning, and safety checklists before the procedure, and before and after intraoperative MRI scanning, are important considerations in the implementation of iMRI programs. Additional discussion of MRI safety is presented in Chapter 41.

Myelodysplasia

Because myelomeningocele is usually diagnosed prenatally with ultrasound, selected patients are eligible for fetal surgery for this disorder. Results have been encouraging in major series; i.e. avoidance of CSF shunting and improved functional outcomes [166]. Chapter 21 presents a detailed discussion of this approach.

Anesthetic considerations

- *Coexisting disease*. Additional pathology may accompany myelodysplasia (Arnold–Chiari, hydrocephalus, congenital heart disease, prematurity).

Figure 25.9 Patient being placed into movable 1.5-T iMRI. Note the degree of draping to pad and protect the patient as well as maintain sterility. *Source*: Reproduced from McClain and Landrigan-Ossar [165] with permission of Elsevier.

- *Age-related pathophysiology*.
- *Airway management*. Encephaloceles may be associated with difficulty in control of the airway.
- *Positioning*. Protection of the neuroplaque.
- *Volume status*. High third-space losses from the skin defect.
- *Potential for hypothermia*. Exposure of large body surface area and loss of third-space fluid.

Monitoring

Routine monitoring is necessary. Blood loss can be insidious, especially if the sac is large and significant undermining of skin, relaxing incisions, or skin grafting is required for closure of the defect. Blood transfusion may be necessary. Patients with encephaloceles who must undergo craniotomy for repair should have an arterial line placed for blood pressure and

hemoglobin measurement. A central venous line may be indicated for repair of a nasal encephalocele when the repair is done in a semi-sitting position.

Preinduction

Infants presenting for repair of meningomyeloceles rarely exhibit increased ICP. The majority of myelodysplastic patients have an associated Arnold–Chiari malformation, and most have hydrocephalus, which usually requires ventricular shunt placement. Preoperative assessment of these children reveals a variety of neurological deficits, depending on the level of the lesion. Seventy-five percent of all lesions occur in the lumbosacral region. Lesions above the level of T4 usually result in paraplegia, whereas lesions below S1 allow ambulation. The legs are severely affected by lesions between L4 and S1. Before induction of anesthesia, the patient's volume status should be assessed. These patients have the potential for large third-space losses from the exposed myelomeningocele. These patients will be receiving preoperative antibiotics, and subsequent doses must be maintained on schedule to reduce the risk of infection, which can be a devastating complication.

Induction and intubation

Anesthesia for patients with lumbosacral or thoracic myelomeningoceles can be induced either in the left lateral position or supine with the sac protected by a cushioned ring. Anesthesia can be induced in a majority of patients with propofol, atropine, and a muscle relaxant. Either a non-depolarizing muscle relaxant or succinylcholine can be used safely [167]. Patients with nasal encephalocele commonly have airway obstruction, and it may be difficult to obtain a good mask fit.

Maintenance

After tracheal intubation the patient is turned to the prone position. Injury to the exposed neural tissue must be prevented. Chest and hip rolls are placed to ensure that the abdomen is free, to facilitate ventilation, and to reduce intra-abdominal pressure and decrease bleeding from the epidural plexus. Since most of these children have an Arnold–Chiari malformation, excessive rotation of the neck should be avoided. The extremities should lie in a relaxed position and be well padded. The lungs are mechanically ventilated. Barotrauma in the immature lung must be prevented. Premature infants (especially those of less than 32 weeks' gestation) are at increased risk for retinopathy of prematurity [168] and lung injury from prolonged exposure to high oxygen concentrations. Anesthesia can be maintained with a variety of agents, but higher-dose opioids and ketamine may cause postoperative apnea. Muscle relaxants are contraindicated during maintenance of anesthesia because nerve stimulation is often required to identify neural structures. The large area of exposed tissue and the liberal use of cold surgical

Figure 25.10 (*Continued*)

preparation solutions increase the risk of hypothermia in these patients. Care must be taken to prevent drying or thermal injury to the exposed neural tissue by radiant heat lamps. Myelomeningocele repair is often accomplished with the aid of the surgical microscope, and some surgeons will request that NMB not be used during the repair so that motor response in the lower extremities can be detected.

Emergence

Neonates at risk for apnea after anesthesia, patients with severe central neurological deficits, and those undergoing craniotomy for encephalocele repair should be extubated fully awake. Patients with nasal encephalocele repairs may have residual airway obstruction or blood in the oropharynx, and may require postoperative tracheal intubation.

Basic anesthetic considerations for the postoperative period have been discussed previously.

Spinal cord surgery

Common diseases of the spinal cord that require surgery include herniated disks, spondylosis, syringomyelia, primary or metastatic tumors, hematomas or abscesses, and trauma (Fig. 25.11). In all cases, compression of the spinal cord may produce ischemia, interstitial edema, and venous congestion, and may interfere with nerve transmission. Maintaining spinal cord perfusion pressure and reducing

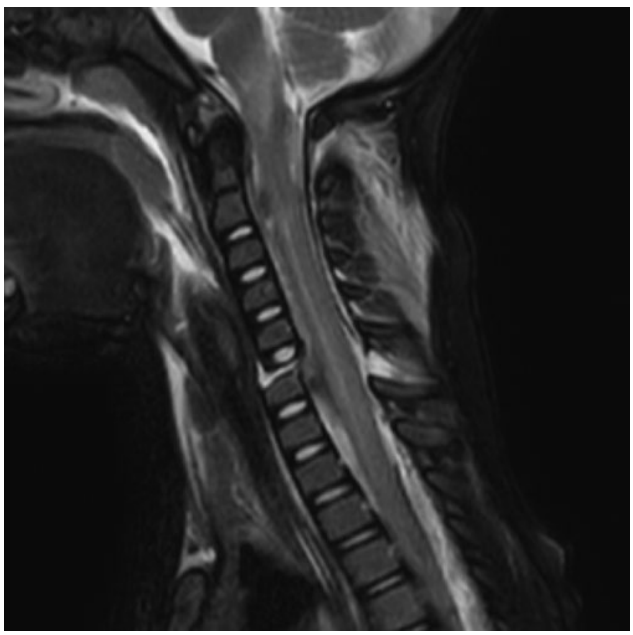

Figure 25.11 MRI of cervical spine demonstrates a large extradural hematoma. Sagittal T2 fat-saturated image of the cervical spine again demonstrating oblique, comminuted C6 vertebral body synchondroses fractures with mild distraction and retrolisthesis of the superior fracture fragment. Disruption of the anterior and posterior longitudinal ligaments and interspinous ligament. Epidural hemorrhage is present with subsequent mass effect on the cord. Diffusely increased signal of the cord consistent with long segment cord injury from the medulla oblongata down to the level of C7.

spinal cord compression are crucial. Despite apparently optimal surgical and anesthetic management, devastating neurological complications still occur with spinal surgery. Intraoperative monitoring of spinal cord function includes the wake-up test, somatosensory-evoked potentials (SSEP), and motor-evoked potentials (MEP). The wake-up test remains the traditional method for assessing spinal cord well-being during corrective procedures on the spinal column. Its main advantage is that it assesses anterior spinal cord (i.e. motor) function, but it does so only at one time. Evoked potential monitors (e.g. SSEP monitoring) generate an electrical potential by stimulation of peripheral nerves (e.g. the median nerve at the wrist or the posterior tibial nerve at the ankle). If nerve transmission is intact, a signal is recorded from the scalp or at various sites along the neural pathway. The electrical signals arise from axonal action potentials and graded postsynaptic potentials as the impulse is propagated from the periphery to the brain. The technique measures only the response of the sensory nervous system. This limitation can be overcome by use of MEPs, in which the motor cortex is stimulated by a transcranial electric current or a pulsed magnetic field generated by a coil placed over the scalp. See Chapter 29 for a more detailed discussion of spinal cord monitoring and scoliosis surgery.

Head injury

Head trauma is a major cause of morbidity and mortality in the pediatric population. Skull fractures (Fig. 25.12) are found in more than 25% of all children who present at hospitals with head injuries and in more than 50% of fatal cases of childhood head trauma. The incidence of post-traumatic intracranial hematomas varies considerably, but some children with head injuries do require surgical treatment. Failure to recognize the presence of a hematoma may transform an otherwise mild head injury into a fatal or permanently disabling one.

Head injury causes several different pathophysiological events, including intracranial hematomas (epidural, subdural, intracerebral, and brain contusion), brain edema, and systemic effects. Adults suffer more hematomas than children, and children have diffuse cerebral edema more frequently [169].

Epidural hematoma

This lesion is frequently caused by laceration of a middle meningeal artery during a deceleration injury. Children do not necessarily have an overlying skull fracture (Fig. 25.13). Epidural hematomas comprise 25% of all intracranial hematomas in pediatric patients and are a true neurosurgical emergency. In adults there is a lucid interval between the initial loss of consciousness and later neurological deterioration. Children often do not have the initial alteration in the state of consciousness observed in adults. The child who is old enough to talk complains of an increasing headache and then becomes confused or lethargic. Rapid development of hemiparesis, posturing, and pupillary dilation occurs frequently and may confuse the diagnosis. Rapid expansion of the hematoma causes herniation of the temporal lobe downward through the tentoria incisura. Anisocoria is an early sign. Herniation eventually leads to rostrocaudal deterioration and is associated with bradycardia, slowed and irregular breathing, and widened pulse pressure (Cushing triad). The relationship between the degree of brain shift and the level of consciousness has been confirmed; the role of uncal herniation in the syndrome has been questioned.

Subdural hematoma

Subdural hematomas are associated with parenchymal contusion, blood vessel laceration, and cortical damage (Fig. 25.14). The mass effect of the contused and edematous brain may prompt surgical removal of the hematoma if the brain region involved is not functionally important. Studies using positron emission tomography have demonstrated that cerebral metabolism and blood flow are reduced by 50% with brain contusion [170]. Severe edema and elevated ICP often lead to persistent neurological deficits.

Intracerebral hematoma

Intracerebral hematomas are rare but carry a poor prognosis. Surgery is usually avoided for fear of damaging viable brain tissue (Fig. 25.15).

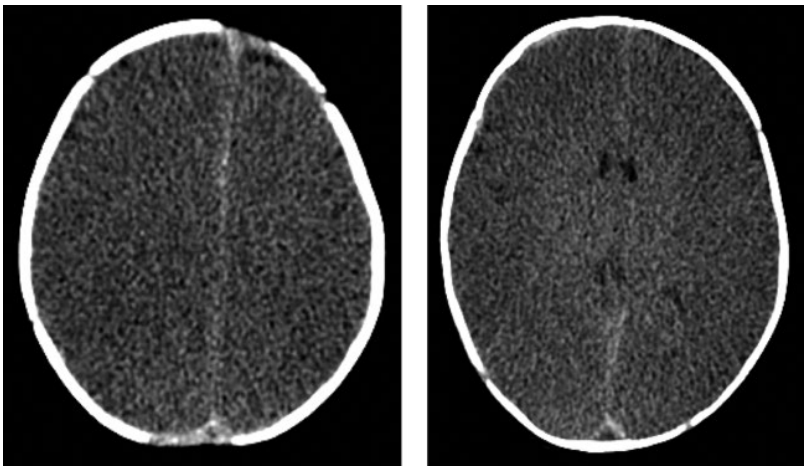

Figure 25.12 Axial non-contrast CT showing loss of gray/white differentiation in a 2-year-old boy with traumatic brain injury after non-accidental trauma. Note bilateral frontal skull fractures. The cerebral parenchyma is diffusely hypodense, with loss of the normal gray-white differentiation and global sulcal effacement. Also note small extra-axial hyperdensity within the interhemispheric fissure, compatible with hemorrhage.

Figure 25.13 This non-enhanced axial CT reveals a typical lens-shaped epidural hematoma. Although the patient presented with a Glasgow coma score (GCS) of 14, he quickly became very lethargic.

Figure 25.15 Non-enhanced axial CT in a 20-year-old with history of congenital heart disease. Although the patient presented with a GCS of 14, he quickly became very lethargic. Imaging found a large left basal ganglia hemorrhage resulting in 10 mm left to right midline shift/subfalcine herniation.

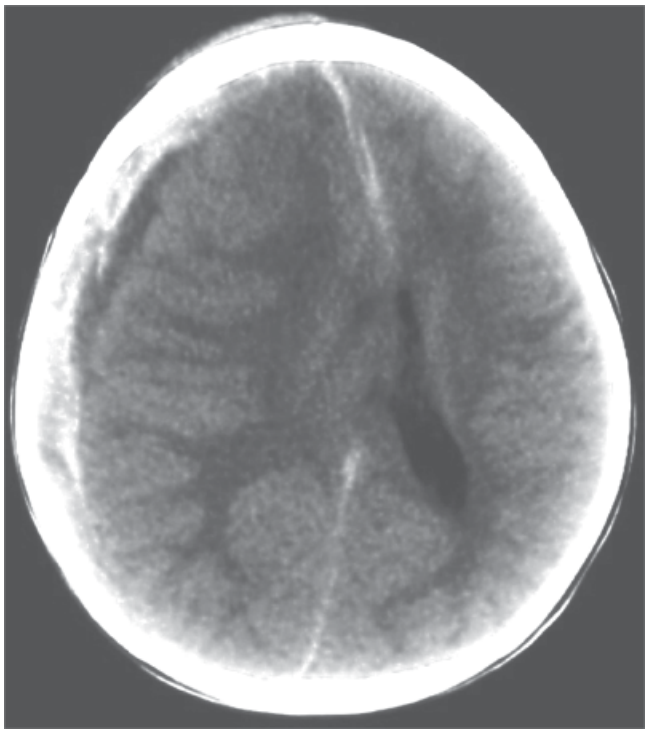

Figure 25.14 Non-contrast axial CT in a 2-year-old comatose boy shows a large right acute subdural hematoma. It is important to notice the tremendous shift of the midline to the left.

Anesthetic considerations

- *Resuscitation and stabilization*. Airway, breathing, and circulation are essential components of the initial clinical assessment. Traumatized patients often have a variety of physiological disturbances, including acid–base and electrolyte imbalances and abnormalities of glucose homeostasis and body temperature control.
- *Neurological status*. The Glasgow Coma Scale provides a means of detecting changes in the patient's condition. Symptoms of raised ICP must be evaluated.
- *Associated injuries*. Pediatric trauma often occurs from high-velocity energy transfer, which leads to injuries to the neck, chest, and abdominal organs.
- *Full stomach*. Vomiting leads to pulmonary aspiration and respiratory complications.
- *Age-related pathophysiology*.

Monitoring

Arterial catheter and central venous line placement are indicated. A urinary catheter should be inserted unless contraindicated by an associated bladder neck injury. Central body temperature should be monitored at all times.

Preinduction

CT is the procedure of choice for evaluation of head injury during the first 72 h after the accident. Management of an elevated ICP is essential to provide a safe anesthetic. Adequate hemodynamic resuscitation and stabilization must be achieved to maintain a normal CPP and brain tissue oxygenation.

Induction and intubation

Providing a patent airway is an essential part of the management of patients with head injury. Although the airway of an unconscious patient may not be compromised by the injury, tracheal intubation will protect the lungs against aspiration of stomach contents or secretions and allow ventilatory support of patients with increased ICP. The association of head injury and neck injury occurs so often in infants and children that tracheal intubation must be accomplished with minimal manipulation of the neck. The neck should be stabilized by an assistant who applies axial traction. Since a cervical spine fracture is always considered present, until proven otherwise, in patients with head injury, use of the Sellick maneuver is contraindicated. Patients should be hemodynamically stable before anesthesia is induced. After airway injury has been ruled out, anesthesia should be induced rapidly with atropine, propofol, lidocaine, and either succinylcholine or a non-depolarizing muscle relaxant such as vecuronium. Ketamine is contraindicated. If the patient is suspected to have a difficult airway, a two-person technique may be required for tracheal intubation. Depending on the age of the patient, the use of a volatile anesthetic and assisted ventilation or the use of neuroleptanesthesia with topicalization of the larynx is recommended.

Maintenance

Anesthetic considerations for maintenance of anesthesia are similar to those previously described for supratentorial surgery. Evacuation of an intracranial hematoma usually requires a craniotomy, which can commonly be done without opening the dura mater. Evacuation of a large hematoma may suddenly decrease ICP and allow upward movement of the brainstem through the tentoria incisura. This may result in transient hemodynamic instability and cardiac arrhythmias.

Emergence and postoperative management

Patients with severe head injury remain intubated after surgery to provide ventilatory support and to control elevated ICP. Transfer to an ICU is indicated for continued care.

Cervical spinal cord injury

Isolated cervical spine injury is uncommon in the pediatric population. However, all children with severe head injury should be treated as though they have a cervical spine injury, until proven otherwise. Injury to the high cervical cord is usually caused by high-velocity injuries to the cranium (Fig. 25.16). Children with cord injury or disruption of the cord often present without respiratory efforts, often in cardiac arrest or with profound hypotension. They frequently die from hypoxic-ischemic encephalopathy and may have serious traumatic brain injury. In one study, all patients with absent vital signs had high cervical cord luxation on a lateral view radiograph of the neck [171]. Physicians caring for such patients might think that the hypotension is related to blood loss from intra-abdominal, pelvic, or thoracic injury, or even from devastating cerebral injury and loss of brainstem function.

Anesthetic considerations and management

Some cervical spine injury victims have signs of brain shift and elevated ICP. The anesthetic considerations for these patients include:

- Resuscitation and stabilization of cardiopulmonary function, i.e. spinal shock.
- Decreasing ICP and improving cerebral perfusion.
- Stabilization of the cervical spine.
- Correction of metabolic disturbances.
- Treatment of adult respiratory distress syndrome (ARDS).
- Identification of the central rostrocaudal deterioration and uncal herniation.

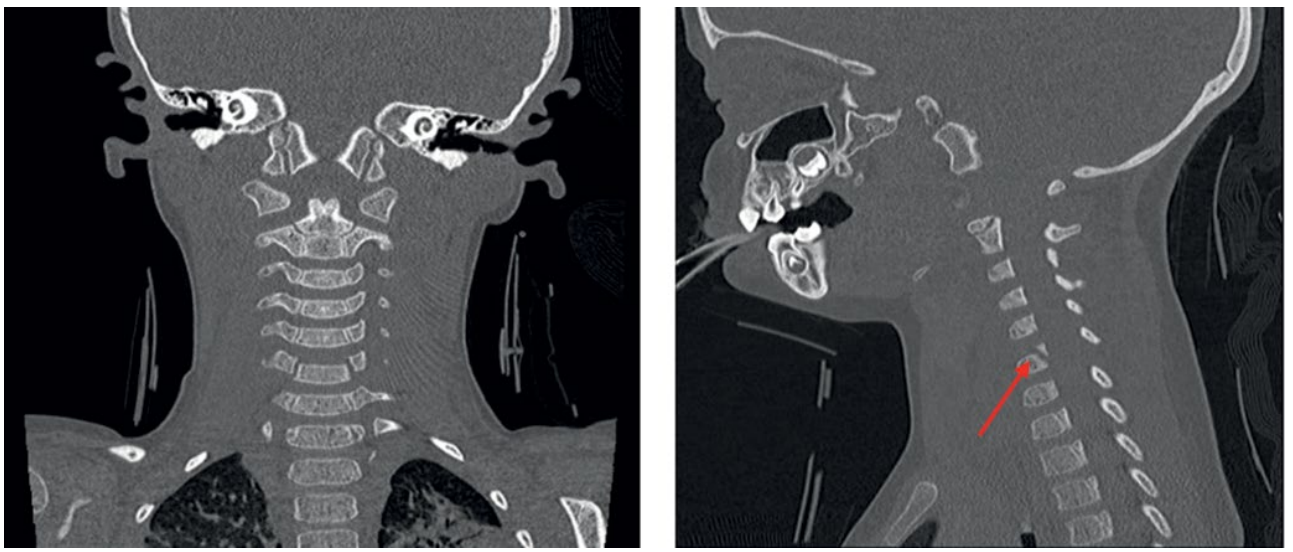

Figure 25.16 Lateral CT scan of the cervical spine of a 3-year-old girl following motor vehicle accident presents intubated in field with GCS of 3 and no spontaneous respiration. CT scan demonstrates a distraction injury, with abnormal widening of the joint space between the right occipital condyle and C1 lateral mass and between the right C1 and C2 lateral masses. Fracture through bilateral C6 vertebral body synchondroses (red arrow). There is associated paraspinal soft tissue swelling and focal hemorrhage in the C5–C6 disk.

- Meeting the fluid requirements for trauma victims with isoosmolar solutions such as normal saline.
- Monitoring arterial pressure, CVP, and urine output.
- Correcting the coagulopathy often caused by brain tissue thromboplastin release.
- Treatment of DI (see section "Craniopharyngioma").
- Treatment of SIADH.
- Controlling the hyperglycemia that frequently occurs in head-injured patients, which is thought to be a good indicator of the severity of the injury and a predictor of outcome. It is advisable to prevent the increase in glucose associated with head injury [172].
- Maintaining corticosteroid dosing for spinal cord injury: although controversial, this approach is still used in many institutions.

Chapter 39 presents further discussion of the approach to the neurotrauma patient.

KEY POINTS: MYELODYSPLASIA, SPINAL CORD SURGERY, AND NEUROTRAUMA

- Myelomeningocele is a neonatal emergency, and induction and intubation must be accomplished while protecting the sac and neural placode from damage or infection
- Spinal cord monitoring with sensory and motor evoked potentials is essential for spinal cord surgery; anesthetic regimens to maximize accurate monitoring must be planned

Anesthesia for pediatric epilepsy and movement disorders

Anesthesia for brain mapping during epilepsy surgery

Introduction to epilepsy and brain mapping

Advances in pediatric neurosurgery have offered many new treatment options for patients with medically intractable seizures. With the advent of intraoperative brain mapping and electrocorticography (ECoG), precise anatomical targets can be obtained and planned for resection. Intraoperative brain mapping is an essential tool for neurosurgical procedures that involve lesions near functional or "eloquent" cortex. Eloquent areas include primary motor cortex, primary somatosensory cortex, language areas such as Broca's and Wernicke's, primary visual areas, angular gyrus, and mesial temporal regions for memory. When tumors or epileptic foci are located adjacent to these areas of functional cortex, both intraoperative electrophysiological monitoring and neurocognitive testing aid in aggressive resection of the pathological lesion while attempting to minimize neurological deficits.

The demands of electrophysiological monitoring have a profound effect on the anesthetic technique and agents that can be used during the procedure. In some instances the patient must be awake, such as when language testing is being performed. ECoG and motor mapping can be performed under general anesthesia. Anesthetic goals include providing adequate surgical conditions, minimizing interference with intraoperative brain mapping, and maintaining patient comfort and safety throughout the procedure [173].

Any procedure involving brain mapping requires constant communication between the anesthesia team and surgeon. Preoperatively, this ensures that the entire team understands the surgical and anesthetic plan; intraoperatively, neurophysiological monitoring may require adjustments of anesthetic depth and anesthetic agents.

Adding to the difficulty of providing anesthesia to these patients is the lack of prospective, randomized trials comparing anesthetic techniques. Most evidence involves case series or retrospective analysis. These studies can be confusing to an anesthesiologist naïve to the technical neurophysiology language, and the available studies form conclusions that are sometimes contradictory and inconsistent. This has resulted in protocols that vary by institution, and there is no consensus as to the optimal anesthetic technique for mapping procedures.

Brain mapping techniques and anesthetic concerns

Electrocorticography

ECoG is utilized during epilepsy surgeries to help identify abnormal EEG patterns that result from epileptogenic foci. ECoG can be obtained via the placement of dural grids (Fig. 25.17) or via the placement of depth electrodes while under anesthesia. Spike waves identify the seizure focus and allow precise resection. After resection, ECoG recordings can be performed again to ensure there is no further spike activity.

Most anesthetics affect intraoperative ECoG recordings, yet ECoG has successfully been performed with local anesthetic only, monitored anesthetic care, and general anesthesia. The commonly used agents, including volatile anesthetics, nitrous oxide, propofol, dexmedetomidine, and opioids, will be discussed in greater detail.

Volatile agents

Volatile agents are commonly used for maintenance of general anesthesia when patients are not candidates for an awake

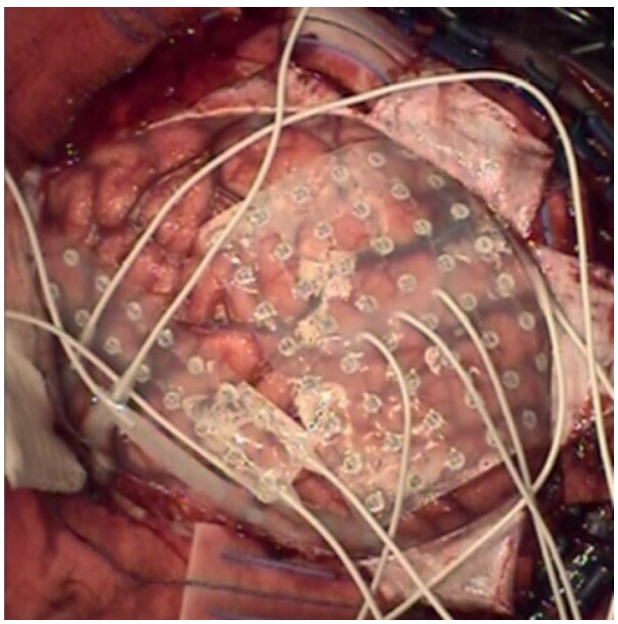

Figure 25.17 Intraoperative electrode grid placement. *Source*: Photo courtesy of Daniel J. Curry, MD.

craniotomy. However, their use still varies between institutions. For instance, sevoflurane has been shown to significantly reduce spike activity in epileptic patients at 1.5 MAC [174]. However, this study was performed with patients under the effects of a fentanyl-based anesthetic. Fentanyl, like many opioids, has been shown to induce spike wave activity, especially at high doses, and may have increased spike activity at the baseline recordings for this study [175]. Other studies have shown that sevoflurane can increase spike activity at higher concentrations, just prior to causing burst suppression [176–178]. One can see the confusion as one agent, sevoflurane, has both epileptic and antiepileptic properties. Indeed, some institutions' protocols avoid volatile agents altogether for fear that they may make reliable ECoG impossible, while others have attempted to use the epileptogenic properties of higher-dose sevoflurane to localize seizure foci.

As shown by Kurita et al [179], sevoflurane's ability to increase epileptiform activity may help in accurate resection of seizure foci. This study showed that ECoG recordings at 0.5 MAC sevoflurane were similar to those at ictal onset in the awake state, whereas at 1.5 MAC the ECoG recordings were more similar to those in the interictal period in the awake state. These interictal spikes correspond to "irritative" zones, whereas the ictal onset zone is the area where a seizure originates, and is the gold standard for localizing the epileptogenic zone, the smallest area needed to be resected to prevent further seizures. Higher sevoflurane levels may increase the "volume" of the recordings; however, they may not increase the specificity of recordings to allow for resection of the smallest area necessary. Isoflurane, like sevoflurane, does appear to have some epileptogenic potential, but not to the same degree [178]. When used to maintain general anesthesia during ECoG monitoring, low levels of volatile anesthetic combined with higher-dose opioid administration should not interfere with ECoG [179,180]. A dexmedetomidine infusion is commonly added to further lower the volatile agent dose needed to maintain an adequate level of anesthesia.

Nitrous oxide

Nitrous oxide is often used in neurosurgical procedures. It has been shown to attenuate spike activity on ECoG, especially when combined with volatile anesthetics [181,182]. Despite this, nitrous oxide is a key component of many successful anesthetic protocols for epilepsy surgery. If used, it should not be combined with additional volatile agent, but rather with liberal opioid administration. Opioid and nitrous oxide alone should not interfere with ECoG [164].

Of note, when patients already have an ECoG grid in place and are returning for resection, one should avoid using nitrous oxide until the dura is open to prevent pneumocephalus [183].

Propofol

As with sevoflurane, propofol has been shown to have both epileptic and antiepileptic properties that appear to be dose dependent. In low doses, propofol causes activation of EEG activity [184,185]. It may even cause background activity, which may resemble epileptiform spiking [186]. Larger doses lead to slowing and attenuation of spike activity, and at sufficient doses may lead to burst suppression and isoelectricity.

Both Herrick et al [186] and Soriano et al [187] reported that propofol did not affect the ability to obtain ECoG recordings if terminated at least 20 min prior to the start of ECoG. In light of the evidence, propofol should be discontinued before the start of ECoG.

Dexmedetomidine

Dexmedetomidine has minimal effect on ECoG and can be continued during recordings at low infusion rates [188]. Because of its minimal respiratory depression, titratability, and ability to provide a cooperative, relaxed patient, dexmedetomidine is an excellent anesthetic for procedures that require a patient to be awake during a portion of the procedure. In addition, dexmedetomidine has been shown to provide hemodynamic stability during neurosurgical procedures [189]. Modest reductions in blood pressure and heart rate are secondary to α_2-mediated adrenoreceptor activity. Reductions in circulating catecholamines result in a decreased incidence of tachycardia and hypertension during the perioperative period [190].

When used for maintenance of general anesthesia in combination with sufentanil, dexmedetomidine did suppress epileptiform activity [191]. However, at this author's institution, high infusion rates of dexmedetomidine are typically used throughout brain mapping procedures requiring ECoG with minimal to no effect on intraoperative recordings.

Opioids

Opioids are a mainstay of neuroanesthesia, and this is particular true with brain mapping procedures performed under general anesthesia. Because both volatile agents and propofol are discontinued or used in very low doses during brain mapping, there is potential for patient awareness, discomfort, and movement. Using large doses of short-acting opioids, one can maintain patient comfort, minimize the chance of patient movement, and not affect brain mapping. During awake craniotomies, opioids help manage pain and discomfort that may occur despite an adequate scalp block with local anesthesia.

Opioids do not alter seizure threshold or interictal spike activity. Moderate doses may result in muscle rigidity without EEG spiking, and extremely high doses will induce seizures [192–194]. Patients with partial complex epilepsy given moderate doses of fentanyl may experience increases in interictal spikes (IIS) that are not confined to the previously identified seizure foci [195]. Alfentanil, an opioid with a shorter terminal half-life than fentanyl, has been used in bolus dosage to increase IIS activity for mapping foci [196]. Remifentanil has a similar effect on IIS but its duration of action is much shorter than fentanyl, making it a better choice during awake craniotomy when ventilation cannot be mechanically supported [197].

Direct cortical stimulation

Direct cortical stimulation is the process of applying direct electrical stimulation to the cortex to help map eloquent areas responsible for motor function, language, vision, or sensation. Only motor mapping may be performed under general anesthesia, as all other forms of mapping inherently require the patient to be awake to participate in testing and provide feedback while testing is being performed.

There are few limitations on anesthetic agents for motor mapping, the main one being that cortical motor evoked potential (cMEPs), just like transcranial motor evoked potentials, are especially sensitive to volatile agents. Concentrations as low as 0.2–0.4 MAC have been shown to interfere with the ability to obtain adequate recordings. Intravenous agents and an awake anesthetic technique have less interference with motor mapping than the use of volatile agents and general anesthesia [198,199].

Motor mapping may be performed by the surgeon stimulating the cortex, and either the anesthesiologist or another member of the operating team assessing whether there is a visually observed motor response to a particular area, such as hand, foot, or face. This allows for mapping of the functional motor cortex during the operation so that it may be spared during resection. For motor mapping to be performed, the patient cannot receive neuromuscular blocking agents.

Protocols for brain mapping procedures

Awake or asleep

The decision to perform either a general anesthetic or an awake craniotomy is complex and depends on patient factors, institutional culture, surgeon preference, and the anesthesia provider's familiarity and comfort with various techniques. Some basic rules are evident that may simplify the decision process.

- Language/sensory testing can only be performed in an awake patient.
- General anesthesia can be performed during ECoG and motor mapping.
- Less anesthetic equals less interference with neurophysiological monitoring; if a patient is a candidate for an awake craniotomy, one should strongly consider it.
- Do not perform an awake anesthetic on a patient who cannot be expected to cooperate.

This puts the anesthesiologist in a unique situation. What might be best for the surgical excision of the lesion (awake patient minimizing the chance of interference with neuromonitoring or neurological deficit) might not be best for the patient (traumatic experience from awake craniotomy or risks from lack of cooperation/movement).

While these rules are helpful, they ignore the complexity of the challenges involved in patient selection and the risk/benefit ratio inherent to the decision to perform an awake craniotomy or general anesthetic.

Patient selection

Some institutions have absolute age cut-offs for performing an awake craniotomy. Ideally, the decision involves many team members including surgeon, patient and parents, anesthesiologist, neurologist, and if possible someone with expertise in helping ascertain whether a patient is mature and capable of dealing with the procedure, such as a child psychiatrist. The importance of a thorough preoperative assessment and communication with the child cannot be overemphasized. The patient should have a clear understanding of what will be done, what he/she will experience, and be reassured that they will be kept comfortable and safe. Other issues that can make the decision more clear-cut include comorbidities such as anxiety disorder, developmental delay, obesity, obstructive sleep apnea, and anything that would make conversion to general anesthesia challenging (difficult airway). Such co-morbidities are strong contraindications to performing an awake craniotomy.

Adding to the difficult decision as to whether an awake or general anesthetic is more appropriate are the opposing risks and benefits of both techniques. To simplify, an awake anesthetic will benefit aggressive surgical excision of the tumor or seizure focus and allow for neurocognitive assessment to look for neurological deficits during resection. However, inherent to this technique is a certain loss of control of parameters that as anesthesiologists we are accustomed to maintaining. These include the ability to precisely control hemodynamics and ventilatory status (blood pressure control, secure airway, adjustment of CO_2). These parameters not only allow us to feel more comfortable, they benefit surgical conditions by preventing a "tight brain" and ensuring patient cooperation. By performing a general anesthetic, the risk of interference with mapping techniques and neural deficits postoperatively may be increased. As one can see, the decision as to anesthetic choice can be quite complex, and requires communication between surgeon, anesthesiologist, and patient.

General anesthesia

The following are some examples of protocols for epilepsy surgery involving brain mapping with ECoG and cortical mapping under general anesthesia. The basic premise is to minimize anesthetic agents that may interfere with mapping procedures (volatile agents, propofol, benzodiazepines), yet still ensure patient safety and comfort. To do this, one should consider opioid administration as the mainstay of the anesthetic technique.

Protocol

1. Minimal or no benzodiazepines for premedication.
2. Opioid infusion: sufentanil 0.3–1 μg/kg/h or remifentanil 0.1–0.5 μg/kg/min.
3. Volatile agent <0.5 MAC.
   - N_2O may be substituted for volatile agent.
   - Propofol infusion 100–250 μg/kg/min (discontinued 20–30 min prior to ECoG).
4. Motor mapping: no NMB, low volatile agent (0.2–0.4 MAC) but may still attenuate cortical MEPs.
5. *Consider adding dexmedetomidine 0.2–0.7 μg/kg/h* for all variations of this protocol. This has minimal effect on ECoG recordings while helping deepen the anesthetic while other agents are discontinued.
6. Local anesthetic: as general anesthesia during ECoG is a time when the patient may be "light," one should consider the scalp block just as important as it is for an awake craniotomy. This may lower the chance of patient discomfort or movement during this time.

Methods to improve electrocorticography

Despite strict attention to anesthetic technique, poor signals are still sometimes present. Drugs that have been used to increase epileptiform activity include:

- methohexital 0.3–0.5 mg/kg [200]
- etomidate 0.1–0.2 mg/kg [201]
- alfentanil 50 μg/kg [202,203]
- remifentanil 2.5 μg/kg [204].

Awake craniotomy

Two common methods for "awake craniotomy" are local anesthesia with conscious sedation and the asleep/awake/asleep (AAA) technique whereby general anesthesia is induced and then completely stopped during mapping. The benefits of the AAA technique include shortened time needed for patient cooperation, increased depth of anesthesia during stimulating portions of the procedure (craniotomy), and more control of ventilation if an airway is in place. The disadvantages include the need to remove an airway during the procedure with limited access to reacquire it and the chance of patient bucking or delirium on awakening.

All combinations of anesthetic agents have been used successfully for all anesthetic techniques during awake craniotomy. The most popular agents for sedation include propofol and dexmedetomidine. These agents have been used alone or in combination with an opioid, with fentanyl and remifentanil being the most commonly used. Volatile agents have also been used during the asleep portion of AAA techniques. When deciding on which agents to choose the following should be considered:

- *Dexmedetomidine* causes minimal respiratory depression and has been shown to provide stable hemodynamics during craniotomy [189]. It also allows for smooth emergence from anesthesia and provides a cooperative patient who is easily arousable. Typical infusion rates during the asleep portion range from 0.5 to 1 μg/kg/h and during the awake portion from 0.1 to 0.5 μg/kg/h [188].
- *Propofol* is widely used during awake craniotomies because of its easy titratability. Its antiemetic properties are also beneficial for an awake patient. It does cause dose-dependent ventilatory depression, and should be terminated 20–30 min prior to ECoG to prevent attenuation of spike activity [187].
- *Remifentanil* is easily titratable, allowing for rapid emergence from anesthesia. These characteristics make it an ideal opioid for an AAA technique.

Tips for awake craniotomy

The success or failure of an awake craniotomy is dependent on many variables. However, with attention to detail and proper planning, most patients tolerate the procedure very well.

- Local anesthetic for scalp block is essential for patient comfort.
- Antiemetic: nausea may occur from opioids, hypotension, hypovolemia, or pulling on the dura.
- Laryngeal mask airway for less straining/bucking on emergence.
- If endotracheal intubation is chosen, local anesthetic to the trachea may prevent bucking/straining.
- A processed EEG monitor may help with timing of removal of airway.
- Patient padding and positioning are crucial to patient comfort while awake.

Hemispherectomy

Children with severe seizure disorders, unresponsive to medical management, may be candidates to undergo resection of the affected cerebral hemisphere, or hemispherectomy [205]. The criteria for surgery typically demand that the child has had a generalizable seizure that comes from a focus in a single hemisphere. Localization may require prior grid placement with mapping, functional MRI, or other imaging prior to the grid removal and hemisphere resection. Hemispherectomy is an extensive procedure with potential for massive blood loss, and planning for this is essential when approaching these patients.

Vagal nerve stimulator

Vagal nerve stimulators were first implanted in humans in 1988 and have proved an effective method of reducing seizure burden for many patients. The procedure has the benefit of avoiding any intracranial intervention, and may reduce the seizure burden up to 50% in some patients. The stimulator is attached to the vagus nerve, usually on the left side of the patient's neck, to avoid any cardiac efferent nerves whose stimulation may result in bradyarrhythmias or asystole. The generator is then placed under the left pectoralis fascia similar to a pacemaker. There are minimal anesthetic concerns for this procedure, however general endotracheal intubation is usually desired because of the surgical site and proximity to major vascular structures including the internal jugular vein and internal carotid artery.

MRI-guided laser interstitial thermal therapy for epilepsy

MRI-guided laser interstitial thermal therapy (LITT) is a new minimally invasive technique in which a small laser fiber is stereotactically placed into a seizure focus in the brain via occipital, parietal, or frontal entry, and the focus is thermally ablated while monitoring tissue temperatures via MRI thermography [206]. This approach has been employed for focal and generalized pediatric epilepsy, and can be utilized instead of traditional epilepsy surgery when open surgery poses an unacceptably high risk of morbidity or patient and family preference precludes craniotomy. The workflow for LITT procedures is complex and institution-dependent; all involve stereotactic systems that operate with or without stereotactic head frame placement, and intraoperative MRI to guide placement of the laser and monitoring of the ablation and tissue temperature (Figs 25.18, 25.19). An MRI scanner within the operating room is ideal for this procedure, but other protocols involve induction of anesthesia in the operating room and transport to an MRI scanner, or the entire procedure can be performed in an MRI suite. Adequate endotracheal anesthesia with muscle relaxation is required to prevent dislodgement or movement of the laser. ECoG or other means to identify ablation targets will normally have been performed prior to the procedure, but occasionally ECoG is performed immediately prior to the laser ablation procedure during the same anesthetic. Extensive multidisciplinary planning is an essential component when approaching MRI–LITT procedures.

Deep brain stimulation

The most common indications for deep brain stimulation (DBS) in the pediatric population include movement disorders such as dystonia and Tourette syndrome. The challenge with DBS procedures concerns balancing the desire for an awake patient with a patient population that, because of the

disease process, can be difficult to manage with an awake technique. Additionally, microelectrode recordings place many limitations on anesthetic agents.

Surgical procedure

DBS involves the placement of electrodes into deep nuclei of the brain, with common targets being the globus pallidus internus (GP_i) and subthalamic nuclei (STN). The procedure has two parts: the insertion of electrodes, and subsequent internalization of the connecting wires and pacemaker. These can be done on the same day of surgery and are separated into a two-part procedure [207].

The first step is placement of the head frame, which in pediatric patients is usually done after induction of anesthesia. MRI or CT is then performed, and for the initial surgery burr hole(s) are placed. If DBS insertion is bilateral, then bilateral burr holes are made. After that, electrode placement begins. There are three steps by which proper electrode placement in the target nuclei is achieved. The first is frame-based imaging, which calculates depth and trajectory to get electrodes close to the target nuclei. Second, neurophysiological monitoring via microelectrode recordings (MER) further guides electrodes to the proper placement, and third, macrostimulation takes place [208]. MER details the electrical activity of individual neurons and can distinguish between such tissues as the globus pallidus externa and interna, and even the border between the two. MER is started about 10 mm away from the target, and then the probe is inserted millimeter by millimeter as recordings are taken. This is a painstaking process, and may take hours. After this, macrostimulation of the awake patient occurs. The patient needs to be awake in order to express if there is alleviation of his/her symptoms and if there are any side-effects during stimulation of the electrodes.

After the electrode is in place, the rest of the procedure involves placement of the wires and pacemaker (usually subclavicular); this portion can be performed under any anesthetic technique.

With newer technology, some DBS insertions are being performed with only MRI-based imaging. This eliminates the need for MER and an awake patient, and relieves many of the limitations on anesthetic agents.

Anesthetic agents and microelectrode recording

Anesthetic agents have a profound effect on MER, although the mechanisms by which this occurs are not completely understood. The effects appear to depend on both the target nuclei (GPi versus STN) and disease process [208–210]. MER is less affected in dystonia than in Parkinson disease, and the GP_i is more sensitive to anesthetic agents than the STN. This may be due in part to higher GABA input to the GP_i.

All GABA agents affect MER; despite this, propofol is the most widely used agent for these procedures. Agents with the least effect include the opioids remifentanil and fentanyl, as well as dexmedetomidine and ketamine, likely due to their non-GABAergic action [211,212].

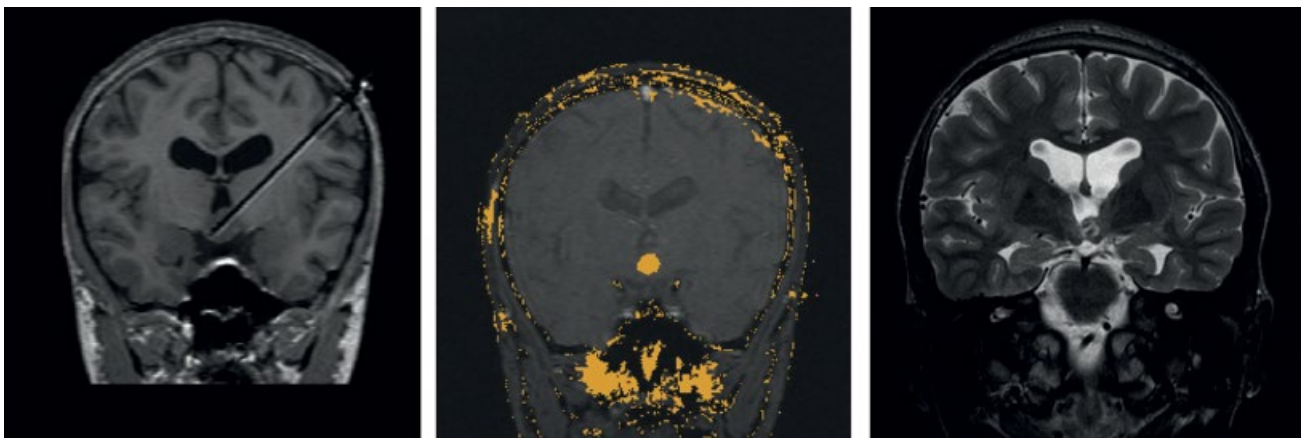

Figure 25.19 MRI of stereotactic laser ablation of hypothalamic hamartoma using laser interstitial thermal therapy for epilepsy. (A) Coronal MRI showing cannula placement before ablation on T1-weighted imaging (left). (B) The irreversible damage map (orange) superimposed upon a phase scan (middle). (C) A 3-month follow-up T2-weighted MRI showing ablated hamartoma. *Source*: Reproduced from North et al [206] with permission of Elsevier.

Volatile agents have also been used for DBS, but most success has been shown in procedures where the STN was the target [213–215]. Unfortunately for the pediatric anesthesiologist, the primary target in dystonia patients is the GP_i. Information as to acceptable concentrations of volatile agents, or whether one agent is preferable over another, is lacking.

MER has been successfully performed with commonly used anesthetic agents such as propofol, volatile agents, opioids, ketamine, and dexmedetomidine. However, any agent with GABA agonism may attenuate MER. Benzodiazepines have been shown to abolish MER, and propofol may attenuate MER. As such, our protocol for DBS relies heavily on combinations of dexmedetomidine, remifentanil, and ketamine. In our experience, these agents cause minimal interference with MER, and allow for an awake and comfortable patient during macrostimulation.

Macrostimulation

Macrostimulation requires an awake and cooperative patient. The benefit of performing macrostimulation is that it allows for confirmation of correct placement of electrodes by relief of symptoms and assessment of side-effects such as rigidity, nausea, pain, and paresthesia.

DBS can be a long, tedious procedure, with a lengthy period during which the patient must be awake if macrostimulation must be performed. An AAA technique is employed at this author's institutions, but DBS has been performed under conscious sedation in pediatric patients with success using combinations of dexmedetomidine and propofol [216].

KEY POINTS: ANESTHESIA FOR PEDIATRIC EPILEPSY AND MOVEMENT DISORDERS

- Electrocorticography (ECoG) can be accomplished via dural grids or depth electrodes; although most anesthetics affect ECoG, it can be performed with local anesthetic only, sedation, or general anesthesia
- Language or sensory testing can only be performed in an awake/lightly sedated patient; careful patient selection (age, maturity, ability to cooperate) and patient preparation are essential
- General anesthesia without benzodiazepines, with sufentanil or remifentanil infusion, volatile agent <0.5 MAC, and adding dexmedetomidine and local scalp anesthesia is a successful approach for ECoG
- "Awake" craniotomy with dexmedetomidine and remifentanil, adding propofol as needed, is a successful approach

Cerebrovascular anomalies

Patients with intracranial vascular malformations such as AVMs or cerebral aneurysms are commonly co-managed by the pediatric anesthesiologist in conjunction with neurologist, neurosurgeons, and interventional neuroradiology [217]. This may require that one or more anesthetics be provided to facilitate the diagnosis and/or intervention for the lesion. Since congenital and acquired forms of AVM can prove to be one of the greatest anesthetic challenges throughout life, we will focus on their general management in infants and children. AVMs and arterial aneurysms can be acquired, but the majority arise from abnormal development of the arteriolar–capillary network that connects the arterial and venous systems. These vascular malformations often consist of large arterial feeding vessels that lead to dilated connecting vessels and then to the venous system. Flow of blood through this low-resistance connection results in progressive distention of the venous structures and increased venous mixed oxygen content from the shunting of blood. Specific AVM scenarios that occur in infants and children involve the posterior cerebral artery and the great vein of Galen (Fig. 25.20). These anomalies often present in the neonatal period with congestive heart failure. Alternatively, the patients can present with obstructive hydrocephalus from saccular enlargement or dilatation of the vein of Galen that directly compresses the aqueduct and prevents drainage of the CSF.

Outside the neonatal period, many AVMs go undetected until the fourth or fifth decade of life, with only 18% reported in patients under 15 years of age. Although the incidence is low, when intracranial AVMs occur, neurological injury can result from one or more causes:

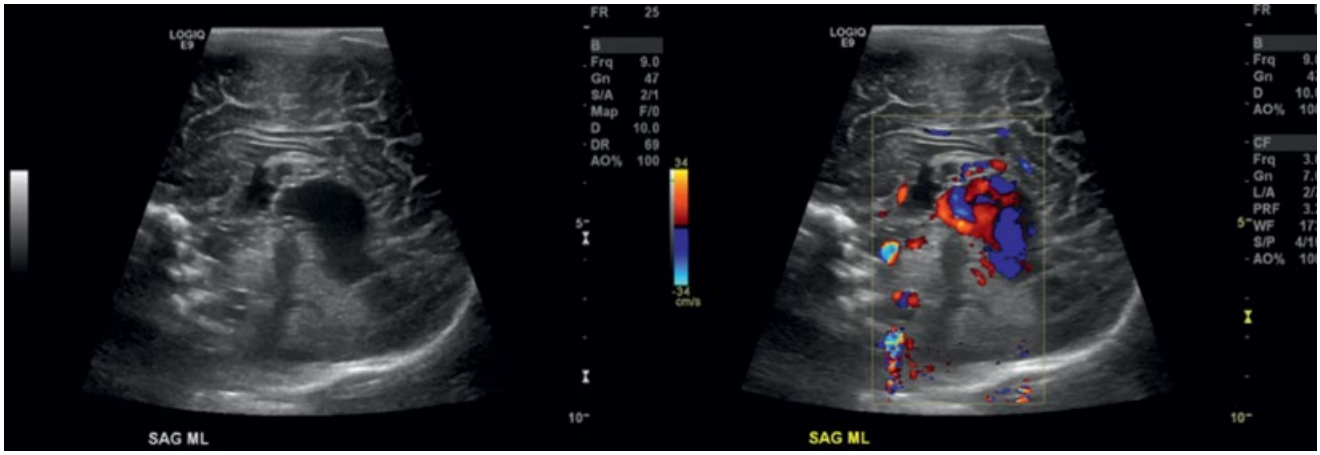
- hemorrhage with thrombosis or acute infarction
- compression of adjacent brain tissue or intracranial structures
- parenchymal ischemia created by "steal" of blood flow through the AVM
- congestive heart failure from the shunt
- surgical or interventional injury resulting in disruption or diversion of blood flow from viable brain tissue supplied by the AVM during treatment.

Families and physicians must therefore balance these potential outcomes when deciding between surgical versus interventional treatment options. Regardless, patients with complex AVM lesions may undergo interventional or stereotactic radiosurgical procedures to control blood flow as definitive or adjunctive therapy. In addition, surgical clipping of feeding vessels or removal of aneurysmal tissue may need to be done as either a single or staged procedure. Again, clear communication between the anesthesiologist and the various treatment teams is necessary to facilitate optimal care.

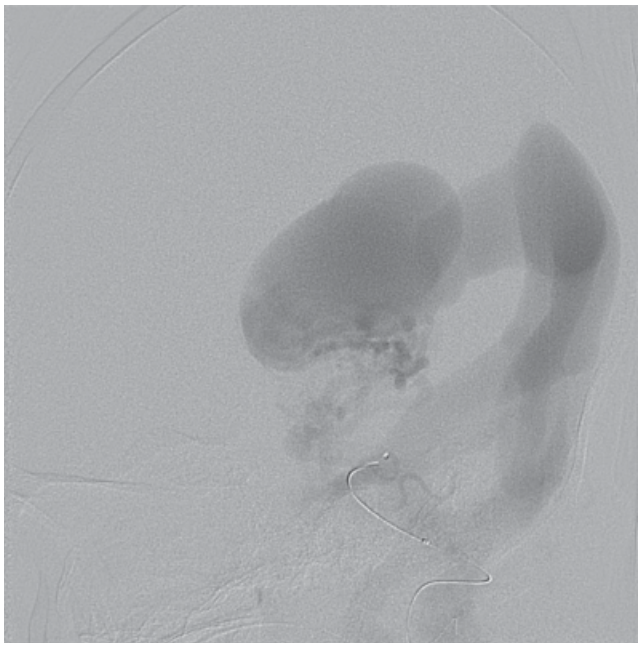
Anesthetic considerations

Considerations for patients undergoing AVM resection or embolization include the following:

- *Assessment for pre-existing pathophysiology*. Does the patient present with increased ICP or congestive heart failure? Does the patient have additional congenital defects?
- *Age-related pathophysiology*. Will organ system maturity impact on the anesthetic technique?
- *Blood loss*. The possibility of massive blood loss is high, especially if pre-resection therapies for embolization were limited.
- *Ventilation pattern*. Hyperventilation to control cerebrovascular tone and reduce inflow is a therapeutic consideration for most AVM treatment.



(A)



(B)

Figure 25.20 (A) Head ultrasound – grayscale and color Doppler sagittal image of the brain demonstrates a large aneurysmal vascular structure within the midline just above the tentorium with multiple adjacent dilated vessels, compatible with vein of Galen malformation. (B) Fluoroscopic image during intervention – lateral view of an aneurysm of the great vein of Galen. The main arterial contribution is from the anterior cerebral artery. The dilated vein of Galen empties directly into an enlarged straight sinus.

Monitoring

Routine monitoring is as previously described. Patients undergoing AVM resection should have vascular access via two large-bore peripheral IV catheters that are capable of delivering blood products should hemorrhage occur. Intravenous solutions should be warmed throughout the procedure. Invasive hemodynamic monitoring with an arterial line is essential. CVP monitoring is useful to determine intravascular status and to facilitate administration of medications. A urinary catheter is essential and should be placed after induction of anesthesia.

Preinduction

Symptoms can vary depending on the age of the patient and the size of the AVM [218]. Older children often present with evidence of subarachnoid hemorrhage (SAH) or intraventricular hemorrhage (IVH). Up to 50% of children who present with spontaneous SAH have an AVM as the etiology [219]. In 24% of children, seizure is a common presenting feature. However, the neonatal presentation of AVMs is often associated with congestive heart failure and deserves special attention.

The low-resistance pathway of the AVM creates a situation of volume overload and high-output heart failure. The symptoms of congestive heart failure rarely manifest *in utero* because the patency of the ductus arteriosus provides for increased systemic flow through the AVM and reduces the work of the ventricles. However, after birth, with closure of the ductus, the left ventricle alone must meet the demands of increased arterial to venous flow. The degree of the arterial to venous shunt will affect the demand on the left ventricle. In addition, with the low resistance of a cerebral AVM, a low systemic diastolic pressure results. This low intra-aortic pressure during diastole, combined with increased left end-diastolic

pressure and heart rate from the ventricular failure, results in reduced coronary perfusion and worsening myocardial function from ischemia [220]. The cycle of ventricular failure and decreased oxygen delivery to the systemic tissues results in the cascade of adaptive mechanisms that results in decreased urine output and increased fluid retention [218,221]. Physical examination of the infant shows signs such as tachypnea, pulmonary edema, tachycardia, hepatomegaly, and ECG changes. Echocardiography will often confirm the hyperdynamic nature of the congestive heart failure, and evidence of functional failure of one or both ventricles. Laboratory studies may provide evidence of electrolyte abnormalities from aggressive diuretic management. Some infants may require endotracheal intubation and mechanical ventilation support, and inotropic support, all of which may help reduce the workload of the failing myocardium.

Induction and intubation

Prevention of hypertension during induction is desirable, given the possible association between AVM bleeding and hypertension. Inhalation or IV induction of anesthesia can be performed if there is no evidence of increased ICP. This can be accomplished with a variety of anesthetic agents. In the patient with AVM and elevated ICP, an IV induction is preferable with attention to avoiding hypotension and low cerebral perfusion pressure. In the neonate with AVM and congestive heart failure, special consideration should be taken when inducing anesthesia to maintain cardiac output. Extreme caution should be maintained as many anesthetic agents are myocardial depressants and could precipitate cardiac arrest. To this end, placement of an IV and an arterial line is useful prior to induction. Either oral or nasal tracheal intubation is reasonable after induction of anesthesia.

Maintenance

Considerations for maintenance of anesthesia include the following:

- positioning
- ventilation
- anesthetic agents
- blood loss and fluid management
- temperature maintenance.

Positioning for the procedure will be dictated by the site of the AVM. Typically, AVMs receive their blood supply from the middle cerebral artery, and the majority are approached by a supratentorial craniotomy.

All patients should undergo mechanical ventilation with intended maintenance of normocapnia. Patients with evidence of elevated ICP may require transient hyperventilation to control ICP, and ongoing ICP monitoring may be a consideration. In general, normocarbia is preferable and hypocarbia should be avoided, as the resultant cerebrovascular vasoconstriction may result in more shunting of blood flow away from normal tissues and into the AVM, potentially contributing to increased cerebral ischemia and increased bleeding from the AVM.

The anesthetic agents used for maintenance are similar to those for any intracranial procedure. If congestive heart failure is absent, then permissive or controlled hypotension can be applied to facilitate control of bleeding from the AVM during ligation. This can be accomplished with infused antihypertensive agents such as nicardipine, nitroprusside, or fenoldopam. Neonates with congestive heart failure undergoing AVM ligation or treatment require inotropic support and are not candidates for permissive hypotensive strategies. For these infants, vasoactive drugs should be readily available and administered through a central venous catheter.

Fluid management in these patients is challenging. Neonates may not tolerate large volume shifts or drops in hemoglobin concentration, especially if they have elements of cardiac dysfunction. Early efforts to maintain normal intravascular volume and stable hemoglobin content should be the goal. This may necessitate early blood replacement and judicious supplementation with inotropic support.

Maintaining a normal body temperature is important and can be difficult given the fluid losses and sometimes massive transfusion requirements. This usually requires the use of both fluid and convective warming devices that should be adjusted to avoid profound hypothermia and coagulopathy. Although the merits of hypothermia (temperature < 35°C) for neuroprotection in neurosurgical procedures are debated, hyperthermia (temperature >38°C) should be avoided as this can propagate ischemic injury by increasing metabolic demands of the brain and the body.

Emergence

Considerations for emergence from anesthesia after AVM treatment include:

- elimination of anesthetic agents
- reversal of NMB
- assessment of respiratory effort and airway patency
- assessment of neurological function.

Patients without a history of congestive heart failure can be extubated at the end of surgery if they are neurologically appropriate and hemodynamically stable. However, those patients with a history of significant congestive heart failure or at risk for significant neurological deficits (i.e. required brain resection, significant brain retraction, or obvious cerebral edema) should remain sedated and be transitioned to the ICU with an endotracheal tube in place.

Postoperative management

The basic anesthetic considerations for postoperative care of patients following AVM treatment include:

- cerebral edema
- congestive heart failure
- hypertension
- vasospasm.

Cerebral edema can arise from either the AVM itself or from the therapeutic approach – be it surgical or interventional. Certainly, the interventional procedures for embolization or radiosurgery incur less injury to the tissues getting to the AVM, however they can still result in significant edema [222]. In those situations where the edema is anticipated or recognized, leaving the patient intubated and monitoring in the ICU is indicated. Following resection of a large AVM, it may take several days for the cerebral edema to resolve and the patient's neurological examination and level of consciousness to become appropriate. During this period, supportive care and careful neurological monitoring are of greatest importance.

Despite removal or reduction of the extracardiac shunting of blood, patients with preoperative myocardial dysfunction remain critical in the days following recovery from the surgery and require ICU care. In addition to maintaining an adequate cerebral perfusion pressure, the care team must balance the needs of the myocardium to reduce afterload. Aggressive analgesic and antihypertensive management may be required to prevent sudden increases in arterial blood pressure, which not only stress the heart but increase the risk for acute intracranial bleeding.

Vasospasm is not a common postoperative complication but must be a consideration if the patient's neurological status deteriorates or if SAH was present in the perioperative period. The pathogenesis of vasospasm is not completely understood, but early diagnosis and intervention can be beneficial. Transcranial Doppler sonography has been used to guide therapy in adults, but its role in children remains limited. Certainly, Doppler ultrasonography can detect increased blood flow velocities and allow for diagnosis of vasospasm as well as provide a means of guiding therapy. Treatment is typically with adequate hydration, stable/generous blood pressure, and use of calcium channel blockers [223].

Interventional neuroradiology

Over the past three decades, neuroradiological techniques and expertise in the diagnosis and treatment of diseases of the CNS have undergone significant advances. Interventional neuroradiology (INR), or endovascular neurosurgery, has evolved as a hybrid of traditional neurosurgery and neuroradiology. Although practice varies between institutions, INR has developed a clear role in the management of a variety of neurosurgical conditions, particularly neurovascular diseases (see section "Arteriovenous malformations"). INR, like interventional cardiology, can be broadly defined as treatment by endovascular access for the purpose of diagnosis and/or treatment by delivering therapeutic drugs and devices. The number, variety, and complexity of conditions treated using this route are increasing, and this creates challenges for the pediatric anesthesiologist [224]. The pediatric anesthesiologist has a crucial role in facilitating neuroradiological procedures, and this requires an understanding of the indication and purpose of the procedures, their potential complications, and the management goals of the involved neurologist, neurosurgeons, and neurointerventionalist, which will vary depending on the individual child.

Although most diagnostic neurological imaging can be accomplished with MRI and CT techniques, the power to both diagnose and intervene makes interventional techniques appealing, though they are often not the first line for diagnosis [225]. INR procedures can be broadly classified on the basis of treatment goals:

- *Closing or occluding procedures*. Common examples include: embolization of aneurysms, AVMs, and fistulae of the brain and spine; preoperative embolization of vascular tumors such as meningiomas; and temporary or permanent occlusion of intra- or extracranial arteries.
- *Opening procedures*. Common examples include: treatment of vasospasm or stenosis by angioplasty and stenting; and chemical and mechanical thrombolysis in stroke.

The most common INR procedures in children are endovascular treatment of aneurysms, AVMs, and preoperative embolization of tumors.

Although specific procedures will have different neurological complications, INR procedures are at higher risk for the following:

- *Hemorrhage*. This can result from vascular injury or dissection of an arterial vessel and/or aneurysmal perforation.
- *Ischemia*. This can result from malpositioning of a catheter or absence of collateral blood flow to a region, thromboembolic complication, displacement of a coil or stent that results in occlusion, and/or vasospasm of the vessel.

Non-neurological complications can also occur and are typical of other interventional procedures. They involve contrast reactions, contrast nephropathy, and hematoma/bleeding/hemorrhage at the femoral puncture site.

Anesthetic considerations

At many institutions, the interventional suites are situated remotely from the operating rooms. Because this not only involves multiple floors and distance, but sometimes multiple anesthetic locations (i.e. pre-/post-procedure CT angiography in one location and the INR procedure in a different location), technical support must be coordinated for the anesthesia team, patient transport, and potentially remote patient recovery. Other potential problems typical of interventional radiological locations include working in reduced light, limited or poor access to the patient and equipment during the procedure, and concerns about ionizing radiation. Anesthetic considerations when caring for patients undergoing INR procedures include maintenance of patient immobility and physiological stability, manipulating systemic and regional blood flow, managing anticoagulation, and treating sudden unexpected complications during the procedure. The medical management of critically ill patients during transport to and from radiology suites and smooth and rapid recovery from anesthesia to facilitate neurological examination are equally important [226,227].

There are no studies demonstrating a clear benefit of one anesthetic management technique over another in the INR suite. Multiple approaches have been reported including general anesthesia, MAC, and even sedation and/or awake techniques [195]. Because of the need for immobility in many of these procedures, we favor a general anesthetic with endotracheal intubation. Routine anesthetic monitoring is applied, and arterial blood pressure monitoring can often be obtained from the femoral arterial sheath. If postoperative ICU admission is anticipated with continued hemodynamic control (i.e. permissive normotension) then a radial arterial catheter should be placed. Vascular access should include two good peripheral IV catheters for fluid and blood product administration. A Foley catheter should be placed to monitor urine output. If vasoactive drugs are to be administered as part of the procedure, a central venous catheter is desirable.

Postoperative considerations

Postanesthetic management of children following diagnostic or mapping neuroradiographic procedures is similar to other interventional cardiology and radiology procedures. Monitored transport to the postanesthetic care unit, with

careful monitoring of bleeding complications from the femoral vein and arterial sheath sites, is necessary. In addition, careful neurological monitoring should be performed to assure return to the patient's baseline examination. Any new deficits or decline in neurological status should prompt aggressive assessment and management by the anesthesiologist and neuroradiologist, as bleeding complications may necessitate imaging, repeat intervention, and/or surgery.

Patients with anticipated swelling, neurological deficit, or continued need for hemodynamic monitoring following the procedure should be transferred directly to an ICU with or without tracheal extubation. Management goals should be discussed carefully between the neuroradiologist, neurosurgeons, anesthesiologist and intensivist, so that patient care can be optimized and the risk of ongoing neurological injury minimized. We will often transport a patient with anticipated swelling and/or deficits, to the ICU sedated, intubated, and monitored, and then facilitate extubation in the ICU where all concerned parties can examine the patient and agree with the postprocedural neurological examination. This approach can also facilitate any additional neuroimaging, such as CT or MRI, that might be planned or unplanned, prior to admission to the ICU. Chapter 41 presents additional discussion of neuroradiology procedures.

KEY POINTS: CEREBROVASCULAR ANOMALIES AND INTERVENTIONAL NEURORADIOLOGY

- Arteriovenous malformations and other cerebrovascular anomalies may be found in critically ill neonates with severe congestive heart failure and pulmonary hypertension, patients who have suffered subarachnoid or intracranial hemorrhage, or relatively asymptomatic older children with smaller lesions
- Tracheal intubation with controlled ventilation, blood pressure control, and preparation for lengthy procedures are often necessary for interventional neuroradiology procedures
- Rapid and smooth emergence from anesthesia, and early neurological assessment are important after interventional neuroradiology procedures; emergent neuroimaging should occur if emergence is delayed or new neurological examination findings occur

CEREBRAL PROTECTION, RESUSCITATION, AND OUTCOME

A comprehensive discussion of these topics is beyond the scope of this chapter. See Chapter 8 for a presentation of the physiology of the central nervous system. General principles are presented here for completeness [228].

Cerebral protection

After ischemic injury, the CNS has limited regenerative ability. *Brain protection* has been defined as the "prevention or amelioration of neuronal damage evidenced by abnormalities in cerebral metabolism, histopathology, or neurological function occurring after an hypoxic or ischemic event" (i.e. treatment that is instituted before and often sustained throughout the insult) [227]. Brain resuscitation refers to the treatment of the secondary brain injury or simply to therapy given after the primary insult. The secondary consequences of ischemia are those that occur after the cerebral circulation is restored and are usually termed postischemic injury or reperfusion injury. Cell vulnerability differs, depending on the type of neuron. For example, the limbic system, especially the pyramidal cells of the CA1 layer of the hippocampus, Purkinje cells of the cerebellum, and layers three, four, and six of the cortex, are extremely vulnerable to ischemia; spinal cord cells, on the other hand, seem to tolerate a longer period of oxygen deprivation before they are injured.

Cerebral protection either increases oxygen delivery, reduces its demands, or ameliorates the pathological process by free radical scavenging or by reducing the effects of excitatory amino acids (glutamate, aspartate) and ionic fluxes. The difficulty with cerebral protection is that these strategies must be instituted before the onset of ischemia. With complete global ischemia, the brain tolerates 4–6 min of oxygen deprivation. The goal of cerebral protection is to delay the onset of irreversible CNS damage. There are no proven methods of cerebral protection except for mild hypothermia in animal models of neurotrauma [229–231]. However, recent human trials using hypothermia following neonatal birth asphyxia, cardiac arrest, or trauma, have demonstrated an unclear benefit to neurological outcome or survival. Whether this variable result is due to differences in the method and degree of hypothermia administration, variability in clinical practice with the initiation and maintenance of a cooling method, variation in the patient population with co-morbid factors (i.e. renal failure or lung injury), or heterogeneity of the secondary brain injury remains unclear [232]. Therefore, maintaining adequate cerebral perfusion and oxygen delivery, avoiding hyperglycemia, and aggressively managing hyperthermia are, at this time, the only means we have to reduce CNS injury.

Cerebral resuscitation

Intracellular events that occur during ischemia or after restoration of circulation and oxygenation contribute to the ultimate neurological damage. Ischemia depolarizes neurons and allows ionic fluxes (Na^+ and Ca^{2+}) into the cells, probably owing to release of glutamate and aspartate and activation of the NMDA receptors. Depletion of ATP stores leads to the energy-dependent ion pump's failure to eject Na^+ and Ca^{2+} from the cells. This leads to formation of prostaglandins and oxygen free radicals, to mitochondrial respiratory chain paralysis, to acidosis, and finally to membrane destruction.

Cerebral outcome

The future of cerebral well-being depends on our level of understanding of the pathophysiology of hypoxic-ischemic injury and our broad-based medical and pharmacological knowledge. Future therapy depends on development of a better understanding of the molecular and cellular processes that cause CNS injury and the development of specific treatments to salvage or protect injured tissue. Ultimately, the goal is to provide effective therapeutic measures that reverse the cascades of cellular events leading to injury. Table 25.7 is a summary of neuroprotective strategies.

Table 25.7 General neuroprotective principles for elevated intracranial pressure (ICP)

Goals	Clinical management/treatment
Avoid edema formation	Corticosteroid to reduce vasogenic edema from tumors Maintain normal sodium >140 mg/dL Maintain serum osmolality >300 mOsm/L
Avoid cerebral hypoxia	Controlled ventilation, maintain $ETCO_2$ <40 mmHg Avoid seizure activity
Avoid cerebral hypoperfusion	Early insertion and monitoring of ICP and CPP Avoid elevations in ICP >20 mmHg Avoid hypotension Maintain CPP >50 mmHg Maintain head of the bed at 30° to promote venous drainage
Avoid cerebral hypermetabolism	Avoid hyperthermia (>38°C) May require paralysis to prevent shivering and increased ICP Use antipyretics Use cooling blankets

CPP, cerebral perfusion pressure; $ETCO_2$, end-tidal CO_2.

CASE STUDY

A 2-year-old girl chases a ladybug to her open second-story bedroom window. The window screen is unable to support her weight and she falls two flights, plus an additional half-flight into the basement stairwell, striking the side of her head on a concrete step. Paramedics transport the child from the scene to a prearranged Medivac flight waiting at a nearby school parking lot. She arrives at the trauma bay with generalized tonic-clonic seizure activity, cyanotic lips, pulse oximeter registering a heart rate of 80 bpm, and 88% arterial saturation. Her left antecubital region is swollen around the insertion site of an IV that does not run freely, and her last blood pressure recorded on the transport monitor is "timed out."

The trauma team consists of a general pediatric surgeon, pediatric anesthesiologist, pediatric emergency room physician, and three nurses: one from the trauma service, one from the pediatric ICU, and one from the pediatric emergency department. Prior to the arrival of the child, the anesthesiologist has chosen from a shelf of prepackaged, age-dependent trauma supplies, a kit labeled "toddler: 1–3 years; 8–14 kg." The package is unwrapped on the trauma table to reveal the following supplies: size 3 airway mask, laryngoscope handle with Miller 1 and Mac 2 blades and spare bulbs, uncuffed 3.5, 4.0 and 4.5 tracheal tubes and a cuffed 4.5 tracheal tube, sizes 6 and 14 French stylets, sizes 2 and 2.5 laryngeal mask airways, 8 French suction catheters, 60 mm oral airway, sizes 18 and 20 nasal trumpet with lidocaine jelly, tongue blades, an IV start kit with 20 and 22 gauge IV catheters and a 15 gauge interosseous needle.

A pediatric respiratory therapist and a pharmacist have also been paged to the room per rapid response protocol. The pharmacist has a tackle box filled with syringes predrawn and sealed in a sterile hood, including: atropine 0.1 mg/mL, epinephrine 100 µg/mL, lidocaine 20 mg/mL, phenylephrine 100 µg/mL, rocuronium 10 mg/mL, succinylcholine 20 mg/mL, pancuronium 1 mg/mL, etomidate 2 mg/mL, fentanyl 50 µg/mL, ketamine 100 mg/mL, midazolam 1 mg/mL, and thiopental 25 mg/mL. The cover of the tackle box is a table of weights and standard doses (in mL) for each of the predrawn medications included.

According to roles predetermined and practiced in a simulator setting, the pediatric anesthesiologist commences with the management and stabilization of the airway and hemodynamics of the patient while the surgeon and ER physician perform the trauma survey. Initial concerns for securing the airway are overridden by the more pressing concern for impending herniation, which might be hastened by an uncontrolled and unmedicated laryngoscopy. Bag mask ventilation is applied to the child with 100% oxygen and jaw thrust while the respiratory therapist holds in-line traction, stabilizing the neck, and cricoid pressure is held while supporting the back of the neck to avoid posterior displacement in case of C-spine fracture. The anesthesiologist confirms that the lungs of the child are easily ventilated with a mask, whereas the trauma surgeon reports a large, minimally responsive left pupil, and the ED physician reports a left hemotympanum. Neurosurgery is called. The ED nurse has transferred the patient monitoring to the overhead monitor, visible to all members of the team, with audible pulse oximeter tone and a blood pressure cuff cycling every minute. The child is still unresponsive with a Glasgow Coma Score of 5, no eye opening, no verbal response, and abnormal flexor posturing with stimulation.

The immediate benefit of CO_2 reduction and restoration of normoxia is a reduction in cerebral blood volume, and the heart rate rises to 120 bpm. The pulse oximeter reads 100% but the mean blood pressure reads only 45 mmHg. The PICU and trauma nurses are attempting IV placement, which is difficult because of the tonic-clonic seizure activity. The anesthesiologist requests the ED nurse to prepare the interosseous needle, estimates the patient weight at 12 kg, and requests the intramuscular administration of 0.2 mg/kg

midazolam to abort the seizure activity. Seizure activity stops within a minute of injection and 2 IVs are quickly placed. An IV bolus of 20 mL/kg of acetate-balanced 2% saline, which is part of the pharmacist tackle kit, is administered. After hypertonic saline administration, the arterial blood pressure is 105/45, mean 65 mmHg, and the heart rate is 105 bpm. Both pupils are now responsive. The anesthesiologist requests drugs for laryngoscopy and intubation. Lidocaine 1 mg/kg and atropine 0.15 mg are given. After 1 min, and an additional 20 mL/kg of normal saline, the arterial blood pressure is 100/45, mean 60 mmHg, and the heart rate is now 120 bpm. Thiopental 2 mg/kg (half of the usual induction dose) and rocuronium 1.2 mg/kg are given. The child is easily intubated with in-line traction and cricoid pressure still in place. The 4.5 cuffed ETT is secured after confirming placement, and ventilation is initiated and titrated to keep the end-tidal CO_2 between 30 and 35 mmHg.

The arterial blood pressure after intubation is now 65/25 with a mean of 35 mmHg. Phenylephrine 5 μg/kg is given and the repeat blood pressure is 90/45, mean 55 mmHg. The dose is repeated, along with an additional 10 mL/kg of 2% saline. Repeat blood pressure is 105/55, mean 65 mmHg. The trauma survey is completed and the child is taken to the CT scanner which reveals a large epidural hematoma with midline shift, effacement of cortical sulci and the ipsilateral ventricle, as well as imperceptible basal cisterns.

The child is taken immediately to the operating room for decompression. The anesthesiologists prepare for incision. O-positive trauma release blood is requested to the room. An arterial line is started and a second IV is placed. Anesthesia is maintained with IV remifentanil and propofol. The child is ventilated without positive end-expiratory pressure (PEEP) to an end-tidal CO_2 of 30 mmHg and an arterial blood gas is sent, but the result is not available until the procedure is well underway. Blood pressure is stabilized with phenylephrine infusion titrated to keep systolic blood pressure greater than 90 mmHg and mean arterial blood pressure between 60 and 65 mmHg. Temperature is maintained between 36° and 36.5°C without the need for a warming blanket. Mannitol 25 mg/kg is given and a Foley catheter is placed.

Incision is made 50 min after the initial trauma, and the hematoma is evacuated through a craniotomy within 5 min. After evacuation of the hematoma, the heart rate falls to 65 bpm and the arterial blood pressure falls to 65/25. Phenylephrine and 10 mL/kg of trauma release blood are immediately given and the pressure responds. An additional 10 mL/kg of saline is required to replace the brisk urine output following mannitol administration.

A parenchymal fiberoptic ICP monitor is placed upon closure of the dura and skull, reading 12 mmHg with a normal waveform. The child is taken to the ICU with only the remifentanil infusion, as cerebral perfusion pressure is 55 mmHg without phenylephrine. In the ICU, the remifentanil is stopped hourly for neurological checks and within 6 h of admission the child is opening her eyes and reaching purposefully for the tracheal tube, which is removed. After a night without ICP elevations at a serum sodium of 145 mg/dL, she is interacting appropriately with her parents at the bedside and her ICP monitor is removed.

This case illustrates the main anesthetic considerations presented in this chapter in critically ill patients with neurotrauma and increased ICP undergoing emergent procedures, with choices for airway, drug, and hemodynamic management to facilitate successful outcomes.

Introduction

Thoracic surgery and thoracic anesthesia in the pediatric population have changed significantly over the last two decades with the advent of video-assisted thoracoscopic surgery (VATS) and robotic surgery, and evolution of anesthetic practice to facilitate this type of surgery. While the less invasive approach of VATS has undoubtedly changed certain aspects of the perioperative and particularly the postoperative management of the pediatric thoracic patient, thoracotomy remains a relatively frequent surgical procedure, particularly in the very small infant where thoracoscopic equipment can be too large and cumbersome to perform complex procedures. Hence, the pediatric anesthesiologist needs to have the capacity to manage both approaches to surgery within the thoracic cavity.

Certain aspects of anesthetic practice remain common to both thoracoscopic and open procedures, namely the requirement for one-lung ventilation (OLV). Indeed, due to the initial access to the thoracic cavity by trocar in VATS, the goal of OLV is even more sought after than in open thoracotomy, where the surgical team can use a combination of retraction and packing to facilitate surgical access and visualization without damaging the underlying lung parenchyma. This requirement in the younger child has led to the development of a multitude of devices to allow lung isolation in children for whom the smallest size of traditional double-lumen tube (26 Fr) is too large.

VATS has significantly decreased the requirement for neuraxial blockade during the intraoperative and postoperative period due to its less invasive and hence less painful nature. This has radically decreased the number of inpatient days following complex thoracic procedures [1]; however, due to the ongoing requirement for thoracotomy within the pediatric population, the pediatric anesthesiologist is still required to maintain within their armamentarium the ability to provide adequate postoperative analgesia when necessary.

The relatively recent development of rapid-onset and -offset anesthetic agents, specifically the highly insoluble desflurane and rapidly metabolized remifentanil [2], has had a huge impact on the ability of the anesthesiologist to provide the rapid-onset and profoundly deep anesthesia that is necessary for thoracic surgery. These agents are so rapidly reversed at the end of thoracic cases that fast operating room turnover with alert, awake, compliant postoperative patients has become a reality.

This chapter reviews the pathophysiology of OLV, discusses the anesthetic practice and tools necessary to facilitate the perioperative management of the pediatric thoracic surgery patient, discusses analgesia for thoracic surgery, and finally describes in a little more detail some of the finer nuances of certain specific thoracic surgical challenges within the pediatric population, namely lobectomy, pneumonectomy, congenital cystic lung disease, anterior mediastinal mass, pectus excavatum, and empyema.

Pathophysiology of one-lung ventilation

During thoracic surgery, several factors have profound effects on ventilation/perfusion (V/Q) matching. General anesthesia, neuromuscular blockade, mechanical ventilation, the open hemithorax, and surgical retraction all affect normal

Gregory's Pediatric Anesthesia, Sixth Edition. Edited by Dean B. Andropoulos and George A. Gregory.

V/Q matching, primarily because of their effects on lung compliance [3]. OLV uncouples V/Q matching to the operative lung, which may result in significant hypoxemia if not properly managed [3]. These factors apply equally to children and adults.

The lateral decubitus position

When awake, spontaneously breathing adults with unilateral lung disease are placed in the lateral decubitus position, oxygenation is optimal when the healthy lung is dependent ("down") and the diseased lung is non-dependent ("up") [4,5]. Because of the hydrostatic pressure gradient between the two lungs, there is greater perfusion of the dependent, healthy lung than the non-dependent, diseased lung, improving V/Q matching.

Studies suggest that infants, both those breathing spontaneously and those receiving positive pressure ventilation, demonstrate the opposite effect to that seen in adults. Oxygenation is improved with the healthy lung "up" and the diseased lung "down" [6,7]. Ventilation may be distributed differently in infants and adults because the soft, more compliant ribcage in infants cannot fully support the underlying lung. This results in a lower functional residual capacity (FRC), which is closer to residual volume, making airway closure more likely to occur in the dependent lung, even during tidal breathing [8]. In smaller children there is less cephalad displacement of the dependent hemidiaphragm by abdominal organs than in larger subjects, thus in accordance with Starling's law, contraction is less forceful in the dependent hemidiaphragm than in the upper hemidiaphragm, limiting the efficiency of ventilation of the dependent lung. Ventilation is therefore distributed preferentially to the non-dependent lung in infants.

The infant's small size reduces the hydrostatic pressure gradient between the dependent and non-dependent lungs that is seen in the adult. Consequently, the favorable increase in perfusion to the dependent, ventilated lung that is seen during OLV in adults is attenuated in infants. It is not known at what age the adult pattern appears. It is suggested that during the postoperative period the child with unilateral lung disease should be nursed in both lateral decubitus positions, as well as supine, to determine the position of optimal gas exchange.

Pulmonary perfusion during one-lung ventilation

Current lung separation techniques have made it easier to deliver the entire tidal volume to the dependent lung. When OLV is initiated, residual oxygen will gradually be absorbed from the unventilated alveoli until complete absorption atelectasis results. Continued perfusion of the unventilated lung leads to a large increase in V/Q mismatch or shunt fraction in addition to positional effects. This right-to-left shunt through the unventilated lung should result in an overall shunt fraction in excess of 50%. Observed shunt fractions are fortunately much lower. The operation of passive (mechanical) and active (biological) forces accounts for the lower than expected shunt fraction. Surgical manipulation, the effects of the open or artificial pneumothorax, and physical kinking of pulmonary vessels with lung deflation reduce blood flow to the operative lung. In addition, hypoxic pulmonary vasoconstriction (HPV) increases vascular resistance in the unventilated lung, resulting in a gradual decrease in blood flow and shunt fraction. The true clinical importance of HPV has been questioned [9].

Ventilation during one-lung ventilation

Ventilatory management of patients undergoing OLV has long focused on the issue of hypoxia avoidance. Hypoxia, however, has become less frequent because of more effective lung isolation, particularly with the use of fiberoptic bronchoscopy for confirmation of bronchial blocker or double-lumen tube position, and the use of anesthetic agents with fewer or no detrimental effects on HPV. Recent publications have focused on prevention of acute lung injury (ALI) associated with OLV. ALI has been found in 2.45% of lung resections in adults, with a peak incidence of 7.9% after pneumonectomies. It is associated with significant morbidity and a mortality rate around 40% in adults [10]. Similar outcome data are not available in children. Recommendations for protective lung ventilation (PLV) during OLV include: reducing tidal volume to 6 mL/kg with acceptance of mild hypercapnia, limiting the plateau airway pressure to <20 cmH_2O, and 5–10 cmH_2O positive end-expiratory pressure (PEEP) to preserve dependent lung unit aeration, prevent atelectasis, and reduce injury from mechanical stress [11]. Continuous positive airway pressure (CPAP) or oxygen insufflation may need to be added to the operative lung to treat hypoxemia. Resumption of two-lung ventilation with 100% oxygen during surgery may be required to treat severe or refractory hypoxemia. If this is not possible, the surgeon should consider placing a pulmonary artery clamp on the operative side during pneumonectomy or lung transplant.

KEY POINTS: PATHOPHYSIOLOGY OF ONE-LUNG VENTILATION

- In the lateral decubitus position, infants have improved oxygenation with the healthy lung "up" and diseased lung "down" – opposite from adults
- During one-lung ventilation, V/Q mismatch and shunt fraction are less than expected in children due to reduced perfusion of the "up" lung from mechanical factors and probably hypoxic pulmonary vasoconstriction
- During one-lung ventilation, tidal volumes of 6 mL/kg, limiting peak pressure, applying 5–10 cmH_2O PEEP, and oxygen insufflation to the operative lung are recommended

Anesthetic requirements for thoracic anesthesia

One-lung ventilation

There are three principal indications for OLV [12]:

1. To control the distribution of ventilation: bronchopleural (cutaneous) fistulas, gigantic unilateral lung cysts or bullae, and differential lung ventilation.
2. To avoid spillage or contamination: infection, hemorrhage, and unilateral pulmonary lavage.
3. To provide a quiet operative field: thoracoscopy, thoracotomy, and thoracic non-pulmonary surgery.

To facilitate this, there are three basic techniques or devices that are currently widely available to help isolate one lung from the other in the pediatric patient:

1. Selective endobronchial intubation with a conventional single-lumen endotracheal tube.
2. A bronchial blocker.
3. A double-lumen tube (DLT).

In the modern era and with widespread availability of the fiberoptic bronchoscope (FOB), the authors feel that clinicians should strive to directly visualize and verify device placement where possible. The choice of device is dependent upon patient age and size and device availability (Table 26.1, Fig. 26.1).

Endobronchial intubation

The simplest method of isolating one lung involves advancing a standard endotracheal tube (ETT) past the carina and into the desired main bronchus. When passed blindly, the ETT will almost always pass into the right main bronchus.

Table 26.1 Device selection for one-lung ventilation (OLV) in children

Age	OLV airway device
Less than 2 years	Selective endobronchial intubation
	Fogarty catheter (4 Fr) as a bronchial blocker
	Extraluminal wire-guided endobronchial blocker (5 Fr)
2–6 years	Fogarty catheter (4 Fr or larger) as a bronchial blocker
	Wire-guided endobronchial blocker (5 Fr)
6–10 years	Wire-guided endobronchial blocker (5 Fr or larger)
	Univent tube (3.5 ID)
Over 10 years	Wire-guided endobronchial blocker
	Univent tube
	Double-lumen tube (26 Fr or larger)

ID, internal diameter.
Source: Reproduced from Choudhry [15] with permission of Elsevier.

In order to selectively intubate the left main bronchus, the ETT must be rotated so that the bevel faces the right, the patient's head is rotated to the right, and the ETT is advanced [13]. Placement should be confirmed with a FOB, which requires a good working knowledge of the anatomy of the bronchial tree distal to the carina.

An alternative is to place the ETT in the trachea and pass the FOB into the left or right main bronchus before advancing the ETT over it. Note that the smallest size of FOB available is 2.2 mm in diameter and is not rigid enough to withstand aggressive advancement of a rigid ETT without the potential of significant damage to the FOB fibers, so care should be taken when using this scope to guide intubation.

Bronchial blockers

Embolectomy catheter/blocker

Embolectomy catheters are effective in achieving lung isolation in the smallest of patients [14]. The blocker can be positioned either within or alongside the ETT. Fogarty catheters have a central stylet that can be bent to facilitate the catheter being placed in either bronchus whilst being observed with a FOB through the ETT (Fig. 26.2). The open tip of the catheter

Figure 26.2 4 Fr Fogarty catheter within a standard 3.5 endotracheal tube.

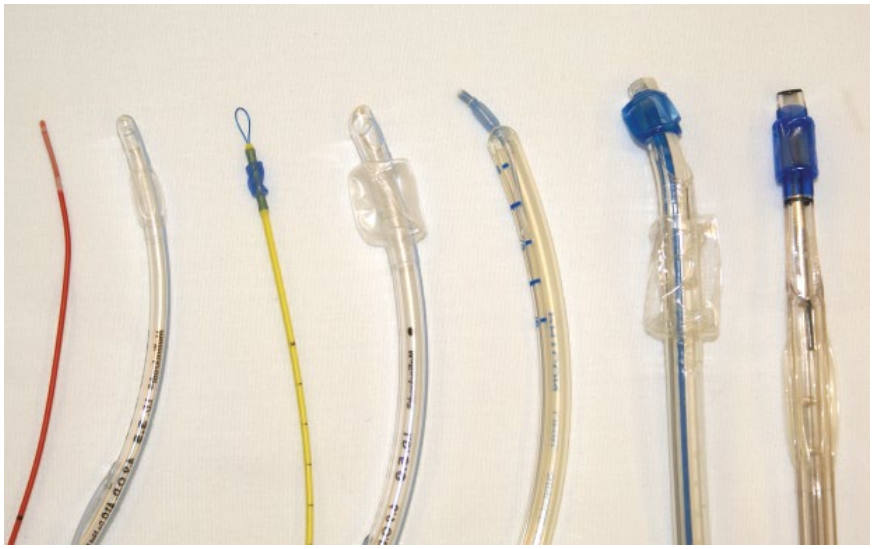

Figure 26.1 The devices available for facilitation of one-lung ventilation in children. Left to right (smallest to largest): 4 Fr Fogarty catheter, endotracheal tube (standard), 5 Fr wire-guided endobronchial blocker, 5.0 endotracheal tube (standard), 3.5 internal diameter Univent tube, 26 Fr (Rusch, Buluth, GA, USA) double-lumen tube (DLT), 28 Fr (Mallinckrodt Medical, St Louis, MO, USA) DLT.

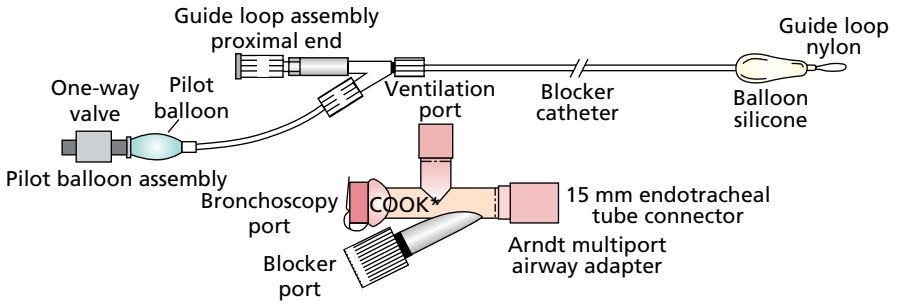

Figure 26.3 The components of the wire-guided endobronchial blocker (WEB).

allows for lung collapse following isolation and insufflation with oxygen if necessary.

Wire-guided endobronchial blocker

Wire-guided endobronchial blockers (WEBs) are available in a "pediatric" size – 5 Fr. The blocker is designed to be placed within a standard ETT, and a guidewire loop attached around the end of a FOB allows direct visualization and placement of the blocker. This device has the benefit of three ports, allowing ventilation while the blocker is manipulated into place (Fig. 26.3). The smallest ETT that can be used with the smallest 5 Fr WEB is a 5.0 mm ETT, hence this device is generally limited to children over 2 years of age (Fig. 26.4).

Bronchial blockers may alternatively be placed alongside (rather than within) an ETT for children under 2 years old. The WEB is prepared with a 35–45° bend just proximal to the occlusive cuff to facilitate maneuvering into the correct position. The WEB may then be placed either nasally or orally into the larynx and the ETT placed alongside the WEB. Employing an ETT 0.5 mm internal diameter (ID) smaller than standard size for the patient facilitates free movement of the WEB. Under fiberoptic visualization through the ETT, the WEB can then be manually directed into the appropriate bronchus. This technique allows use of bronchial blockers in children as young as 3 months old (Figs 26.5–26.8) [15,16].

Univent™ tube and blocker

The Univent tube (Fuji Systems Corporation, Tokyo, Japan) has a second lumen containing a separate bronchial blocker that is styletted and can be bent to facilitate positioning (Fig. 26.9). The smallest size Univent tube is 3.5 mm ID; however, the total external diameter is 8 mm, making it comparable in size to a 6.0 mm ID uncuffed ETT and limiting its use to older children (approximately 8 years of age). There are two main disadvantages to Univent tubes that should be noted: (1) Univent tubes, unlike double-lumen tubes, have a low-volume, high-pressure cuff that may contribute to mucosal injury; and (2) the blocker channel occupies a significant cross-sectional area, leaving a smaller lumen available for ventilation of the patient [17,18].

Double-lumen endotracheal tube

DLTs are considered the gold standard for lung isolation in the adult population; however, the smallest sizes available are a 26 Fr (Rusch, Duluth, GA, USA) and a 28 Fr (Mallinckrodt Medical, St Louis, MO, USA) (Fig. 26.10). These devices can only be realistically utilized in older children (8–10 years of age) and are positioned in the same manner as in adults. Due

to the wide variation in the size of pediatric patients, there are no designated depth measurements for the placement of the DLT, hence its location should be confirmed with a FOB.

Anesthetic techniques

Preoperative evaluation and preparation is important and should be thorough and complete, as in all pediatric operative candidates. Some children will be otherwise completely fit and healthy; others may have significant concurrent and severe systemic illness. Premedication and induction technique is at the discretion of the anesthetic provider and needs to be tailored to the individual [19].

Lung isolation, if required, and analgesic technique should be planned well in advance. The authors advocate arterial line placement for thoracotomy and consideration in VATS, particularly in small infants and babies where the potential for accidental overinflation of the pleural cavity and iatrogenic tension pneumothorax is significant. Lung isolation and deflation should be initiated early, particularly in VATS patients, to allow adequate time for the lung to collapse

KEY POINTS: ANESTHETIC REQUIREMENTS FOR THORACIC ANESTHESIA

- One-lung ventilation (OLV) is indicated to control distribution of ventilation, avoid contamination, and provide a quiet operative field
- OLV can be provided even in small infants, but in these patients the technical difficulty may outweigh any benefits, and a pack and retract technique can be used
- Embolectomy catheters or wire-guided endobronchial blockers may be employed inside or outside the ETT, with fiberoptic guidance, to provide OLV in smaller patients
- Univent ETT and double-lumen tubes can provide OLV in larger patients, with fiberoptic guidance

(up to 20 min) and minimize the need for lung retraction [15]. Once OLV is instituted, the patient should be ventilated with as high a concentration of oxygen as is necessary to achieve adequate oxygen saturation. Nitrous oxide should be avoided to prevent overinflation of tracheal and bronchial balloons leading to airway trauma [20].

There is a perception that isoflurane may be beneficial in decreasing V/Q mismatch during OLV because it is thought to have less impact on HPV than other volatile agents [21]; however these data are limited to older anesthetic vapors, and isoflurane's slow offset time makes it less appealing as a primary anesthetic agent. The rapid offsets of the more recently developed volatile agents, such as desflurane, particularly after a long protracted case, make them very appealing agents for thoracic anesthesia. However, in order to minimize inhibition of HPV, the authors advocate using a maximum of 1 minimum alveolar concentration (MAC) of the chosen volatile anesthetic. In order to ensure that awareness is not encountered, a balanced anesthetic approach is therefore necessary using an adjunct intravenous agent such as propofol that will not impact HPV [22] and/or opiates.

When a short-acting volatile agent such as desflurane is coupled with the profound μ agonism of remifentanil, regional anesthesia, a non-steroidal anti-inflammatory drug (NSAID) and, where available, intravenous acetaminophen/paracetamol at the end of the case, the anesthesia practitioner has a number of tools that can facilitate rapid emergence with a coherent and interactive patient at the end of a major surgical procedure.

Analgesic requirements for thoracic surgery

Thoracic surgery, especially open thoracotomy and minimally invasive pectus excavatum repair, may result in significant postoperative pain. Thoracotomy results in severe chest wall trauma, including fractured ribs and damage to peripheral nerves. The chest wall cannot be immobilized to control this pain. It must remain in constant motion for effective gas transfer to take place, and vigorous motion is required for effective clearing of secretions. Shallow respirations and a poor cough predispose the child to atelectasis, sputum retention, and postoperative pneumonia. Sensitization to painful stimuli can cause chronic pain and/or higher pain levels during subsequent surgical procedures. Recent studies suggest that around one-third of adult patients suffer from chronic pain after thoracic surgery, with similar incidence for thoracotomy or VATS [23–26]. The incidence is likely somewhat lower in children [27].

Some surgical literature suggests that children should understand "that they are going to have to learn to be comfortable with being uncomfortable" [28]. The authors would contest this statement and contend that it is the anesthesiologist's responsibility to offer his or her patients optimal pain relief. The authors agree with Suresh, who asked the question: "If placing a thoracic epidural catheter in adults is considered the 'standard of care' in many institutions across the country, why is the child deprived of the same privilege?" [29].

Various pain treatment modalities have been described to treat post-thoracotomy pain, but when the factors influencing the generation of post-thoracotomy pain are considered,

regional analgesia is the most logical approach [30]. This is because neurogenic pain, which results from intercostal nerve damage as well as chest wall trauma, and central nervous system hyperexcitability are both known to be poorly sensitive to opioids [31,32]. Reliance on these drugs may have detrimental effects on respiration and oxygenation [33,34]. In order to achieve the optimal effect, it is logical to start the regional analgesic regimen preoperatively [35]. A multimodal analgesic approach combining an effective afferent nerve block with a NSAID, acetaminophen/paracetamol, and low doses of opioids is expected to achieve an optimal level of postoperative analgesia. Although regional anesthesia is addressed in Chapter 20, several regional techniques deserve emphasis in a discussion of anesthesia for thoracic surgery.

Epidural analgesia

In contrast to older children and adults, epidural and subarachnoid blockade in infants and children under the age of about 6 years is characterized by hemodynamic stability, even when the level of the block reaches the upper thoracic dermatomes [36]. Although heart rate variability is lower, heart rate is preserved, because the parasympathetic activity modulating heart rate appears to be attenuated in infants [37]. This attenuated vagal tone allows the heart rate to compensate for peripheral vasodilation. Other factors playing a role in the preservation of hemodynamic stability are the relatively small venous capacitance in the lower extremities of infants, and the relative lack of resting sympathetic peripheral vascular tone [38].

Thoracic epidural blockade has been shown to improve several measures of respiratory function [39–41]. There is evidence to suggest that improved postoperative tidal volume and diaphragmatic shortening after thoracic epidural blockade may be due to changes of chest wall conformation and diaphragmatic resting length, and a shift of the workload of breathing from the ribcage to the diaphragm, caused by motor block of intercostal muscles [42].

In infants, thoracic catheter placement can be achieved via the caudal space with cephalad threading of a styletted catheter [43]. Although successful application of this technique has been described in children up to 10 years of age [44], in children over the age of 1 year there is an increased chance of the catheter exiting a dural sleeve or becoming knotted or tangled [45,46]. Epidurograms [47], epidural electrocardiography [48], and electrical stimulation [49] have been used to confirm catheter tip positioning at the desired level. As clinicians gain confidence in the use of ultrasound for regional anesthesia, it is becoming the modality of choice for the visualization of the epidural catheter tip [50–53]. Ultrasound localization is non-invasive, avoids exposure to radiation and contrast medium, and is not affected by the use of neuromuscular blocking drugs or epidural local anesthetics.

Epidural placement near the dermatomal level of the surgical incision(s) allows the safest and most effective application of local anesthetics. A thoracic epidural catheter has less risk of contamination by stool and urine than a caudally placed catheter. Thoracic epidural catheters may be safely placed in anesthetized infants and children by experienced anesthesiologists [54]. A prospective study from the French-Language Society of Pediatric Anesthesiologists found no lasting complications in over 10,000 epidural blocks [55]. Another recent study from the Pediatric Regional Anesthesia Network (PRAN) demonstrated no deaths or sequelae lasting longer than 3 months in nearly 3000 epidural catheters [56].

Paravertebral analgesia

The paravertebral space is wedge shaped. Its boundaries are: posteriorly, the superior costotransverse ligament; laterally, the posterior intercostal membrane; anteriorly, the parietal pleura; and medially, the posterolateral aspect of the vertebrae, intervertebral disks, and intervertebral foramen. The space contains spinal nerves and dorsal rami, rami communicantes, and anteriorly, the sympathetic chain. Injection of local anesthetic into the paravertebral space avoids possible complications of central neuraxial blockade.

Paravertebral block (PVB) has been employed in children since 1992, when two different techniques were described: Lönnqvist's modification of the original Eason–Wyatt percutaneous catheter technique [57] and Eng and Sabanathan's surgical catheter placement during thoracotomy [58]. More recently, ultrasound-guided techniques have been described and are becoming increasingly popular [59]. The main indication for thoracic PVB is unilateral thoracic surgery. Continuous infusion is possible via a catheter placed transcutaneously or surgically via thoracotomy. A rate of 0.25 mL/kg/h is recommended [57,60–62]. The advantage of a PVB is that deposition of local anesthetic into the paravertebral space will lead to a unilateral block of one or more adjacent dermatomes. Because all the effects of PVB are unilateral, hypotension, which limits the dosage of local anesthetic used in epidural analgesia in children over the age of 6 years, is rarely a problem. Relatively large doses of drug can therefore be used with a consequent improvement in efficacy of the unilateral blockade. The sympathetic chain that is known to be important in pain transmission is reliably blocked by PVB, whereas the central sympathetic blockade produced by epidural and spinal anesthesia leaves this pathway unaffected, thereby allowing central relaying of information (bypassing the blockade) [63]. Confirmation of the lack of provision of high-quality afferent blockade with epidural analgesia is shown by its failure of inhibition of somatosensory-evoked potentials and the failure of stress inhibition for any surgery more rostral than gynecological, or more distal surgery [64,65]. There are far fewer PVB data for comparison, but thoracic somatosensory-evoked potentials have been shown to be abolished [66] and some parameters of the stress response have been inhibited [35,67].

Intercostal analgesia

Intercostal blocks after thoracotomy and in children with rib fractures can reduce opioid requirements and improve respiratory function [68–70]. The disadvantage of single-shot blocks is their limited duration of action. The development of degradable bupivacaine microspheres, which produce dramatically prolonged duration of action, may increase the usefulness of these blocks in the future [71,72]. Plasma concentrations of local anesthetics after intercostal blocks are greater than after any other regional block. Plasma concentrations rise faster in children than in adults [73,74].

A continuous infusion of local anesthetic via an extrapleural catheter, placed during thoracotomy wound closure by the

surgeon, can prolong the analgesic effect [69]. The infusion may have an analgesic effect by delivering local anesthetic to the paravertebral space [75].

Summary

How can clinicians decide which regional analgesic technique to use in thoracic surgery in children? A meta-analysis of 10 trials that had enrolled 520 adult patients concluded that PVB and epidural analgesia provide comparable pain relief after thoracic surgery, but PVB has a better side-effect profile and is associated with a reduction in pulmonary complications [76].

For adult thoracic surgery, the Procedure-Specific Postoperative Pain Management (PROSPECT) Working Group evaluated the available literature comparing various regional analgesic techniques for the management of post-thoracotomy pain [77]. Seventy-four randomized studies in thoracotomy were identified that compared regional analgesic techniques with systemic opioid analgesia or with each other. The Working Group concluded that evidence supported the use of thoracic paravertebral block as an effective alternative to thoracic epidural local anesthetic (LA) alone, and showed that PVB reduced the incidence of postoperative pulmonary complications compared with systemic analgesia. They suggested that further studies were required to determine whether thoracic PVB is equivalent to thoracic epidural combining LA plus opioid in terms of pain relief and morbidity. Apart from thoracic PVB, all other regional analgesic techniques were inferior to thoracic epidural analgesia. In particular, interpleural techniques do not provide adequate analgesia. However, when thoracic epidural or paravertebral techniques are not possible or are contraindicated, intercostal nerve block or preoperative intrathecal opioid is recommended.

KEY POINTS: ANALGESIC REQUIREMENTS FOR THORACIC SURGERY

- Chronic pain is common after thoracotomy; a multimodal approach to analgesia may be preventative
- Epidural, paravertebral, or intercostal analgesia can be provided for thoracotomy pain
- A caudal approach with the catheter threaded to the thoracic regions is effective in small infants, with epidurogram, electrocardiogram, electrical stimulation, and ultrasound useful for proper placement

Thoracoscopy

The field of minimally invasive surgery (MIS) is the fastest growing area of surgical innovation. Each year, as new techniques and tools are developed, more patients benefit from surgical procedures previously associated with a significantly more invasive approach. Thoracoscopy has several potential advantages over thoracotomy for resection or repair of intrathoracic abnormalities in children. Scoliosis develops in up to 30% of neonates after thoracotomy [78]. In addition, thoracoscopy appears to be associated with decreased pain and better pulmonary mechanics postoperatively and improved cosmesis when compared to thoracotomy. Shorter hospital stays, a faster return to normal activity, and a shorter recovery period are just a few of the advantages that MIS offers to pediatric patients.

Box 26.1: Thoracoscopic procedures in infants and children

- Diagnostic thoracoscopy
- Lung biopsy
- Pectus repair
- Empyema drainage
- Lung decortication
- Bronchopulmonary sequestration resection
- Congenital pulmonary airway malformation resection
- Lobar emphysema resection
- Bronchogenic cyst excision
- Esophageal duplication resection
- Congenital diaphragmatic hernia repair
- Esophageal atresia and tracheo-esophageal fistula repair
- Thymectomy
- Aortopexy
- Vascular ring division
- Patent ductus arteriosus (PDA) ligation
- Thoracic duct ligation
- Sympathectomy
- Mediastinal mass excision
- Anterior spinal fusion

Originally, VATS was developed to provide biopsy specimens of thoracic structures in immunocompromised patients when a definitive diagnosis otherwise could not be obtained [79]. Although VATS continues to be used widely for this indication in pediatric patients, an increasing number of pediatric surgical conditions also are being addressed using a thoracoscopic approach (Box 26.1).

With the advances in thoracoscopic equipment, including the availability of smaller scopes and improvements in fiberoptics and the quality of digital video signals and screen resolution, these techniques are being applied to younger and younger children, and even to neonates and infants.

Blood loss during thoracoscopic surgery is generally minimal; however, adequate venous access should be secured prior to the start of these procedures because of the possibility of inadvertent injury to intrathoracic vascular structures by one of the trocars or endoscopic instruments. Because these procedures are routinely performed in the lateral decubitus position, access to the extremities to obtain additional venous access during the procedure can be limited. Standard perioperative monitoring includes pulse oximetry, electrocardiogram, end-tidal CO_2 and inhaled volatile agent concentration, non-invasive blood pressure measurement, and temperature.

In patients with normal cardiovascular function, routine monitoring of central venous pressure offers little additional information to improve or influence anesthetic care. Central venous access generally is reserved for cases in which adequate peripheral intravenous access is unavailable. Invasive monitoring of arterial blood pressure is not routinely used but is guided by the clinical status of the patient.

OLV is highly desirable during thoracoscopy because lung deflation improves visualization of thoracic contents and may reduce the risk of lung injury caused by the use of retractors. If OLV cannot be achieved, thoracoscopy can be performed

during two-lung ventilation using CO_2 insufflation and placement of a retractor to displace lung tissue from the operative field [80]. This technique also can be used to improve visualization if there is an inadequate separation of the two lungs with overflow ventilation into the operative side. Cardiopulmonary function should be monitored during the creation of the artificial pneumothorax because the displacement of intrathoracic contents and creation of an excessive pneumothorax related either to excessive volume or pressure can lead to significant cardiovascular compromise resulting from decreased venous return or increased left ventricular afterload. The effects of the artificial pneumothorax can be minimized by slowly adding the CO_2 (flow rate 1 L/min), limiting the inflating pressure to 4–6 mmHg, and optimizing cardiovascular function, including the optimization of myocardial contractility (if required) and restoration of intravascular status [81]. The other significant risk during the creation of the artificial pneumothorax is inadvertent CO_2 embolism [82]. CO_2 embolism can occur from the entry of the insufflating gas into the circulation either from direct injection during insufflation into the vasculature or from the entry of the gas, which is under pressure in the hemithorax, into an internal vessel that has been damaged during the procedure [83].

Comparative analysis of outcomes of VATS versus open thoracotomy has been limited to retrospective comparative studies [84]. A systematic analysis of 21 studies found that five scenarios had been studied: repair of congenital diaphragmatic hernia (CDH), esophageal atresia/tracheo-esophageal fistula (EA/TEF) repair, lung resection, treatment of pneumothorax, and resection of neuroblastoma. The level of evidence was 3 on the Oxford Center for Evidence Based Medicine Scale of 1–5. Advantages of VATS included less postoperative pain for CDH, EA/TEF, and pneumothorax; shorter hospital stay for all conditions except neuroblastoma; shorter ventilation time and lower $PaCO_2$ for CDH; shorter chest drain duration for lung resection; and less blood loss for neuroblastoma. However there were some disadvantages to VATS, including higher recurrence rates for CDH, higher $PaCO_2$ for EA/TEF, and longer operative times for CDH and EA/TEF.

Robotic surgery

The field of robotic surgery continues to progress, and robotic instruments increasingly are considered for implementation in pediatric surgery because of their ability to articulate, increasing surgeon dexterity while working in small spaces. Although robotic thoracic surgery use in children is infrequent, there are a few literature reports demonstrating feasibility and safety for some conditions, including thymectomy, EA, cyst resection, and diaphragmatic hernia. Small patients, including neonates, are included in case series [85,86]. Articulated tools and a three-dimensional optical stereoscopic view make the procedure more similar to an open procedure for the surgeon, using all the advantages of traditional thoracoscopy. Good preoperative communication with the surgeon is essential to plan for positioning of the operating room table within the operating room, positioning of the operating robot to allow the anesthesia providers to gain good access to the child's airway, and positioning of the child on the operating table. It is of enormous benefit to perform robotic surgery in a dedicated operating room with staff who are experienced in the management of robotic surgery cases [87].

KEY POINTS: THORACOSCOPY AND ROBOTIC SURGERY

- Video-assisted thoracoscopy (VATS) can be utilized for essentially any thoracic operation for which open thoracotomy would be used
- OLV is desirable for VATS; however CO_2 insufflation with lung retraction can be used if OLV is not feasible
- VATS results in less postoperative pain and shorter hospital stay than thoracotomy
- Robotic thoracic surgery may be used increasingly in pediatric patients in the future

Lung resection

In developed countries, the age of children undergoing pulmonary resection has steadily decreased over the last decades, reflecting a decline in such procedures performed for infectious etiologies and a rise in resections performed for congenital malformations. An understanding of normal lung growth in the postnatal period is essential to predict pulmonary function after lung resection in children. It is well established that alveoli multiply after birth [88]. The number of alveoli rises from approximately 20×10^6 at birth to approximately 300×10^6 by the age of 8. The most rapid increase in the number of alveoli occurs during the first 3 years of life. After 8 years of age, the number of alveoli remains constant. The lung volume doubles between the ages of 8 and 25, which can be accounted for by the increase in the volume of individual alveoli [89].

Lobectomy

Pulmonary resection in an adult leads to a proportional decrease in lung volume; however, case series evaluating pulmonary function after lung resection performed during infancy point out that these patients develop normally, live normal lives, and have no physical impairment at rest. McBride et al [90] evaluated pulmonary function of 15 patients who had undergone lobectomies for congenital lobar emphysema as infants between 1 week and 3 years of age. They found the vital capacity and total lung capacities to be within the normal range in the vast majority of these patients after a follow-up period of 8–30 years. However, they observed an association between the resected anatomical portion and the extent of compensatory growth. The most vigorous compensatory growth was seen after upper lobectomies. This could be related to elevation of the hemidiaphragm after lower and middle lobectomies. In addition, normal residual volumes in these patients are a further indication that the compensatory growth was consistent with multiplication of alveoli.

Pneumonectomy

Early studies described preserved pulmonary function after pneumonectomies performed during childhood. In 1947, Cournard [91] reported outcomes of four patients who had

undergone left pneumonectomies for pulmonary infections between the ages of 6 and 16 years. It was observed that the total lung capacity for the remaining lung was greater than would have been predicted for the right lung of an individual without a history of pulmonary resection. In three of the four patients, the vital capacity was greater than the predicted value for a right lung.

Laros and Westermann [92] stratified a population of 130 pneumonectomy patients by age at the time of their operation. Preservation of total lung capacities decreased with increasing age at the time of the pneumonectomy. The total lung capacity was 96% of the predicted value in patients who were younger than 5 years at the time of their pneumonectomy, and 85% of predicted in patients between 6 and 20 years of age, but only 70% of predicted in patients between 31 and 40 years of age.

Postpneumonectomy syndrome

The postpneumonectomy syndrome is associated with progressive hyperinflation of the remaining lung and typically leads to progressive dyspnea. It can also lead to the development of bronchomalacia and can predispose to pulmonary infections. Postpneumonectomy syndrome is most commonly seen after a right pneumonectomy [93]. It is associated with counterclockwise rotation of the mediastinal structures, which leads to compression of the left mainstem bronchus or left lower lobe bronchus between the aorta and spine posteriorly and the pulmonary artery anteriorly. Postpneumonectomy syndrome can also be encountered after a left pneumonectomy when a right-sided aortic arch is present, and the airway is compressed between ascending and descending aorta [94]. However, this complication has also been reported after a left pneumonectomy in patients who have a left-sided aortic arch [95]. In this case, the bronchus intermedius is thought to be compressed between the right pulmonary artery anteriorly and the thoracic spine posteriorly after clockwise rotation of the mediastinal structures into the right pleural cavity.

Early attempts to prevent mediastinal shifts after pneumonectomies in children included thoracoplasties, which were eventually abandoned because of resulting crippling deformities. Other attempts to prevent mediastinal shifts in the past included instillation of inert substances such as oil into the pleural cavity. The principles of treating this syndrome today include a combination of anterior pexy of mediastinal structures such as pericardium and pulmonary artery, and an intervention in the postresection pleural cavity to prevent future shifting [96]. For many years, rigid prostheses such as Silastic testicular or breast prostheses were placed in the pleural cavities to stabilize the mediastinum [97]. One shortcoming of this method is the inability to adjust the size of the prosthesis in a growing child. In 1992, Kosloke and Williamson [98] first reported the use of expandable tissue-expander prostheses in an effort to address this problem. Finally, placement of endobronchial stents has been reported, mostly in adults.

Thoracic surgical lesions

Thoracic surgery in neonates is primarily performed to treat congenital pulmonary anomalies such as congenital cystic lesions, CDH, and TEF. These anomalies often present *in utero* or in the newborn period. Others, such as neoplasms, infectious diseases, and musculoskeletal deformities are found in later childhood. CDH and TEF are described in Chapter 23, but the remainder of the surgical lesions affecting infants and children are reviewed here, along with specific anesthetic considerations (Table 26.2).

Congenital cystic lung disease

Of the many types of congenital cystic lesions, the overwhelming majority can be categorized into four groups: congenital cystic adenomatoid malformation (CCAM), bronchopulmonary sequestration (BPS), congenital lobar emphysema (CLE), and bronchogenic cyst (BC). These malformations have distinct features but there is significant overlap, suggesting there may be a single pathological mechanism for their development [99]. Of note, CCAM is more correctly termed CPAM (congenital pulmonary airway malformation) since many are neither cystic nor have adenoid tissue [100], and will henceforth be referred to as CPAM in this text.

Cystic lung lesions are often identified around 20 weeks' gestation, when they are found on routine fetal ultrasound [101]. Management in a fetus depends on the lesion itself as well as the status of the fetus and mother. Large lesions may cause compression of the esophagus, lung, or vena cava, resulting in polyhydramnios, pulmonary hypoplasia, or low-output cardiac failure and fetal hydrops, respectively. With evidence of fetal hydrops, intervention options include thoracocentesis, thoracoamniotic shunting, open fetal surgery and resection, *ex utero* intrapartum therapy and resection (EXIT procedure), or early delivery with postnatal resection. For a fetus greater than 32 weeks' gestation, resection during EXIT procedure is recommended, while in those less than 32 weeks' gestation there is an option for intrauterine surgery [102]. Anesthesia for fetal surgery and EXIT procedure is discussed in Chapter 21.

Small lesions may be asymptomatic or cause respiratory distress in the newborn period. Initially asymptomatic lesions may lead to infection, pneumothorax, or malignant degeneration later in life. Serial imaging has revealed, however, that many large lesions may actually decrease in size [103,104]. Postnatal presentation depends on the size, location, and type of lesion as well as any communication with the gastrointestinal tract or bronchopulmonary tree. Pulmonary hypoplasia can lead to pulmonary hypertension and respiratory failure and may need extracorporeal membrane oxygenation (ECMO). Many lesions can remain asymptomatic and undiagnosed for many years. Almost all patients will eventually develop complications, most often presenting as pneumonia unresponsive to medical management.

Patients with prenatally diagnosed lesions should have a computed tomography (CT) scan of the chest after birth. In a patient not identified prenatally who presents in respiratory distress after birth, chest radiography is the first diagnostic test, with confirmatory studies such as CT to follow (Figs 26.11, 26.12). Occasionally, magnetic resonance imaging (MRI) and bronchoscopy may be necessary. CPAM, CLE, and extralobar BPS are occasionally associated with other congenital anomalies and may necessitate additional preoperative work-up, including echocardiography [99].

Table 26.2 Pediatric thoracic lesions

Lesion	Evaluation	Treatment	Anesthetic considerations
Tracheal stenosis			
Acquired	Laryngoscopy/ bronchoscopy	Cricoid split	TIVA
Congenital	Laryngoscopy/ bronchoscopy	Laryngotracheoplasty	TIVA, postoperative ventilation
Congenital cystic lung disease			
Congenital pulmonary airway malformation	CT	VATS versus thoracotomy	Minimize inflating pressure, avoid N_2O
Bronchopulmonary sequestration	CT, MRI	VATS versus thoracotomy	Minimize inflating pressure, avoid N_2O
Congenital lobar emphysema	CT	VATS versus thoracotomy	Spontaneous ventilation, N_2O contraindicated
Bronchogenic cyst	CT	VATS versus thoracotomy	Minimize inflating pressure, avoid N_2O
Congenital diaphragmatic hernia	CXR	Replace abdominal contents Repair defect	Decrease PVR, minimize inflating pressure, avoid N_2O, may need nitric oxide, HFOV, ECMO
Tracheo-esophageal fistula	CXR	Repair defect	Minimize inflating pressure, occlude fistula with ETT or blocker
Neoplasms			
Mediastinal	CT, MRI, PFTs	Needle or open biopsy, resection	Respiratory and/or cardiovascular collapse, possible OLV
Thoracic	CT, MRI	VATS versus thoracotomy	OLV, effects of chemotherapy and/or radiation therapy
Pectus excavatum	CXR, CT, PFTs, echocardiogram	Nuss versus Ravitch	Postoperative analgesia
Scoliosis	CXR, PFTs	Spinal fusion	Possible OLV with anterior fusion
Empyema	CXR, CT, pleurocentesis	Thoracostomy versus VATS or thoracotomy	Possible OLV

CT, computed tomography; CXR, chest X-ray; ECMO, extracorporeal membrane oxygenation; ETT, endotracheal tube; HFOV, high-frequency oscillatory ventilation; MRI, magnetic resonance imaging; OLV, one-lung ventilation; PFTs, pulmonary function tests; PVR, pulmonary vascular resistance; TIVA, total intravenous anesthesia; VATS, video-assisted thoracic endoscopy.

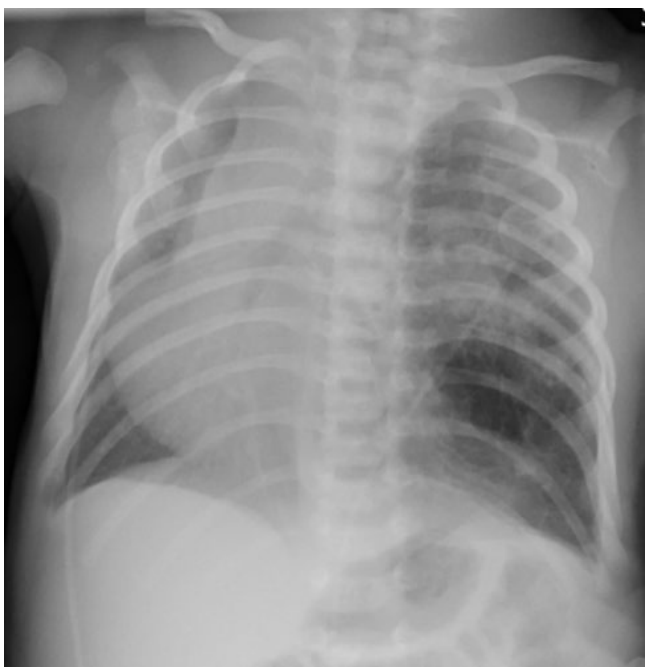

Figure 26.11 Chest radiograph of a newborn with congenital pulmonary airway malformation (CPAM).

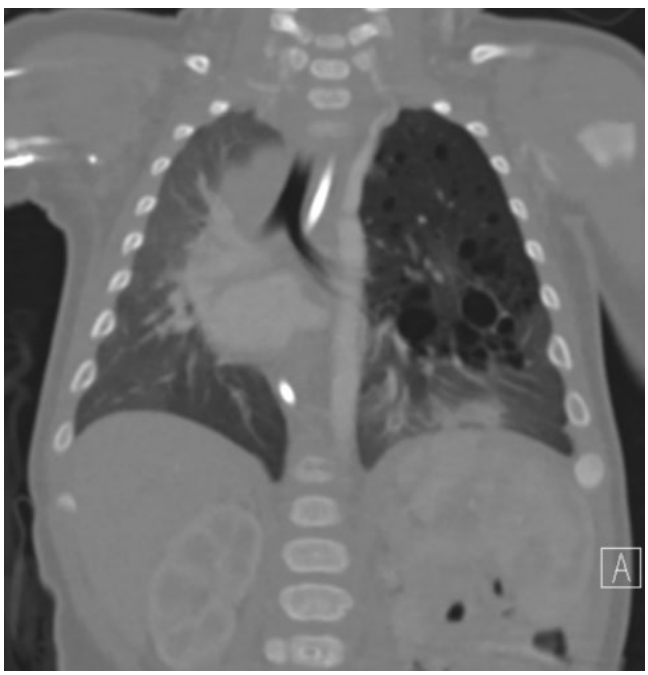

Figure 26.12 Chest CT of a newborn with congenital pulmonary airway malformation (CPAM).

Although there is consensus that all symptomatic lesions should be resected, there is some debate whether asymptomatic lesions should merely be observed. CPAMs and BPS sometimes resolve spontaneously on fetal ultrasound, but there is no evidence that this occurs after birth.

Pulmonary lesions that become undetectable by fetal US and postnatal radiograph may be visible postnatally on CT Asymptomatic CPAMs that were followed conservatively had complication rates of 10% requiring surgery [103]. It is therefore still recommended that CPAM, intralobar BPS, and

BC are resected between 3 and 6 months of age. Extralobar BPS can remain asymptomatic for life but can also result in complications. A period of observation has been advocated [101]. Asymptomatic CLE may resolve spontaneously and should be observed. The preferred surgical approach in recent years has been thoracoscopic lobectomy for most lesions, with repeat CT imaging just before the time of elective resection at age 6 months for asymptomatic lesions [105].

When anesthetizing neonates with congenital lung lesions, it is important to determine if positive pressure ventilation (PPV) will be tolerated. PPV in lesions that contain a bronchial connection to abnormal lung parenchyma could result in overdistension of the abnormal lobe with compression of normal lung tissue due to a ball-valve effect. This can lead to compromised ventilation, mediastinal shift, compression of the great vessels, and decreased cardiac output. If there is doubt as to the bronchial connections of the thoracic lesion, spontaneous ventilation during induction and maintenance of anesthesia is indicated. If OLV is planned, once the affected lung is isolated, PPV and neuromuscular blockade can be safely used. Postoperative analgesia can be in the form of intravenous opioids or, preferably, a thoracic epidural catheter, either placed directly at the desired level or threaded from the caudal canal. Recently, more congenital lung lesions have been resected using VATS. While this technique is challenging in the infant population and results in significantly longer operative time, it is safe and may reduce hospital stay [106].

Congenital pulmonary airway malformation

A CPAM is a discrete intrapulmonary mass that may be solid or contain cysts, and is typically characterized by increased adenomatous respiratory bronchioles (see Chapter 21). Cysts can be of various sizes, from 1 mm to over 10 cm. Although the lesion is non-functional, it does communicate with the normal tracheobronchial tree and can lead to air trapping during PPV [102]. CPAM is usually found only in one lobe; it occurs in all lobes with equal frequency. When it does involve more than one lobe it may require pneumonectomy. Associated anomalies are uncommon.

CPAMs are usually detected *in utero* by ultrasound (see Chapter 21). They can rarely result in pulmonary hypoplasia, hydrops fetalis, or fetal demise. Most CPAMs are asymptomatic and are resected electively in the neonatal period. Those that cause cardiac or respiratory distress may necessitate emergency resection either in the immediate postnatal period or by EXIT procedure [102].

Although there is a communication between the lesion and the tracheobronchial tree, CPAMs are usually solid or have small cysts, acting more like solid lesions and allowing for safe use of PPV. Most lesions can be resected without lung isolation, but if necessary OLV can be accomplished by mainstem intubation. Intraoperative and postoperative pain management can be accomplished with good results using an epidural catheter [107].

Bronchopulmonary sequestration

A BPS is a portion of non-functioning lung tissue without a bronchial connection. It typically has an anomalous blood supply, arising from bronchial or aortic vessels, and has systemic, bronchial, or azygous venous drainage. BPS is usually found in the lower lobes with the majority being intralobar (inside lobe pleura) while the rest are extralobar (with their own pleura). BPS can be confused with CPAM, and some lesions are considered "hybrid," having features of both BPS and CPAM.

BPS is often diagnosed *in utero*. Detection of a systemic artery from the aorta to fetal lung tissue by color flow Doppler is pathognomonic for BPS [103]. At birth, most BPS are asymptomatic and present later in life as pneumonia resistant to antibiotic therapy. Sometimes, when a BPS is large, it can compress the lungs and lead to respiratory distress. If it has a large blood supply it can also lead to high-output heart failure. BPS can be diagnosed using CT, but MRI can be helpful to map the blood supply and drainage before surgical resection.

There are few unique anesthesia concerns. OLV is helpful for surgical resection, but because there is no connection between a BPS and the bronchial tree, PPV is safe. However, nitrous oxide can cause expansion and should be avoided.

Congenital lobar emphysema

CLE is an abnormally emphysematous pulmonary lobe that communicates with the bronchial tree. It is most common in the left upper lobe, followed by the right middle lobe and the left lower lobe, and can be distinguished from other cystic lesions by ultrasound. It often enlarges before 28 weeks' gestation because of fetal lung fluid trapping, similar to air trapping found postnatally. After this time, it may regress and may look like normal lung tissue at birth [102].

Even though they are usually asymptomatic, it is important that patients with CLE are carefully evaluated at birth because they are at risk of air trapping of the emphysematous lobe. Overinflation may ultimately lead to "tension emphysema" and compression of the contralateral lung [108]. At this stage CLE can be confused with tension pneumothorax and a chest tube may be inappropriately placed, leading to further respiratory distress. Large lesions may lead to decreased cardiac output and eventually cardiac collapse. These patients need emergent thoracotomy and rapid lobe exteriorization.

The primary anesthetic concern is to avoid overdistension of the affected lung tissue (Fig. 26.13). PPV can lead to rapid expansion of the lesion due to a ball-valve effect, so an effort to maintain spontaneous ventilation should be made. If PPV is necessary, low inflating pressures should be used. OLV is typically necessary for isolation of the affected area, and once initiated it is also safe to switch to PPV. Nitrous oxide should be avoided throughout the case. At the end of the procedure two-lung ventilation is instituted to check for air leaks at the resection site. Patients should be extubated early or, if they remain intubated, allowed to breathe spontaneously to avoid air leak. VATS has been described for resection of cystic lesions, but is more challenging with CLE [104]. As with other congenital cystic lesions requiring thoracotomy, pain is well controlled with a thoracic epidural.

Bronchogenic cyst

BCs are usually mediastinal, solitary, unilocular cysts filled with air, fluid, or mucus. They do not communicate with the bronchopulmonary tree and therefore, like BPS, pose few additional anesthetic concerns. PPV can be used, and some authors have even reported the safe use of nitrous oxide [109].

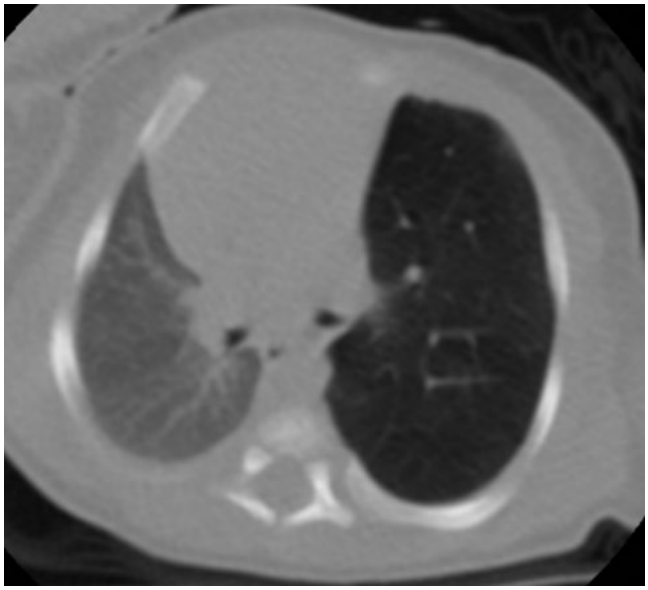

Figure 26.13 Chest CT of an infant with congenital lobar emphysema complicated by hyperinflation and mediastinal shift.

KEY POINTS: LUNG RESECTION AND THORACIC SURGICAL LESIONS

- Because of ongoing lung growth, lobectomy in infants and young children often results in normal lung function
- Congenital pulmonary airway malformation, bronchopulmonary sequestration, congenital lobar emphysema, and bronchogenic cyst comprise the majority of cystic lesions in children
- All symptomatic lesions are resected; asymptomatic lesions may be observed for 3–6 months; most are resected by age 6 months

Anterior mediastinal mass

Anesthetizing children with anterior mediastinal mass can be associated with a high risk of morbidity and even mortality [110–113] as a result of cardiovascular and/or respiratory collapse. Fortunately, over the past several decades as anesthesiologists have become more aware of these risks and perioperative management has improved, the reported morbidity and number of fatalities have decreased [114].

Mediastinal masses can be located in the anterior, middle, or posterior mediastinum. While this designation is somewhat arbitrary and there is some overlap, those masses in the anterior mediastinum cause the most severe complications in relation to general anesthesia [115]. An anterior mediastinal mass may be caused by several types of tumors, most commonly neuroblastoma in young children and lymphomas (Hodgkin and non-Hodgkin) in adolescents [116]. Other tumors include germ cell tumors, thymoma, bronchogenic cyst and carcinoma, granuloma, and cystic hygroma [114]. A biopsy diagnosis is necessary to guide chemotherapy, radiation therapy, and/or surgical resection. Biopsy is usually accomplished with CT guidance; however, surgical biopsy through the mediastinum or thorax may be necessary.

While most adults with anterior mediastinal mass will be asymptomatic, 70% of children will manifest symptoms [117]. Typical symptoms include dyspnea, cough, and stridor. Children may prefer to sleep in the lateral, semi-erect, or even upright position. Symptoms that may be associated with increased risk of anesthetic complications include orthopnea, upper body edema, or compression of trachea, bronchus, or great vessels [113,116,118,119].

Imaging of the mass is mandatory before an elective anesthetic. Chest radiograph may reveal a widened mediastinum, but CT is needed to demonstrate the size of the mass and the presence and severity of tracheal or great vessel compression (Figs 26.14–26.16). Angiography or echocardiography may be indicated for further evaluation of vascular compression. Greater than 50% compression of the trachea is associated with obstruction during induction of anesthesia [118]. The size of the tumor, as defined by mediastinal mass ratios, equal to the maximal width of the mass divided by the maximal

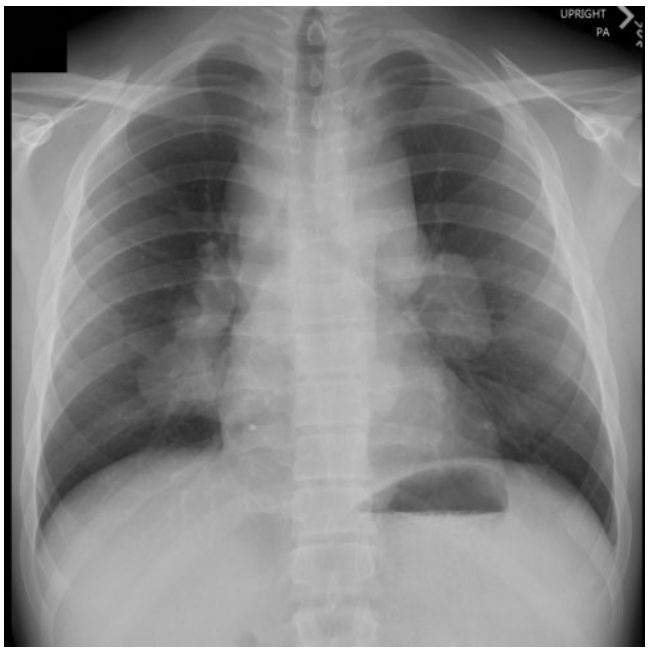

Figure 26.14 Chest radiograph of a 7-month-old patient with anterior mediastinal mass.

Figure 26.15 Chest CT of a 7-month-old patient with anterior mediastinal mass, showing compression of the trachea.

Figure 26.16 Chest CT of a 10-year-old patient with anterior mediastinal mass. There is no visible compression of the trachea.

width of the thorax, has also been shown to correlate with tracheal compression and the development of airway obstruction [110]. One risk stratification system is displayed in Table 26.3 [120].

Pulmonary function tests (PFTs) are commonly ordered with the thought that a decreased peak expiratory flow rate (PEFR) or an increased mid-expiratory plateau when changing from upright to supine position is indicative of variable intrathoracic airway obstruction and a risk for airway collapse during induction of anesthesia [114,121]. Most studies fail to show any correlation between PFTs and degree of airway narrowing [118,121,122] or correlation between a decrease in any specific preoperative PFT and postoperative morbidity [123]. However, flow-volume studies may demonstrate dynamic compression of the airways which may not have been identified on CT.

The first consideration in determining an anesthetic plan is whether the proposed procedure is diagnostic or therapeutic. Diagnostic procedures such as bone marrow biopsy or CT- or ultrasound-guided biopsy of peripheral lymph nodes can be done with local anesthesia alone or with minimal sedation in most children. Ketamine (along with an antisialogog) has the advantage of maintaining hemodynamics in patients with cardiovascular compromise. Respiratory complications are still common, however, even when general anesthesia is avoided [116]. Elective procedures requiring general anesthesia should be delayed until chemotherapy and/or radiation has reduced the size of the mediastinal mass. If tissue diagnosis is necessary prior to chemo/radiation therapy, efforts to proceed under local anesthesia should be made [124]. Therapeutic procedures obviously necessitate general anesthesia.

Anesthesia protocols developed for anterior mediastinal masses in adults [125], using techniques such as awake fiberoptic intubations, are not practical in pediatric patients [121,126] and are dependent on available resources such as cardiopulmonary bypass and radiation therapy. There are, however, anesthetic strategies that can be generally applied (Fig. 26.17).

Before proceeding with general anesthesia, equipment and personnel should be immediately available to perform rigid bronchoscopy. Induction of general anesthesia should be done while maintaining spontaneous ventilation. This can be accomplished by inhalation induction with a volatile anesthetic. The addition of CPAP may help maintain airway patency and prevent atelectasis. Some patients may require induction in the semi-reclined or upright position. Because the loss of airway muscle tone can lead to complete airway obstruction, negative thoracic airway pressure should be maintained and neuromuscular blocking agents should be avoided. Intubation should be accomplished while maintaining spontaneous ventilation.

In the event of airway collapse, maneuvers that may help alleviate obstruction include:

- changing the position of the patient to lateral, recumbent, or prone
- intubating the patient or advancing the endotracheal tube past the obstruction
- rigid bronchoscopy followed by endotracheal tube placement under direct vision or double-lumen tube placement to the most patent bronchus.

Some institutions advocate having a means of cardiopulmonary bypass (CPB) on standby. While there are several reports of patients successfully placed on ECMO or CPB, in each case this was done before the induction of anesthesia [127–131]. We could find no published reports of patients successfully placed on support after the induction of anesthesia with CPB previously available only on standby. Even with a team ready and a primed bypass machine, by the time the

Table 26.3 Risk stratification system for pediatric patients with anterior mediastinal mass

	Low risk	Intermediate risk	High risk
Signs	No radiographic airway compression No cardiac or vascular compression	• Mild tracheal compression <70% • No bronchial compression	• Tracheal • compression >70% • Tracheal CSA <70% with bronchial compression • Great vessel compression • Tamponade physiology on ECHO
Symptoms	None	Mild to moderate postural	Orthopnea Stridor or cyanosis

CSA, cross-sectional area; ECHO, echocardiography.

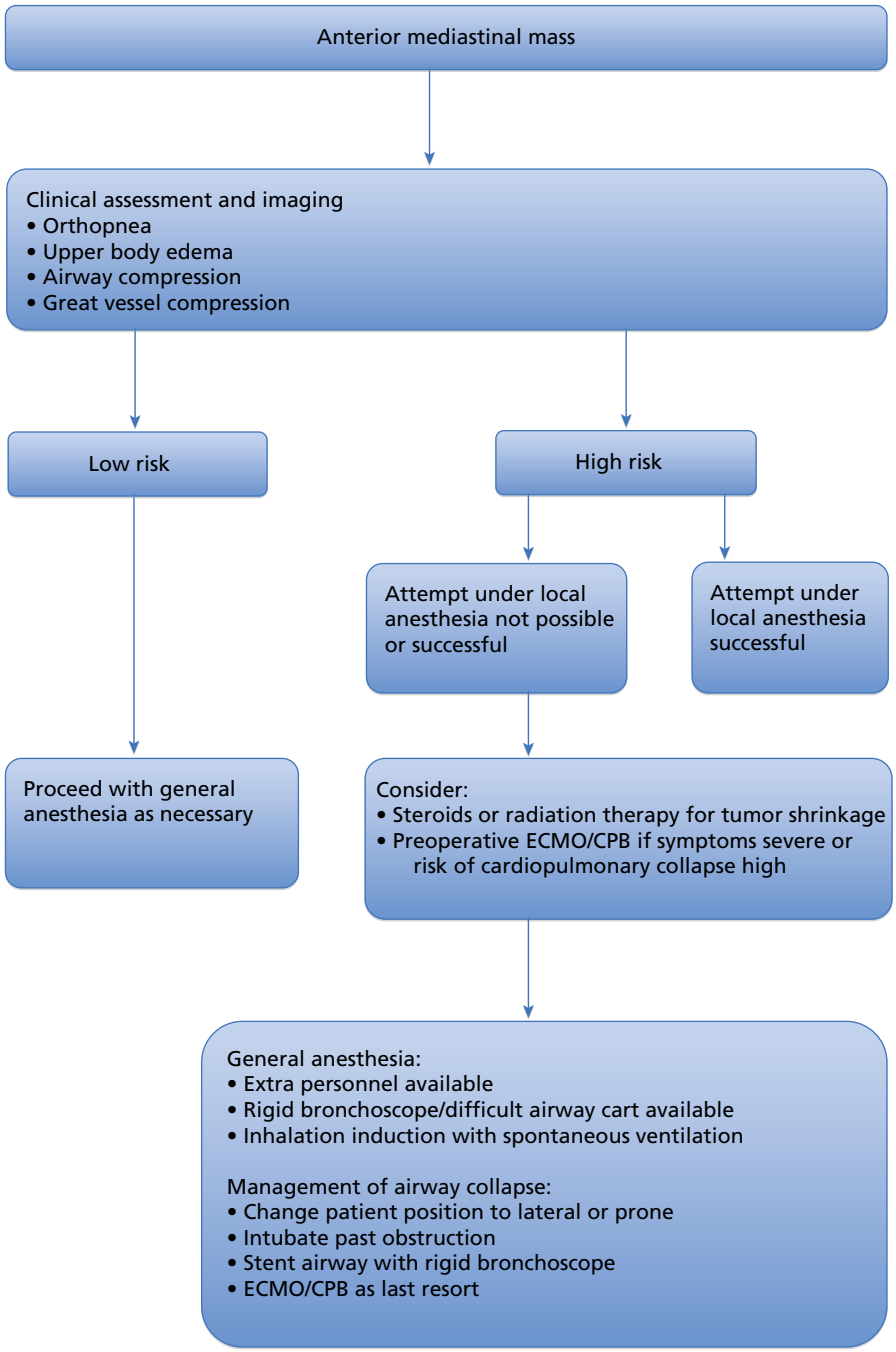

Figure 26.17 An algorithm for management of anterior mediastinal mass.

patient is cannulated and circulation restored, the patient will likely suffer neurological injury [116]. Therefore one should not consider CPB as a reasonable salvage plan. If the risk of cardiopulmonary collapse during induction is high, the patient should be placed on CPB before induction.

For patients presenting for thoracotomy for mediastinal mass resection or open biopsy, thoracic epidural or paravertebral block are excellent techniques to reduce the need for intravenous opioids and maintain spontaneous ventilation [132]. Postoperative symptoms may be worse after surgery, particularly after a biopsy procedure with the adverse effects of anesthesia without the benefit of resection [115]. Surgical complications may also include phrenic or recurrent laryngeal nerve damage.

Pectus excavatum

Pectus excavatum is the most common chest wall deformity. It is a congenital defect, the result of excessive growth of the costochondral cartilages leading to the inward depression of the sternum. It comprises 90% of chest wall deformities with an incidence of approximately 1 in 1000 and a male preponderance (4:1). Pectus carinatum (pigeon chest) comprises most of the remaining chest wall deformities. Pectus excavatum is sometimes associated with connective tissue disorders such as Ehlers–Danlos and Marfan syndrome. As many as 50% of pectus excavatum/carinatum patients have a family history of pectus deformity [133].

The severity of the lesion varies widely, from mild asymptomatic cases to severe deformities associated with

distortion of the heart and great vessels (Figs 26.18, 26.19). Lung compression can lead to respiratory compromise and can be associated with chronic airway obstruction and large negative inspiratory pressures. Compression of the stomach can lead to appetite loss and impairment of weight gain [134,135]. Most symptoms worsen with adolescence, and more than half of adults have some physical complaints [136]. Psychological complaints are also not uncommon [133]. Cardiorespiratory complaints can be resolved with surgery [137].

Figure 26.18 Chest radiograph of a 12-year-old patient with pectus excavatum.

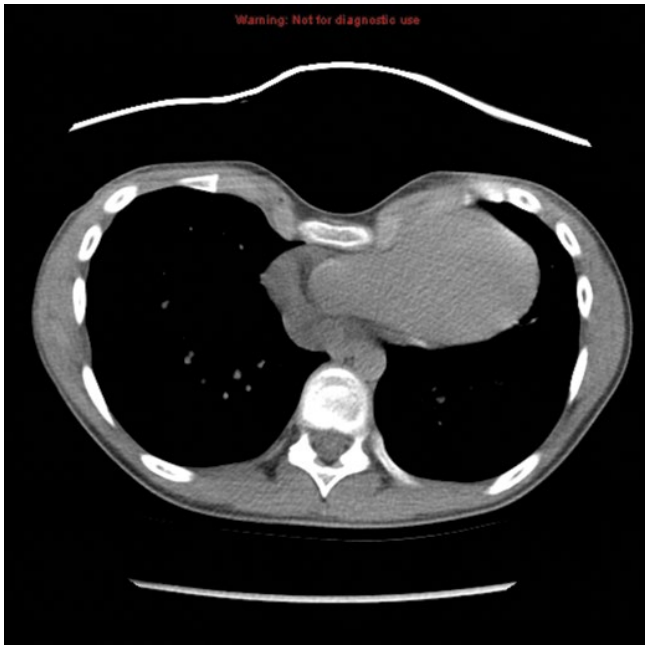

Figure 26.19 Chest CT of a 12-year-old patient with severe pectus excavatum showing cardiac compression.

Diagnosis of pectus excavatum is made by physical examination. Scoliosis is sometimes also seen, particularly in female patients. Many patients have a murmur from compression of the chest wall onto the right ventricle or from mitral valve prolapse [138]. Characteristic ECG findings include a negative P wave in V1, negative T wave in V1 to V2 or V4, and incomplete bundle branch block [136].

Surgical repair is typically delayed until late childhood to allow calcification of the sternum and ribs. Techniques have evolved from rib resection to external traction to cartilage resection, sternal osteotomy, and internal fixation [139]. A new minimally invasive procedure reported by Nuss et al in 1998, in which a preformed convex steel bar is inserted through bilateral thoracic incisions under the sternum and then turned to elevate the sternum, has gained acceptance as the preferred method of repair [140]. It is associated with shorter operative time, smaller incisions, less dissection, and less blood loss than the traditional Ravitch procedure and is successful 92% of the time compared to 70% for the Ravitch procedure [139]. Pneumothorax is common but resolves spontaneously in nearly all cases [139,140]. Less common complications include cardiothoracic injuries, dysrhythmias, pleural effusions, hemorrhage, subcutaneous emphysema, and bar infection [140,141].

Preoperative concerns include possible heart compression, right ventricular outflow tract obstruction, dysrhythmia, scoliosis, and V/Q mismatch. Studies to help delineate the severity of disease include chest radiograph, CT, ECG, and possibly echocardiography. Positioning can be a challenge, and placing patients' arms in arthroscopy slings instead of over the head can help reduce the incidence of brachial plexus injuries [142]. Arterial blood pressure monitoring may be of benefit in patients with cardiac disease. Both the Ravitch and Nuss procedures are painful, and postoperative pain control can be a challenge [143]. Epidural analgesia is effective [144–146] and superior to patient-controlled analgesia [146,147]. A systematic review of six studies (three prospective randomized controlled studies and three retrospective comparison studies) in 430 patients concluded that pain scores were modestly lower with epidural analgesia immediately after surgery (0.5–1 points on a 10-point visual analog scale), through 48 h postoperatively [148]. There were no significant differences with regard to side-effects, complications, operating room time, or length of hospital stay.

Clonidine is an effective alternative to epidural opioids with fewer side-effects [44] and there may even be a role for perioperative hypnosis [149].

Empyema

Empyema, or pleural space infection, is a complication of bacterial pneumonia. Historically, only 0.6% of admissions for pneumonia progressed to empyema [150] but the incidence is rising and more virulent strains of resistant organisms are implicated [151,152]. Empyema should be considered in any child with pneumonia. There is neither much consensus nor evidence on the best treatment of pleural infections, mostly because there are few prospective randomized controlled studies [152,153]. Options range from conservative

therapy with antibiotics to thoracocentesis, chest tube drainage, fibrinolysis, and finally surgical intervention [152].

Empyema evolves over three stages [154]:

1. exudative, in which fluid is thin with low cellular content and easily aspirated
2. fibrinopurulent, in which there is accumulation of leukocytes, fibrin deposition, and loculation
3. organized, with the formation of a thick fibrous peel causing lung entrapment.

During this last stage, drainage alone is ineffective in re-expanding the lung, and decortication may be necessary. The exudative stage can be as short as 24 h, the fibrinopurulent 2–10 days, while the organizing stage generally lasts between 2 and 4 weeks [155].

Pleural fluid analysis has long been used to stage empyema based on leukocytes, lactate dehydrogenase (LDH), glucose, and pH, but these criteria, developed for adult patients, have not been validated in pediatric patients [152]. Chest radiograph is not specific for diagnosis or staging. CT scanning is a useful tool for the diagnosis and evaluation of empyema with respect to consolidation, loculation, and pleural thickening (Figs 26.20, 26.21). Ultrasound has the advantage of being portable, benefiting those unable to undergo CT. It can estimate the size of effusion, show pleural thickening or loculi, and guide chest tube insertion.

Initial treatment for pleural infection is uncontroversial and consists of intravenous antibiotics, analgesics, and antipyretics. Effusions that are enlarging and/or compromising respiratory function should not be treated with antibiotics alone, but need drainage. The dilemma is which treatment option should follow next. The options include: (1) thoracocentesis, (2) thoracostomy tube drainage without or (3) with fibrinolysis, or (4) surgery. Tube drainage is recommended over repeated taps for larger pleural infections, especially for younger children who will not tolerate thoracocentesis

Figure 26.20 Chest CT of a 2-year-old patient with empyema, coronal view.

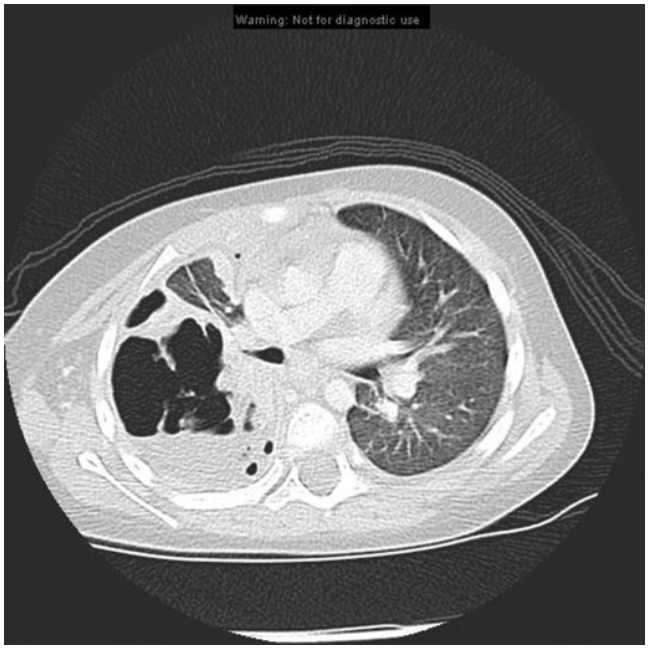

Figure 26.21 Chest CT of a 2-year-old patient with empyema, transverse view.

under local anesthesia alone. Intrapleural fibrinolytics may lyse fibrinous strands in a loculated empyema, leading to improved pleural drainage and successful outcomes without surgery in up to 90% of cases [156]. Failure of chest tube drainage, fibrinolytics, and antibiotics should, however, prompt surgical intervention.

Surgical management of empyema consists of VATS, minithoracotomy, or open thoracotomy. Patients who undergo thoracotomy and debridement versus chest tube placement may have earlier resolution of fever and shorter hospitalization [152], but the procedure is associated with significant morbidity [157]. VATS is less traumatic than open thoracotomy and has been advocated by many, but is more likely to be effective when used early (within 1 week of diagnosis) in the course of empyema [155]. A small prospective randomized trial of 18 patients studying VATS versus thoracostomy drainage showed that hospital length of stay, number of chest tube days, opioid use, and number of radiographic and interventional procedures were all less in patients receiving VATS [158]. Several meta-analyses showed that primary operative therapy is associated with shorter hospital length of stay [159–162] and lower failure rate (by 11-fold) when compared to non-operative treatment [159]. Patients with necrotizing pneumococcal pneumonia or preoperative ICU admission, however, are more likely to have complications and prolonged admissions after thoracoscopy [163]. A recent systematic review of six randomized controlled studies in children of VATS versus open thoracotomy revealed no difference in mortality, but shorter hospital stay by 2.5 days and significantly fewer procedural complications (by 54%) with VATS [164].

Patients who are treated conservatively (tube thoracostomy) for an extended period of time may have an empyema that was initially treatable by VATS progress to the organized stage, when open thoracotomy is likely the only viable treatment. Treatment with VATS should be done early while empyema is still in the fibrinopurulent stage.

For this reason, many now advocate VATS as initial therapy before tube thoracostomy [165]. There is, however, no clear single therapy strategy for all patients. Each must be evaluated based on stage of the disease and therapeutic recourses available.

KEY POINTS: ANTERIOR MEDIASTINAL MASS, PECTUS EXCAVATUM, AND EMPYEMA

- High-risk features of anterior mediastinal mass include orthopnea, upper body edema, airway compression, great vessel involvement, and cardiac tamponade
- Pectus excavatum is repaired by the minimally invasive Nuss bar procedure; pain management via epidural or patient-controlled analgesia is equally effective
- Empyema treatment with VATS results in shorter hospital stay and fewer complications versus open thoracotomy

Anesthetic technique for patients with empyema will depend on the procedure performed. Many patients will tolerate pleurocentesis or tube thoracostomy placement with local anesthesia or minimal sedation. VATS or thoracotomy may necessitate OLV. Good postoperative pain control is necessary to allow the patient adequate lung re-expansion postoperatively. A paravertebral block or a thoracic epidural should be considered in non-septic patients requiring a thoracotomy.

Conclusion

Over the course of this chapter we reviewed the pathophysiology of OLV, discussed the anesthetic practice and equipment necessary to facilitate the perioperative management of the pediatric thoracic surgery patient, including analgesia for thoracic surgery, and finally discussed in a little more detail some of the finer nuances of certain specific thoracic surgical challenges within the pediatric population, namely lobectomy, pneumonectomy, congenital cystic lung disease, anterior mediastinal mass, pectus excavatum, and empyema.

CASE STUDY

A 14-year-old otherwise healthy girl presents for VATS for biopsy of a mediastinal mass.

- What additional information would you want to know at this point? *Additional information should include a detailed history, physical examination, and review of radiological studies with specific emphasis on evaluation of airway and vascular compression.*

The patient presented with a 6-week history of cough, increasing shortness of breath, and wheezing. After failed antibiotic treatment for suspected pneumonia, symptoms progressed to dyspnea and then orthopnea. A chest radiograph showed anterior mediastinal mass and CT showed a mass obstructing approximately one-third of the distal trachea.

- Would you proceed to surgery? *No. There are alternatives to proceeding with general anesthesia for thoracoscopy. A tissue diagnosis can often be made from a lymph node biopsy with local anesthesia. Alternatively she can receive radiation therapy until the mass is no longer compressing the bronchus and she is asymptomatic.*

Lymph node biopsy under local anesthesia was unsuccessful and the oncologist wanted a tissue diagnosis prior to initiating radiation therapy.

- How would you induce anesthesia in this patient? *First, the proper equipment and personnel must be available, including a difficult airway cart, rigid bronchoscope, and personnel trained in its use. We would perform an inhalation induction maintaining spontaneous ventilation then place an endotracheal tube under deep inhalational anesthesia, avoiding the use of muscle relaxation.*
- You are having difficulty ventilating the patient, what would you do next? *The anesthesiologist would first try to position the patient on her side. If this failed to relieve the obstruction, we would advance the endotracheal tube in an attempt to stent past the obstruction, even to the point of endobronchial intubation. Finally, the available otolaryngologist could perform rigid bronchoscopy to stent the airway.*
- The obstruction was relieved by advancing the endotracheal tube slightly. What other intraoperative and postoperative considerations need to be considered? *Maintenance of spontaneous ventilation for the remainder of the case with judicial use of opioids would be prudent. The patient should be extubated awake in the operating room and admitted to the pediatric ICU for close postoperative monitoring and early intervention if needed.*

Acknowledgments

The authors would like to thank Teresa Chapman from the Department of Radiology, Seattle Children's Hospital, for her assistance in acquiring radiographic images.

This is a recent, thorough review of the evidence for management of empyema, with most studies in children, including six randomized controlled trials of VATS versus open thoracotomy. VATS resulted in shorter hospital stay by 2.5 days, and significantly fewer procedural complications by 54%. Also, in the one randomized controlled trial of chest tube drainage versus open thoracotomy, open thoracotomy resulted in much shorter hospital stay and much lower rate of procedural complications.

CHAPTER 27
Anesthesia for Congenital Heart Disease

David Whiting, James A. DiNardo, and Kirsten C. Odegard
Cardiac Anesthesia Service, Boston Children's Hospital; and Department of Anesthesia, Harvard Medical School, Boston, MA, USA

Introduction

Congenital anomalies comprise the largest diagnostic category among the causes of infant mortality in the United States [1]. Structural heart disease leads the list of congenital malformations. Approximately 4 million children are born each year in the United States and nearly 40,000 of these have some form of congenital heart disease (CHD). Approximately half of these children present for therapeutic intervention within the first year of life, and the vast majority of them require care by an anesthesiologist.

Initial reports of anesthetic mortality ranging from 3% to 10% in operations for CHD indicated a significant risk of anesthesia in this patient population [2,3]. However, the principles and techniques of pediatric anesthesia presented in this volume allow one to anesthetize CHD patients with minimal anesthetic mortality and morbidity [4–6]. This low anesthetic risk is predicated not only on adherence to these principles but also on an understanding of the pathophysiological circumstance of each patient and the nature of the planned surgical procedure. Implicit in all surgical procedures are potential complications that anesthesiologists, by virtue of their primary role in monitoring and maintaining vital functions, are able to identify and treat. For cardiac surgery, knowledge of specific problems related to each type of cardiac repair helps to identify complications during the post-bypass and postoperative periods, as well as later complications that affect subsequent anesthesia for non-cardiac procedures. The diagnostic information now available intraoperatively, in the form of intracardiac pressures and oxygen saturations as well as echocardiographic diagnoses, provides the pediatric cardiac anesthesiologist with the opportunity and responsibility to assess the adequacy of surgical intervention and its impact on hemodynamics.

This chapter describes general principles relevant to anesthesia for children with CHD. It does not present care

Gregory's Pediatric Anesthesia, Sixth Edition. Edited by Dean B. Andropoulos and George A. Gregory.

protocols for individual cardiac defects. The pathophysiology is presented as it relates to principles of management, patient assessment, selection and application of an anesthetic regimen, and specific cardiac lesions and procedures. Knowledge of these principles should permit safe administration of anesthesia to children with CHD undergoing both cardiac and non-cardiac operations. Optimal management will occur when the anesthesiologist regularly becomes involved in the care of these patients and has special insight and rapport with the entire cardiovascular staff, such that care is provided by a cohesive team in a smooth continuum from the preoperative preparation and diagnosis through postoperative discharge.

Pathophysiology of congenital heart disease

Principles of management

The pathophysiological consequences of CHD are derived primarily from anatomical circumstances that produce abnormalities of flow: outflow obstruction, regurgitant lesions, shunt lesions, and common mixing lesions. In more complex lesions, shunts and obstructions may occur in combination. The pathophysiology of the most common purely obstructive lesions occurring outside the neonatal period is comparable to adult disease (e.g. aortic and mitral valve stenosis) and is not extensively reviewed here. Regurgitant lesions rarely exist as pure primary congenital defects except in Ebstein malformation of the tricuspid valve, in which a regurgitant volume flows back through the tricuspid valve and is directed across the patent foramen ovale to produce cyanosis and varying degrees of heart failure. Regurgitant lesions produce a volume-overload circulation with progressive ventricular dilation and failure. This is seen most commonly in regurgitation associated with atrioventricular canal defects, semi-lunar valve incompetence as seen in tetralogy of Fallot with absent pulmonary valve, in truncal valve regurgitation in truncus arteriosus, or after interventions for aortic stenosis. Much of the remaining pathophysiology of CHD can be best understood by characterizing lesions with regard to the nature and magnitude of the shunt and the interaction of these shunts with obstructive lesions. Understanding the interactions of the various types of shunts and obstructions simplifies the variety of congenital heart lesions.

Many congenital heart lesions alter pulmonary blood flow and have intracardiac shunts with some degree of pulmonary and systemic venous blood mixing. Varying degrees of hypoxemia may occur. These pathophysiological mechanisms alter the volume and pressure load of the heart as well as cardiovascular development. Although such acquired developmental abnormalities may be adaptive, they can also further compound the effects of the original CHD. The resultant cardiac and pulmonary vascular structural changes may become as important as the pathophysiology of the original heart defects (e.g. severe left ventricular hypertrophy, seen with coarctation of the aorta, and right ventricular hypertrophy with progressive outflow obstruction, seen with tetralogy of Fallot). However, the intracardiac shunting and alterations in pulmonary blood flow comprise the major unique problems encountered with CHD. These problems complicate the task of administering adequate anesthesia while maintaining normal cardiac output and oxygen transport.

Shunt lesions

Cardiac shunting is the process whereby venous return of one circulatory system flows to the arterial outflow of the same circulatory system without passing through a capillary bed. Flow of blood from the systemic venous (right) atrium (RA) to the aorta produces recirculation of systemic venous blood. Flow of blood from the pulmonary venous (left) atrium (LA) to the pulmonary artery (PA) produces recirculation of pulmonary venous blood. Recirculation of pulmonary venous blood produces a physiological left-to-right (L-R) shunt, whereas recirculation of systemic venous blood produces a physiological right-to-left (R-L) shunt. A physiological R-L or L-R shunt is often the result of an anatomical R-L or L-R shunt. In an anatomical shunt, blood moves from one circulatory system to the other via a communication orifice at the level of the cardiac chambers or great vessels. Physiological shunts can exist in the absence of an anatomical shunt. Transposition physiology is the primary example of this process.

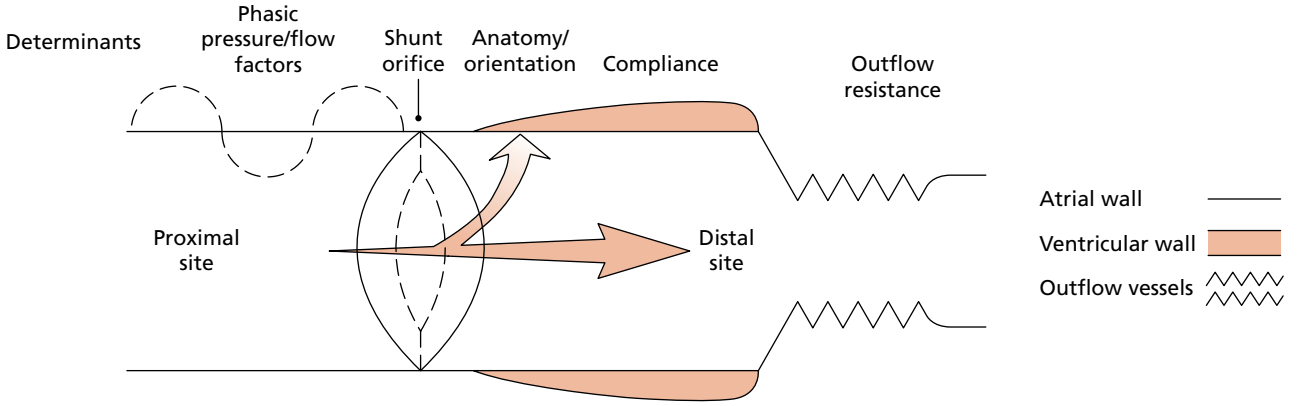
Shunts may occur alone as simple shunts (e.g. a ventricular septal defect (VSD)) or with complicating obstructive lesions in complex shunts such as tetralogy of Fallot. The direction and magnitude of shunts are variable, both within each cardiac cycle and as a consequence of anesthesia and operative manipulation of the heart, great vessels, and lungs, potentially destabilizing the circulation.

The hemodynamics in intracardiac shunts are complex and depend on many factors that determine shunt magnitude and direction (Fig. 27.1). Complete description of the dynamics of a particular shunt requires more data than are usually clinically available. The determinants of shunting may change considerably during anesthesia and operative manipulations without being readily measurable. Nevertheless, the concepts of control of shunting outlined here are useful during the perioperative period when it must be decided which shunts are hemodynamically significant and which are subject to intraoperative change.

Shunt orifice and outflow resistance are the most important determinants of shunting, particularly in ventricular and great vessel shunts. Ventricular compliance may also be important particularly with atrial level shunts. To simplify this discussion, ventricular compliance as a determinant of shunting is not further considered.

Simple shunts

Simple shunts are shunts without a fixed obstruction to outflow distal to the vessels or chambers involved in the shunt. Outflow resistance is determined by the pulmonary vascular resistance (PVR) on the right side and systemic vascular resistance (SVR) on the left side of the heart (Fig. 27.2). The effects of SVR and PVR on the magnitude of the shunt are small when the shunt orifice is small and a large pressure gradient exists across the shunt. These shunts are considered restrictive. The effects of shunt orifice and vascular resistances on simple shunts are outlined in Table 27.1. A simple shunt is non-restrictive when there is no pressure gradient across the shunt. The direction and magnitude of a non-restrictive shunt is dependent on the relative differences in the PVR and SVR. When the communication becomes large enough, the structures connected by the shunt effectively become a common chamber and complete mixing occurs.



Level	Potential effect on shunt				
Atria	Large	Large	Small	Large	Possible with high PVR
Ventricles	Conduction related	"	Moderate	Small	Large
Great vessels	Conduction related	"	Moderate	NA	Large

Figure 27.1 Effects of the many determinants on central cardiac shunting at various levels. PVR, pulmonary vascular resistance. *Source*: Reproduced from Berman [353] with permission from Wolters Kluwer.

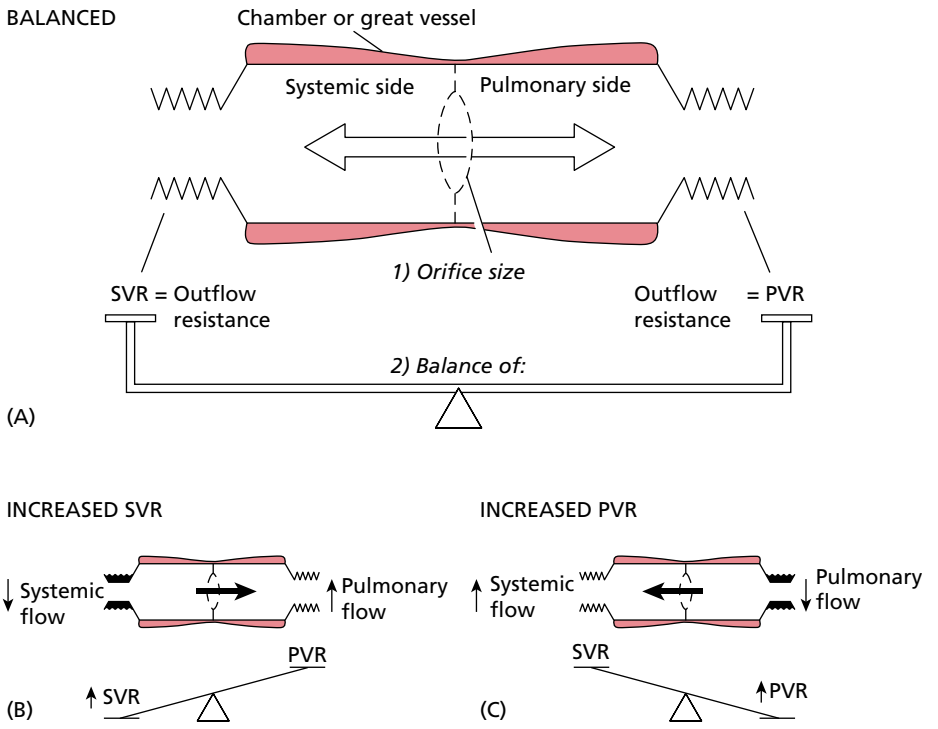


Figure 27.2 Determinants of the magnitude and direction of simple central shunts. (A) Balanced pulmonary vascular resistance (PVR) and systemic vascular resistance (SVR). (1) Orifice size, generally fixed, is important for determining the magnitude of shunting and the pressure gradient across a shunt. (2) Balance of PVR and SVR is dynamic and determines the direction of shunt and variations in magnitude around the limits fixed by the orifice size. (B) Increased pulmonary flow with increased SVR. (C) Increased systemic flow with increased PVR. *Source*: Reproduced from Hickey and Wessel [354] with permission from Elsevier.

A number of factors affect PVR/SVR. Some are relatively fixed whereas others are variable and dynamic. Simple shunting can change intraoperatively as dynamic factors change. Shunting may be manipulated to varying degrees depending on the size of the communication and the ability to alter the dynamic portions of the PVR and SVR. Non-restrictive shunts with a large orifice are more amenable to manipulation of the SVR and PVR. Because normal PVR is often much less than SVR (as little as 5% of SVR in older children and adults), pulmonary blood flows can become large with a non-restrictive simple shunt, even during the neonatal period when the PVR is relatively high.

Complex shunts

A complex shunt has a fixed obstruction distal to the shunt (Fig. 27.3). A fixed outflow obstruction can be present at the

Table 27.1 Simple shunts, no obstructive lesions

Restrictive shunts (small communications)	Non-restrictive shunts (large communications)	Common chambers (complete mixing)
Large pressure gradient	Small pressure gradient	No pressure gradient
Direction and magnitude more *independent* of PVR/SVR	Direction and magnitude more dependent on PVR/SVR	Bidirectional shunting
Less subject to control	More subject to control	Net Qp/Qs totally depends on PVR/SVR
Examples: small VSD, small PDA, Blalock shunts, small ASD	*Examples:* large VSD, large PDA, large aortopulmonary shunts	*Examples:* single ventricle, truncus arteriosus, single atrium

PDA, patent ductus arteriosus; PVR, pulmonary vascular resistance; Qp, pulmonary blood flow; Qs, systemic blood flow; SVR, systemic vascular resistance; VSD, ventricular septal defect.

level of the ventricular outflow tract (subvalvular, valvular, or supravalvular), or in major vessels such as the pulmonary artery or aorta. Resistance caused by the fixed obstruction is additive to resistance across the shunt and resistance of the downstream vascular bed (PVR/SVR). If the fixed outflow obstruction is large, the resultant shunting away from the obstructed side is substantially affected by the fixed obstruction and is less dependent on the downstream vascular bed. This is particularly true for the right side of the circulation, where normal PVR is low compared with the resistance of most right-sided obstructive lesions. For example, in tetralogy of Fallot with severe pulmonary stenosis, a component of the R-L shunting across the VSD is fixed by the pulmonary valve stenosis, but an additional variable component of shunting may be due to variations in PVR or, more commonly, dynamic infundibular obstruction in the right ventricular outflow tract. Dynamic changes in variable portions of the total right-sided outflow obstruction may increase or decrease the total amount of R-L shunting, thereby increasing or decreasing cyanosis. Right-to-left shunting in the baseline state when the dynamic obstructive components are minimal is determined largely by the fixed pulmonary stenosis. These statements presume a constant SVR and cardiac output; large changes in SVR, of course, change shunting by altering the other side of the balance (Fig. 27.3). Characteristics and examples of complex shunts are listed in Table 27.2.

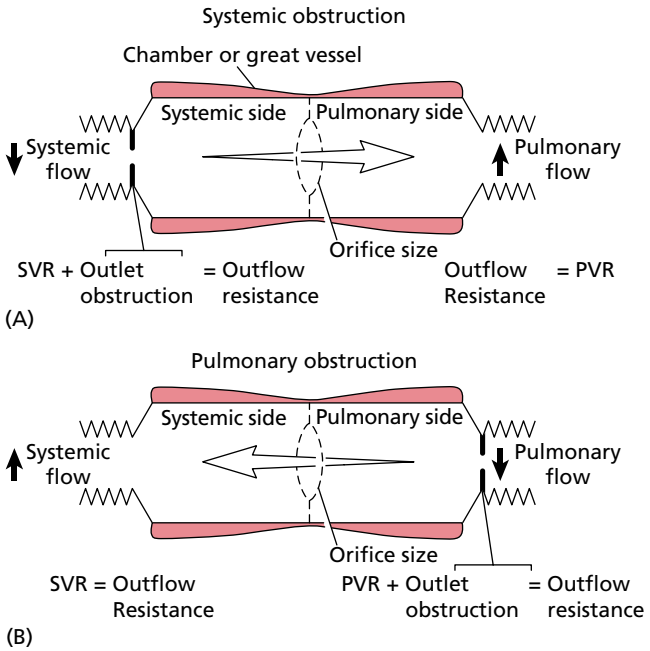

Figure 27.3 Determinants of complex shunting with (A) systemic or (B) pulmonary outflow obstruction. Orifice size limits the magnitude of the shunt. Outflow resistances are balanced by outlet obstruction on either side of the circulation and by the systemic vascular resistance (SVR) or pulmonary vascular resistance (PVR). Addition of outlet obstruction increases flow on the opposite side and decreases flow on the same side. *Source*: Reproduced from Hickey and Wessel [354] with permission from Elsevier.

Complete obstruction and shunts

When obstruction to central outflow of blood becomes complete as in tricuspid atresia, pulmonary atresia, or aortic atresia, shunting across communications proximal to the obstruction becomes total and obligatory. This type of shunting must be associated with another downstream shunt that provides flow to the obstructed side of the circulation. An example of a downstream shunt is a patent ductus arteriosus (PDA) which provides pulmonary blood flow when pulmonary valvular atresia is present or provides systemic blood flow when aortic valvular atresia is present. The downstream shunting is variably dependent on PVR/SVR, depending on the restrictive nature of the shunt orifice.

Table 27.2 Complex shunts (shunt and obstructive lesion)

Partial outflow obstruction	Total outflow obstruction
Shunt magnitude and direction largely fixed by obstructions	Shunt magnitude and direction totally fixed
Shunt depends less on PVR/SVR	All flow goes through shunt
Orifice and obstruction determine pressure gradient	Pressure gradient depends on orifice
Examples: tetralogy of Fallot, VSD and pulmonary stenosis, VSD with coarctation	*Examples:* tricuspid atresia, mitral atresia, pulmonary atresia, aortic atresia

PVR, pulmonary vascular resistance; SVR, systemic vascular resistance.

Manipulation of pulmonary and systemic resistance

Alterations in PVR and SVR allow some measure of control over shunting. Manipulation of PVR is particularly important because of the frequency of right-sided defects in CHD with disturbances in pulmonary blood flow. PVR can be decreased to improve pulmonary blood flow and right heart function or increased to improve systemic blood flow when pulmonary blood flow is excessive. Intraoperative events including sympathetic stimulation, encroachments on lung volumes that produce atelectasis (surgical retraction, pleural and peritoneal

collections, abdominal packing), cardiopulmonary bypass (CPB), alveolar hypoxia, and hypoventilation may increase PVR because of the increased reactivity and resistance of the abnormal pulmonary vasculature often found with CHD.

Ventilatory control of pulmonary vascular resistance

The PVR can be controlled independently of the SVR by manipulating various aspects of ventilation (Table 27.3), whereas specific or selective pharmacological control of PVR is difficult unless the pulmonary vascular bed is responsive to inhaled nitric oxide. Even with selective infusions of rapidly metabolized vasoactive drugs into the pulmonary circulation, systemic drug concentrations and systemic hemodynamic effects can be appreciable [7]. In contrast, high levels of inspired oxygen, especially 100% oxygen, decrease elevated PVR in infants without changing (or slightly increasing) SVR, whereas inspired oxygen concentrations of 21% or less increase PVR [8,9]. The effectiveness of oxygen (i.e. hyperoxia) as a pulmonary vasodilator after CPB, however, is unclear [10]. Hypoventilation, with associated acidosis and hypercapnia, also increases PVR (Fig. 27.4) [9]. In contrast, hyperventilation to a pH of more than 7.5 reliably decreases PVR in infants with dynamically vasoconstricted small vessels [11,12]. This maneuver increases pulmonary blood flow and decreases R-L shunting in neonates, increasing the PaO_2

Table 27.3 Manipulations altering pulmonary vascular resistance

Increased PVR	Decreased PVR
Hypoxia	Oxygen
Hypercarbia	Hypocarbia
Acidosis	Alkalosis
Hyperinflation	Normal FRC
Atelectasis	Blocking sympathetic stimulation
High hematocrit	Low hematocrit
Surgical constriction	

FRC, functional residual capacity; PVR, pulmonary vascular resistance.

[13,14]. Some caution is required as prolonged hyperventilation to decrease PVR may in theory cause problems from decreased cerebral blood flow. Recent clinical observations support a link between the extent and duration of hypocapnia and development of white matter injury and subsequent neurobehavioral deficiencies in neonates [15].

The pattern of ventilation and use of positive end-expiratory pressure (PEEP) can alter PVR. PVR is lowest at normal functional residual capacity (FRC) and increases at lower lung volumes because of alveolar collapse [16]. The application of PEEP can treat atelectasis and pulmonary edema and lower PVR, however high levels of PEEP may overinflate alveoli and increase PVR. Different patterns of ventilation may further reduce PVR by stimulating production of prostacyclin in the pulmonary vasculature [17,18].

Anesthetics and pulmonary vascular resistance

The direct effects of anesthetic agents on PVR are minimal, however anesthetic agents can attenuate stress responses in the perioperative period and prevent stress-induced increases in PVR. Large doses of synthetic opioids (e.g. fentanyl) attenuate pulmonary vascular responses to noxious stimuli, such as endotracheal suctioning in infants, but they do not change the baseline PVR [19,20]. Reactive hypertensive responses in the pulmonary bed are partially mediated by the sympathoadrenal axis and therefore are attenuated by an adequate depth of anesthesia, usually without changing the baseline PVR. Ketamine and nitrous oxide have been reported to increase PVR in adults, particularly in patients with mitral stenosis, but do not affect the PVR of infants with normal or elevated PVR when ventilation and FiO_2 are held constant [21–23]. A rise in PVR with ketamine given to sedated children spontaneously breathing room air during cardiac catheterization has been noted [24]. However, in a cohort of patients with pulmonary hypertension spontaneously breathing 0.5% sevoflurane, no change in PVR was seen with ketamine administration.

Manipulation of systemic vascular resistance

When deleterious intracardiac shunting cannot be controlled by manipulating PVR, it may be necessary to change SVR. In the presence of a complex shunt with fixed pulmonary outflow obstruction and R-L shunting (e.g. tetralogy of Fallot), an increase in SVR decreases the R-L shunting and increases arterial oxygen saturations [25]. Dynamic increases in infundibular outflow obstruction with tetralogy of Fallot that acutely increase baseline R-L shunting (hypercyanotic spells) can be treated with IV pressor agents, which are shunted right to left directly into the systemic circulation, thus increasing SVR and decreasing R-L shunting.

Increases in systemic arterial pressure (SVR) with pressor agents can increase pulmonary blood flow in the presence of a severely restrictive aortopulmonary shunt (e.g. Blalock–Taussig, Waterston, or Potts shunt) and increase coronary blood flow when coronary perfusion is compromised by low diastolic blood pressure. Use of phenylephrine, norepinephrine, or other α-agonists to maintain high systemic perfusion pressure may be beneficial under these circumstances. Alternatively, partially occluding the aorta with a clamp mechanically increases pressure in the proximal aorta and left ventricle, thus increasing the SVR.

Pulmonary circulation

Alterations in pulmonary blood flow caused by shunting in patients with CHD may produce different problems as the PVR changes with development (Fig. 27.5). These problems include pulmonary vascular occlusive disease and systemic arterial desaturation as well as chronic sequeale from an increased volume load on the heart. Dramatic alterations in pulmonary blood flow are seen during the neonatial period as the transition to adult-type circulation occurs.

Transitional circulation

The transitional circulation of normal neonates can be viewed as a transient form of CHD. Shunting occurs in either direction through the ductus arteriosus and the foramen ovale until these structures functionally, and later anatomically, close. Neonates have high PVR that promotes R-L shunting through the ductus arteriosus and foramen ovale causing hypoxemia (Fig. 27.6). Later, as PVR falls, shunting through the ductus reverses and becomes left to right until the ductus closes anatomically (Figs 27.5 and 27.6).

Neonates may revert to transitional circulation despite previous functional closure of the ductus arteriosus and foramen ovale. Hypoxia, acidosis, hypercapnia, hypothermia, sepsis, and prolonged stress increase PVR and favor return to the transitional circulation pattern. These changes are sometimes seen when neonates undergo major non-cardiac surgery. The degree of reactive hypoxic pulmonary vasoconstriction is much greater in normal newborns than in adults. The resulting high pulmonary artery pressure may exceed aortic pressure and produce intermittent or continuous R-L shunting through a PDA or foramen ovale [26]. Once the period of perioperative stress is over, high PVR returns to age-determined normal levels and the developmental changes resume to functionally eliminate the ductus arteriousus.

Transitional circulation can be continued after birth by maintaining patency of the ductus arteriosus with prostaglandin E1 (see section 'Severe hypoxemia'). In these cases, maintenance of transitional circulation serves a palliative role by providing either adequate pulmonary or systemic flow.

Precapillary pulmonary artery hypertension

In the presence of a non-restricted simple shunt (e.g. a large VSD), blood flow into the lungs increases as PVR falls (Fig. 27.5). The increase in pulmonary artery pressure and volume resulting from such shunts may over time alter pulmonary vascular development and cause precapillary pulmonary artery hypertension (Fig. 27.7) [27,28]. This can occur when a large VSD, atrioventricular canal, transposition of the great arteries, truncus arteriosus, or a large PDA is present. Pulmonary vascular disease can occur even during the first year of life in patients with an atrioventricular canal or in the first weeks of life in those with transposition of the great arteries and VSD [29]. A progressive rise in PVR may lead to chronic R-L shunting and right ventricular failure. In contrast, pulmonary vascular disease takes decades to develop with lesions such as atrial septal defect (ASD), where only flow is increased and pulmonary artery pressures are initially normal [30].

The resistance to flow in pulmonary arteries with pulmonary vascular occlusive disease is increased because of higher smooth muscle content and a reduction in arborization of the pulmonary arteries. The pulmonary vasculature is also more reactive to intraoperative changes in surgical stimuli and stress. Right-to-left shunting may appear or increase dramatically. Minimizing the reactive component of PVR without lowering SVR is often critical in anesthetic management.

Decreased flow in the pulmonary circulation during development can also lead to significant abnormalities in the pulmonary arterial tree. Hypoplasia may result in areas seeing reduced blood flow, and vascular obstructive disease may occur in regions seeing increased blood flow [31]. This is especially true in patients with tetralogy of Fallot and pulmonary atresia, in whom the pulmonary artery anatomy must be addressed early in life.

Arterial oxygen desaturation

Systemic arterial desaturation in CHD is usually from shunting of systemic venous blood directly into the systemic arterial circulation. Pulmonary parenchymal disease can also be

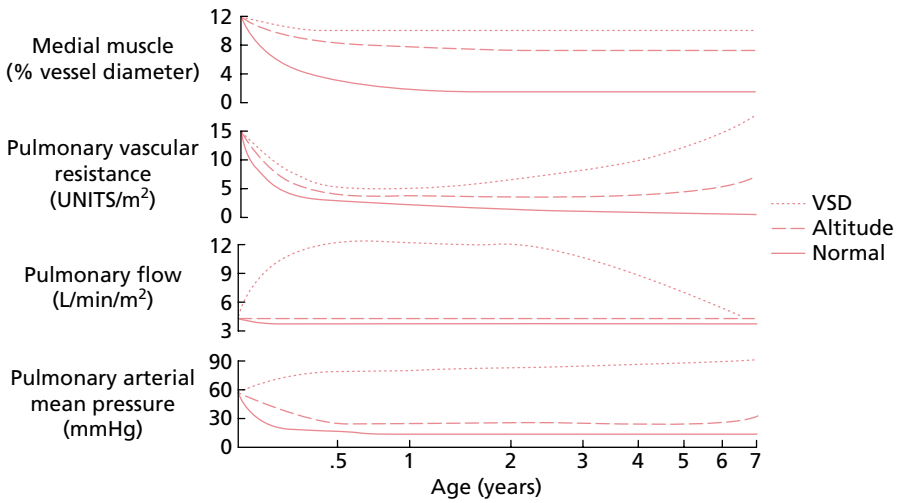

Figure 27.5 Normal and abnormal developmental changes in the pulmonary arterial tree during the first years of life. Pulmonary vascular resistance, arterial smooth muscle (%) and pressure normally decrease during the first year of life. A large, non-restrictive VSD with a large left to right shunt results in an immediate increase in flow and a later increase in vascular resistance. *Source*: Reproduced from Rudolph [355] with permission of John Wiley and Sons.

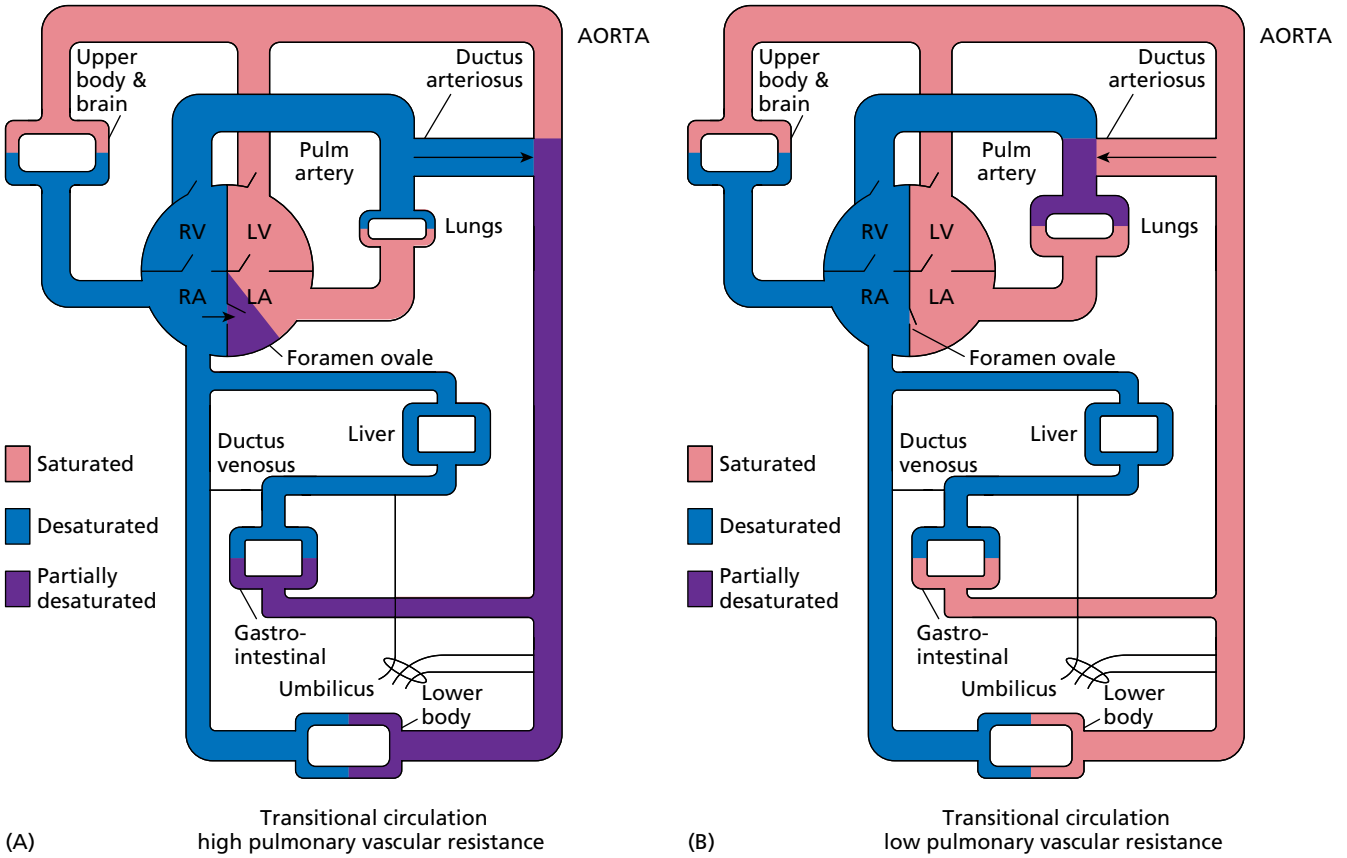

Figure 27.6 Central shunting and blood saturations that occur normally in the transitional circulation during the first few hours and days after birth. (A) During the first few hours, the foramen ovale is widely patent and PVR is high, leading to right-to-left shunting. (B) A second, later stage of transitional circulation occurs when PVR decreases and the ductus arteriosus remains patent, resulting in left-to-right shunting. The foramen ovale is functionally closed. *Source*: Reproduced from Hickey and Crone [356] with permission from Elsevier.

present, making it even more difficult to achieve adequate arterial oxygenation. Shunt-related arterial desaturation can occur when pulmonary blood flow is greater than, equal to, or less than systemic flow. The effects of alterations in pulmonary blood flow on arterial oxygenation in the presence of various shunts are listed in Table 27.4. It is important to realize that an FiO_2 of more than 0.21 has little effect on arterial oxygen tension in the presence of a large R-L shunt since the hypoxemia is caused by a reduction in pulmonary blood flow, but the effect increases as the shunt becomes smaller (Fig. 27.8). This statement presumes no pulmonary parenchymal disease and fully saturated pulmonary venous blood.

Hypoxemia also occurs in situations other than those with a pure R-L shunt with decreased pulmonary blood flow. If systemic and pulmonary venous blood mix in a vascular chamber, arterial desaturation occurs, even though pulmonary blood flow may be normal or increased (Table 27.4). Mixing can occur at any anatomical level: right atrium (e.g. total anomalous pulmonary venous connection), left atrium (e.g. tricuspid atresia), ventricle (e.g. single ventricle), or great vessel (e.g. truncus arteriosus and aortopulmonary window). When mixing is complete and pulmonary blood flow is normal or increased, hypoxemia is mild. When mixing is incomplete, hypoxemia may be severe, as occurs with the parallel circulation seen in patients with transposition of the great arteries.

Many poorly understood adaptations occur in patients with severe hypoxemia to allow acceptable levels of oxygen transport and consumption. Adaptations include erythrocytosis, increases in 2,3-diphosphoglutarate concentrations, systemic vasodilation with increased blood volume, neovascularization, and alveolar hyperventilation with chronic respiratory alkalosis [32]. These and other poorly defined adaptive mechanisms maintain near-normal levels of mitochondrial oxygen utilization at rest without increases in lactate production. Elevated cardiac output and substantial shifts in the oxyhemoglobin dissociation curve are not significant adaptations in patients with severe hypoxemia [33].

These adaptations may be associated with adverse physiological effects. Erythrocytosis increases blood viscosity, vascular resistance, and therefore ventricular afterload, especially in the pulmonary circulation [34]. Increased blood viscosity elevates ventricular afterload so cardiac output decreases, opposing the benefit of erythrocytosis to oxygen-carrying capacity. The net reduction in oxygen delivery is maladaptive and occurs when the hematocrit (Hct) exceeds 60%. Such high Hcts are associated with an appreciable incidence of cerebral and renal thrombosis, which increases with dehydration. This situation makes pre- and postoperative hydration crucial in these patients.

Cyanosis has been implicated in the genesis of coagulation and fibrinolytic defects particularly when secondary erythrocytosis produces a Hct greater than 60%. The majority of studies investigating the effects of cyanosis on hemostasis have been conducted in chronically cyanotic adults and children more than 1 year old. Thrombocytopenia and qualitative

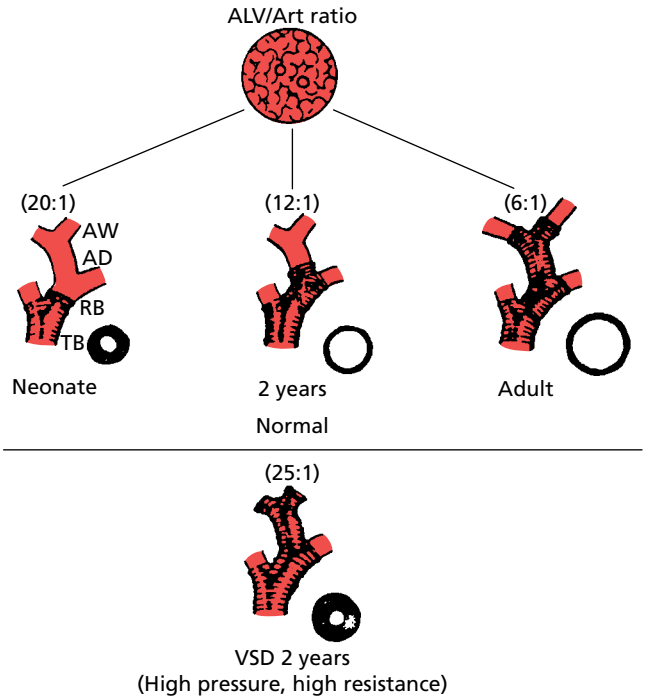

Figure 27.7 Developmental changes in the peripheral pulmonary arterial tree in normal infants and in those with a ventricular septal defect (VSD) and large left-to-right shunt. The alveolar/arteriolar (ALV/Art) ratio decreases with age becasue of extensive arborization of the arterial tree as the arteriolar lumen increases and the muscle layer thins and spreads distally. Pulmonary hypertension and high flow of blood from a left-to-right shunt in a patient with a VSD cause pulmonary vascular obstructive disease as evidenced by a decreased number of pulmonary arterioles (ALV/Art of 25:1), a decrease in vessel lumen, an increase in muscle thickness and a more distal spread of muscle. Letters indicate arterioles from the level of the terminal bronchiolus (TB) to the alveolar wall (AW). platelet defects are common and are positively correlated with the level of erythrocytosis and arterial oxygen desaturation [35–42]. Defects in bleeding time, clot retraction, and platelet aggregation to a variety of mediators have all been described [37,38,43,44]. The importance of erythrocytosis in the genesis of these quantitative and qualitative defects is underscored by the observation that multiple therapeutic phlebotomies using either plasma or isotonic saline to replace whole blood and reduce the Hct to the 50–60% range result in improvement of the platelet count and platelet aggregation [37,39]. In addition, shortened platelet survival time has been reported. Reduced survival time was weakly positively correlated with the level of erythrocytosis and arterial oxygen desaturation [40]. More recently, a baseline deficit in platelet glycoprotein 1b receptors has been reported in cyanotic children [45]. These receptors play a pivotal role in inducing platelet aggregation and adhesion via von Willebrand factor. The platelets of cyanotic neonates and infants exhibit a hyporeactive response to protease activated receptor 1 agonists compared to non-cyanotic neonates and infants.

Prolonged prothrombin time, partial thromboplastin time, and low levels of fibrinogen and factors II, VII, IX, X, XI, and XII have also been reported in association with cyanosis [35,36,38,42,46]. Therapeutic phlebotomies using isotonic saline to replace whole blood and reduce the Hct to the 50–60% range result in an increase in factor II, VII, and V levels [39]. Coagulation factor abnormalities appear to occur with lower frequency than platelet defects but the full extent of coagulation factor abnormalities is unknown because this issue has been incompletely studied.

Chronic disseminated intravascular coagulation (DIC) has been proposed as an additional mechanism leading to a coagulopathic state in cyanotic heart disease [47]. While evidence of accelerated ongoing thrombin generation and fibrinolysis has been detected in cyanotic versus non-cyanotic patients, chronic DIC has not been substantiated [48,49].

Recent evidence documents the overproduction of platelet microparticles in erythrocytotic CHD patients whose Hct is greater than 60% [50]. Microparticles are cellular fragments that result from exocytotic budding and contain both cytoplasmic and membrane components. These microparticles express factor Va and Xa and are highly procoagulant. Microparticle formation occurs as a result of the high microvascular shear forces that accompany erthrocytosis and can be reduced via hematocrit reduction with therapeutic phlebotomy [50].

Table 27.4 Effects of central shunting and pulmonary blood flow on oxygenation

Pulmonary blood flow Qp	L→R shunt only	L→R + R→L (mixing)	R→L shunt only
Qp > Qs	Normoxemia	Hypoxemia*	–
Qp = Qs	–	Hypoxemia	–
Qp < Qs	–	Hypoxemia (severe)	Hypoxemia (severe)

* Normoxemia when Qp/Qs ≥7–10.
Qp, pulmonary blood flow; Qs, systemic blood flow; –, does not occur.

Increased pulmonary blood flow

A volume load is imposed on the heart when pulmonary flow is greater than systemic flow (Qp/Qs greater than 1). The additional pulmonary flow does not increase arterial oxygen content. This increased volume load decreases not only cardiovascular reserve but also pulmonary reserve, because the work of breathing is increased owing to decreased pulmonary compliance and increased airway resistance [51]. These changes are due to increased lung water, compression of bronchi by distended pulmonary vessels at all levels, and generalized pulmonary vascular congestion. Lung compliance improves immediately when L-R shunts are closed (e.g. ligation of a PDA) [52].

KEY POINTS: PATHOPHYSIOLOGY OF CONGENITAL HEART DISEASE

- Manipulating pulmonary vascular resistance by altering ventilation (FiO_2 and $PaCO_2$), and systemic vascular resistance with vasodilators or vasoconstrictors is a fundamental principle of management of congenital heart disease
- Neonates with CHD often revert to the state of transitional circulation with stresses such as acidosis and hypoxemia, with high pulmonary vascular resistance and continued R-L shunting through the PDA and foramen ovale
- Right-to-left shunting lesions can result in profound arterial desaturation, and maintaining the PDA with prostaglandin E1, as well as adequate hemoglobin, inotropy, and oxygenation with mechanical ventilation, are important principles in preoperative stabilization
- Increased pulmonary blood flow from L-R shunting lesions can worsen in the first few weeks postnatally as PVR drops and Qp/Qs increases dramatically

Preoperative assessment and preparation

Successful anesthetic management of patients with CHD begins with a complete preoperative assessment and adequate patient preparation. Involvement of the anesthesiologist in preoperative preparation and early postoperative management is imperative and improves perioperative care. The clinical and laboratory information routinely available preoperatively (Box 27.1) should be integrated with information from continuous monitoring during surgery and the immediate recovery phase. The anesthesiologist must be aware of the physical and laboratory findings that are of particular importance for CHD.

Box 27.1: Clinical and laboratory preoperative assessment

- History and physical examination
- Laboratory data
- Chest radiography
- Electrocardiogram
- Echocardiography and Doppler assessment
- Cardiac catheterization
- Magnetic resonance and computed tomographic imaging and angiography

History and physical examination

A history and physical examination is the beginning of a complete preoperative assessment. Attention should be directed to the extent of cardiopulmonary impairment and the presence of associated extracardiac congenital anomalies. Upper and lower airway problems in patients with Down syndrome, calcium and immunological deficiencies in patients with aortic arch abnormalities, and renal abnormalities in patients with esophageal atresia and CHD are a few of the associated congenital abnormalities with which the anesthesiologist should be familiar. Intercurrent pulmonary infection is a common and significant finding in lungs with chronically elevated pulmonary blood flow.

Laboratory data

The complete blood count, blood urea nitrogen, creatinine, and serum electrolytes can reflect the patient's condition and affect perioperative management. An elevated hemoglobin, for example can reflect the presence, degree, and duration of hypoxemia (in the absence of iron deficiency). A low hemoglobin, as seen in the nadir of physiological anemia during infancy, may contribute to L-R shunting by decreasing the relative PVR [34]. Electrolyte abnormalities caused by congestive heart failure and forced diuresis must also be evaluated preoperatively. Severe hypochloremic metabolic alkalosis may occur in some patients. Digoxin may need to be discontinued perioperatively in these patients, as ventricular fibrillation is more likely to occur in patients with hypochloremic metabolic alkalsosis, particularly when induction of anesthesia is associated with hypotension and treated with calcium chloride or gluconate. Serum calcium and glucose levels must be monitored in critically ill infants.

Chest radiography

A chest radiograph is helpful for evaluating heart size, the presence and degree of pulmonary vascular congestion, airway compression, and lung consolidation or atelectasis.

Electrocardiogram

The electrocardiogram (ECG) may reveal rhythm disturbances and demonstrate ventricular strain patterns (ST and T wave changes) characteristic of unphysiological pressure or volume burdens on the ventricles.

Echocardiography and Doppler assessment

Two-dimensional and real-time three-dimensional echocardiography has revolutionized imaging in pediatric cardiology. Comprehensive cardiac assessment of the pediatric patient by transthoracic echocardiography is possible since echocardiographic windows are usually acceptable. Doppler measurements expand diagnostic capabilities. Measurements

of pressure gradients across semi-lunar valves and other obstructions are reproducible but may not always correlate with peak systolic ejection gradients measured at catheterization. Three-dimensional echocardiography may add new information about valvular lesions, particularly the site and mechanism of regurgitation [53]. In addition, 3D echocardiography offers new perspectives on atrial and ventricular septal defects, and more complex lesions such as atrioventricular septal defect, complex transposition of the great arteries, truncus arteriosus, and double outlet right ventricle.

Cardiac catheterization

Catheterization is necessary to clarify anatomy and physiology when clinical information is ambiguous or contradictory, or to clarify coronary or aortopulmonary collateral anatomy. Nonetheless, most neonates are able to proceed to surgery without catheterization studies. Normal intracardiac pressure and saturation values in children are shown in Figure 27.9.

Shunt localization is usually accomplished using a combination of angiography and measurement of O_2 saturations in the pulmonary veins, superior and inferior vena cavae, right and left heart chambers, aorta, and pulmonary arteries. Oxygen saturation sampling is used to detect an O_2 saturation step-up in the right heart in the case of a L-R shunt. A step-up is defined as a greater than 5% increase in the O_2 saturation of blood in a particular location that exceeds the normal variability in that location, whereas a step-down is a greater than 5% decrease in saturation for a given location.

Shunt quantification is based on comparison of systemic and pulmonary blood flows. Systemic (Qs) and pulmonary (Qp) blood flows are calculated by the Fick method:

$$Qp = VO_2 / (PvO_2\,\text{content} - PaO_2)$$

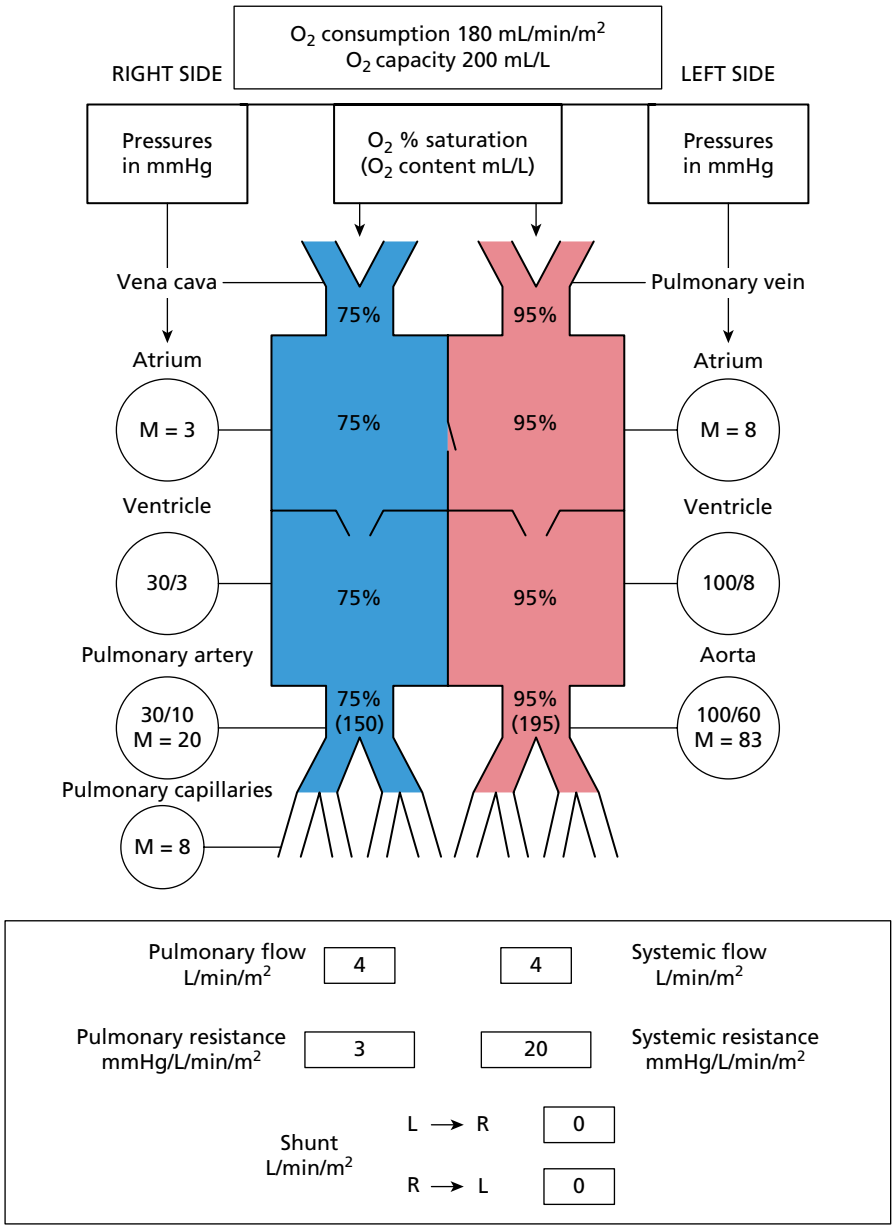

Figure 27.9 Cardiac catheterization findings in a normal child. Numbers in chambers are oxygen saturation (percent) and numbers in parentheses are oxygen content. Pressure in chambers are shown in circles. Note "probe-patent" foramen ovale. M, mean pressure. *Source*: Reproduced from Nadas and Fyler [357] with permission of Elsevier.

PaO_2 content is the pulmonary arterial O_2 content, PvO_2 content is the pulmonary venous O_2 content, and VO_2 is oxygen consumption. Sampling blood from the left atrium (when the pulmonary veins return to the left atrium) will provide a weighted average O_2 content of the four pulmonary veins. If a R-L atrial level shunt is present, this sampling site will not provide an accurate assessment of pulmonary vein O_2 content. Each of the four pulmonary veins can be entered and sampled separately to assess for pulmonary sources of venous admixture (e.g. pneumonia, atelectasis, or other pulmonary disease). When this is done, segmental areas of intrapulmonary shunt and V/Q mismatch can be detected. The PaO_2 or saturation of pulmonary venous blood from a lung segment with V/Q mismatch will improve with an increase in FiO_2 while there will be no improvement if an intrapulmonary shunt is present.

$$Qs = VO_2 / (SaO_2\,\text{content} - MvO_2\,\text{content})$$

SaO_2 content is systemic arterial O_2 content and MvO_2 content is mixed venous O_2 content. True mixed venous blood is a mixture of desaturated blood from the inferior vena cava (IVC), superior vena cava (SVC), and coronary sinus. In a normal heart a mixed sample of venous blood from these three locations can be obtained from the pulmonary artery. In the presence of an intracardiac L-R shunt, PaO_2 saturation will overestimate true MvO_2 saturation because pulmonary arterial blood will be a mixture of mixed venous blood and oxygenated pulmonary venous blood from the left heart. In children, SVC O_2 content is commonly used as a surrogate for MvO_2 content.

After Qp and Qs have been calculated, shunts can be quantified. For an isolated L-R shunt, the magnitude of the shunt is Qp – Qs. For an isolated R-L shunt, the magnitude of the shunt is Qs – Qp. The ratio Qp/Qs is also useful. It can be calculated from content data alone because the VO_2 term cancels out:

$$Qp / Qs = \frac{(SaO_2\,\text{content} - MvO_2\,\text{content})}{(PvO_2\,\text{content} - PaO_2\,\text{content})}$$

Furthermore, if the blood is sampled using a low FiO_2, the dissolved O_2 portion of the content equation ($PO_2 \times 0.003$) can be ignored. The hemoglobin × 1.34 term cancels out and the equation can be simplified further using just the oxygen saturation data from the four sites:

$$Qp / Qs = \frac{(SaO_2\,\text{saturation} - MvO_2\,\text{saturation})}{(PvO_2\,\text{saturation} - PaO_2\,\text{saturation})}$$

A Qp/Qs >2.0 constitutes a large shunt, whereas a Qp/Qs of 1.25–1.5 constitutes a small shunt. A Qp/Qs <1.0 indicates a net R-L shunt.

Effective pulmonary blood flow (Qp_{eff}) and effective systemic blood flow (Qs_{eff}) must be calculated when birectional shunts are present. Qp_{eff} is the quantity of desaturated systemic venous blood that traverses the pulmonary capillaries to be oxygenated. Qs_{eff} is the quantity of oxygenated pulmonary venous blood that traverses the systemic capillaries to deliver oxygen to tissue. Qs_{eff} and Qp_{eff} are always equal.

$$Qs_{eff} = Qp_{eff} = VO_2 (PvO_2\,\text{content} - MvO_2\,\text{content})$$

The L-R shunt is defined as $Qp - Qp_{eff}$ while the R-L shunt is defined as $Qs - Qs_{eff}$. The net shunt is the difference between these two calculated shunts.

In the presence of a L-R shunt and elevated PVR, pressure and saturation measurements are often repeated with the patient breathing 100% oxygen to assess both the reactivity of the pulmonary vascular bed and any contribution of ventilation/perfusion abnormalities to hypoxemia. If breathing 100% oxygen or nitric oxide increases pulmonary blood flow and dramatically increases Qp/Qs with a fall in PVR, potentially reversible processes such as hypoxic pulmonary vasoconstriction might be contributing to the elevated PVR. Patients with high PVR not responsive to 100% oxygen or nitric oxide and a small L-R shunt despite a large shunt orifice may have extensive pulmonary vascular damage from irreversible obstructive pulmonary vascular disease.

Anatomical abnormalities are identified angiographically during cardiac catheterization. Special angled views provide specific information about the location and extent of congenital defects. Ventricular function is assessed angiographically and physiologically (e.g. by pressure measurements). The calculated size of cardiac chambers may have an important bearing on its ability to support the circulation of a child with hypoplastic ventricles.

Magnetic resonance and computed tomography imaging and angiography

Magnetic resonance imaging (MRI) and angiography (MRI/A) has emerged as an important diagnostic modality in the evaluation of the cardiovascular system following the development of ECG-gated MRI technology. Image acquisition is triggered by the patient's ECG to counter motion artifacts and to acquire cine sequences that allow imaging of cardiac structures and visualization of blood flow throughout the cardiac cycle. MRI/A can provide excellent anatomical and three-dimensional images, particularly of the pulmonary veins and thoracic aorta. It is also possible to qualitatively assess valves and quantify flow as well as measure ventricular function, volume, mass, and ejection fraction [54,55]. Contraindications include patients with non-MRI compatible pacemakers, recently implanted endovascular or intracardiac implants, and aneurysm clips on vessels that will be exposed directly to the magnetic field. Ferromagnetic implants near the region of interest produce imaging artifacts, but sternal wires and vascular clips from previous procedures usually produce relatively minor imaging artifacts.

Sedation is necessary for most children undergoing cardiac MRI/A procedures as the small bore of the magnet and noise during imaging may induce claustrophobia and anxiety. Breath holding is necessary for acquisition of many three-dimensional MRI/A images and gradient echo sequences to measure blood flow. General anesthesia with neuromuscular blockade is required for neonates, infants, young children, and older children who are not able to follow instructions from the technologist. Dobutamine stress MRI/As may require additional monitoring and MRI compatible infusion pumps or extension tubing for pumps outside of the imaging area. The environment for MRI is often a difficult one in which to administer sedation or general anesthesia and hemodynamic monitoring may be limited [56].

Computed tomography (CT) imaging and angiography is also useful for visualizing intra- and extracardiac structures. The imaging time is brief but sedation is usually required in infants and children, and general anesthesia is necessary when breath holding is important for imaging. Imaging may require slowing the heart rate with a βblocker. Careful communication with the cardiologist and imaging technician is imperative to make sure hemodynamics are not compromised by induced bradycardia. CT imaging exposes the patient to ionizing radiation so the risks and benefits of the procedure must be assessed when other imaging modalities are possible.

Assessment of patient status and predominant pathophysiology

Congenital heart defects are complex and can be difficult to conceptualize. Understanding physiological concepts and their management is more helpful than trying to individualize an approach to each anatomical defect. Organization of preoperative patient data, preparation of the patient, and decisions about monitoring, anesthetic agents, and postoperative care are best accomplished by focusing on a few major pathophysiological problems. Some useful questions to consider include:

- Is the patient in congestive heart failure (suggesting low cardiac output or excessive pulmonary blood flow versus systemic blood flow)?
- Is the patient cyanotic (suggesting decreased pulmonary blood flow or low cardiac output)?
- Is the circulation in series or parallel?
- What intracardiac mixing, shunting, or outflow obstruction exists?
- How is ventricular function? Is there a volume load or pressure load on the ventricles?

Optimal preparation of the patient usually involves consideration of one of the following major problems: severe hypoxemia, excessive pulmonary blood flow, congestive heart failure (CHF), obstruction of blood flow from the left heart, or poor ventricular function. Although some patients with CHD present with only one problem, many have multiple interrelated problems.

Severe hypoxemia

Many of the cyanotic forms of CHD present with severe hypoxemia, defined as PaO_2 less than 50 mmHg during the first few days of life despite adequate ventilation. Cyanotic patients may have an elevated hemoglobin and require adequate preoperative and postoperative hydration to prevent thrombotic complications. Neurological examination and blood chemistry analysis of renal, hepatic, and hematological function is necessary to assess the effects of hypoxemia as well as potentially altered systemic blood flow caused by an end-organ function. Sedation-related hypoventilation can exacerbate hypoventilation and worsen hypoxemia. Infusion of prostaglandin E1 (PGE1) in patients with decreased pulmonary blood flow maintains or re-establishes pulmonary flow through the ductus arteriosus. Consequently, neonates rarely require surgery while they are severely hypoxemic.

Prostaglandin E1 dilates the ductus arteriosus of the neonate with life-threatening ductal-dependent cardiac lesions and improves the patient's condition before surgery. It can reopen a functionally closed ductus arteriosus for several days after birth, or it can maintain patency of the ductus arteriosus for several months postnatally [57,58]. Pulmonary blood flow is improved by shunting blood from the aorta through the ductus arteriosus to the pulmonary artery. PGE1 usually improves the arterial oxygenation of hypoxemic neonates who have poor pulmonary perfusion due to obstructed pulmonary flow (critical pulmonary stenosis or pulmonary atresia), and may also improve the mixing of venous and arterial blood at the atrial level in patients with transposition of the great arteries [57]. The improved oxygenation reverses the lactic acidosis that may have developed during episodes of severe hypoxemia. PGE1 administration for 24 h usually markedly improves the condition of a severely hypoxemic neonate with restricted pulmonary blood flow [59].

The common side effects of PGE1 infusion (apnea, hypotension, fever, central nervous system excitation) are easily managed in the neonate when normal therapeutic doses of the drug (0.01–0.1 μg/kg/min) are used [60]. However, PGE1 is a potent vasodilator, so intravascular volume frequently requires augmentation. Patients with intermittent apnea resulting from administration of PGE1 may require mechanical ventilation preoperatively.

Excessive pulmonary blood flow

Excessive pulmonary blood flow is sometimes the primary problem of patients with CHD. Children with L-R shunts may have chronic low-grade pulmonary infection and congestion that cannot be eliminated despite optimal preoperative preparation. If so, surgery should not be postponed further. Respiratory syncytial virus infections are particularly prevalent in this population, but improvements in intensive care and palivizumab prophylaxis have markedly improved outcome with this and other viral pneumonias [61].

The hemodynamic effects of excessive pulmonary blood flow and L-R shunts may include CHF as cardiac ouput is ineffectively circulated back to the lungs. Pulmonary venous return may be many times normal causing the left heart to dilate so the heart responds less efficiently to increased demand. Most of the increment in cardiac output is recirculated to the lungs, worsening symptoms of CHF.

Congestive heart failure

Children with failing hearts have elevated endogenous catecholamine production that increases heart rate and cardiac output and redistributes output from the extremities to highly perfused organs. In severe cases, the patient may be tachypneic, tachycardic, and dusky in room air with body weight below the third percentile for age. The child may have intercostal and substernal retractions and skin that is cool to the touch. Capillary refill may be prolonged. Expiratory wheezes are usually audible (Box 27.2). These clinical signs and symptoms suggest that profound pathophysiological alterations have occurred and the patient has significant respiratory compromise and minimal cardiac reserve. Medical management with digoxin, diuretics, and afterload reduction may improve the patient's condition, but the diuretics may induce profound hypochloremic alkalosis and potassium depletion. The anesthetic plan needs to be tailored accordingly, potentially

Box 27.2: Symptoms and signs of cardiac failure in a neonate and infant

Failure to thrive
- Poor feeding
- Diaphoresis

Increased respiratory work
- Tachypnea
- Wheezing
- Grunting
- Flaring of ala nasi
- Chest wall retraction

Altered cardiac output
- Tachycardia
- Gallop rhythm
- Cardiomegaly
- Poor extremity perfusion
- Hepatomegaly

avoiding potent inhaled anesthetics in favor of an opioid-based technique that is expected to provide more hemodyamic stability than high concentrations of potent anesthesia vapor. Inotropic support and pressor drugs should be immediately available. Mildly symptomatic patients should tolerate premedication and sevoflurane/nitrous oxide inhalation induction of anesthesia for an elective operation.

Obstruction of left heart outflow

Patients with obstruction to outflow from the systemic ventricle are often critically ill. Neonates present with inadequate systemic perfusion and profound metabolic acidosis. The initial pH may be below 7.0 despite a $PaCO_2$ of less than 20 mmHg. Systemic blood flow is largely or completely dependent on blood flow into the aorta from the ductus arteriosus. These lesions include interruption of the aortic arch, coarctation of the aorta, aortic stenosis, and mitral stenosis or atresia as part of the hypoplastic left heart syndrome.

Ductal closure in the neonate causes dramatic worsening of the patient's condition. The patient becomes critically ill or even moribund and requires PGE1 infusion for survival. PGE1 allows blood flow into the aorta from the pulmonary artery because it maintains the patency of the ductus arteriosus [59,62,63]. In neonates with acidosis, metabolic derangements, and renal failure due to inadequate systemic perfusion, PGE1 infusion improves perfusion and metabolism, and surgery can be deferred until the patient's condition improves. Ventilatory and inotropic support and correction of metabolic acidosis, along with calcium, glucose, and electrolyte abnormalities are indicated preoperatively. The stabilization period also allows assessment of the magnitude of end-organ dysfunction caused by inadequate systemic perfusion. Adequacy of resuscitation as well as severity of illness at presentation has an important influence on postoperative outcome [64].

Ventricular dysfunction

Ventricular dysfunction in CHD may be multifactorial. Cyanotic CHD patients who have a large shunt and complete mixing of systemic and venous blood may have excessive pulmonary blood flow that imposes a large volume load on the heart leading to left heart dilation and dysfunction. Ventricular function can be further worsened by poor systemic and coronary perfusion secondary to excessive pulmonary blood flow.

Preoperative assessment should include an estimation of the patient's functional limitation as an indicator of myocardial performance and reserve, quantification of the degree of hypoxia and the amount of pulmonary blood flow, and evaluation of PVR. Narrowing of the shunt or a staged approach to single-ventricle palliation may be indicated before additional palliation or definitive repair can be undertaken.

Anesthetic management may need to be altered to increase or decrease pulmonary blood flow. Systemic blood flow needs to be optimized during induction of anesthesia in patients with increased Qp/Qs without further augmenting pulmonary flow. Hypoxemia may be exacerbated during emergence from anesthesia and intraoperatively by positional changes, retraction of the lungs, and abdominal distention, further compromising the function of a potentially dilated and dysfunctional ventricle.

Older patients with CHD and poor ventricular function due to chronic ventricular volume overload (aortic or mitral valve regurgitation or long-standing pulmonary-to-systemic arterial shunts) may have systolic and diastolic ventricular dysfunction. Systolic function of the ventricle may be impaired by intrinsic myopathic abnormalities related to drug toxicity (e.g. anthracycline-based chemotherapy), inborn enzyme deficiencies, or acquired inflammatory or infectious disease. Patients with such dilated cardiomyopathies require optimization of ventricular performance with an emphasis on inotropic support and afterload reduction.

KEY POINTS: PREOPERATIVE ASSESSMENT AND PREPARATION

- Besides a through history, physical examination, and laboratory data, echocardiography is the mainstay of preoperative assessment in the CHD patient
- Cardiac catheterization, magnetic resonance imaging, and computed tomography imaging and angiography also can add crucial data to aid in preanesthetic planning
- Classification of patients into predominant pathophysiology can aid in planning an appropriate anesthetic: severe hypoxemia, excessive pulmonary blood flow, obstruction to systemic ventricular outflow, or ventricular dysfunction

Principles of anesthetic management

The variations of severity and pathophysiology of CHD mandates individualized anesthetic management based on the known effects of anesthetics and other drugs. Once the critical aspects of the patient's pathophysiology are understood, the anesthetic management plan is formulated to manage anticipated pre-, intra-, and postoperative events.

General care of patients with congenital heart disease

The patient's condition should be optimized prior to elective cardiac or non-cardiac surgery. Cardiac medications such as antiarrhythmic drugs should be continued preoperatively except for angiotensin-converting enzyme inhibitors and angiotensin receptor blockers, which are usually discontinued 24 h prior to induction of anesthesia. In addition, aspirin or other antiplatelet agents or anticoagulants are often discontinued up to 7–10 days preoperatively. Consultation with the patient's cardiologistand surgeon is important to formulate a perioperative plan.

Systemic air emboli are a constant concern in children with CHD. Usual shunting patterns may change during anesthesia and surgery. Transient R-L shunts may occur during some portions of the cardiac cycle or during straining or coughing in patients with open communications between the left and right sides of the heart when normal transatrial pressure gradients are transiently reversed [65]. Right-to-left shunting may occur across functionally closed communications. A probe-patent foramen ovale is common in children, regardless of whether or not they have CHD, and transient R-L shunting through the foramen ovale has been documented during emergence from anesthesia [66]. Air traps or filters are advisable in all IV lines and constant vigilance is necessary to prevent systemic embolization of air.

Prevention of infective endocarditis is an important consideration in patients with CHD undergoing non-cardiac surgery [67]. The American Heart Association (AHA) recommends antibiotic prophylaxis only for patients deemed at highest risk (Box 27.3) who are undergoing procedures at risk for transient bacteremia. Prophylaxis is recommended prior to all dental procedures that involve the manipulation of gingival tissue or the periapical region of teeth or with anticipated perforation of the oral mucosa. Prophylaxis is also recommended for all respiratory tract procedures that involve perforation of the mucosa and for all procedures on infected skin or musculoskeletal tissues. Antibiotic therapy should be continued and expanded to cover enterococci in patients being treated for infections in the gastrointestinal or urinary tracts. Antibiotic prophylaxis is no longer recommended for routine gastrointestinal or urinary tract endoscopy even with biopsies. It is best to consult the literature for the most current recommendations.

Box 27.3: Cardiac conditions associated with the highest risk of adverse outcome from endocarditis for which prophylaxis with dental procedures is recommended

- Prosthetic cardiac valve
- Previous infective endocarditis
  - Congenital heart disease (CHD)*
  - Unrepaired cyanotic CHD, including palliative shunts and conduits
  - Completely repaired congenital heart defect with prosthetic material or device, whether placed by surgery or by catheter intervention, during the first 6 months after the procedure†
  - Repaired CHD with residual defects at the site or adjacent to the site of a prosthetic patch or prosthetic device (which inhibit endothelialization)
- Cardiac transplantation recipients who develop cardiac valvulopathy

* Except for the conditions listed, antibiotic prophylaxis is no longer recommended for any other form of CHD.
† Prophylaxis is recommended because endothelialization of prosthetic material occurs within 6 months after the procedure.

Preanesthetic management

The immediate preoperative period is an anxious time for patients and parents. Many patients may have undergone prior surgery or diagnostic procedures and separation from parents may be difficult. Many patients are now admitted on the day of surgery so adequate preparation for surgery in the preoperative clinic with a thorough explanation of the planned procedure and conduct of anesthesia, including a plan for induction, is essential. Clear fluids can be administered up to 2 h preoperatively, and an extended period of fasting should be avoided when possible, particularly in cyanotic patients.

Given the many types of pathophysiology in CHD patients, no single premedication regimen is recommended. Ideally, one wants a sedated, quiet patient who maintains adequate ventilation and circulation. Oral midazolam 0.5–1.0 mg/kg is an effective anxiolytic and should enable separation from parents without producing hypnosis. The addition of oral ketamine 5–7 mg/kg is sometimes necessary. An intramuscular premedication with ketamine 3–5 mg/kg and midazolam 0.1 mg/kg is also effective. Adequate premedication reduces separation anxiety and facilities inhalational induction of anesthesia with lower concentrations of potent anesthetic vapors. This is particularly beneficial in patients with limited hemodynamic reserves. Patients must be continuously monitored after premedication. CHD patients often have fragile circulatory and ventilatory status. Cyanotic patients, in particular, have decreased hypoxic drive [68].

Induction of anesthesia

Because of the potential for rapid and dramatic hemodynamic changes in young patients with CHD, especially infants, complete preparation of anesthetic and monitoring equipment and required drugs is essential. Adequate assistance should be immediately available during the induction of anesthesia in case problems develop.

The choice of induction technique is influenced by the response to premedication, the parent–child–anesthesiologist relationship, and the anesthetic management plan. In older, non-hypoxemic patients who have minimal compromise of their cardiac reserve, the choice of induction techniques is large. Inhalation, intravenous, or intramuscular induction of anesthesia can be accomplished with a variety of drugs with reasonable degrees of safety if individual pathophysiological limitations are understood. For younger, sicker, and less cooperative patients, the choices diminish.

In children with adequate peripheral veins, the quick insertion of a small-bore IV catheter for induction of anesthesia can be virtually painless. Preoperative use of a topical anesthetic preparation may facilitate intravenous placement. Cooperative children with an adequate cardiac reserve and difficult intravenous access or a morbid fear of needles can have anesthesia induced cautiously with inhaled anesthetics, even if they are cyanotic. An IV catheter can then be inserted to facilitate

administration of muscle relaxants; these drugs facilitate tracheal intubation and avoid the risk of deep levels of inhalational anesthesia for tracheal intubation in patients whose circulatory systems may have little reserve.

An intravenous induction should be used for all patients with severely limited hemodynamic reserve, particularly those with severe ventricular failure or pulmonary hypertension. In situations where hemodynamic instability during induction is likely, starting an inotropic agent such as dopamine prior to induction should be considered. While the stress of placing an IV catheter may be considerable for some patients, particularly those with difficult IV access following previous procedures, this is preferable to potential myocardial depression during an inhalation induction with sevoflurane.

Fentanyl 15–25 μg/kg attenuates the stress-induced increase in PVR associated with endotracheal intubation, provides hemodynamic stability, and facilitates prompt airway control when given with rocuronium 1 mg/kg. Ketamine 1–3 mg/kg IV is also a safe and reliable anesthetic and provides hemodynamic stability with minimal increases in PVR. It is particularly useful in patients with severe CHF and ventricular outflow obstructions. Atropine 20 μg/kg or glycopyrrolate 10 μg/kg can be given concurrently to mitigate the ketamine-induced oral secretions. If intravenous access is difficult in infants, a combination of 3 mg/kg ketamine, glycopyrrolate 10 μg/kg, and succinylcholine 2 mg/kg IM allows prompt induction and airway control.

Propofol can be used in patients with normal ventricular function and no systemic outflow tract obstruction. Titrated doses are suitable for short procedures such as cardioversion or transesophageal echocardiography (TEE). Midazolam 0.1–0.2 mg/kg is also a useful adjunct during an opioid induction but may cause hypotension in patients who are dependent on a high sympathetic drive.

An inhalation induction with sevoflurane (not to exceed an inhaled concentration of 4%) in order to obtain intravenous access is suitable for most infants and children, provided they have stable ventricular function and adequate hemodynamic reserve. This emphasizes the importance of preoperative evaluation when planning the induction technique. Inhalational induction can be used safely in patients with cyanotic heart disease, although uptake may be slower due to the R-L shunt [69]. Saturations will generally increase, provided cardiac output is maintained and airway obstruction avoided.

For many younger children, the presence of a parent during inhalation induction may be preferable for both the patient and parent. This is a common technique for normal children undergoing induction of anesthesia for non-cardiac surgery, but careful preoperative preparation and explanation are necessary before this is undertaken in the cardiac operating room.

Maintenance of anesthesia

Anesthesia maintenance techniques depend on the patient's preoperative cardiorespiratory status and pathophysiology of the underlying cardiac defect, the surgical procedure, the conduct of CPB, potential postoperative surgical problems, and the anticipated postoperative management. Once induction of anesthesia and control of the airway are accomplished and monitoring is adequate, anesthesia can be maintained with inhaled anesthetics or additional intravenous drugs as dictated by the response of each patient, intraoperative events, and postoperative plans.

Stress responses to pain and other noxious stimuli are profound in even the youngest neonates, regardless of postconceptual age [70–72]. These hormonal and metabolic stress responses can be deleterious [73], particularly in patients with marginal hemodynamic reserve. Intraoperative deterioration in the patient's condition is not always clear, but changes in shunting, surgical manipulation of the heart, lungs, or great vessels, and depression of the myocardium by anesthetics are common causes. Decreases in arterial oxygenation or in systemic blood flow and pressure frequently are due to alterations in intracardiac shunting. When circulating blood volume is adequate and anesthesia-related myocardial depression is unlikely, these problems are corrected by appropriately manipulating PVR and SVR. If PVR cannot be altered or is not part of the problem, vasopressor and inotropic drugs are used where indicated to increase SVR and cardiac function.

KEY POINTS: PRINCIPLES OF ANESTHETIC MANAGEMENT

- In general, all cardiac medications should be continued on the day of surgery, except angiotensin-converting enzyme inhibitors and angiotensin receptor blockers, and possibly aspirin, other antiplatelet agents, and anticoagulants
- Meticulous attention to prevent systemic air emboli is important in all patients with intra- or extracardiac shunting
- Infective endocarditis prophylaxis should be administered according to the latest guidelines; both a cardiac indication and a surgical indication are needed
- Judicious use of oral premedication with midazolam and/or ketamine, and parental presence as appropriate, can minimize anxiety and hemodynamic perturbation in the preanesthetic period
- Induction techniques vary, but sevoflurane inhaled induction is appropriate for many CHD patients with preserved ventricular function. Intramuscular induction with ketamine can be used in cyanotic patients; and in very ill patients or those with easily accessible peripheral veins, intravenous induction with agents such as ketamine, fentanyl, or etomidate may be appropriate
- Propofol induction can be used for patients with preserved ventricular function and no systemic ventricular outflow tract obstruction

Choice of anesthetic agents

Use of inhaled anesthetics in children with intracardiac shunting is complicated by differences in uptake and distribution of these agents. A complex computer model has suggested that induction of anesthesia is slowed by the presence of central R-L shunts, slowed less by mixed shunts, and changed little by pure L-R shunts; the changes are proportional to the size of the shunt [69]. These theoretical effects assume a constant

cardiac output and are most marked for insoluble gases (e.g. nitrous oxide). Induction of anesthesia with more soluble gases (e.g. halothane) is less affected. Similar studies comparing the speed of induction with sevoflurane to other potent inhalation agents have not been performed; however, because it is less soluble than halothane, induction with sevoflurane should be expected to be slower in patients with a right-to-left shunt. In children with left-to-right shunts, the speed of inhalation induction is little altered clinically [74]. Data from children with right-to-left shunts corroborate this slower rise in blood to inhaled concentration of halothane, that is corrected when the shunt is closed during cardiac catheterization (Fig. 27.10) [75,76]. Inhalation induction often seems slower in children with pure R-L shunts but this effect is not marked, probably because multiple other variables are affecting uptake. The potentially slow induction of anesthesia in children with pure R-L shunts should be remembered when one must rapidly increase the concentration of potent inhaled anesthetics in these patients. The direct effect of inhaled agents on Qp/Qs appears to be limited. Sevoflurane, halothane, isoflurane, and fentanyl/midazolam do not change Qp/Qs in children with atrial and ventricular septal defects when cautiously administered with 100% oxygen [77].

Potent inhaled anesthetics

The volatile agents most commonly used during pediatric anesthesia are desflurane, isoflurane, and sevoflurane. Halothane is rarely, if ever, used at present. All three can be used safely to maintain anesthesia in children with cardiac disease, although this depends to some extent on the child's cardiac anomaly and related pathophysiology. Cyanotic children with reasonable functional cardiac reserve can have anesthesia induced with sevoflurane or halothane and oxygen (even 70% nitrous oxide does not significantly decrease arterial oxygen saturation) [78–80]. Nevertheless, it is important that the anesthesiologist has an understanding of the potential effects of these anesthetics in young children with CHD.

Increased sensitivity of the immature cardiovascular system and decreased cardiovascular reserves are more serious problems with potent inhaled anesthetics. Use of these agents may considerably reduce the margin of safety in infants and younger children with severe CHD. Volatile anesthetics depress myocardial function primarily by limiting calcium availability within the myocyte, i.e. by reducing trans-sarcolemmal and sarcoplasmic reticulum calcium flux. The net result is depletion of intracellular calcium stores and, given the immaturity of the neonatal and infant myocardium, the potential for systolic dysfunction in these patients may be increased when volatile agents are used. In addition, diastolic ventricular function may also be impaired because of limited reuptake of calcium into the immature sarcoplasmic reticulum, and dependence upon trans-sarcolemmal sodium–calcium exchange [81].

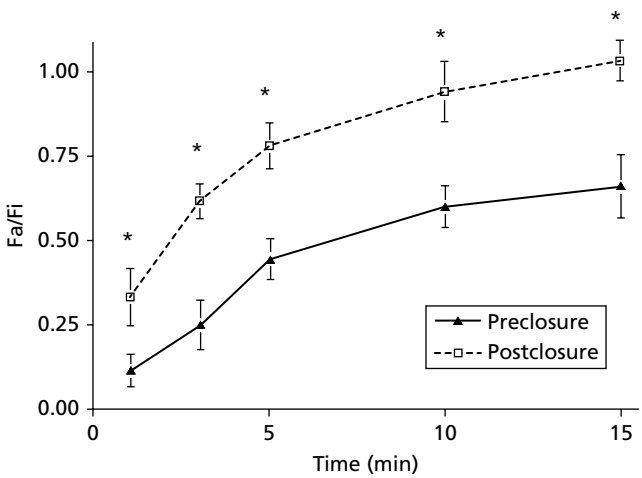

Figure 27.10 Mean ratio values of arterial to inspired halothane in patients pre- and postclosure of right-to-left shunt in cardiac catheterization laboratory. *P = 0.05 versus preclosure.

Therefore, it is not surprising that numerous studies have shown that the immature cardiovascular system of normal infants does not tolerate high concentrations of halothane and isoflurane well; up to 50% of infants with normal cardiovascular systems develop substantial hypotension and bradycardia during induction of anesthesia with these agents unless the cardiovascular system is supported [82,83]. The ventricular function of normal infants declines when anesthesia is induced with isoflurane; stroke volume and ejection fraction decrease by as much as 38% [83]. Somewhat less myocardial depression occurs with halothane in older children [84]. Halothane (1 and 1.5 minimum alveolar concentration (MAC)) depresses cardiac index and contractility in patients with CHD more than comparable levels of sevoflurane, isoflurane, and fentanyl/midazolam anesthesia [85]. In addition, halothane anesthesia may result in more severe hypotension and emergent drug use than sevoflurane anesthesia in infants and children with CHD [86]. Isoflurane causes less direct myocardial depression, is less soluble and therefore has a faster uptake and emergence, has no effect on intracardiac conduction, and much less sensitization of the myocardium to catecholamines compared with halothane. As with isoflurane, sevoflurane causes less myocardial depression and has a low risk for arrhythmias in children compared with halothane [87–89]. Sevoflurane anesthesia is associated with prolongation of the QTc interval in infants [90]. Sevoflurane (1 MAC) and fentanyl/midazolam anesthesia have no significant effect on myocardial function in patients with a single ventricle [91]. Desflurane's effects on myocardial contractility and cardiac rhythm have not specifically been studied in CHD. A single, small, randomized trial of desflurane-based anesthesia versus opioid-based anesthesia for systemic-to-pulmonary shunt surgery in infants revealed no discernable differences in hemodynamic parameters, inotrope use, or complications [92].

Nitrous oxide

The use of nitrous oxide in children with CHD and shunts is controversial because of its potential for enlarging systemic air emboli and for increasing PVR. Nitrous oxide may expand intravascular air emboli and exaggerate the effects of other anesthetics on the circulation, even without systemic air embolization [93]. However, neither has been demonstrated to be a clinical problem in patients with CHD.

Nitrous oxide has been reported to decrease cardiac output, systemic arterial pressure, and heart rate in adults, and toincrease PVR, especially when the pre-existing PVR is elevated [94,95]. The latter would be detrimental to children with R-L

shunts, pulmonary hypertension, and decreased pulmonary flow. However, increases in pulmonary artery pressure or PVR in infants given 50% nitrous oxide do not occur, regardless of pre-existing PVR [19]. Mild but significant decreases in cardiac output, systemic arterial pressure, and heart rate were seen in these infants. Furthermore, inhalation induction of anesthesia with 70% nitrous oxide and halothane did not decrease the arterial oxygen saturation of cyanotic children, suggesting that pulmonary blood flow is not decreased and that PVR is not substantially increased by nitrous oxide [77,78]. Although the administration of nitrous oxide prevents the use of 100% oxygen, the arterial oxygen saturation of cyanotic children may not decrease because changes in FIO_2 have little effect on the arterial oxygenation of these patients (see Fig. 27.8) [96]. Arterial desaturation that is caused by pulmonary disease is, however, probably a contraindication to the use of nitrous oxide.

Intravenous anesthetics

Some intravenous anesthetics provide a large margin of safety for induction of anesthesia in the immature and compromised cardiovascular system of neonates and infants with severe cardiac disease. However, very high transient arterial, cardiac, and brain concentrations of IV agents can occur when normal IV doses of drugs are given as a rapid infusion in children with known R-L shunts because mixing, uptake, and metabolism in the pulmonary circulation are bypassed. In dogs with R-L shunts, a 1 mg/kg bolus of IV lidocaine resulted in arterial drug concentrations above those reported to cause irreversible myocardial toxicity [97]. Routinely administered bolus doses of lidocaine used for dysrhythmias or intubation, or other drugs such as barbiturates, β-blockers. or calcium channel blockers, may be potentially toxic to children with substantial R-L shunts.

Ketamine

Intramuscular ketamine 3–5 mg/kg is well tolerated in sick infants and children with cyanosis or congestive heart failure when IV access or lack of patient cooperation is a problem [98]. The use of an antisialagogue (e.g. atropine or glycopyrrolate) should be considered because of the potential effects of ketamine-induced oral secretions on airways and ventilation, especially in children with decreased oxygen reserves. Ketamine can be mixed with atropine and succinylcholine in the same syringe, the final volume being relatively small, and injection of this mixture allows rapid control of the airway. Small IV doses of ketamine (1–3 mg/kg) are effective for supplemental sedation in uncooperative or apprehensive children who are unwilling to leave their parents. Excessive secretions, airway problems, and apnea do not occur with these doses as they occasionally do with larger IM doses and frequently do with IV doses of ketamine.

Although increased PVR is reported with ketamine in adults, 2 mg/kg IV in premedicated infants and young children usually does not increase pulmonary artery pressure or PVR, even when the baseline PVR is elevated [20,21,23,99]. If hypoventilation or apnea occurs after an IV dose of ketamine, undesirable increases in PVR can occur because of the associated changes in PaO_2 and $PaCO_2$ [20]. Little change in cardiac output, heart rate, or arterial pressure is seen after IV ketamine in infants and small children with CHD [20,21]. Despite reports of ketamine having a negative inotropic effect on isolated heart muscle in animal studies (at very high doses), the ejection fraction of children with CHD is well preserved after ketamine. Furthermore, arterial saturation, for the most part, is improved when ketamine is used to induce anesthesia in cyanotic patients. Clinical experience with ketamine as the induction agent has been excellent for sick infants and children with most forms of heart disease, including those with limited pulmonary blood flow and cyanosis. Ketamine alone or in combination with propofol or dexmedetomidine is also useful for sedation and for anesthesia for cardiac catheterization in children with CHD [100].

Opioid anesthesia

The doses of synthetic opioids required to blunt systemic and pulmonary stress responses in younger and sicker children are generally well tolerated [24,70]. The changes in pulmonary and systemic hemodynamics are usually not significant in infants with bolus doses of fentanyl up to 15–25 μg/kg. Used with 100% oxygen, high-dose opioids are safe and result in increased arterial oxygenation in cyanotic children [101]. High doses of opioids (fentanyl 25–75 μg/kg or sufentanil 5–15 μg/kg) used for induction of anesthesia provide excellent cardiovascular stability in children with CHD. A bolus dose of 10–15 μg/kg effectively ameliorates the hemodynamic response to intubation in neonates, however rapid infusion of high doses of synthetic opioids produces chest wall rigidity and glottic closure in neonates, children, and adults [102,103], so a muscle relaxant needs to be co-administered. Pancuronium is theoretically the muscle relaxant of choice to facilitate endotracheal intubation since its vagolytic effects balance the bradycardia often seen with high doses of synthetic opioids [101,104–107]. Pancuronium is no longer available in most institutions. Rocuronium, vecuronium, and cistracurium all can be used effectively in this setting.

Fentanyl doses as low as 10 μg/kg/h may be sufficient for effective baseline anesthesia in neonates, but larger doses are necessary for prolonged anesthesia [108–110]. Small amounts of potent inhaled anesthetics may be necessary for complete suppression of hemodynamic responses to intense stimulation in vigorous babies and children. Morphine 1 mg/kg or more given slowly provides reasonable cardiovascular stability but histamine-induced hypotension can occur.

The high-dose opioid technique is most suitable for sick infants and older children in whom postoperative mechanical ventilation is planned. Traditionally, fentanyl doses of 50 μg/kg were administered prior to CPB depending on hemodynamic stability. Additional doses of opioids (fentanyl 25 μg/kg with onset of rewarming and fentanyl 25 μg/kg post CPB, for example) or a continuous infusion were necessary as opioid concentrations are known to decrease markedly during CPB [111]. This technique provides hemodynamic stability although it does not guarantee suppression of the endocrine response to surgical stimulation.

Neonates and infants undergoing deep hypothermic CPB surgery are able to generate a significant stress response [72]. A 17-fold increase in epinephrine and 10-fold increase in norepinephrine levels in infants were seen after 1 h of circulatory arrest at 18°C [112]. The reported magnitude of the stress response after cardiac surgery is variable and is influenced by

patient age, type of anesthesia, level of hypothermia, and the duration of CPB and circulatory arrest [113]. In a recent study of stress hormone release during infant cardiac surgery and deep hypothermic CPB using this fentanyl dosing regimen, the endocrine response was not obtunded, yet there were no adverse outcomes. In addition, no specific relationship between opioid dose, plasma fentanyl level, and hormone or metabolic stress response was established [114]. Most centers have abandoned the routine use of high-dose opioid anesthesia in favor of low or moderate doses (fentanyl 5–25 μg/kg or sufentanil 0.5–2.5 μg/kg) in conjunction with volatile anesthetics agents, benzodiazepines, or dexmedetomidine. These lower doses of opioids also facilitate early postoperative tracheal extubation, which has been increasingly adopted in many centers [115]. The high-dose opiate technique is usually reserved for critically ill and hemodynamically vulnerable patients.

Remifentanil is a synthetic ultrashort-acting opioid, rapidly metabolized by non-specific tissue esterases [116]. It is unique among the currently available opioids because of its extremely short context-sensitive half-time (3–5 min), which is largely independent of the duration of infusion. Remifentanil may cause significant respiratory depression and is usually administered to patients who are mechanically ventilated. It may be useful for patients with limited cardiorespiratory reserve undergoing procedures such as cardiac catheterization or pacemaker placement because intense analgesia is provided without significant hemodynamic complications. It may also be used to maintain anesthesia during mild hypothermic CPB for patients who are extubated immediately after surgery in the operating room, such as after atrial septal defect repair [117]. Patients usually emerge quickly once the infusion has been stopped, and opioid side-effects are reduced because of the short duration of action.

Other intravenous agents

The benzodiazepine derivatives (e.g. midazolam) can be useful when titrated in small doses (0.05–0.1 mg/kg), especially in older patients with CHD. Lack of pain on injection and lack of vascular damage make water-soluble midazolam a more useful benzodiazepine than diazepam, particularly because it has a shorter duration of action. Benzodiazepines are commonly used to ensure adequate hypnosis during opioid-based anesthesia, but may also improve hemodynamic stability. In a study of children with acyanotic heart disease undergoing cardiac surgery, the addition of diazepam to fentanyl-based anesthesia (75 μg/kg) resulted in a more stable hemodynamic profile without an increase in epinephrine levels when compared with an isoflurane-based anesthetic technique [118]. In a study of younger children undergoing correction of tetralogy of Fallot, the combined use of sufentanil and flunitrazepam provided a more stable hemodynamic profile and catecholamine response compared with a sufentanil-based technique alone [119].

Propofol can be used judiciously in patients with CHD. The predominant hemodynamic effect of propofol 1–3 mg/kg is a reduction in SVR with no effect on PVR. In patients with R-L shunting this results in a decrease in pulmonary blood flow and arterial oxygenation saturation [120,121]. Propofol should be avoided or used with great caution in patients with systemic outflow tract obstruction because the decrease in SVR can exacerbate the obstruction and lead to coronary ischemia and cardiovascular compromise. The venodilation associated with propofol administration also requires that it be used with caution in patients who have undergone a previous cavopulmonary connection. The resting venous tone is increased in this patient group, and the fall in preload could result in significant hypotension during induction.

Etomidate is an anesthetic induction agent with the advantage of minimal cardiovascular and respiratory depression. An intravenous dose of 0.3 mg/kg induces a rapid loss of consciousness with minimal respiratory depression for a duration of 3–5 min. At this dose it does not substantially alter hemodynamics or either R-L or L-R shunting in patients with CHD [122,123]. It may cause pain on injection and is associated with spontaneous movements, hiccoughing, and myoclonus. Etomidate may be used as an alternative to the synthetic opioids for induction of patients with limited myocardial reserve. A single dose of etomidate can suppress adrenal steroidogenesis and as a result it is not approved for continuous infusion [124].

Dexmedetomidine is an imidazole derivative presynaptic α2-binding agent that binds to the locus ceruleus and spinal cord to provide sedation and some analgesia. It is highly selective for α2 binding (1600:1 α2 to α1), and is US Food and Drug Administration (FDA) approved in adults 18 years or older for intensive care unit (ICU) sedation, procedural sedation, and as an adjunct to intraoperative anesthesia and sedation [125,126]. It is now being used extensively in the postoperative cardiac surgery ICU setting in children, and increasingly in the operating room, and in the catheterization laboratory as a sedative agent and an adjunct to general anesthesia [127]. Dexmedetomidine can cause bradycardia, hypotension, heart block, sinus arrest, and junctional bradycardia; the mechanism is decreased sympathetic outflow from the central nervous system [125,126,128,129]. Slow loading doses over 10 min, and avoiding excessive infusion dosing, reduces the risk of these adverse effects. Dexmedetomidine preserves normal breathing patterns and may facilitate early extubation protocols [130]. In addition, dexemedetomidine reduces the incidence of postoperative tachydysrhythmias, both supraventricular and ventricular [131]. It also reduces the dose of opioids and volatile anesthetic agents when used for congenital cardiac surgery with bypass [132]. Dexmedetomidine is contraindicated in patients with pre-existing heart block or junctional or other bradyarrythmias.

Pharmacokinetics of dexmedetomidine both during and after infant cardiac surgery have been studied; clearance is significantly lower in neonates and loading and infusion doses should be reduced by about 50% in this age group [133]. Loading doses of 0.5–1.0 μg/kg and infusions of 0.5–0.75 μg/kg/h will result in therapeutic plasma concentrations of 300–700 pg/mL. This dose, added to other sedative and analgesic agents such as midazolam and fentanyl, may be adequate for procedural sedation for CHD. Intraoperatively, the same doses can be utilized in conjunction with a reduced dose of opioids, e.g. fentanyl 10–20 μg/kg, and volatile agents to provide surgical anesthesia [130]. Caution must be exercised to monitor heart rate and rhythm carefully, and reduce the dose or discontinue dexmedetomidine if bradyarrythmia occurs. Dexmedetomidine should be avoided in electrophysiological studies because it is likely to suppress many tachydysrhythmias [134]. Dexmedetomidine will also

reduce pulmonary artery pressure and maintain pulmonary vascular resistance in patients with pulmonary hypertension [135]. Finally, large rapid bolus doses above 0.75–1.0 μg/kg can cause hypertension due to some peripheral α1 receptor binding [136].

KEY POINTS: CHOICE OF ANESTHETIC AGENTS

- Right-to-left shunting slows the rate of rise of the arterial level of volatile anesthetic agents as blood bypasses the lungs; the effect is greatest with less soluble agents such as sevoflurane, and less with more soluble agents such as halothane
- Right-to-left shunts can result in high arterial and brain levels of IV induction agents
- Left-to-right shunting has minimal effect on the uptake of volatile anesthetic agents
- Nitrous oxide does not affect PVR in children, but may have a mild effect in decreasing cardiac output and systemic arterial pressure
- Volatile agents, ketamine, propofol, opioids, benzodiazepines, etomidate, and dexmedetomidine provide a wide variety of choices for anesthetic maintenance. Knowledge of the patient's pathophysiology and the hemodynamic effects of these drugs is essential to formulate an appropriate anesthetic plan

Anesthesia for cardiac surgery

Communication between the anesthesia and surgical teams is of utmost importance during surgery for CHD. The manipulations of each team influence the other, and close coordination of activities is necessary for optimal patient care. Specific problems occurring with total repair or palliation of specific congenital cardiac lesions are covered later in the chapter. General problems that occur with various types of closed and open cardiac surgical procedures are considered here.

Anesthetic management of closed cardiac procedures

Patent ductus arteriosus, coarctation of the aorta, and repair of vascular rings are the only congenital cardiac anomalies corrected with closed procedures. Closed palliative procedures, including systemic-to-pulmonary shunts, pulmonary artery banding, and procedures to improve interatrial mixing (Blalock–Hanlon atrial septectomy), are performed infrequently as the trend to definitively correct the CHD early continues. Anesthesia for closed palliative procedures is in some ways more demanding because CPB is not available if the patient's hemodynamic status deteriorates. Therefore, monitoring requirements are stringent, and central venous and arterial access are usually mandatory. Pulse oximetry is invaluable in these cases to evaluate the infant's condition and to assess the effectiveness of the closed surgical procedure.

Acid–base and electrolyte balance are meticulously maintained at normal levels throughout closed procedures. When these procedures are done via a thoracotomy, the operative field is rarely visible to the anesthesiologist, and marked deterioration of cardiopulmonary function may result from surgical manipulations. Any deterioration in the infant's condition should be immediately communicated to the surgeon, who has a view of the surgical field and knows what is being done there. Some compromise of ventilation and pulmonary blood flow inevitably occurs during these procedures, occasionally with severe decreases in arterial oxygen saturations. Surgical manipulations can be altered or temporarily stopped while maneuvers are undertaken to recover the patient's status to baseline.

Mechanical ventilation

Altered lung mechanics and ventilation/perfusion abnormalities are common problems in the immediate postoperative period [137]. Besides preoperative problems secondary to increased Qp/Qs, additional considerations include the surgical incision and lung retraction, increased lung water following CPB, possible pulmonary reperfusion injury, surfactant depletion, and restrictive defects from atelectasis and pleural effusions.

In general, neonates and infants with their limited physiological reserve should not be weaned from mechanical ventilation until hemodynamically stable, and factors contributing to an increase in intrapulmonary shunt and altered respiratory mechanics have improved.

Volume-limited ventilation

A traditional approach to mechanical ventilation in children with CHD has been the use of a volume-limited, time-cycled mode, with large tidal volumes of 15–20 mL/kg and no PEEP. This approach was developed in the early years of congenital heart surgery when older generations of ventilators existed and the monitoring of ventilation was frequently less than ideal. While the peak inspiratory and mean airway pressure are usually increased using large tidal volumes in this mode, changes in compliance and resistance can be readily detected. If there is a sudden change in pulmonary mechanics from atelectasis, pneumothorax, or endotracheal tube obstruction, the peak inspiratory pressure alarm limit is reached as the ventilator tries to deliver the preset tidal volume.

However, for neonates and infants, the compressible volume of the ventilator circuit (1–1.5 mL/cmH_2O peak inspiratory pressure) means that the delivered tidal volume is less than the preset volume. For older patients receiving larger tidal breaths, the volume lost by compression of gas in the circuit is minimal and rarely affects their tidal ventilation. But for neonates and infants, this compressible volume may be a considerable component of their tidal ventilation. Further, any leak around the endotracheal tube means that a proportion of the delivered tidal volume may be lost. Inspiratory and expiratory times also need to be closely observed to prevent excessive auto-PEEP. Variable time constants (i.e. compliance × resistance) within regions of the lung are common in children with defects associated with high pulmonary blood flow, as well as following CPB. Using a volume-limited, time-cycled mode, those areas of lung with an increased time constant may be preferentially ventilated and overdistended, contributing to ventilation/perfusion mismatch and potential lung

injury. Contemporary approaches to volume-limited ventilation emphasize reduction in risk for volutrauma and barotrauma and recommend lower tidal volumes of 5–7 mL/kg, which have been demonstrated to reduce lung injury in ventilated adult patients in the intensive care setting; outcome data are less clear in pediatric patients [138]. Modern anesthesia ventilators with smaller internal compression volumes, and more accurate calibration of tidal volumes accounting for internal and external compression volumes, enable more accurate volume ventilation even in smaller infants [139].

Pressure-limited ventilation

A pressure-limited, time-cycled mode of ventilation is often appropriate in children weighing less than 10 kg, particularly those with significant alteration in lung compliance and airway resistance. A decelerating flow pattern is used when a breath is delivered to the patient until a preset peak inspiratory pressure is achieved. The delivered tidal volume will vary according to the compliance and resistance of the lung, and therefore from breath to breath. Both the peak inspiratory pressure and the inspiratory time can be manipulated to increase or decrease the delivered tidal volume. A square wave pressure waveform is generated by changing the inspiratory time, which will also alter the mean airway pressure. In general, it is preferable to set a minute ventilation using the lowest possible mean airway pressure. In-line monitoring enabling breath to breath assessment of tidal volume and mean airway pressure is essential, with appropriate alarm limits set such that acute changes in compliance and resistance can be detected.

Cardiorespiratory interactions

Cardiorespiratory interactions vary significantly between patients, and it is not possible to provide specific ventilation strategies or protocols that will cover all patients. Rather, the mode of ventilation must be matched to the hemodynamic status of each patient to achieve the appropriate cardiac output and gas exchange. Frequent modifications to the mode and pattern of ventilation may be necessary during recovery after surgery, with attention to changes in lung volume and airway pressure.

Lung volume

Changes in lung volume have a major effect on PVR, which is lowest at FRC, while both hypo- and hyperinflation may result in a significant increase in PVR (Fig. 27.11). At low tidal volumes, alveolar collapse occurs because of reduced interstitial traction on alveolar septae. In addition, radial traction on extra-alveolar vessels such as the branch pulmonary arteries is reduced, thus reducing the cross-sectional diameter. Conversely, hyperinflation of the lung may cause stretching of the alveolar septae and compression of extra-alveolar vessels.

An increase in PVR increases the afterload or wall stress on the right ventricle (RV), potentially compromising RV function and contributing to decreased left ventricle (LV) compliance secondary to interventricular septal shift. In addition to low cardiac output, signs of RV dysfunction including tricuspid regurgitation, hepatomegaly, ascites, and pleural effusions may be observed.

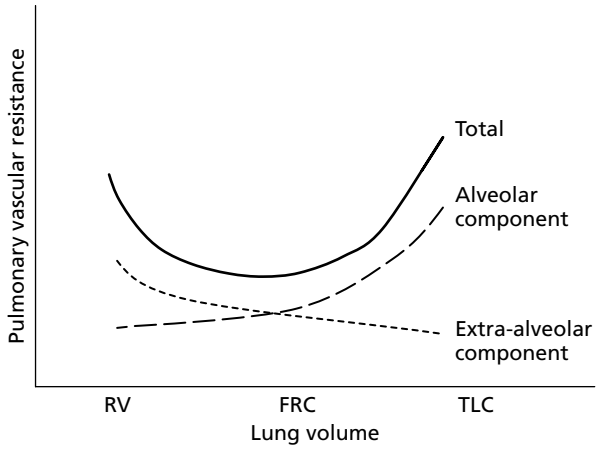

Figure 27.11 Lung volume impacts pulmonary vascular resistance (PVR). In the diagram, there is a marked decrease in PVR when increasing lung volume from residual volume (RV) to functional residual capacity (FRC). This is mainly a function of opening alveoli and shutting open extra-alveolar vessels (a drop in extra-alveolar resistance; dotted line). Further increases in lung volume from FRC to total lung capacity (TLC) cause increases in PVR. This is mainly due to compression of intra-alveolar vessels by air trapping (alveolar component; dashed line). Total PVR is minimized at FRC (solid line).

Intrathoracic pressure

An increase in mean intrathoracic pressure during positive pressure ventilation decreases preload to both pulmonary and systemic ventricles, but has the opposite effect on afterload to each ventricle (Table 27.5)[140].

Right ventricle

The reduction in RV preload that occurs with positive pressure ventilation may reduce cardiac output (Fig. 27.12) Normally the RV diastolic compliance is extremely high and the pulmonary circulation is able to accommodate changes in flow without a large change in pressure. An increase in mean intrathoracic pressure increases the afterload on the RV from direct compression of extra-alveolar and alveolar pulmonary vessels.

Table 27.5 The effect of a positive pressure mechanical breath on afterload and preload to the pulmonary and systemic ventricles.

	Afterload	Preload
Pulmonary ventricle	Elevated effect: ↑ RVEDp ↑ RVp ↓ Antegrade PBF ↑ PR and/or TR	Reduced effect: ↓ RVEDv ↓ RAp
Systemic ventricle	Reduced effect: ↓ LVEDp ↓ LAp ↓ Pulmonary edema	Reduced effect: ↓ LVEDv ↓ LAp Hypotension

LAp, left atrial pressure; LVEDp, left ventricle end-diastolic pressure; LVEDv, left ventricle end-diastolic volume; PBF, pulmonary blood flow; PR, pulmonary regurgitation; RAp, right atrial pressure; RVEDp, right ventricle end-diastolic pressure; RVEDv, right ventricle end-diastolic volume; RVp, right ventricle pressure; TR, tricuspid regurgitation.

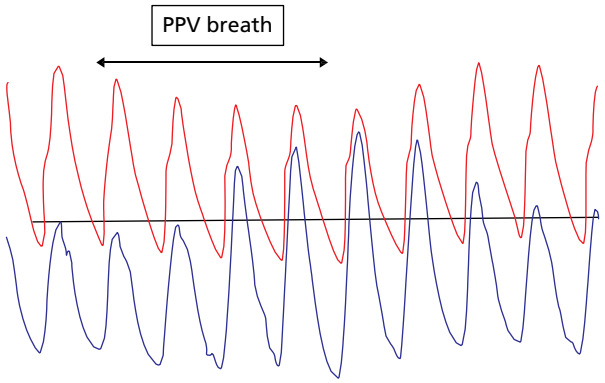

Figure 27.12 Positive pressure ventilation (PPV) effects on the right ventricle. Simultaneous tracings of aortic (red) and right ventricle (blue) pressure waveforms during PPV in a child with pulmonary artery stenosis. Note the increase in right ventricular pressure to approximately systemic (aortic) level during mechanical inspiration when the afterload on the right ventricle is increased.

Patients with normal RV compliance and without residual volume load or pressure load on the ventricle following surgery usually show little change in RV function from the alteration in preload and afterload that occurs with positive pressure ventilation. However, these effects can be magnified in patients with restrictive RV physiology, in particular neonates who required a right ventriculotomy for repair of tetralogy of Fallot, pulmonary atresia, or truncus arteriosus. While systolic RV function may be preserved, diastolic dysfunction is common with increased RV end-diastolic pressure and impaired RV filling.

The potential deleterious effects of mechanical ventilation on RV function are important to emphasize. The aim should be to ventilate with a mode that enables the lowest possible mean airway pressure, while maintaining lung volume. While the use of a low peak inspiratory pressure, short inspiratory time, increased intermittent mandatory rate, and low levels of PEEP has been recommended as one ventilation strategy in patients with restrictive RV physiology, the smaller tidal volumes (e.g. 6–8 mL/kg) during this pattern of ventilation may reduce lung volume and FRC, thereby increasing PVR and afterload on the RV. An alternative strategy in a pressure-limited mode of ventilation is to use larger tidal volumes of 12–15 mL/kg, with a longer inspiratory time of 0.8–1.0 s, increased peak inspiratory pressure of around 30 cmH_2O and low PEEP (i.e. wide ΔP), and slow intermittent mandatory rate of 12–15 breaths/min. For the same mean airway pressure, RV filling is maintained and RV output augmented by maintaining lung volume and reduced RV afterload.

Left ventricle

Left ventricular preload is also affected by changes in lung volume. Pulmonary blood flow, and therefore preload to the systemic ventricle, may be reduced by an increase or decrease in lung volume secondary to alteration in radial traction on alveoli and extra-alveolar vessels.

The systemic arteries are under higher pressure and not exposed to radial traction effects during inflation or deflation of the lungs. Therefore, changes in lung volume will affect LV preload, but the effect on afterload is dependent upon changes in intrathoracic pressure alone rather than changes in lung volume.

In contrast to the RV, a major effect of positive pressure ventilation on the LV is a reduction in afterload (Fig. 27.13). Using LaPlace's Law, wall stress is directly proportional to the transmural LV pressure and the radius of curvature of the LV. The transmural pressure across the LV is the difference between the intracavity LV pressure and surrounding intrathoracic pressure. Assuming a constant arterial pressure and ventricular dimension, an increase in intrathoracic pressure, as occurs during positive pressure ventilation, will reduce the transmural gradient and therefore wall stress on the LV [140]. Therefore, positive pressure ventilation and PEEP can have significant beneficial effects in patients with LV failure.

Patients with LV dysfunction and increased end-diastolic volume and pressure can have impaired pulmonary mechanics secondary to increased lung water, decreased lung compliance, and increased airway resistance. The work of breathing is increased and neonates can fatigue early because of limited respiratory reserve. A significant proportion of total body oxygen consumption is directed at the increased work of breathing in neonates and infants with LV dysfunction, contributing to poor feeding and failure to thrive. Therefore, positive pressure ventilation has an additional benefit in patients with significant volume overload and systemic ventricular dysfunction by reducing the work of breathing and oxygen demand.

Lung injury

It is important to appreciate that mechanical ventilation may result in significant lung injury, particularly when high tidal volumes are used [141]. Large, rapid changes in tidal volumes may lead to shear stress on the alveolar septae and subsequent alveolar capillary disruption. The same mechanisms that result in air leak may also result in disruption of the microcirculation, causing an increase in total lung water with subsequent increase in airway resistance and reduction in lung compliance.

Lung disease is usually not homogenous, with regions of the lung having different time constants, i.e. the concept of "fast" alveoli and "slow" alveoli. When using a volume-limited strategy, the more compliant alveoli will distend in preference to regions of lung that are collapsed or have slow time constants, thereby resulting in regional alveolar overdistension and trauma. This may be less evident with a pressure-limited strategy, as the more compliant or faster alveoli will distend to the preset pressure limit and then, depending on the inspiratory time, regions of lung with reduced time constants will gradually distend and be recruited.

While a relatively large tidal volume of 12–15 mL/kg is beneficial for many patients following congenital heart surgery for maintaining lung volume at lower PVR, lung injury may occur if a high-volume strategy is continued for a prolonged period (i.e. volutrauma). Using a pressure-limited mode of ventilation will enable a relatively constant tidal volume without a wide swing in peak inspiratory pressure or regional alveolar overdistension. It is essential to continually re-evaluate the mode of ventilation and modify it according to hemodynamic responses. Fortunately, most patients undergoing congenital cardiac surgery do not have parenchymal lung disease and changes in pulmonary mechanics, such as secondary to changes in lung water, are generally resolved following complete surgical repair and diuresis after CPB.

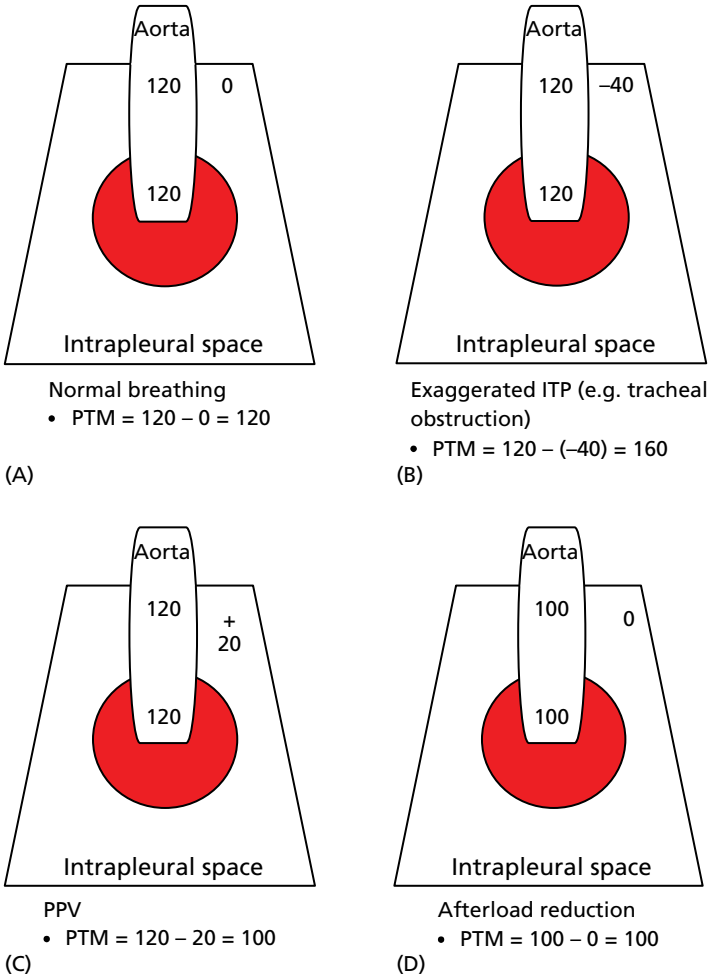

Figure 27.13 Transmural aortic pressure affects left ventricular afterload. LaPlace's Law, the transmural aortic pressure (PTM) is affected by intrapleural pressure. (A) During normal breathing there is very little effect of the intrapleural pressure on PTM and thus left ventricular afterload. (B) The generation of pathological degrees of negative intrapleural pressure (as with severe airway obstruction or decompensated heart failure) significantly increases left ventricular afterload. (C, D) Provision of positive pressure ventilation (PPV) (C) or pharmacological afterload reduction (D) can both independently reduce left ventricular afterload. Pressure units are in mmHg. ITP, intrathoracic pressure.

Positive end-expiratory pressure

The use of PEEP in patients with CHD has been controversial. It was initially perceived not to have a significant effect in terms of improving gas exchange, and there was concern that the increased airway pressure could have a detrimental effect on hemodynamics and contribute to lung injury and air leak.

Nevertheless, PEEP increases FRC, enabling lung recruitment, and redistributes lung water from alveolar septal regions to the more compliant perihilar regions. Both of these effects will improve gas exchange and reduce PVR. However, excessive levels of PEEP may be detrimental by increasing afterload on the RV. Usually 3–5 cmH_2O of PEEP will help maintain FRC and redistribute lung water without causing hemodynamic compromise.

Management of cardiopulmonary bypass

The cardiac anesthesiologist must be familiar with CPB techniques and their effects on multiple organ systems. A schematic representation of a common arrangement for a pediatric cardiopulmonary bypass circuit is depicted in Figure 27.14. An important component of the improvement in early outcome following congenital heart surgery has been the advances in CPB techniques, myocardial protection, and perioperative pharmacological and mechanical support. The exposure of blood elements to the non-epithelialized CPB circuit induces a systemic inflammatory response (Fig. 27.15). The effects of the interactions of blood components with the extracorporeal circuit are magnified in children due to the large bypass circuit surface area and priming volume relative to patient blood volume. Humoral responses include activation of complement, kallikrein, eicosanoid, and fibrinolytic cascades. Cellular responses include platelet activation and an inflammatory response with an adhesion molecule cascade stimulating neutrophil activation and release of proteolytic and vasoactive substances [142].

The clinical consequences of the systemic inflammatory response include increased interstitial fluid and generalized capillary leak with the potential for multiorgan dysfunction. Total lung water is increased with an associated decrease in lung compliance and increase in the alveolar-to-arterial O_2 ($A–aO_2$) gradient. Myocardial edema results in impaired ventricular systolic and diastolic function. Impaired myocardial function is sometimes exacerbated by an additional 20–30% decrease in cardiac output frequently seen in neonates in the

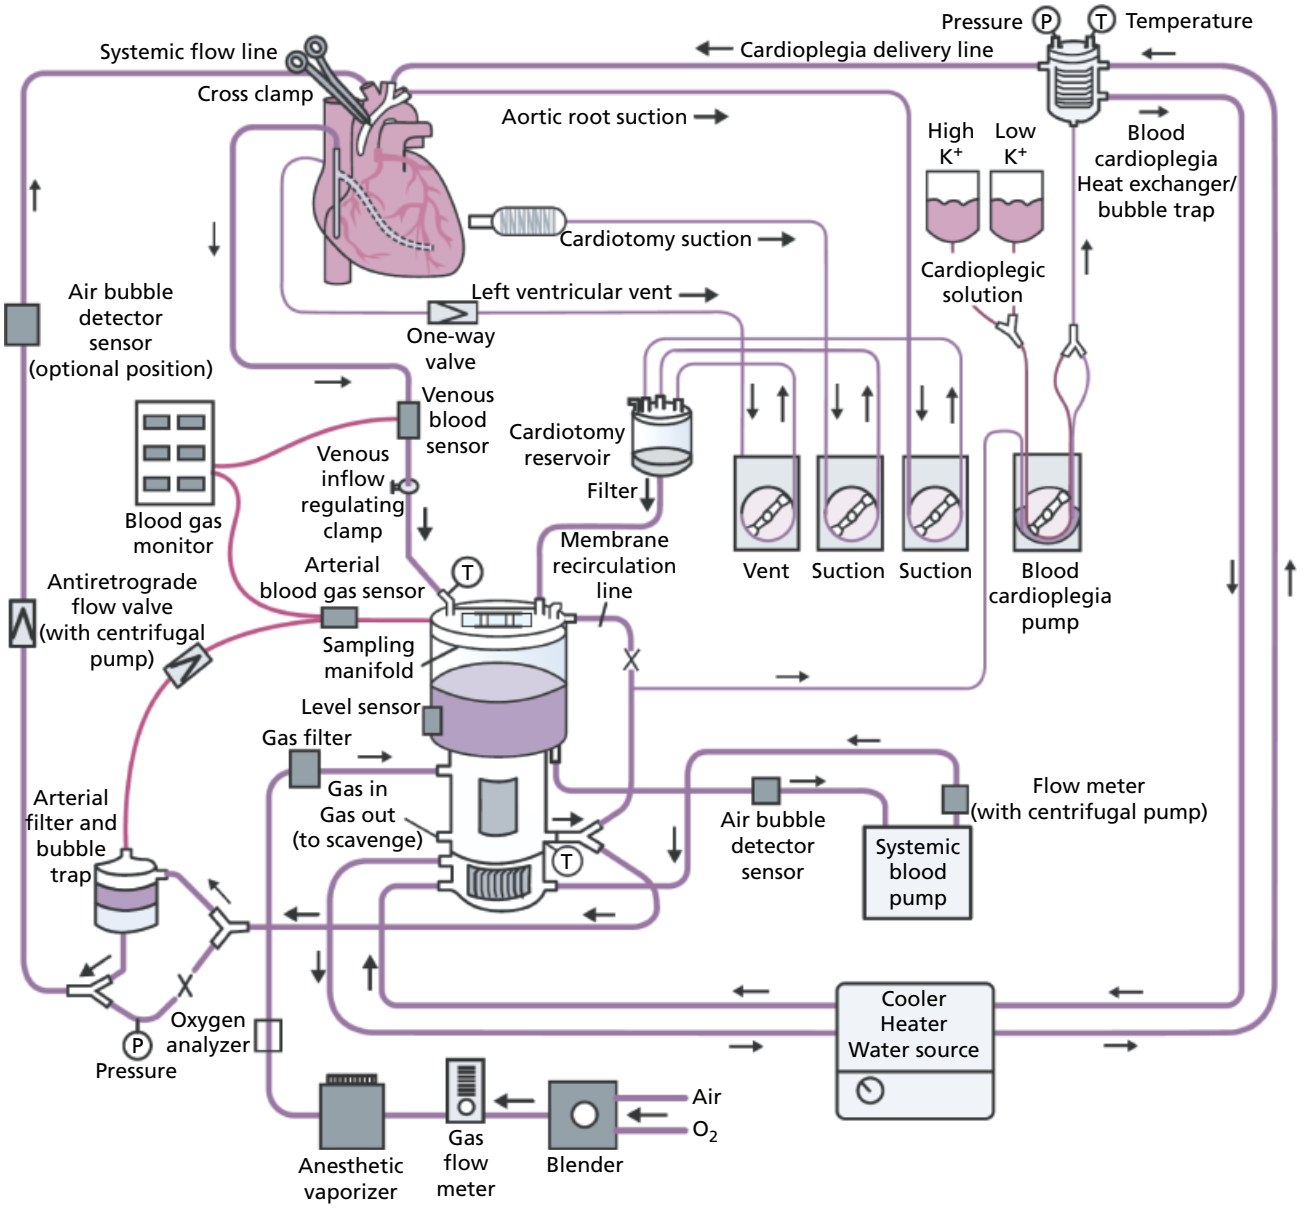

Figure 27.14 Schematic diagram of a cardiopulmonary bypass circuit. This scheme depicts a membrane oxygenator with integral hard-shell venous reservoir and external cardiotomy reservoir. Many circuits have the cardiotomy reservoir, venous reservoir, and oxygenator integrated into one single unit. The systemic blood pump may be either a roller or centrifugal pump. Most pediatric venous cannulations are bicaval with two separate venous cannulas instead of the single venous cannula depicted here. Carbon dioxide can also be added to the inspired gas to facilitate pH stat blood gas management. There are many variations of the CPB circuit and the anesthesiologist needs to be familiar with the configuration in their local institution. Arrows indicate the direction of flow; X, placement of tubing clamps; P, pressure sensor; T, temperature sensors. *Source*: Reproduced from Hessel and Hill [358] with permission of Wolters Kluwer.

first 6–12 h following surgery. Renal function is compromised by the inflammatory response and by lower cardiac output. Sternal closure may need to be delayed due to mediastinal edema if cardiorespiratory compromise is noted when closure is attempted. Ascites, hepatic congestion, and bowel edema may lead to abdominal distention that affects mechanical ventilation and can cause a prolonged ileus that delays feeding. An inflammatory-based coagulopathy post CPB may contribute to delayed hemostasis.

Numerous strategies have evolved to limit the effect of endothelial injury resulting from the systemic inflammatory response. The most important strategy is limiting the time spent on bypass and the duration of deep hypothermic circulatory arrest. Hypothermia and corticosteroids are important pre-bypass measures to limit activation of the inflammatory response, as is the use of antioxidants such as mannitol. Interstitial fluid accumulation can be reduced by increasing the oncotic pressure of the circuit prime with albumin or blood products and by using ultrafiltration to reduce body water and tissue edema.

Ultrafiltration during CPB

A number of different ultrafiltration techniques can be used in association with pediatric CPB. Conventional ultrafiltration (CUF) refers to ultrafiltration during CPB. CUF can only be performed if the volume in the venous reservoir is sufficient

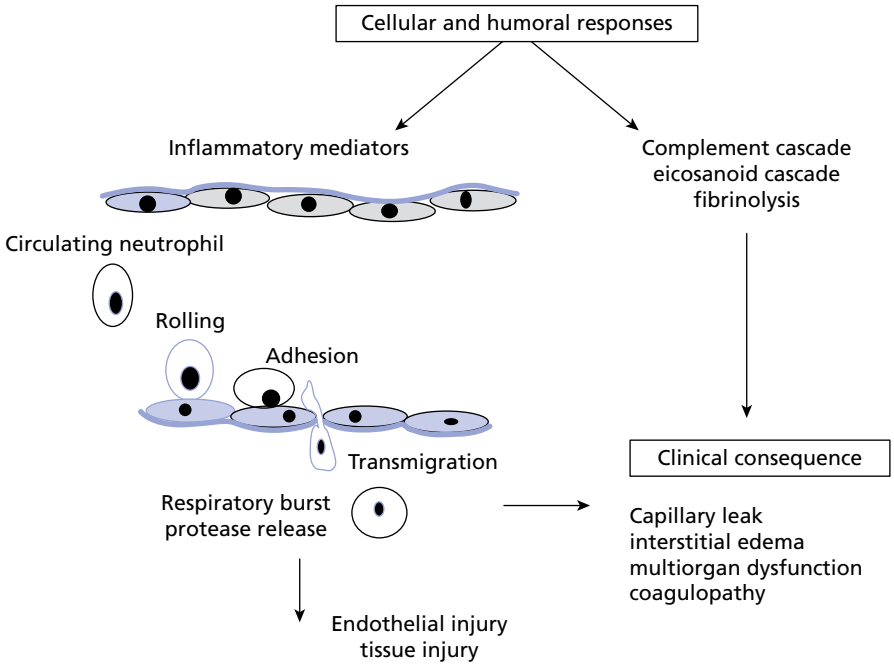

Figure 27.15 Cellular and humoral response to cardiopulmonary bypass.

to allow removal of ultrafiltrate fluid volume. Modified ultrafiltration (MUF) is a similar technique that allows ultrafiltration to continue after weaning from CPB. Blood from the CPB circuit is pumped to an ultrafiltrator through an arteriovenous or venovenous limb before returning to the patient. The CPB circuit remains primed while the CPB and patient's blood is ultrafiltrated. Blood volume is kept constant by adding blood from the CPB circuit to the ultrafiltration circuit as ultrafiltrate volume is removed. The major advantage of MUF over CUF is that it allows hemoconcentration to continue once CPB has been terminated. As a result, MUF normally allows a greater degree of hemoconcentration than can be obtained with CUF alone, particularly in small children. Some institutions utilize both CUF and MUF as the techniques are not mutually exclusive [143]. Heparin anticoagulation must be maintained during MUF with protamine reversal of heparin initiated after termination of MUF. The endpoint for termination of MUF following CPB varies from institution to institution with some institutions terminating MUF after a set time interval (e.g. 15–20 min), a set hematocrit (e.g. 40%), or a set volume removed (e.g. 750 mL/m^2).

Dilutional (DUF) and zero-balance ultrafiltration (ZBUF) are similar to CUF but produce a high-volume ultrafiltrate that is continuously replaced with crystalloid solution during CPB. DUF is performed throughout CPB with ultrafiltration rates of 40–80 mL/kg/h [144,145]. ZBUF is usually done during rewarming and utilizes ultrafiltration rates of 200 mL/min/m^2. These methods do not result in hemoconcentration but may be beneficial in removing inflammatory mediators. MUF is usually used in conjunction with these techniques to obtain hemoconcentration.

MUF has been demonstrated to reduce total body water, attenuate dilutional anemia and coagulopathy, reduce homologous blood requirements, narrow the A–aO_2 gradient, improve LV compliance and systolic function as well as arterial blood pressure, and decrease inotropic requirements in the immediate postfiltration period [146–153]. In a non-randomized, retrospective analysis of cavopulmonary connection procedures (primarily hemi-Fontan and lateral tunnel Fontan procedures), patients in whom MUF was used had a lower incidence of pleural and pericardial effusions and a shorter hospital stay than patients in whom MUF was not used [148]. MUF may reduce postoperative ventilatory support times but this has not been a consistent finding despite short-term improvements in pulmonary compliance [148,150,154].

A number of studies have shown MUF to be effective in removing both anti-inflammatory (interleukin (IL)-10 and IL-1 receptor antagonist) and proinflammatory (tumor necrosis factor α, IL-1β, IL-6, IL-8, complement fragments C3a and C5a, and endotoxins) mediators generated during CPB, while other studies have not confirmed this efficacy [150,155–161]. In addition, MUF may offer no advantage over CUF in terms of inflammatory mediator removal [157]. The extent to which the beneficial effects of MUF are related to reduction of tissue edema, removal of inflammatory mediators, and hemoconcentration has not been clarified [143].

ZBUF in conjunction with MUF has been shown to be more effective than MUF alone in reducing inflammatory mediator concentrations measured immediately following ultrafiltration Patients in the ZBUF group also had reduced blood loss, a shorter duration of postoperative ventilatory support, and a narrower 24 h A–aO_2 gradient [144]. DUF in conjunction with MUF has been shown to be more effective than CUF alone in reducing plasma endothelin 1 and thromboxane B_2 levels following CPB and in attenuating postoperative pulmonary hypertension [145,149,161]. In addition, the duration of postoperative ventilatory support and transfusion requirements was reduced in a group of high-risk patients (neonates, patients with pulmonary hypertension, and patients with prolonged CPB times) [149,162]. A recent study demonstrated a modest reduction in IL-6, a narrowed A–aO_2 gradient, and improved pulmonary compliance but no reduction in the

length of postoperative ventilatory support with CUF in conjunction with MUF as compared with no ultrafiltration [163]. No advantage in terms of improved postoperative course was demonstrated when CUF combined with MUF was compared with CUF alone, despite the fact that a larger filtrate volume was obtained in the combined group [164,165]. In addition, MUF alone and CUF alone were indistinguishable in their effect on hematocrit, mean arterial pressure, heart rate, and LV shortening fraction when equal filtrate volumes were removed in another trial [166]. Finally, combining DUF and MUF offered no clinical advantage over DUF or MUF alone despite larger filtrate volumes in the combined group [167].

Ultrafiltration techniques are useful for hemoconcentration, removal of inflammatory mediators, and reducing total body water following CPB but they do not prevent or treat the inflammatory response to CPB. Inflammation is a multifactorial response to CPB and needs to be treated at multiple levels of the process. Drugs that prevent or modify adhesion molecule–endothelial cell interactions will likely be pivotal in controlling the inflammatory response and are being pursued in laboratory and clinical studies.

CPB in patients with CHD involve different techniques than those used in adult patient undergoing correction of acquired heart disease. Venous cannulation in neonates and infants may be more complicated than in adults. Multiple cannulas may be required depending on the anatomy and bypass technique, and positioning of the cannulas may be challenging because of the small size of the vessels. Malpositioned venous cannulas may result in elevated venous pressures that will decrease perfusion pressures, particulary in the cerebral and splanchnic circulations. Signs of malpositioned venous cannulas include reduced venous return to the bypass circuit, abdominal distention from splanchnic congestion, and head suffusion secondary to cerebral congestion. Elevated SVC pressures will reduce cerebral blood flow, increase the risk of cerebral edema, and reduce the rate of cerebral cooling.

Adequacy of systemic perfusion cannot be estimated by pump flow in the presence of systemic-to-pulmonary shunts that are common in patients with CHD (e.g. Blalock–Taussig shunts, patent ductus arteriosus, and native aortopulmonary collateral vessels) These shunts must be controlled prior to onset of CPB, otherwise systemic blood flow will be shunted to the pulmonary circulation. Excessive pulmonary blood flow may lead to pulmonary congestion and myocardial distension from the increased blood return to the heart. Systemic hypoperfusion and uneven cooling or rewarming may result unless perfusion flow is increased to compensate for flows through these shunts.

Moderate and deep hypothermic CPB are frequently used in patients with CHD. Moderate hypothermia requires pumps flows that meet the metabolic needs of the patient on CPB. The metabolic needs of neonates and infants indexed to surface area are higher than in adults. Flow rates of 100–150 mL/kg/min or indexed flows to 2.2–2.5 L/min/m^2 should provide adequate flow at normothermia or moderate hypothermia. Systemic perfusion in young patients is regulated primarily by flow rate, so that perfusion pressures of 30 mmHg or less are usually adequate in these patients especially when hemodilution decreases blood viscosity and SVR. A venous oxygen saturation of >75%, even differential temperature cooling, and low lactate levels suggest adequate perfusion [168]. Perfusion flow and pressure are misleading indices of adequate tissue perfusion in patients with poor venous drainage, severe hemodilution, malposition of the aortic cannula, or in the presence of a large left-to-right shunt. Deep hypothermia (<18°C) is often required to meet metabolic demand if reduced flow or "low-flow" CPB (flow rates of 30–50 mL/kg/min) is indicated for a particular surgical repair.

Optimal flow rates during moderate or deep hypothermic CPB cannot be determined by flow rate calculations alone, so adequacy of perfusion must be assessed by other measures. There is no one measure of index that assures adequate systemic perfusion on CPB, but a venous oxygen saturation of >75%, low lactate levels, and evenness of temperature measured at multiple sites suggest adequate perfusion [168]. Continuous monitoring of blood gases and oxygen saturation is important to identify trends in tissue oxygen extraction, but these numbers only provide global indices of perfusion, and monitoring regional perfusion is ideal. Cerebral perfusion can be monitored using transcranial sonography, near infrared spectroscopy, and electroencephalograms, but to date there are no monitors available for routine clinical use to monitor perfusion of other vascular beds.

Low-flow CPB and deep hypothermic circulatory arrest

Some cardiac repairs cannot be completed with aortic or venous cannulas in place. Deep hypothermic circulatory arrest (DHCA) allows cessation of CPB, removal of venous and arterial cannula, and exsanguination of the heart into the venous reservoir of the CPB circuit to improve surgical exposure. The technique is utilized primarily for the aortic arch reconstruction component of the stage 1 procedure for hypoplastic left heart syndrome, the repair of interrupted aortic arch, neonatal repair of total anomalous pulmonary venous return, and complicated intracardiac repairs in small (<2.5 kg) neonates and infants [169]. There has been substantial refinement of the technique of DHCA since its successful inception in the 1970s, but DHCA is still used selectively and for relatively short intervals (<45 min). The development of brain and body ischemia is directly related to core temperature prior to the onset of DHCA and circulatory arrest time. Arrest times of less than 40 min are associated with a lower incidence of seizures and fewer neurobehavioral deficiencies than longer intervals [170–173].

The large body surface area to mass ratio in neonates and infants makes cooling particularly efficient. A 2–3°C reduction in core temperature is common following induction of anesthesia and prior to CPB. The use of cooling blankets, low ambient room temperature, and reduced overhead operating light intensity helps maintain a low temperature during bypass and minimizes radiant heating of the myocardium. Cooling of the brain is improved by placing bags of ice around the head.

Regional low-flow perfusion (RLFP) techniques have been developed to perfuse limited area of the body to help prevent the potentially deleterious effects of DHCA on cerebral and somatic perfusion and oxygenation. In particular, antegrade cerebral perfusion (ACP) is sometimes used in aortic arch reconstruction in children with hypoplastic left heart syndrome undergoing the stage 1 procedure and in children with

aortic hypoplasia or interruption undergoing repair. A number of techniques to provide ACP via the right innominate artery have been described and are used in conjunction with deep hypothermia [174–177]. These techniques provide both cerebral and somatic perfusion to subdiaphragmatic viscera. Somatic perfusion is thought to occur via the extensive network of arterial collaterals in the neonate which link the supra- and subdiaphragmatic viscera. This network includes the internal thoracic and intercostal arteries.

The flow rates necessary to provide optimal cerebral and somatic perfusion during ACP have yet to be determined, although rates of 30–70 mL/kg/min are common. Efforts to optimize ACP flow rates utilizing near infrared spectrographic analysis of cerebral oximatery and transcranial Doppler have been undertaken [178].

Neurological injury is an inherent risk for any patient undergoing cardiac surgery and CPB, especially in neonates and infants where DHCA or low-flow techniques are commonly used. Reducing modifiable sources of neuronal injury during CPB is essential [179] as brain immaturity, coexistant congenital neurological abnormalities, and perinatal injury also contribute to long-term neurobehavioral deficiencies in CHD patients undergoing repair as a neonate or infant. Strategies to optimize cerebral protection during deep hypothermic CPB or arrest include prolonged duration of cooling (usually over 20 min) [180–182] and pH stat arterial blood gas management that normalizes pH during cooling by adding CO_2 to the sweep gas. Higher partial pressure of CO_2 causes dilation of the cerebral vasculature and allows for more even cooling of the brain [183]. A higher hematocrit (approximately 30%) prior to DHCA [184] and short DHCA intervals of <40 min have also been associated with improved neurological outcome [185].

Weaning from cardiopulmonary bypass

Arterial blood gases, electrolytes, and levels of anticoagulation are checked periodically during CPB and during the rewaming phase when the metabolic demand of the patient is expected to return to prehypothermic levels. Adequacy of rewarming is judged by measuring body temperature at multiple sites, including rectal or bladder and nasopharyngeal or esophageal temperatures. Prior to separation from bypass, electrolytes are normalized and any air is vented from the heart so air does not enter the systemic circulation as the heart begins ejecting blood. When rewarming is complete and cardiac function is judged adequate, weaning from CPB is accomplished by slowly allowing the heart to fill and eject while ventilation is re-established

Epicardial or transesophageal echocardiography can be used to assess ventricular function, competency of the atrioventricular and semi-lunar valves, outflow obstruction, and the presence of residual intracardiac shunts across the ventricular or atrial septa. Cardiac rhythm is assessed by continuous electrocardiograph monitoring. Direct observation of the heart can sometimes identify rhythm or contractility problems. Any necessary inotropic and vasopressor support is optimized prior to and after separation from CPB. Intracardiac and arterial pressures and waveforms are monitored to assess cardiac function, but there is seldom a specific number that needs to be achieved to ensure successful separation from CPB. The small size of the heart and the presence of residual defects sometimes make interpretation of pressures from monitoring lines difficult so trends are usually followed. Optimal ventricular filling pressures are estimated using filling pressures from preoperative catheterization data, the appearance of the heart, and infusion of small increments of volume while watching filling and systemic arterial pressures. The direct measurement of oxygen saturations from chambers of the heart enables calculations of residual intracardiac shunts immediately following surgery, and direct pressure measurements across systemic and pulmonary outflow tracts enable detection of residual obstructions. If systemic arterial pressure or gas exchange is inadequate, CPB is reinstituted while the problem is analyzed and appropriate corrective measures are taken.

Mild hypothermia often develops in neonates and infants after separation from CPB, so active warming of the patient and reduction in radiant and evaporative losses are important. Increased metabolic stress, pulmonary vasoreactivity, coagulopathy, and potential for dysrhythmias are associated with hypothermia. Hyperthermia must also be avoided because neurological injury may occur if the increased metabolic rate is not met when myocardial function is depressed and cerebral autoregulation is impaired post CPB [185].

Dilution of coagulation factors, damage to and dilution of platelets, and endothelial cell injury all contribute to post-CPB coagulopathy. Exposure of blood to surfaces of the CPB circuit leads to stimulation of the intrinsic pathway as well as the activation and aggregation of platelets, also contributing to post-CPB coagulopathy. Prompt management and meticulous control of surgical bleeding is often complicated by concealed suture lines but adequate hemostasis is essential to prevent the complications associated with transfusion of blood products. Preoperative risk factors for prolonged bleeding after bypass include chronic cyanosis in older patients, low cardiac output with associated tissue hypoperfusion, hepatic immaturity, and the use of platelet inhibitors such as PGE1 in neonates and infants [186,187]. See Chapter 12 for more detailed discussion of the management of hemostasis and blood transfusion.

Sternal closure and tamponade after cardiac operations

Chest closure is a time of potential hemodynamic instability in neonates and infants. The mediastinum is small and the presence of myocardial edema, blood, and tubes in the mediastinum can compress the heart and lead to tamponade physiology. This sometimes necessitates leaving the sternum open with closure after edema and any ongoing hemorrhage has resolved. The clinical signs of tamponade are frequently not present in small children even with impending cardiovascular collapse. Tamponade should always be suspected when hemodynamic instability occurs when ventilation and rhythm are adequate after chest closure. The chest is sometimes reopened in this situation with return of hemodynamic stability while the causes of tamponade are being investigated.

KEY POINTS: ANESTHESIA FOR CARDIAC SURGERY

- Non-bypass (closed) procedures include systemic-to-pulmonary artery shunting, coarctation of the aorta, and pulmonary artery banding. These are often performed via thoracotomy in small infants, and cardiorespiratory instability can be significant
- Positive pressure mechanical ventilation may have deleterious effects on hemodynamics, including right ventricular output, pulmonary hypertension, and decreased venous return in single-ventricle patients. It can also be beneficial to reduce systemic ventricle afterload in cases of ventricular dysfunction or obstruction
- Modern cardiopulmonary bypass techniques have reduced the incidence of immediate postoperative complications including severe coagulopathy, acute neurological insults, and severe inflammatory syndromes. Ultrafiltration, limiting deep hypothermic circulatory arrest, and avoiding extreme hemodilution are three approaches that have improved outcomes

Anesthesia for non-cardiac surgery

The approach to anesthesia for children with CHD just outlined is the same whether the proposed operation is cardiac or non-cardiac. Familiarity with the patient's pathophysiology guides preoperative evaluation and preparation, choice of monitors, and facilitates the smooth induction, maintenance, emergence from anesthesia, and helps plan postoperative care. Consultation with the patient's cardiologist to delineate the cardiac lesion and current functional status is an important part of the preoperative evaluation. Some cardiologists may have an incomplete appreciation of the physiological stresses of non-cardiac surgical procedures so preoperative discussion with the anesthesiologist and surgeon prior to the procedure is important. Physiological stresses might include blood loss, prolonged operative time, and surgical manipulations of the airway and peritoneal, thoracic, or cranial cavities. Intraoperatively, surgical manipulations that affect the cardiovascular balance of patient must be anticipated, recognized, and communicated to the surgeon.

Status of the disease

Children with CHD may present for non-cardiac operations before or after surgical repair or palliation. Surgical corrections are classified as anatomical where the circulation is in series and the LV is connected to the aorta, or physiological where the circulation is also in series but the actual anatomy is not corrected. Single-ventricle pallations or repairs where the RV is functioning as a systemic ventricle are examples of physiological corrections (Table 27.6). Palliated CHD in particular may have abnormal circulation with CHF, as well as hypoxemia, polycythemia, and pulmonary vascular disease. Corrected CHD may have significant residual problems including arrhythmias, ventricular dysfunction, shunts, valvular stenosis or regurgitation, and pulmonary hypertension.

Table 27.6 A classification for congenital cardiac surgical repairs

Type of repair	Outcome
Anatomical LV = systemic ventricle RV = pulmonary ventricle Circulation in series Cyanosis corrected	1. Simple reconstruction: structurally normal after repair (e.g. ASD, VSD, PDA). Late complications unlikely 2. Complex reconstruction: baffle, conduit, outflow reconstruction, or atrioventricular valve repair; late complications likely
Physiological Circulation in series Cyanosis corrected	1. Two ventricles: RV = systemic ventricle (e.g. Senning or Mustard procedure) LV = systemic ventricle 2. Single ventricle: Fontan procedure

ASD, atrial septal defect; LV, left ventricle; PDA, patent ductus arteriosus; RV, right ventricle; VSD, ventricular septal defect.

Chapter 28 presents a detailed discussion of anesthesia for non-cardiac procedures in patients with CHD.

Anesthesia for interventional procedures

The cardiac catheterization laboratory

Adequate sedation or general anesthesia during cardiac catheterization is often necessary to facilitate acquisition of meaningful hemodynamic data in infants and children. A recent study demonstrated an increased frequency of cardiac arrest in children undergoing cardiac catheterization, and is higher than that published for cardiac arrest during pediatric non-cardiac and cardiac surgery. Specific procedures have a higher risk, and infants appear to be at the highest risk [188]. This increased risk supports the notion that these patients ought to be managed by an experienced team of anesthesiologists working closely with the interventional cardiologists, nursing staff, and catheterization technicians to ensure a robust system for care is in place for direct communication and anticipation, and to promptly manage critical events when they occur [189].

Many hemodynamic or diagnostic catheterization procedures can be performed under sedation but general anesthesia may be perferable if the procedure is long, has the potential for significant hemodynamic compromise, or involves dilation of vessels that may be painful. Standard American Society of Anesthesiologists (ASA) monitors are required for all patients undergoing sedation and anesthesia. Hemodynamic data should be attained using conditions that are as close to baseline as possible (e.g. ventilating with room air), and the cardiologist will usually have to qualify hemodynamic data obtained under anesthesia or sedation to consider the effects of mechnaial ventilation and anesthetic agents.

Cardiac catheterization laboratories are usually remote from the operating room and are rarely configured to accommodate anesthesia personnel well. Work space is limited and the anesthesia personnel must position themselves for best access to the patient and anesthesia equipment. The anterior–posterior cameras can restrict acesss to the patient's airway,

and the lateral cameras can make transfer to and from the patient's stretcher challenging. The room is usually darkened to facilitate viewing of images and is often kept cold for best function of the radiological equipment. Care must be taken when positioning a patient on the catheterization table because of the risk of pressure ulcers and nerve traction injury, particulary when the arms are positioned above the head to facilitate imaging. Hypothermia from conductive and convective heat loss, as well as heat loss from the numerous flushes of catheters and sheaths, can be significant, so warming devices and temperature monitoring are important. Anesthesia personnel should also be mindful of the risks of radiation exposure and must wear protective clothing and stand an appropriate distance from the fluoroscopy equipment, particularly during cine acquisition.

Interventional cardiology

Transcatheter procedures for CHD in the interventional laboratory are both replacing and complimenting surgical treatments. Procedures that are routinely performed in the catheterization laboratory now include balloon valvuloplasty of congenitally stenotic aortic, mitral, and pulmonary valves; angioplasty for pulmonary arterial stenoses and postoperative aortic recoarctation, or angioplasty combined with transcatheter placement of endovascular stents for sustained relief of obstruction in arterial or subarterial (intracardiac) locations; radiofrequency ablation of abnormal conduction pathways; and embolization or device occlusion procedures of systemic-to-pulmonary arterial communications, venous channels, fistulas, muscular VSDs, ASDs, or PDA. Transcatheter pulmonary valve replacement is now common, particularly in patients with previous tetralogy of Fallot repair. Transcatheter aortic valve replacement has also been performed in pediatric patients and will likely be more common in the future [190]. Many procedures (e.g. PDA closure) are performed on an outpatient basis with the full participation of the anesthesiologist [191].

A collaborative approach to intervention and repair may offer improved results and new futures for patients with many types of serious CHD. The cardiac anesthesiologist is an integral part of catheter-based treatment and of the coordination of hybrid catheter-based and surgical procedures. A good example is the collaboration of catheter- and surgical -based treatments of teteralogy of Fallot with hypoplastic proximal and distal pulmonary arteries. Antergrade flow to the pulmonary artery early in life is established with a surgically placed homograft from the right ventricle to the pulmonary artery. The patient can then undergo serial balloon dilations of the pulmonary arteries with subsequent growth of these arteries which allows eventual complete surgical correction with VSD closure. Single-ventricle patients with a Fontan palliation may have a fenestration or communication at the atrial level that allows right-to-left shunting so that cardiac output is maintained during sudden increases in pulmonary vascular resistance. This fenestration can subsequently be test occluded in the catheterization laboratory and permanently occluded with a device if indicated [192].

Risks and complications

Placement of catheters in and through the heart increases the risk for dysrhythmias, perforation of the myocardium, damage to valve leaflets and chordae, cerebral vascular accidents, and air embolism. The use of radiopaque contrast material may cause an acute allergic reaction (although this is rare in children with non-ionic contrast media), pulmonary hypertension, and myocardial depression. Blood loss may be sudden and unexpected when large-bore catheters are used or vessels are ruptured. More insidious blood loss may occur over several hours in heparinized small children or neonates owing to bleeding around the catheter site or multiple aspirations and flushes of catheters. Transfusion requirements and appropriate vascular access should be continually assessed.

Arrhythmias, albeit transient, may be recurrent and fatal if not promptly treated. These include catheter-induced supraventricular tachyarrhythmias, ventricular tachycardia, ventricular fibrillation, and occasionally complete heart block requiring temporary transvenous pacing support. On most occasions, removal of the wire or catheter is sufficient for the arrhythmia to resolve, but it is always important that full resuscitation and cardioversion equipment be immediately available. An algorithm for treating catheter-induced arrhythmias is shown in Figure 27.16.

All cases share common risks associated with obtaining percutaneous vascular access that include injury to adjacent structures, vessel perforation, and hemorrhage. The underlying cardiac status or ASA classification of the patient increases the risk for adverse events during catheterization, but in many cases the event is directly related to the specific procedure. Some complications of specific interventional procedures are listed in Table 27.7. Many complications are potentially life threatening, and successful treatment of complications depends on prompt action by anesthesiologists cooperating closely with the interventional cardiologists.

Inadvertent release or detachment of embolic and closure devices results in systemic pulmonary arterial embolization. Embolization usually occurs immediately after attempted placement. Embolized devices can sometimes be retrieved by the use of a variety of retrieval catheters, but surgical removal may be necessary. If the device is lodged in the heart or a great vessel, emergent extracorporeal membrane oxygenation cannulation followed by CPB may be required for removal. Femoral artery and vein reconstruction is sometimes necessary following transcatheter removal of devices. Embolization can also be intentional and therapeutic, as when aortopulmonary collaterals are occluded by coils or hemostatic gelatin to decreased excessive pulmonary blood flow.

Balloon dilation of pulmonary arteries

Pulmonary artery balloon dilation and stent placement to relieve stenosis is a common procedure performed in the catheterization laboratory. Pulmonary artery stenosis may be a congenital or acquired lesion, and may be discrete, involving the main or branch pulmonary arteries, or diffuse, involving multiple distal segmental vessels. Some factors that determine whether dilation should be performed under sedation or general anesthesia include the extent of balloon dilation, anticipated complications, and the duration of the procedure.

Transient unilateral or unilobar pulmonary edema sometimes occurs following pulmonary artery dilation when there is a large increase in pulmonary blood flow and distal pulmonary artery pressure in previously underperfused pulmonary vascular beds. New infiltrate seen on fluoroscopy, blood-tinged

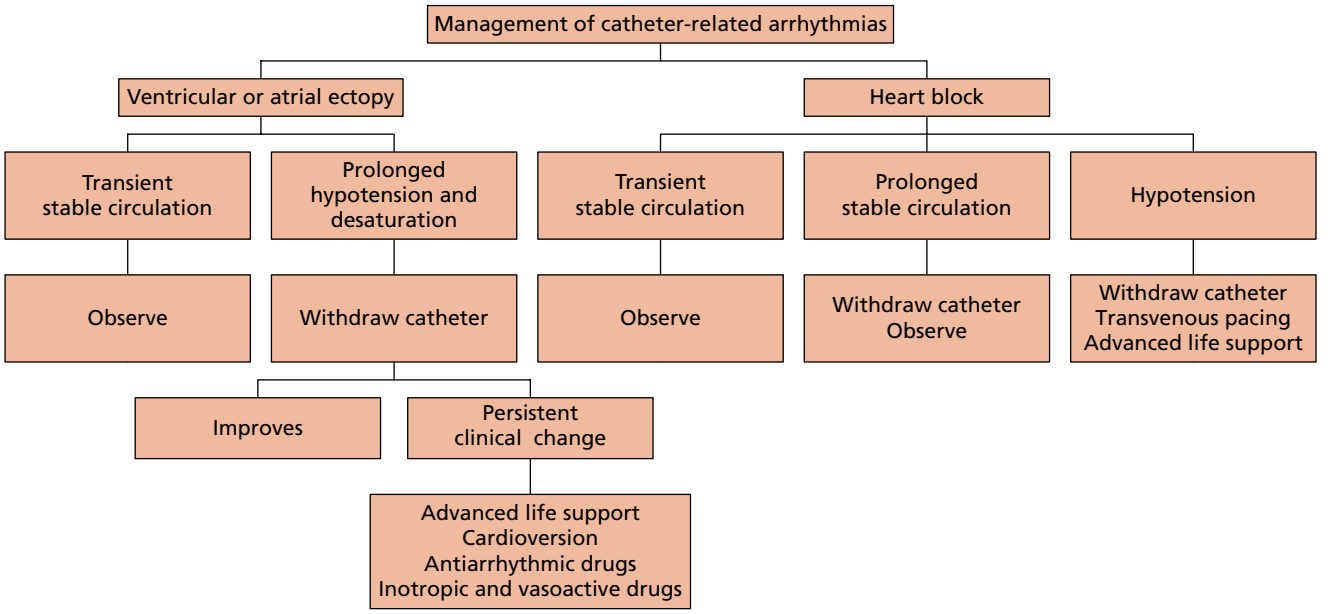

Figure 27.16 Algorithm for treating catheter-induced arrhythmias during cardiac catheterization.

Table 27.7 Complications in specific interventional procedures undertaken in the cardiac catheterization laboratory

Procedure	Representative lesion	Complications
Diagnostic catheterization	Congenital heart disease	Blood loss requiring transfusion Air embolism Cerebral vascular accident Myocardial perforation and tamponade Femoral vessel occusion Arrhythmias; ventricular and supraventricular tachycardia, ventricular fibrillation, complete heart block
Coil embolization	Aortopulmonary collaterals Blalock–Taussig shunts Anomalous coronary arteries Hepatic hemangiomas	Fevers Excessive hypoxemia Systemic embolization Hepatic necrosis
Transcatheter device closure	Patent ductus arteriosus Atrial septal defect Ventricular septal defect Baffle leak	Air or device embolization Blood loss Interference with atrioventricular valve function, ventricular arrhythmias, complete heart block
Balloon and stent dilations	Pulmonary artery stenosis Blalock–Taussig shunt Pulmonary valve stenosis Aortic valve stenosis Mitral valve stenosis Coarctation of the aorta Right ventricular conduit	Pulmonary artery tear and bleeding Unilateral pulmonary edema False aneurysm Cardiac arrest (Williams syndrome) Pulmonary artery tear and bleeding Thrombosis Pulmonary edema Pulmonary insufficiency Aortic regurgitation Ventricular fibrillation (neonate) Mitral insufficiency Pulmonary hypertension Aortic dissection Hypertension False aneurysms Stent embolization
Atrial septotomy	Transposition of the great arteries, mitral stenosis (atresia), and restrictive atrial septum	Perforation of the heart and tamponade
Radiofrequency mapping and ablation	Anomalous conduction pathways	Complete heart block Supraventricular tachycardia Thromboembolus from long sheath and prolonged procedure
Myocardial biopsy	Cardiomyopathy or transplantation	Myocardial perforation Complete heart block

frothy pulmonary secretions, and an increased oxygen requirement may be noted. Pulmonary edema is usually seen shortly after pulmonary artery dilation but can be delayed for up to 24 h. Endotracheal intubation and controlled ventilation are usually necessary until the edema resolves.

Frank hemoptysis may be indicative of a pulmonary artery tear or disruption. The interventionalist might note unusual spread of intravascular contrast medium in the lung parenchyma or the appearance of contrast medium in the pleural space or major lung fissures. Treatment is supportive. Substantial hemoptysis, pulmonary edema, or dyspnea should prompt emergent endotracheal intubation and mechanical ventilation. Avoiding hypertension may decrease hemorrhage, as may the addition of PEEP. Endotracheal suction may be necessary to remove clot that is obstructing the airway, but airway manipulations should be limited to help prevent additional bleeding. Intrapulmonary hemorrhage is often self-limited but can be severe, leading to hemothorax and a need for operation.

The function of the RV is critical during pulmonary artery dilation. Cardiac output may decrease significantly with balloon inflation causing hypotension, bradycardia, arterial oxygen desaturation, and a fall in end-tidal CO_2. These changes are usually temporary with rapid recovery of baseline hemodynamics. Patients who have a hypertrophied, poorly compliant RV with systemic or suprasystemic intraventricular pressures may develop myocardial ischmemia, RV failure, arrhythmias, and loss of cardiac ouput with the sudden increase in afterload associated with balloon dilation. General anesthesia and controlled ventilation are recommended prior to the intervention in this at-risk group of patients.

Patients who have a dilated RV secondary to long-standing volume overload, such as seen with chronic pulmonary regurgitation, are also at risk for arrhythmias and low output during catheter manipulations and interventions. These changes are usually transient and resolve with removal of any intracardiac catheters, but resuscitative equipment including a defibrillator and transvenous pacemaker must be immediately available. Conversion to general anesthesia with endotracheal intubation and mechanical ventilation may be necessary emergently.

Potential movement at the time of balloon dilation or stent placement must be avoided. The dilation of pulmonary arteries is painful in the awake or lightly sedated patient, and may induce dyspnea and coughing. Sedation must be deepened prior to dilations and stent placement, as patient movement may lead to an arterial tear or inadvertent blocking of lobar or segmental pulmonary arteries by a misplaced stent. Balloon dilation of multiple peripheral pulmonary artery stenoses, such as seen in patients with Williams syndrome, is often a prolonged procedure and associated with significant hemodynamic changes so general anesthesia with endotracheal intubation and mechanical ventilation is usually required.

Occlusive device insertion

Umbrella or clamshell device closure of PDA, ASD, and VSD is commonly performed in the catheterization laboratory. The placement of a PDA or ASD device is usually associated with minimal hemodynamic disturbance and can be performed in most patients using sedation techniques. General anesthesia may be necessary for airway protection if transesophageal echocardiography is used to guide device placement or if the procedure is prolonged and procedural complications such as device embolization occur.

In contrast to procedures to close PDAs or ASDs, transcatheter VSD device closure procedures are usually long and associated with profound hemodynamic instability and blood loss [193]. Intensive care management is frequently required following placement. The indications for VSD device placement include closure of a residual or recurrent septal defect, preoperative closure of defects that may be difficult to reach surgically, and closure of acquired defects such as post myocardial infarction or trauma. The preoperative clinical condition or ASA status is not a predictor of hemodynamic disturbance during device placement. Rather, it is the technique necessary for deploying the occlusion device that results in significant hemodynamic compromise and all patients are therefore susceptible. Factors contributing to hemodynamic instability in transcatheter VSD closure include blood loss, arrhythmias from catheter manipulation in the ventricles and across the septum, and atrioventricular or aortic valve regurgitation caused by the stenting open of valve leaflets by stiff-walled catheters. Device-related factors such as malposition of the umbrella device with arms impinging on valve leaflets and dislodgment from the ventricular septum are also potential sources of morbidity. The prolonged duration and positioning required for the procedure increase the risk for peripheral nerve injury and pressure ulcers.

Larger sheaths are required for positioning of transcatheter delivery pods and folded umbrella devices. Considerable blood loss can occur with catheter changes through these large sheaths. This blood loss can be concealed by surgical drapes and is difficult to quantify. A large delivery sheath represents a potential space for air accumulation and subsequent delivery into the heart when unoccupied by the device carrier system and collapsed device. In addition, extreme inspiratory efforts may entrain intracardiac air when the entry port of the sheath is open during removal and reinsertion of various catheters and devices. Meticulous purging of air from the catheter system and sealing of open ports helps to minimize the risk of air embolism.

Air embolization may be life threatening in patients with intracardiac shunts. Air delivered into the right atrium may be shunted right to left across the ASD as shunt direction can transiently change intraoperatively. Left atrial air embolization during these procedures can be seen with fluoroscopy and produces ST segment elevation and often hemodynamic changes as it passes into the aorta. The resultant ST segment changes, hypotension, arterial desaturation, and bradycardia generally respond to hemodynamic support with epinephrine and other inotropic and pressor support. The interventionalist aspirates air and seals the entry port in the sheath to prevent further air entrainment. The use of controlled positive pressure ventilation through an endotracheal tube in an anesthetized, paralyzed patient may also decrease the potential for transcatheter air entrainment during transcatheter closure of intracardiac defects.

Transcatheter radiofrequency ablation

Pediatric patients undergoing radiofrequency ablation vary in age and diagnosis [194]. Ablation may be necessary in the newborn with persistent re-entrant tachycardia or ectopic

atrial tachycardia and cardiac failure, as well as in older children with an ectopic focus and otherwise structurally normal heart. An increasing population of patients undergoing ablation are those who have undergone previous surgical repair of congenital heart defects. Patients with persistent volume or pressure load on the right atrium, and those who have required an extensive incision and suture lines within the right atrium, such as following a Mustard, Senning, or Fontan procedure, may be at increased risk for supraventricular tachyarrhythmia such as atrial flutter and fibrillation. Ventricular tachyarrhythmias may also develop late following repair of certain congenital heart defects, such as RV outflow tract reconstruction for tetralogy of Fallot.

Radiofrequency catheter ablation or cryoablation procedures are usually long procedures that require general anesthesia with mechanical ventilation in most patients. Prior to ablation, the arrhythmogenic focus is located by stimulating areas of the heart until the tachyarrhythmia is induced. This may result in hypotension, but this is usually short lived and can be terminated by intracardiac pacing, if necessary. Transthoracic cardioversion may be necessary and a defibrillator should be immediately available. Movement during ablation may result in a radiofrequency lesion being created at an incorrect site, resulting in heart block if the atrioventricular conduction system is inadvertently ablated. End inspiratory and end expiratory breath holds are sometimes required to ensure adequate contact of the ablation catheter with the arrhythmogenic focus.

A range of techniques can be used to maintain general anesthesia during radiofrequency catheter ablation since anesthetic drugs have minimal effects on intrinsic conduction [88,195–198]. Some tachyarrhythmias, such as ectopic atrial and ventricular tachycardias, are catecholamine sensitive. The focus may be difficult to localize after induction of anesthesia. For this reason, it is preferable to perform the procedure under light sedation or light general anesthesia if necessary. Of note, dexmedetomidine has been demonstrated to lengthen many cardiac conduction intervals, to depress sinus and atrioventricular node function, and to suppress supraventricular and ventricular tachydysrhythmias [131,134]. This agent should probably be avoided in most electrophysiological procedures, and a discussion with the electrophysiologist should ensue before its use.

Cardiac tamponade

Acute myocardial perforation with hemopericardium and tamponade is an occasional complication during interventional cardiac catheterization procedures. Prompt support of the circulation with volume infusions and pressor support, along with immediate catheter drainage of the pericardial space, are essential in the event of this complication. Hemopericardium after ventricular puncture is usually self-limited since the muscular ventricular wall seals the perforation. Punctures of the thin-walled atrium may require suture repair under direct vision in the operating room.

Postoperative tamponade from bleeding immediately after heart surgery usually requires placement of additional chest tube drains or sternotomy with evacuation of mediastinal clots and blood. These patients are usually sedated and mechanically ventilated in the ICU so that new anesthetic considerations and choices are limited. Some children develop pericardial effusions at other phases of their illness owing to hydrostatic influences (e.g. patients with modified Fontan operations) favoring accumulation of pericardial fluid or pericardial fluid from postpericardiotomy syndrome. Fluid in the pericardial space may accumulate under considerable pressure and filling of the heart is impaired. The transmural pressure in the atria diminishes as the pericardial pressures rise and diastolic collapse of the atria can be observed echocardiographically. The patients become symptomatic with a narrow pulse pressure, pulsus paradoxus, tachycardia, respiratory distress, abdominal pain progressing to decreased urine output, hyperkalemia, metabolic acidosis, and hypotension with tremendous endogenous catecholamine response.

Draining pericardial fluid is imperative when hemodynamics are compromised by tamponade physiology. A percutaneous approach to drainage is preferred when the fluid is accessible through a subxyphoid approach. Anesthetic principles guiding sedation for pericardial drainage should focus on maintaining or improving intravascular volume, vascular tone, and the contractile state of the ventricle. Anesthetic agents used for sedation that excessively decrease preload or afterload and transiently impair myocardial function will reduce cardiac output, especially when combined with muscle paralysis and positive pressure ventilation, which further impairs ventricular filling. If a child demonstrates severe tamponade symptoms and a large circumferential, percutaneously accessible pericardial effusion is identified echocardiographically, drainage under sedation using an opioid, benzodiazepine, or ketamine with local anesthesia is safer than an open surgical procedure with a rapid sequence induction and positive pressure ventilation.

KEY POINTS: ANESTHESIA FOR INTERVENTIONAL PROCEDURES

- Diagnostic cardiac catheterization has become less common in recent years; the increasing number of interventional procedures, including occlusion of abnormal communications, stenting of narrowed structures, and percutaneous placement of pulmonary valves, has increased risk for hemodynamic instability and bleeding
- Risk for arrythmias, bleeding, cardiac perforation and tamponade, vascular compromise, extracorporeal membrane oxygenation cannulation, and need for urgent surgery increases with small patients <5 kg undergoing invasive procedures
- Electrophysiological studies with radiofrequency or cryoablation can take a long time and often require general endotracheal anesthesia. Dexmedetomidine should be avoided in most of these procedures because of its multiple effects on the conduction system

Pathophysiology and anesthetic management of specific lesions and procedures

The CHD population is heterogeneous with a wide variety of ages, diagnoses, pathophysiology, and current physical status. The experience at the Boston Children's Hospital over 5 years

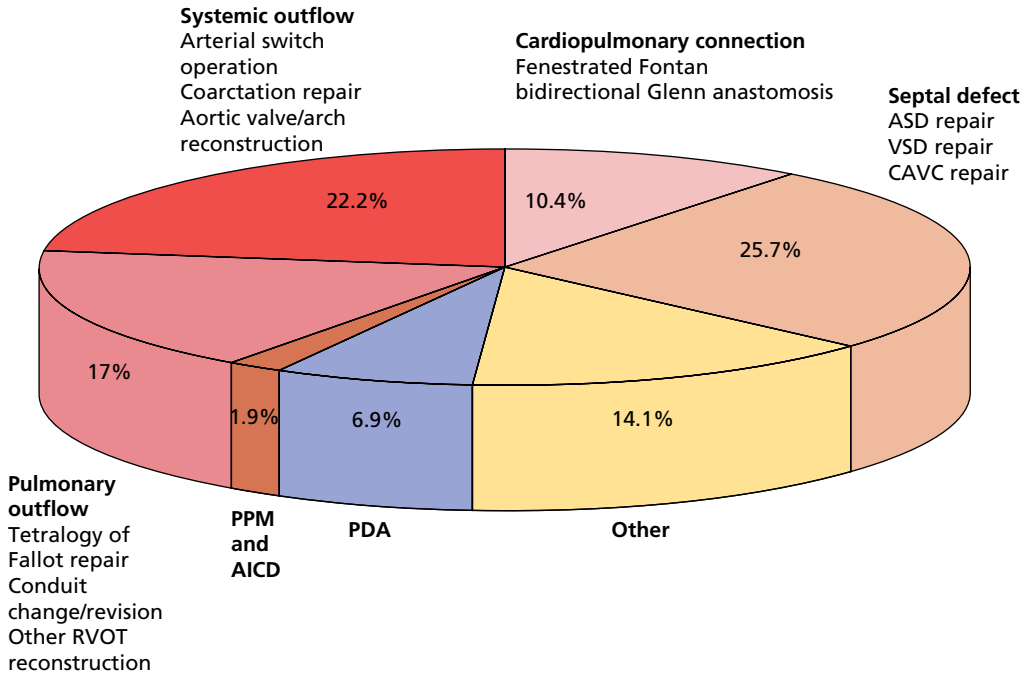

Figure 27.17 Spectrum of congenital cardiac surgical procedures performed at the Children's Hospital, Boston, in a typical year. AICD, automated implantable cardioverter-defibrillator; ASD, atrial septal defect: CAVC, complete atrioventricular canal; PDA patent ductus arteriosus; PPM, permanent pacemaker; RVOT, right ventricular outflow tract; VSD, ventricular septal defect.

is shown in Figure 27.17. There have been changes in management philosophy over the past 20 years towards performing reparative operations on neonates and infants rather than initial palliation and later repair. With the emphasis on early surgical repair, the aim is to promote normal growth and development, and limit the pathophysiological consequences of congenital cardiac defects such as volume overload, pressure overload, and chronic hypoxemia. It is important to note, however, that older children and adults with CHD are an increasing group of patients presenting for cardiac and non-cardiac surgery. This includes patients undergoing a reparative operation, often some years following an initial palliative procedure, and patients who have had previous reparative surgery but subsequently require reintervention because of residual or progressive defects, such as conduit stenosis.

Virtually all congenital cardiac defects are now amenable to either an anatomical or functional repair, but repair is sometimes not complete and there may be short- and long-term consequences of repair. Palliative procedures are often necessary prior to definitive repair. The modified Fontan procedure is the definitive operation for many classes of complex single-ventricle CHD. However, the Fontan procedure requires low PVR and large pulmonary arteries, which are not characteristic of the neonate. Therefore, a shunt may be required to alleviate hypoxemia and allow growth of the pulmonary arteries until the child is older. Alternatively, if the pulmonary blood flow is excessive, a pulmonary band can be placed to restrict pulmonary blood flow to reduce the possibility of CHF and to prevent development of pulmonary vascular obstructive disease until the definitive repair can be done. Palliative procedures have immediate complications and may compromise subsequent complete surgical repair of the lesion.

This section summarizes the basic pathophysiology of each lesion or procedure as a prelude to discussion of anesthetic management of the lesion. The discussion of anesthetic management before the repair applies equally well to non-cardiac procedures in unrepaired patients and to patients undergoing repair of the CHD but before CPB support is initiated. For some lesions, a separate discussion considers the anesthetic complications that occur after repair. This heading, where appropriate, outlines specific complications and problems that may be encountered months or years after repair of the anomaly. Otherwise, this information is found at the end of the section on anesthetic management earlier in the chapter.

Surgical shunts

Pathophysiology

A systemic-to-pulmonary shunt is required when there is severe obstruction to pulmonary blood flow and the patient is not suited for an immediate physiological or anatomical repair. This situation is seen most commonly in patients who have tricuspid atresia with restricted pulmonary blood flow, pulmonary atresia, or single-ventricle patients with severe obstruction to pulmonary blood flow. The surgically created shunt provides sufficient pulmonary blood flow to maintain acceptable arterial oxygen saturation but pulmonary venous blood must mix with systemic venous blood. Optimally, the surgical shunt (a simple shunt) provides restrictive flow to the pulmonary circuit, allowing adequate, but not excessive, pulmonary blood flow.

Types of surgical shunts

Aortopulmonary artery shunts

Systemic-to-pulmonary artery shunts are palliative procedures that increase pulmonary blood flow, thereby relieving severe cyanosis, improving functional status, and allowing for diffuse growth of small pulmonary arteries. The classic

Blalock–Taussig (B-T) shunt redirects subclavian artery blood into the branch pulmonary artery on the side opposite the aortic arch [199]. This graft allows some growth during infancy but is unlikely to induce pulmonary vascular disease. Rather than compromise the subclavian artery and upper limb blood flow, a modified B-T shunt is now preferred using a Gore-Tex™ synthetic tube graft interposed between the subclavian or innominate artery and the pulmonary artery. Performed either via a thoracotomy or median sternotomy, flow across the shunt is dependent upon the size of the Gore-Tex tube (usually 3.5 or 4.0 mm diameter), the length of the tube, and site of take-off from the systemic artery. A shunt arising from the innominate artery is likely to have a higher flow because of a higher perfusion pressure than a more distally placed shunt arising from the subclavian artery. The B-T shunt is associated with low mortality and a low incidence of late postoperative complications. However, distortion of the pulmonary arteries may occur within a few months and affect definitive repair.

The Potts shunt (descending aorta to left pulmonary artery) and the Waterston shunt (ascending aorta to the right pulmonary artery) are rarely used. The size of the shunt orifice is difficult to control precisely and may enlarge substantially with growth, becoming non-restrictive and resulting in excessive pulmonary flow and pulmonary vascular obstructive disease. These shunts distort the branch pulmonary arteries, possibly leading to stenois, and are difficult to dissect and control prior to CPB during subsequent surgery. A central shunt between the ascending aorta and main pulmonary artery is occasionally used when branch pulmonary arteries are hypoplastic and increased flow through the pulmonary artery is expected to increase growth of the pulmonary arteries.

A relatively recent development is the placement of a stent in the PDA of a neonate to create a stable source of pulmonary blood flow, in lieu of a surgically created shunt [200]. This procedure is performed in the cardiac catheterization laboratory, and PDA configuration as determined by angiography is important in determining candidacy for a PDA stent. A PDA that is long and tortuous, or of large diameter but short length, is not suitable for a stent. This procedure is perfomed in neonates and may be accompanied by considerable hemodynamic instability and bleeding. Outcome in carefully selected patients appears to be comparable to surgically created shunts.

Cavopulmonary artery shunt

The first cavopulmonary artery anastomosis (Glenn shunt) was a unidirectional shunt constructed as a palliative procedure for tricuspid atresia, directing systemic venous blood to the lungs for gas exchange. The SVC is disconnected from the right atrium and connected directly to the detached right pulmonary artery, i.e. SVC blood perfuses the right lung and flow depends on the pressure gradient between the SVC and left atrial pressures [201]. Therefore, the Glenn shunt is limited to patients with low PVR, which precludes its use in neonates. This shunt is rarely performed today as the pulmonary arteries are not in continuity, with only the right lung receiving systemic venous blood. Palliation is short lived because of complications such as thrombosis or occlusion leading to SVC syndrome, and progressive cyanosis secondary to the development of pulmonary arteriovenous collaterals.

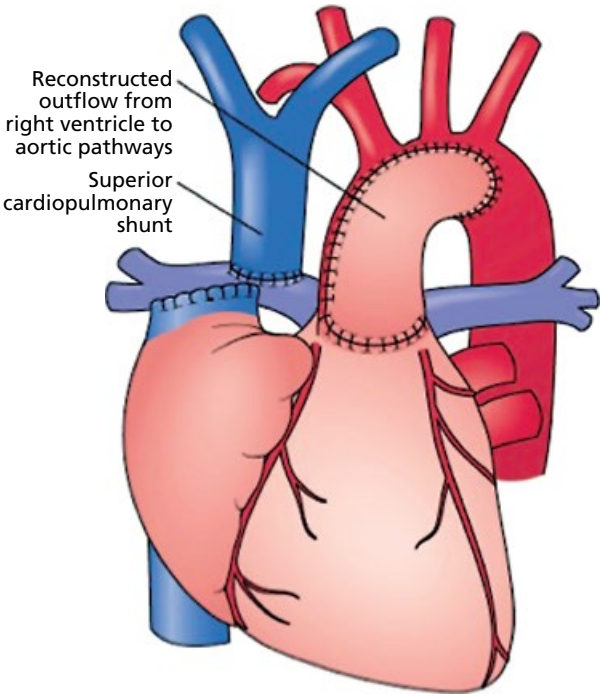

Figure 27.18 Superior cavopulmonary connection. The superior vena cava is anastomosed to the right pulmonary artery. This example demonstrates previous aortic arch reconstruction in the neonatal period. *Source*: Reproduced from Andropoulos and Gottlieb [359] with permission of Elsevier.

An important modification of the Glenn shunt that is now used during staged repair of single-ventricle defects involves the anastomosis of the cephalad portion of the SVC to the right pulmonary artery, as in the original Glenn procedure, except pulmonary artery continuity is maintained and flow is therefore bidirectional through both the right and left pulmonary arteries (hence the term bidirectional cavopulmonary anastomosis or bidirectional Glenn procedure) (Fig. 27.18) [202–204]. It can be performed successfully in children as young as 3–4 months of age, after the PVR has decreased, and has the benefit that effective pulmonary blood flow is increased but with reduced pulmonary artery pressure [205,206]. It avoids imposing the volume load on the ventricle associated with aortopulmonary shunts and minimizes atrial distension and high right atrial pressures inherent in a full Fontan-type operation in a high-risk patient with elevated PVR (see later) [207].

Anesthetic management

Complications of surgical shunts can occur immediately after surgery or years later when another surgical intervention is contemplated. Severe hypoxemia may occur in the operating room during or after creation of the shunt, implying inadequate pulmonary blood flow. Intrapulmonary shunting must always be considered in lungs that are compressed by the surgeons, but mechanical obstruction of flow into the pulmonary artery caused by retraction during surgery or by shunt occlusion (kinking or thrombosis) is the usual cause. An increase in PVR may also reduce flow across the shunt, and inducing an alkalosis by hyperventilation and using a high inspired oxygen concentration may minimize PVR and optimize gas exchange until shunt flow can be improved. As a note of

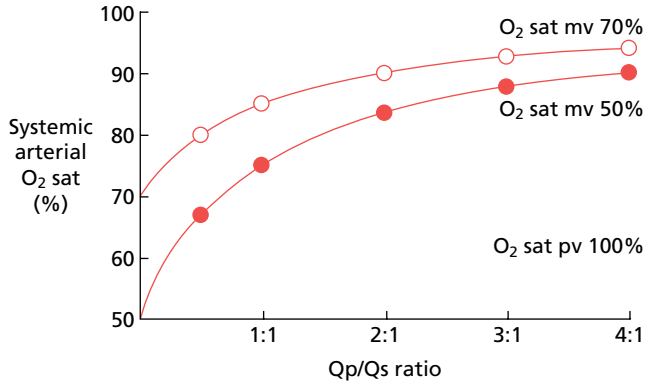

Figure 27.19 Changes in systemic arterial O_2 saturation (sat) with mixing lesions as the Qp/Qs (pulmonary/systemic blood flow ratio) changes with different levels of mixed venous (mv) O_2 saturation. It presumes a pulmonary (pv) O_2 saturation of 100%. *Source*: Reproduced from Rudolph [355] with permission of John Wiley and Sons.

caution, however, an increase in mean intrathoracic pressure and overinflation of the lungs during vigorous mechanical ventilation may further restrict flow across the shunt.

Systemic-to-pulmonary artery shunts are inherently inefficient because they recirculate pulmonary venous blood to the lungs without reaching the systemic circulation. To substantially improve arterial oxygen content, pulmonary blood flow must be several times greater than the systemic flow (Fig. 27.19). However, if the surgically created shunt is not sufficiently restrictive, pulmonary flows become excessive and cause pulmonary edema, wide pulse pressures, and, occasionally, inadequate systemic perfusion. Arterial oxygen saturation is relatively high despite complete mixing of systemic and pulmonary venous blood in the left heart. Maneuvers to increase pulmonary vascular resistance (see earlier) can compensate to a limited degree for excessive pulmonary flow, but shunt revision may be necessary.

Anesthetic considerations after creation of a surgical shunt

Flow through an aortopulmonary shunt is usually restricted by the shunt orifice and regulated by the difference between the pulmonary and systemic vascular resistance. If the shunt is too large, excessive pulmonary blood flow will be evident by high arterial oxygen saturations, reduced systemic perfusion with increasing metabolic acidosis, low diastolic blood pressure, and pulmonary edema. The work of breathing is increased and patients may have difficulty weaning from mechanical ventilation. If the shunt is large enough to allow excessive pressure and flow in the pulmonary vascular bed, precapillary pulmonary artery hypertension may develop over time.

If the shunt is too small, arterial oxygen saturations will remain low, and pulmonary flow will be dependent on systemic arterial pressure. Normal to above normal systemic arterial pressure usually needs to be maintained, as hypotension will lead to hypoxemia, particularly as the shunt becomes more restrictive. Other causes of a low oxygen saturation after shunt placement include a low mixed venous oxygen level secondary to a low cardiac output, and reduced oxygen-carrying capacity of the blood due to relative anemia.

Appropriately sized shunts result in a balanced circulation (Qp/Qs approximately 1:1) with peripheral saturations between 75% and 85% on low FiO_2 and a widened pulse with normal systolic pressure. Tachycardia is common initially once the shunt is open, and volume resuscitation is usually necessary. Inotrope support with dopamine may also be necessary as the increased pulmonary blood flow imposes a volume load on the systemic ventricle. The hematocrit should be maintained between 40% and 45%. Afterload reduction with a systemic vasodilator, such as sodium nitroprusside or a phosphodiesterase inhibitor, may be indicated if the patient has poor extremity perfusion, and to improve systemic perfusion if there is a relatively large shunt and excessive pulmonary blood flow. In general, most patients are mechanically ventilated postoperatively until flow is well balanced and adequate systemic perfusion maintained.

Pulmonary artery banding

Pathophysiology

Pulmonary blood flow can be reduced by placing a surgical band around the pulmonary artery. This is done when pulmonary blood flow is excessive and total correction of the lesion is not possible. Excessive pulmonary blood flow imparts high volume and pressure loads on the pulmonary vasculature. The pulmonary artery band is required to prevent progressive pulmonary vascular obstructive disease or to lessen symptoms of CHF.

Anesthetic management

Induction of anesthesia in a patient with excessive pulmonary flow is challenging because pulmonary vascular resistance may fall with onset of effective mechanical ventilation, leading to increased pulmonary blood flow. This phenomenon is called pulmonary steal and may result in systemic hypotension. Partial occlusion of a branch pulmonary artery with a clamp or ligature reduces pulmonary blood flow and increases peripheral perfusion until the band is applied.

Banding of the pulmonary artery is imprecise, and the hemodynamics after banding are unpredictable. Adequacy of the band is assessed in the operating room by observing a 20–30% increase in systemic blood pressure and a decrease in systemic arterial oxygen saturation. Direct measurement of the pulmonary artery pressure beyond the band may be compared with the systemic arterial pressure. It should be about 50% or less of the systemic pressure. Continuous monitoring of oxygen saturation is helpful for quick assessment of the adequacy of pulmonary blood flow. Saturation by pulse oximeter should be about 80% on low FiO_2 in common mixing lesions [208]. As hemodynamic criteria are used to assess band tightness, anesthesia is best maintained with high-dose opioids, and high concentrations of inhalation agents are avoided. If the band is too tight, bradycardia, hypotension, and cyanosis will develop, requiring urgent band removal.

The large resistance imposed by banding the pulmonary artery stimulates hypertrophy of the ventricle supplying the banded vessel. Consequently, depression of function of that ventricle quickly reduces pulmonary blood flow, particularly if a VSD or ASD is present, allowing shunting of blood into the systemic circulation. Long-term anatomical hazards of pulmonary artery bands relate to distortion of the anatomy and hypertrophy of the ventricle.

Single-ventricle and parallel circulation physiology

Pathophysiology

Patients with a repaired two-ventricle heart have an in series circulation whereby one ventricle ejects blood into the pulmonary artery and another ventricle ejects pulmonary venous blood to the systemic circulation. Systemic oxygenation represents the efficiency of gas exchange in the lungs; lowering PVR and decreasing right ventricular afterload are important objectives when trying to increase pulmonary blood flow and correct hypoxemia in this situation. However, patients with single-ventricle anatomy represent a unique population that requires physiological interpretation of oxygenation and hemodynamics in light of the parallel nature of the circulation. In this circumstance, a single ventricle supplies both pulmonary and systemic blood flow, and lowering PVR in these patients may improve oxygenation but adversely affect hemodynamics in some circumstances.

An infant with single-ventricle physiology may have a variety of anatomical lesions, ranging from tricuspid atresia (a single left ventricle) through double-inlet left ventricle (two atrioventricular (AV) valves and one single ventricle) to mitral atresia (a single right ventricle, i.e. hypoplastic left heart). In single-ventricle lesions, both AV valves enter a single chamber and a small outflow chamber gives rise to one great artery which is usually the aorta. The AV valves may be atretic. Subpulmonary stenosis or atresia is common. Occasionally, subaortic stenosis is present at birth or develops subsequently. Despite the anatomical diagnosis, virtually all patients with effective single-ventricle hearts, as shown in Box 27.4, are amenable to a repair that corrects the physiology, i.e. the Fontan procedure. It is increasingly common to use a stage approach to promote ventricular growth in order to create a biventricular circulation in a subset of patients previously thought to have insufficient ventricular volume such as unbalanced AV canal defects [209].

It is important to note, however, that an effective parallel circulation with single ventricle physiology can exist in patients with two ventricles (Box 27.4). In these circumstances, the balance between pulmonary and systemic vascular resistance is the critical determinant of systemic perfusion and, therefore, a balanced circulation (Qp/Qs = 1). Much of the discussion here regarding maneuvers used to increase or decrease pulmonary blood flow applies in these patients as well prior to surgery. Examples include patients who have a large PDA (left-to-right shunt across the PDA from the aorta to the pulmonary artery), common ventricular outflow tract (as in truncus arteriosus), or aortic arch interruption (right-to-left flow from the pulmonary artery to the distal aorta across the PDA to maintain systemic perfusion).

Patient with a single-ventricle anatomy share a common physiological principle. Desaturated systemic venous blood returns to the heart and mixes completely with oxygenated blood returning to the same chamber from the lungs. Common mixing of systemic and pulmonary venous blood means that the aortic O_2 saturation reflects the Qp/Qs. In the absence of lung disease (pulmonary venous desaturation), the pulmonary venous blood with oxygen saturations of 95–100% will drain to the ventricle and mix with systemic venous blood having saturations of 55–60% or less, depending on the amount of oxygen extraction in the periphery. If pulmonary and systemic blood flows are equal (i.e. Qp/Qs = 1) then the resultant "mixed" O_2 saturation that emerges from the ventricle measured in the systemic artery is 75–80%. As the pulmonary blood flow rises in proportion to systemic blood flow, so, too, rises the arterial oxygenation. Consequently, an arterial oxygen saturation of 90% is achieved at the expense of excessive pulmonary blood flow (Qp/Qs >3) and a substantial volume load to the single ventricle, which is required to supply all systemic and pulmonary (three times systemic) blood flow. CHF therefore ensues. If both the pulmonary artery and aorta are anatomically related to the ventricle and unobstructed, then flow to the pulmonary and systemic beds will be partitioned according to the relative resistances of each circuit (i.e. parallel circulations). As the PVR falls below SVR during the first few hours of life, pulmonary blood flow increases relative to systemic flow and systemic arterial oxygen saturation rises above 80%. Therefore, systemic oxygen saturation is a convenient marker of Qp/Qs. The effects of alterations of Qp/Qs on systemic arterial oxygen saturation for common mixing lesions are shown in Figure 27.20.

Box 27.4: Anatomical diagnoses and surgical procedures that demonstrate parallel or balanced circulation physiology

Defects amenable to a single-ventricle repair (i.e. common mixing lesions)

- Atrioventricular valve atresia
  - Tricuspid atresia
  - Mitral atresia
- Ventricular hypoplasia
  - Hypoplastic left heart syndrome
  - Double inlet left or right ventricle
  - Unbalanced atrioventricular canal
- Outflow tract obstruction
- Aortic atresia
  - Shone's complex
  - Pulmonary atresia and small right ventricle

Defects amenable to a two-ventricle repair

- Common ventricular outflow tract
  - Truncus arteriosus
- PDA-dependent pulmonary blood flow
  - Tetralogy of Fallot and pulmonary atresia
- PDA-dependent systemic blood flow
  - Interrupted aortic arch

Postoperative single-ventricle palliation

- Norwood/Sano procedure for hypoplastic left heart syndrome
- Modified Blalock–Taussig shunt

Increased Qp/Qs

The deleterious effects of overcirculated lungs perfused at high pressure and flows, combined with the adverse effects of this volume load (particularly on the neonatal heart which is less capable of increasing stroke volume in response to increasing preload than the mature myocardium), will culminate in a picture of hyperdynamic CHF in which systemic perfusion is compromised and oxygen delivery is impaired despite the elevated arterial oxygen saturation (Fig. 27.20). The myocardium ultimately cannot provide adequate systemic flow as PVR falls and more and more of the stroke volume is inefficiently recirculated to the lungs. Treatment is

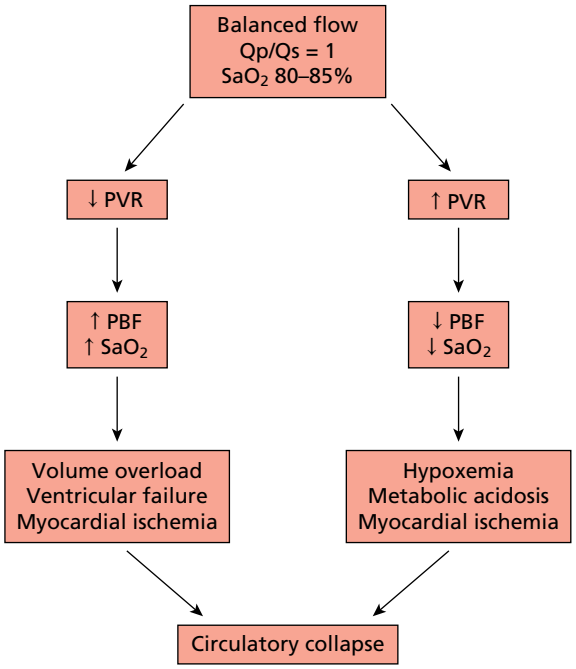

Figure 27.20 Effect of changes in PVR potentially contributing to circulatory collapse in patients with single-ventricle physiology. Qp, pulmonary blood flow; Qs, systemic blood flow; SaO_2, arterial oxygen saturation; PBF, pulmonary blood flow; PVR, pulmonary vascular resistance.

therefore directed toward raising resistance to blood flow to the lungs, balancing pulmonary and systemic blood flow ratios, and maintaining adequate systemic blood flow (Table 27.8).

Pulmonary vascular resistance can be increased with controlled mechanical hypoventilation to induce a respiratory acidosis, and with a low FiO_2 to induce alveolar hypoxia. Ventilation with room air may suffice, but occasionally a hypoxic gas mixture is necessary. This is achieved by the addition of nitrogen to the inspired gas mixture, reducing the FiO_2 to 0.17–0.19. Hypoxic gas mixtures result in lower cerebral oxygen saturation and require complex ventilation set-ups which are prone to accidental delivery of higher than intended nitrogen concentrations, and therefore are rarely used in contemporary practice [210,211]. While these maneuvers are often successful in increasing PVR and reducing pulmonary blood flow, it is important to remember that these patients have limited oxygen reserves and may desaturate suddenly and precipitously. Controlled hypoventilation in effect reduces the FRC of the lung and therefore oxygen reserve, which is also compromised by the use of a hypoxic inspired gas mixture. Inotropic support is often necessary because of ventricular dysfunction secondary to the increased volume load. Systemic afterload reduction with agents such as phosphodiesterase inhibitors may improve systemic perfusion, although they may also decrease PVR and thus not correct the imbalance of pulmonary and systemic flow. Patients who have continued pulmonary overcirculation with high SaO_2 and reduced systemic perfusion despite the above maneuvers require early surgical intervention to control pulmonary blood flow. At the time of surgery, a snare may be placed around either branch of the pulmonary artery to effectively limit pulmonary blood flow. Monitoring the SVC O_2 saturation, as a measure of mixed venous O_2 saturation and therefore cardiac output, often remains useful in patients with single-ventricle physiology. For instance, a patient with too much pulmonary blood flow may have an arterial O_2 saturation that is high (i.e. >85%), but a low SVC O_2 saturation (i.e. <50%) if systemic perfusion and cardiac output are reduced. In contrast, a patient who is hypoxic with a low arterial O_2 saturation (i.e. <75%) but has a normal arterial–SVC O_2 saturation difference of 25–30% can be assumed to have an adequate cardiac output and other causes for hypoxemia need to be evaluated. Monitoring changes in the SVC O_2 saturation during treatment is a useful guide to the adequacy of management. Early surgical repair avoids the problems associated with prolonged pulmonary overciruclation in single-ventricle neonates.

Decreased Qp/Qs

Decreased pulmonary blood flow, i.e. Qp/Qs <1, in patients with a single ventricle and parallel circulation is reflected by hypoxemia with an SaO_2 of <80%. Preoperatively this may be due to restricted flow across a small ductus arteriosus, increased PVR secondary to parenchymal lung disease, or increased pulmonary venous pressure secondary to obstructed pulmonary venous drainage or a restrictive ASD. Initial resuscitation involves maintaining patency of the ductus arteriosus with a PGE1 infusion at a rate of 0.025–0.05 μg/kg/min. Most patients require tracheal intubation and mechanical ventilation either because of apnea secondary to PGE1 or for manipulation of gas exchange to assist balancing the pulmonary and systemic flow. Systemic blood pressure, and therefore perfusion pressure across the ductus arteriosus, is maintained with the use of volume and vasopressor agents. Sedation, paralysis, and manipulation of mechanical ventilation to maintain an alkalosis may be effective if PVR is elevated. Nitric oxide as a specific pulmonary vasodilator may also be of use in this situation. Systemic oxygen delivery is maintained by improving cardiac output and red blood cell transfusions are performed to maintain a hematocrit >40%. Interventional cardiac catheterization with balloon septostomy or dilation of a restrictive ASD may be necessary; however, early surgical intervention and palliation with a systemic-to-pulmonary artery shunt are usually indicated.

Anesthesic considerations

A thorough preoperative assessment is essential to assess the balance of pulmonary and systemic flow, presence of cardiac failure, and possible end-organ injury from reduced systemic perfusion. A spontaneously breathing patient who is well balanced prior to surgery may readily become unbalanced after induction of anesthesia and when mechanically ventilated. The arterial oxygen saturation usually rises once the patient is anesthetized and paralyzed, due to a rise in mixed venous oxygen saturation from reduced peripheral O_2 extraction, and improved cardiac output secondary to reduced myocardial work and afterload on the ventricle. However, PVR may fall as well, leading to an increase in pulmonary blood flow at the expense of systemic perfusion. Hypotension and a fall in diastolic blood pressure may be evident. In this circumstance, it is important to maintain a low inspired O_2 concentration and ventilate with a low rate and tidal volume to maintain a mild respiratory acidosis. Close monitoring of the arterial blood gas is important, with the ideal being a pH of 7.40, PaO_2

Table 27.8 Parallel circulation physiology: management considerations

Clinical circumstance	Etiology	Management
Balanced flow	Qp = Qs ~1 0.	No intervention
SaO_2 80–85% and normotensive		
Overcirculated	Qp ≫ Qs	**Raise PVR**
SaO_2 > 90% and low blood pressure	Low PVR	Controlled hypoventilation
	Large aortopulmonary shunt size (PDA or B-T shunt)	Low FiO_2 (0.21)
	Clinical signs	**Increase systemic perfusion**
	Wide pulse pressure	Afterload reduction
	Poor peripheral perfusion	Inotrope support
	Congestive heart failure	Treat hypertension
	Oliguria	**Surgical intervention**
	Laboratory	Shunt revision
	Metabolic acidosis	
	Low SvO_2 saturation	
	Increased (SaO_2–SvO_2) difference	
Undercirculated	Qp < Qs	**Lower PVR**
SaO_2 <75% and normal/elevated blood pressure	High PVR	Controlled hyperventilation
	Small or occluded aortopulmonary shunt	Alkalosis
	Clinical signs	Reduce stress response
	Cyanosis	Pulmonary vasodilation
	Narrow pulse pressure	**Increase cardiac output**
	Myocardial ischemia	Raise systemic blood pressure
	Loss of murmur (late)	Inotrope support
	Laboratory	**Increase mixed venous O_2**
	Metabolic acidosis	Hematocrit >40%
	Normal (SaO_2–SvO_2) difference	Sedation/anesthesia/paralysis
		Surgical intervention
		Shunt revision
Low cardiac output	Ventricular failure	**Ventricular support**
SaO_2 <75% and hypotension	Myocardial ischemia	Maximize inotrope support
	Clinical signs	Optimize preload
	Poor peripheral perfusion	Open sternum
	Oliguria/anuria	Minimize stress response
	Narrow pulse pressure	**Surgical revision**
	Laboratory	Aortic arch and coronary anastomosis; transplantation
	Metabolic acidosis	**Mechanical support of the circulation**
	Low SvO_2 saturation	
	Increased (SaO_2–SvO_2) difference	

B-T, Blalock–Taussig; FiO_2, inspired oxygen concentration; PDA, patent ductus arteriosus; PVR, pulmonary vascular resistance; Qp, pulmonary blood flow; Qs, systemic blood flow; SaO_2, arterial oxygen saturation; SVC, superior vena cava; SvO_2, SVC oxygen saturation.

40 mmHg, and $PaCO_2$ 40 mmHg. If non-invasively monitored, an SaO_2 of 75–85% and end-tidal CO_2 of 40–45 mmHg are usually appropriate.

It is very important that patients are deeply anesthetized to minimize hemodynamic changes, in particular tachycardia, in response to surgical stimulation. If the patient is overcirculated (i.e. Qp > Qs) and has a low diastolic blood pressure, coronary perfusion may not increase sufficiently to meet the increased demand of myocardial work in response to surgical stress. Myocardial ischemia may therefore occur, usually manifest as ST segment changes on the ECG or sudden onset of dysrhythmias, in particular ventricular fibrillation.

Staged single-ventricle repair/Fontan procedure

The palliative operation for infants with single ventricles is a modified Fontan procedure. Di Donato et al [207] demonstrated in patients with tricuspid atresia that SVC blood could be directed into the lungs without passing through the heart, and Fontan and associates extended this concept to include blood returning from the IVC [212,213]. Since the original description, the Fontan procedure and subsequent modifications have been successfully used to treat a wide range of simple and complex single-ventricle congenital heart defects [214]. The repair is physiological in that the systemic and pulmonary circulations are separated, or in series, after directing the systemic venous return directly to the pulmonary artery (PA), and patients are no longer cyanosed. However, based on longer term outcome data, significant problems and complications may develop over time and the repair is viewed as palliative rather than curative.

The Fontan procedure has undergone numerous modifications since the first description [214]. The original procedure was described by Fontan in a patient with tricuspid atresia, and involved disconnecting the pulmonary arteries from each other, creating a classic Glenn shunt, connecting the right atrium (RA) directly to the left PA using a valved conduit and placing a valve at the IVC–RA junction [212]. It was believed the RA would function as a pumping chamber; however,

following improvements in echocardiography, it was apparent that the RA functioned primarily as a conduit with little pumping action contributing to pulmonary blood flow, and in the low-pressure venous system the valves remained opened. Further, this procedure was complicated in the long term by a high risk of pleuro-pericardial effusions and atrial dysrhythmias secondary to the effects of RA hypertension and distension.

An early modification involved the direct anastomosis of the RA appendage to the PA, closing the ASD and patching over the tricuspid valve, if patent [215]. This procedure, however, continued to have a high risk of complications related to RA hypertension.

Over the past 40 years, the total cavopulmonary anastomoses have become the modified Fontan procedure of preference. The SVC is anastomosed directly to the PA and a lateral tunnel created in the RA, baffling IVC flow to the SVC (Fig. 27.21A) [216]. This was associated with an improvement in mortality, although morbidity related to baffle hypertension persisted [205–207].

A significant advance was the creation of a fenestration or small hole in the intracardiac baffle, thereby creating an opportunity for a R-L shunt at the atrial level. This fenestration is created at the time of surgery using a small 4 mm punch [192]. In the event of an increase in RA or PA pressure with reduced flow across the pulmonary vascular bed, and therefore less preload to the systemic ventricle, patients are able to shunt right to left across the fenestration. While patients develop increased cyanosis, cardiac output is maintained. This proved to be very successful and has enabled patients at relatively high risk to undergo a successful modified Fontan procedure [217–220]. While the early mortality has declined further since the introduction of fenestration techniques, the most significant improvement has been in patient morbidity. The incidence of early pleuro-pericardial effusions, ascites (Fig. 27.22), and atrial dysrhythmias has been significantly reduced. The fenestration can be test balloon occluded and easily closed in the cardiac catheterization laboratory with a clamshell device later in the postoperative period.

More recently, the use of an external conduit baffling the IVC to the pulmonary circulation has been reported (Fig. 27.21B) [221]. Fenestration can be created between the external conduit and RA, if necessary. The major advantage in the immediate postoperative period is that the procedure can be completed on CPB without needing to arrest the heart. In addition, advocates of this technique have contended that it reduced the risk of atrial dysrhythmias by reducing atrial suture lines, lowering RA pressure, and avoiding suture lines

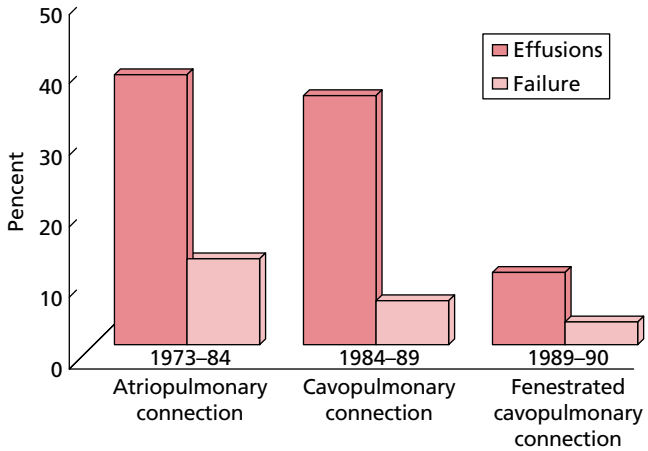

Figure 27.22 Incidence of pleural effusions and failure (i.e. take-down or mortality) during the early surgical evolution of the modified Fontan procedure at the Children's Hospital, Boston. *Source*: Reproduced from Castaneda et al [217] with permission from Wolters Kluwer.

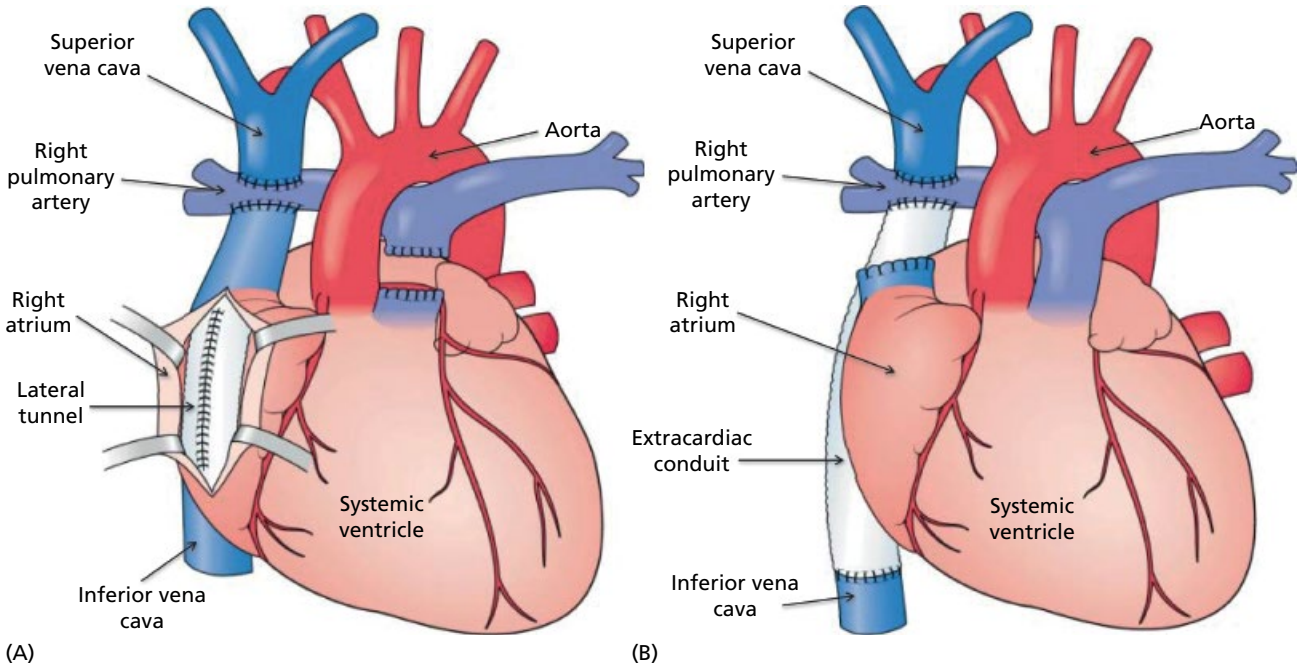

Figure 27.21 (A) Lateral tunnel Fontan total cavopulmonary connection. A polytetrafluoroethylene (PTFE) patch or tube is fashioned inside the right atrium. (B) Extracardiac conduit Fontan. near the sinoatrial node. Nonetheless, there continues to be debate as to whether the lateral tunnel or external conduit technique is the preferred shunt [222,223].

Selection crtieria

Fontan and other investigators originally listed a number of selection criteria that were considered important determinants for a successful early outcome, including age between 4 and 15 years, low PVR (<4 Wood U/m^2), mean pulmonary artery pressure <20 mmHg, systemic ventricle ejection fraction >0.6, normal sinus rhythm, normal AV valve function, and normal systemic and pulmonary venous drainage [207]. Patients with a diagnosis of tricuspid atresia who met these criteria had a mortality rate of less than 5% from this procedure [224]. Modifications to these criteria have subsequently been made over the years as experience and surgical techniques have evolved [225,226]. The modified Fontan procedure is now preferably performed in children under 2–4 years of age to enable earlier correction of chronic hypoxemia and to limit the potential longer term complications associated with prior palliation. The Fontan procedure has also been successfully performed in selected patients older than 15 years with CHD who have appropriate hemodynamics despite long-term palliation. Unobstructed flow across the pulmonary vascular bed is essential. A mean PA pressure <15 mmHg and a PVR <2 Wood U/m^2 are preferable, as they have been associated with a lower early mortality [227]. Diastolic dysfunction of the ventricle with an elevated end-diastolic pressure (e.g. >12 mmHg) secondary to increased myocardial mass or outflow obstruction is an important consideration which could increase postoperative risk; a higher SVC and PA pressure are necessary to maintain the transpulmonary gradient and therefore pulmonary blood flow in this situation.

Bidirectional cavopulmonary (Glenn) shunt

The benefits of a series circuit in patients with single-ventricle physiology include improved systemic oxygenation and a reduction in the obligatory diastolic load borne by the ventricle that simultaneously fills systemic and pulmonary circuits (parallel circulation). The compensatory ventricular dilation that must occur in a parallel circuit places the ventricle at an unfavorable position on the Starling curve and over time will lead to progressive ventricular dysfunction. As previously noted, the increase in ventricular end-diastolic volume, and eventually end-diastolic pressure, may significantly compromise the Fontan physiology and effective pulmonary blood flow [228]. Therefore, early palliation and relief of any volume load from the systemic ventricle is an important interim step in the staged management of patients with single-ventricle physiology. For most patients, this can be achieved by performing a bidirectional cavopulmonary connection or bidirectional Glenn procedure during infancy, commonly around 3–6 months of age. The volume and pressure load is partially relieved from the systemic ventricle and effective pulmonary blood flow is maintained and the chance of a successful conversion to a complete cavopulmonary anastomosis or modified Fontan procedure is improved.

After a bidirectional Glenn procedure, the Qp/Qs is reduced as the source of pulmonary blood flow is from the SVC only. At the time of surgery, the azygous vein is usually ligated to prevent decompression of venous drainage from the SVC to veins below the diaphragm and the IVC, which could contribute to a lower arterial oxygen saturation. Following the procedure, the arterial oxygen saturation should be in the 80–85% range, and preload to the systemic ventricle is maintained by mixing of pulmonary venous blood with systemic venous blood returning via the IVC to the common atrium. As the volume output of the ventricle must meet only the demands of the systemic circulation, the end-diastolic volume (EDV) is therefore substantially reduced. As the EDV decreases, an alteration in ventricular geometry takes place. In some children, the resulting small, hypertrophic ventricle exhibits diastolic dysfunction that was not present at higher EDV [228,229]. In other children, subaortic obstruction may appear across a bulboventricular foramen that was unobstructed in the preoperative state.

The bidirectional Glenn procedure is usually performed on CPB using mild hypothermia with a beating heart. The complications related to CPB and aortic cross-clamping are therefore minimal, and patients can be weaned and extubated in the early postoperative period. Systemic hypertension is common following the procedure. The etiology remains to be determined, but possible factors include improved contractility and stroke volume after the volume load on the ventricle is removed, and brainstem-mediated mechanisms secondary to the increased systemic and cerebral venous pressure. Treatment with vasodilators may be necessary. The cerebral vascular response (vasodilation) to elevated CO_2 over-rides the pulmonary vascular response (vasoconstriction) so mild hypercarbia increases cerebral and pulmonary blood flow, and postoperative permissive hypercarbia enhances systemic oxygen delivery [230].

Ideal physiology immediately after the Fontan procedure

The maintenance of effective pulmonary blood flow and cardiac output following the Fontan procedure depends on the pressure gradient between the pulmonary artery and the pulmonary venous atrium. The factors contributing to a successful cavopulmonary connection are shown in Table 27.9. A systemic venous pressure of 10–15 mmHg and a left atrial pressure of 5–10 mmHg, i.e. a transpulmonary gradient of 5–10 mmHg, are ideal.

Intravascular volume must be maintained and hypovolemia treated promptly. Venous capacitance is increased and as patients rewarm and vasodilate following surgery, a significant volume requirement is common. If the stated selection criteria are followed, patients undergoing a modified Fontan procedure will have a low PVR without labile pulmonary hypertension. Therefore, vigorous hyperventilation and induction of a respiratory and/or metabolic alkalosis to further reduce PVR are often of little benefit in this group of patients; conversely, the increase in mechanical ventilation requirements to induce a respiratory alkalosis may have an adverse effect on pulmonary blood flow. A normal pH and $PaCO_2$ of 40 mmHg should be the goal and, depending on the amount of R-L shunt across the fenestration, the arterial oxygen saturation is usually in the 80–90% range. However, PVR may increase following surgery, particularly secondary to an acidosis, hypothermia, atelectasis, hypoventilation, vasoactive drug infusions, and stress response.

Table 27.9 Management considerations following a modified Fontan procedure

	Aim	Management
Baffle pressure 10–15 mmHg	Unobstructed venous return	→ or ↑ preload Low intrathoracic pressure
Pulmonary circulation	PVR <2 Wood units/m^2 Mean PAp <15 mmHg	Avoid increases in PVR, such as from acidosis, hypo- and hyperinflation of the lung, hypothermia, and excess sympathetic stimulation
	Unobstructed pulmonary vessels	Early resumption of spontaneous respiration
Left atrium pressure 5–10 mmHg	Sinus rhythm Competent AV valve Ventricle: Normal diastolic function Normal systolic function No outflow obstruction	Maintain sinus rhythm, → or ↑ HR to increase CO → or ↓ afterload → or ↑ contractility PDE inhibitors useful because of vasodilation, inotropic and lusitropic properties

AV, atrioventricular; CO, cardiac output; HR, heart rate; PAp, pulmonary artery pressure; PDE, phosphodiesterase; PVR, pulmonary vascular resistance; →, maintain/normal; ↑, increase; ↓, decrease.

Any acidosis must be treated promptly. If the cause is respiratory, ventilation must be adjusted. A metabolic acidosis reflects poor cardiac output, and while correction with bicarbonate may be necessary in the short term to reduce the associated increase in PVR, treatment should be directed at the potential causes, including reduced preload to the systemic ventricle, poor contractility, increased afterload, and loss of sinus rhythm.

The beneficial effect of spontaneous ventilation on the hemodynamics of Fontan patients has been largely overstated [231]. While large instantaneous increases in pulmonary blood flow are seen in Fontan patients with normal inspiration, the incremental improvement in flow associated with normal inspiration is quite modest when considered over the entire respiratory cycle. In fact, in adult total cavopulmonary connection (TCPC) patients, approximately 30% of systemic venous flow to the pulmonary arteries is respiratory dependent as compared with 15% in normal two-ventricle patients. Furthermore, while inspiration augments pulmonary flow in TCPC patients, aortic blood flow (cardiac output) is actually higher during expiration. This is identical to the response seen in normal two-ventricle patients. In two-ventricle patients interventricular dependence results in the inspiratory increase in RV EDV and stroke volume, simultaneously reducing LV EDV and stroke volume. In TCPC patients in whom interventricular dependence is not a factor, a decrease in aortic blood flow is due to the pulmonary vasculature serving as a large-volume reservoir.

Given the effects of negative intrathoracic pressure on pulmonary blood flow, the effects of positive pressure ventilation on Fontan hemodynamics are of concern. Unfortunately, the effects on Fontan hemodynamics of positive pressure ventilation as compared with spontaneous ventilation have never been systematically evaluated. However, because pulmonary blood flow occurs throughout the respiratory cycle, employing a ventilation strategy that minimizes mean airway pressure is a rational, physiologically based approach. Available evidence suggests that a near-linear inverse relationship exists between mean airway pressure and cardiac index. The use of PEEP continues to be debated. The beneficial effects of PEEP include an increase in FRC, maintenance of lung volume, and redistribution of lung water and need to be balanced against the possible detrimental effect of an increase in mean intrathoracic pressure. A PEEP of 3–5 cmH_2O, however, rarely has hemodynamic consequences or substantial effects on effective pulmonary blood flow [231–236]. Early tracheal extubation after the Fontan operation, often in the operating room prior to ICU transfer, can be performed safely and the early hemodynamic advantages of spontaneous ventilation may facilitate rapid recovery [237].

Non-specific pulmonary vasodilators such as sodium nitroprusside, nitroglycerin, PGE1, and prostacyclin have been used to dilate the pulmonary vasculature in an effort to improve pulmonary blood flow after a Fontan procedure. Results have been variable. While PVR may fall, pulmonary blood flow could also increase as a result of reduced ventricular end-diastolic pressure and improved ventricular function secondary to the fall in systemic afterload. The response to inhaled nitric oxide is also variable and the improvement may relate to changes in ventilation/perfusion matching rather than a direct fall in PVR.

An elevated left atrial pressure may reflect systolic or diastolic ventricular dysfunction, AV valve regurgitation or stenosis, and loss of sinus rhythm with cannon "a" waves that raise left atrial pressure. Afterload stress is poorly tolerated after a modified Fontan procedure because of the increase in myocardial wall tension and end-diastolic pressure. Although pulmonary blood flow is phasic to a certain extent, a substantial proportion of flow occurs during diastole as well. The diastolic or relaxation characteristics of the ventricle play a significant role in the volume of pulmonary blood flow and, hence, the preload accepted by the ventricle. Therefore, low cardiac output usually accompanies diastolic dysfunction.

Therapeutic manipulations are not always successful in reversing diastolic dysfunction. Right-sided filling pressure must be increased to maintain the transpulmonary gradient, and treatment with inotropes and vasodilators is initiated; however diastolic relaxation may be impaired with high doses of inotropic medications, and cardiac output may worsen. One should scrupulously maintain or augment circulating volume to avoid additional reductions in EDV. The phosphodiesterase inhibitor milrinone is particularly beneficial. Besides being a weak inotrope with pulmonary and systemic vasodilating properties, its lusitropic action will

assist by improving diastolic relaxation and lowering ventricular end-diastolic pressure, thereby improving effective pulmonary blood flow and cardiac output. If a severe low output state with acidosis persists, take-down of the modified Fontan operation and conversion to a bidirectional Glenn anastomosis or other palliative procedure can be life saving.

Early postoperative complications after the Fontan procedure

Not all patients require a fenestration for a successful, uncomplicated Fontan operation. Those with ideal preoperative hemodynamics often maintain adequate pulmonary blood flow and cardiac output without requiring a R-L shunt across the baffle. Similarly, not all Fontan patients who have received a fenestration will use it to shunt right to left in the immediate postoperative period. These patients are fully saturated following surgery, and may have an elevated right-sided filling pressure, but nevertheless maintain an adequate cardiac output. The problem is predicting which patients are at risk for low cardiac output after a Fontan procedure, and who will benefit from placement of a fenestration. Patients with ideal preoperative hemodynamics may manifest a significant low-output state after surgery. Because of this, essentially all patients have a fenestrated Fontan procedure at the Boston Children's Hospital. Premature closure of the fenestration may occur in the immediate postoperative period, leading to a low cardiac output state with progressive metabolic acidosis and large chest drain losses from high right-sided venous pressures. Patients may respond to volume replacement, inotrope support, and vasodilation; however, if hypotension and acidosis persist, cardiac catheterization and removal of thrombus or dilation of the fenestration may need to be urgently undertaken (Table 27.10) [238].

Arterial O_2 saturation levels may vary substantially following a modified Fontan procedure. Common causes of persistent arterial O_2 desaturation <75% include a poor cardiac output with a low mixed venous O_2, a large R-L shunt across the fenestration, or additional leak in the baffle pathway producing more shunting. An intrapulmonary shunt and venous admixture from decompressing vessels draining either from the PA to the systemic venous circulation or systemic vein to the pulmonary venous system are additional causes [239]. Re-evaluation with echocardiography and cardiac catheterization may be necessary.

The incidence of recurrent pleural effusions and ascites has decreased since introduction of the fenestrated Fontan baffle [240]. Nevertheless, for some patients this remains a major problem with associated respiratory compromise, hypovolemia, and possible hypoproteinemia [241]. The cause is usually related to persistently elevated systemic venous pressure, and cardiac catheterization may be indicated.

Atrial flutter and/or fibrillation, heart block, and, less commonly, ventricular dysrhythmia may have a significant impact on immediate recovery, as well as long-term outcome. Sudden loss of sinus rhythm initially causes an increase in left atrial and ventricular end-diastolic pressure, and a fall in cardiac output. The SVC or PA pressure must be increased, usually with volume replacement, to maintain the transpulmonary gradient. Prompt treatment with antiarrhythmic drugs, pacing, or cardioversion is necessary.

Anesthetic considerations after a Fontan procedure

There are no prospective studies that have evaluated the effects of specific anesthetic techniques and drugs in patients with Fontan physiology. Anesthetic management will vary on a case by case basis according to the functional and clinical status of each patient, and the specific complications unique

Table 27.10 Circumstances, etiology, and treatment strategies for patients with low cardiac output immediately following the Fontan procedure.

Circumstance	Etiology	Treatment
Increased TPG		
Baffle >20 mmHg	Inadequate pulmonary blood flow and preload to left atrium:	Volume replacement
LAp < 10 mmHg	Increased PVR	Reduce PVR
TPG increased >>10 mmHg	Pulmonary artery stenosis	Correct acidosis
Clinical state:	Pulmonary vein stenosis	Inotrope support
High SaO_2/low SvO_2	Premature fenestration closure	Systemic vasodilation
Hypotension/tachycardia		Catheter or surgical intervention
Poor peripheral perfusion		
SVC syndrome with pleural effusions and increased chest tube drainage		
Ascites/hepatomegaly		
Metabolic acidosis		
Normal TPG		
Baffle >20 mmHg	Ventricular failure:	Maintain preload
LAp >15 mmHg	Systolic dysfunction	Inotrope support
TPG normal 5–10 mmHg	Diastolic dysfunction	Systemic vasodilation
Clinical state:	AV valve regurgitation and/or stenosis	Establish sinus rhythm or AV synchrony
Low SaO_2/low SvO_2	Loss of sinus rhythm	Correct acidosis
Hypotension/tachycardia	Afterload stress	Mechanical support
Poor peripheral perfusion		Surgical intervention, including takedown to BDG and transplantation
Metabolic acidosis		

AV, atrioventricular; BDG, bidirectional Glenn anastomosis; LAp, left atrial pressure; PVR, pulmonary vascular resistance; SaO_2, systemic arterial oxygen saturation; SVC, superior vena cava; SvO_2, SVC oxygen saturation; TPG, transpulmonary gradient.

to the Fontan procedure. An increasing hazard function for failure or reintervention, a late decline in functional status, and a 15-year survival between 60% and 73% have been reported on intermediate to late follow-up [242–244]. However, these figures include patients operated upon in the earlier surgical years; with improved surgical techniques and patient selection subsequent survival figures have improved [245,246].

Arrhythmias, in particular atrial flutter, sick sinus syndrome, and heart block, have been reported in 20% or more of survivors 10 years following the Fontan procedure. The probability of freedom from atrial flutter has been reported as about 40% at 15 years post Fontan procedure, although these data include patients from different surgical eras [247]. Predisposing factors include surgery involving the atrium with extensive suture lines, disrupted sinoatrial node blood supply, and chronic atrial distension. In addition, older age at Fontan operation, longer duration of follow-up, and type of surgical procedure are associated with an increased incidence of atrial flutter after the operation. Patients with recurrent arrhythmias are often treated with long-term antiarrhythmic drugs, often present for repeat cardioversions, and may undergo radiofrequency ablation of re-entrant flutter pathways [194,248,249]. There are no recommendations at this time for prophylactic antiarrhythmic drugs, such as digoxin or amiodarone, prior to anesthesia for non-cardiac surgery, but it is important that equipment for immediate external cardiac pacing or cardioversion is readily available in the operating room for these patients.

There is an increased incidence of thromboembolism in patients who have undergone the Fontan procedure, but the routine use of long-term anticoagulation remains controversial. The actual incidence of thromboembolism is difficult to determine because of the heterogeneous patient population. The prevalence of thromboembolic complications after a Fontan operation has ranged from 5% to 33% in mixed cohorts of pediatric and adult patients with different rhythm status [250,251]. The nature of the Fontan circulation with increased venous pressure and stasis of flow through the right atrial baffle, atrial dysrhythmias, alterations in pro- and anticoagulant factors, and possible increased resting venous tone in this population of patients, are all contributing factors [252,253]. The role and efficacy of prophylactic anticoagulant therapy in congenital heart disease in general, and the Fontan population in particular, is poorly defined. Antiplatelet therapy with aspirin is commonly used in the immediate and early postoperative period, although the benefit of long-term use is equivocal [254]. In high-risk patients and those who have had previous thrombus formation, coumadin therapy for an extended period is often utilized. Patients with Fontan physiology may be at increased risk for deep venous thrombosis, or thrombus formation within the Fontan baffle or atrial appendage following non-cardiac surgery. Prophylactic subcutaneous heparin should be considered for older Fontan patients undergoing non-cardiac procedures, and patients should be kept well hydrated and mobilized early after surgery.

Protein-losing enteropathy has been reported in 3–14% of Fontan patients on long-term follow-up [255]. The precise incidence is unknown largely because there is wide variability in the application of laboratory (serum albumin, serum protein, fetal α1-antitrypsin) and clinical criteria to define it [256]. Patients frequently have limited hemodynamic reserve with increased systemic venous pressure, decreased cardiac index, and increased end-diastolic ventricular pressure.

Most patients with stable single-ventricle physiology subjectively report that they are able to lead relatively normal lives with moderate exercise tolerance. Nevertheless, deterioration in function according to New York Heart Association classification has been reported over longer follow-up. Objective evaluation with exercise testing demonstrates the limited cardiorespiratory reserve of many Fontan patients [257,258]. The implications of these findings for subsequent anesthetics have not been studied, but the response to exercise testing may be useful for assessing a patient's ability to tolerate the stress of anesthesia and surgery. Compared with normal control subjects, those with Fontan physiology frequently demonstrate a reduced maximal exercise workload and less endurance, take longer to recover after stopping exercise, and have a lower anaerobic threshold and maximal oxygen consumption. A fall in arterial oxygen saturation and an increase in arteriovenous oxygen saturation difference is common because of the suboptimal increase in cardiac index [259]. The inability to increase effective pulmonary blood flow and stroke volume during strenuous exercise underscores the importance of the pulmonary vascular bed in determining ventricular filling and the dependence upon heart rate to increase cardiac output.

Intraoperative monitoring during major surgery needs careful planning in patients with Fontan physiology. Placement of a central venous line into the SVC will enable monitoring of systemic venous return, pulmonary artery pressure, and mixed venous oxygen saturation. An important consideration, however, is the risk of thrombosis and obstruction to venous return. Cardiac catheterization may be indicated prior to surgery if there has been a change in symptoms or deterioration in function. Performing a hemodynamic study in stable patients prior to major surgery may be beneficial if significant fluid shifts are anticipated. Besides being able to assess baseline hemodynamics, a balloon-tipped catheter can be wedged in a pulmonary capillary to measure the transpulmonary gradient. Positioning the catheter using pressure waveforms alone is difficult because there is no pulsatile arterial pressure waveform and the balloon may not readily float out to a lung segment. Placement under direct vision using fluoroscopy is preferable. Attempted measurement of cardiac output using thermodilution will also be inaccurate.

Tetralogy of Fallot

Pathophysiology

Tetralogy of Fallot (TOF) is a cyanotic heart defect where right ventricular outflow tract (RVOT) obstruction shunts systemic venous blood across a VSD into the aorta producing arterial desaturation (Fig. 27.23). The primary embryological event in TOF is the anterior and cephalad deviation of the conal septum. This causes multilevel RVOT obstruction and a VSD with aortic over-ride. The tetrad is completed by the presence of right ventricular hypertrophy that is secondary to right ventricular hypertension, RVOT obstruction, and the VSD.

In TOF with pulmonary stenosis, there is anterograde flow through the RVOT but it is reduced by fixed infundibular narrowing. Dynamic obstruction is caused by hypertrophied

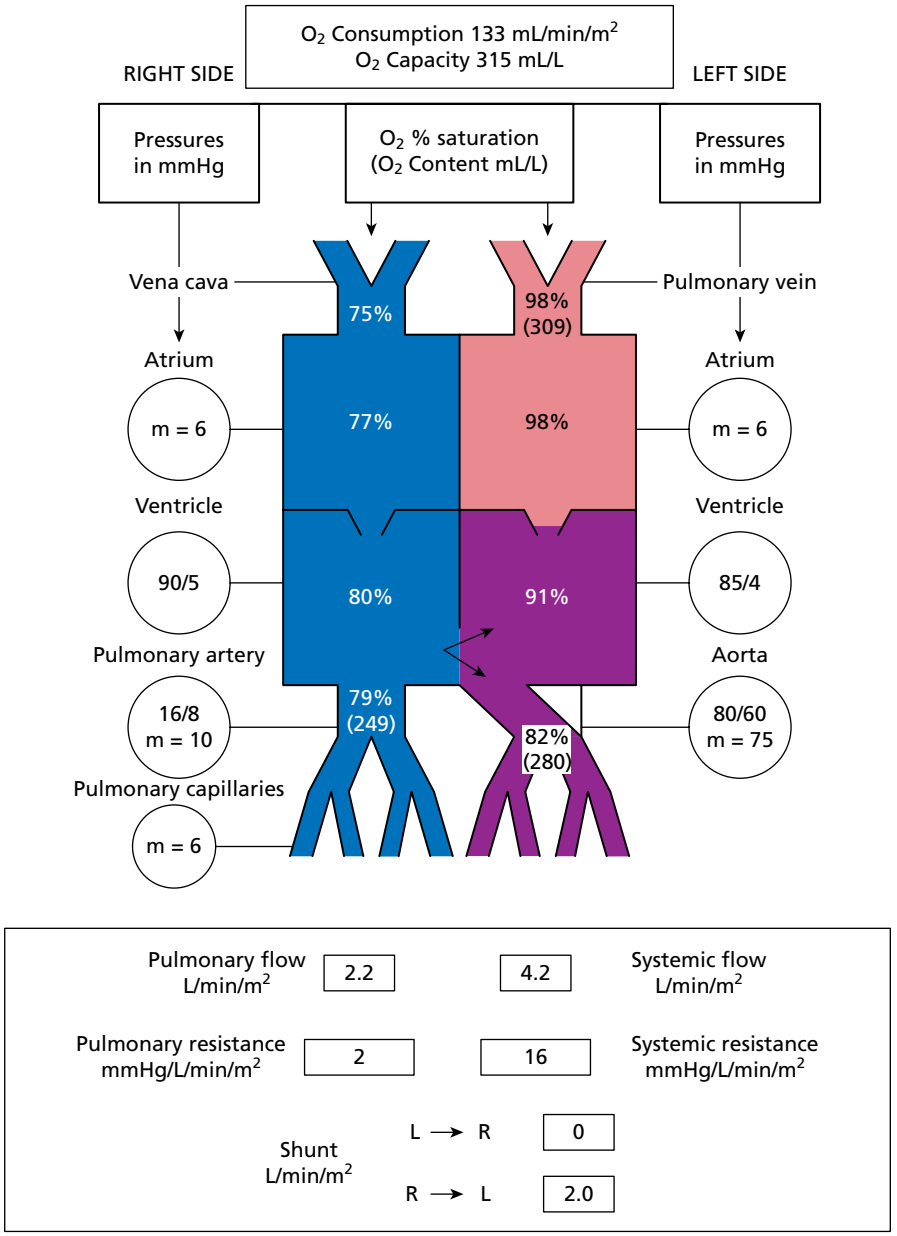

Figure 27.23 Catheterization findings in a patient with tetralogy of Fallot. m, mean pressure. *Source*: Reproduced from Nadas and Fyler [357] with permission of Elsevier.

muscles of the outlet septum, the right ventricular free wall, and the septomarginal trabeculations. The pulmonary valve is usually small and stenotic and branch pulmonary artery obstruction can occur and is usually proportional to the amount of antegrade pulmonary blood flow. Pulmonary artery pressures are normal or low and have little impact on the degree of shunting. The VSD is subarterial and usually perimembranous with fibrous continuity to the aortic and tricuspid valve, but other types of VSDs can also be present. The VSD is large and non-restrictive so the amount of blood that shunts from right to left is dependent on the amount of fixed and dynamic RVOT obstruction. The degree of dynamic obstruction is dependent on the diameter of the RVOT which is affected by the sympathetic tone of the hypertrophied muscles of the RVOT and the preload of the RV.

Hypercyanotic or Tet spells usually occur when infundibular muscle spasms increase RVOT obstruction or SVR is decreased by systemic vasodilation. Hypoxemia worsens when more systemic venous blood is shunted across the VSD to the aorta. Such spells can occur at any time before surgical correction of the anomalies and can be life threatening. Treatment is outlined below. Because the morbidity associated with recurrent hypercyanotic spells is significant, many physicians consider recurrent episodes of hypercyanosis to be an indication for corrective surgery at any age.

Anesthetic management

Tetralogy of Fallot is surgically corrected by relieving the RVOT obstruction and repairing the VSD. Delaying the primary repair for at least 3 months makes a transatrial approach to the VSD and a transpulmonary artery approach to the RVOT technically feasible [260]. Excellent outcomes have been achieved with this approach and the need for a transpulmonary valve annulus outflow patch (transannular patch) at

the time of surgery is reduced. More recently, aggressive efforts to preserve the RVOT and RV pulmonary valve have been used, given the long-term consequences of pulmonary regurgitation and arrhythmogenic scar tissue in the RVOT in this population [261]. In approximately 8% of patients, abnormalities in the origin and distribution of the coronary arteries preclude placement of the right ventricular outflow patch [262,263], making it necessary to bypass the stenosis by placing an external conduit from the body of the RV to the pulmonary artery.

Younger symptomatic patients are first palliated with an aortopulmonary shunt or a stent placed in the RVOT. Some argue for an early complete repair of TOF regardless of symptoms, citing the risks of cyanosis and the potential complications related to palliative aortopulmonary shunts [264]. This may be performed in the neonate or young infant depending upon the degree of obstruction and arterial oxygen saturation level. Complete repair in neonates and young infants more often requires a transventricular approach to close the VSD, with pericardial augmentation of the RVOT. A ventriculotomy is performed in the RVOT and is frequently extended distally through the pulmonary valve annulus and beyond any associated pulmonary artery stenosis. The outflow tract is then enlarged with pericardium or synthetic material, and obstructing muscle bundles are resected to relieve the outflow tract obstruction. Pulmonary regurgitation results after a transannular incision and patch. This combined with the ventriculotomy may compromise ventricular function in the postoperative period.

Anesthetic management of these patients should maintain systemic vascular resistance, minimize pulmonary vascular resistance, and avoid myocardial depression. Hypercyanotic spells in non-anesthetized children are traditionally treated initially with 100% oxygen by facemask, a knee–chest position, and morphine sulfate. This regimen usually causes the dynamic infundibular stenosis to relax while maintaining systemic resistance. Deeply cyanotic and lethargic patients are given IV crystalloid infusions to augment the circulating blood volume and reduce RVOT obstruction by increasing the diameter of the RVOT. Continued severe hypoxemia is treated with a vasopressor (e.g. phenylephrine 1–2 μg/kg) to increase SVR, and sometimes by judicious use of IV propranolol or esmolol to slow the heart rate; the latter allows more filling time and relaxes the infundibulum. If a hypercyanotic spell persists despite treatment, immediate surgical correction of the anomaly is indicated. The child can be anesthetized with IV opioids and hypnotics but anesthetic agents that predominantly decrease SVR should be used with caution. The pattern of mechanical ventilation is critical as excessive inspiratory pressure or short expiratory times will increase the mean intrathoracic pressure and further reduce antegrade flow across the RV outflow.

Patients usually separate from CPB with a satisfactory blood pressure and atrial filling pressures <10 mmHg on inotrope support, such as dopamine 5–10 μg/kg/min. The aim of therapy is to support right ventricular function and minimize afterload on the RV. This is particularly important following repair in neonates or small infants. Systolic dysfunction of the RV may occur following neonatal ventriculotomy, but restrictive physiology reflecting reduced RV compliance and diastolic function is more common [265,266]. Factors contributing to diastolic dysfunction include ventriculotomy, lung and myocardial edema following CPB, inadequate myocardial protection of the hypertrophied ventricle during aortic cross-clamp, coronary artery injury, residual outflow tract obstruction, volume load on the ventricle from a residual VSD, or pulmonary regurgitation and dysrhythmias. A low cardiac output status may occur in neonates in the first 6–16 h after repair, characterized by increased right-sided filling pressures from diastolic dysfunction. Continued sedation and muscle relaxation are usually necessary for the first 24–48 h to minimize the stress response and the associated increase in myocardial work. Preload must be maintained despite elevation of the RA pressure. In addition to high right-sided filling pressures, pleural effusions and/or ascites may develop. Significant inotrope support is often required, and a phosphodiesterase inhibitor, such as milrinone is beneficial because of its lusitropic properties. Because of the restrictive defect, even a relatively small volume load from a residual VSD or pulmonary regurgitation is often poorly tolerated in the early postoperative period. It may take 2–3 days before RV compliance improves following surgery and cardiac output increases. While the patent foramen ovale or any ASD is usually closed at the time of surgery in older patients, it is beneficial to leave a small atrial communication following neonatal repair. In the face of diastolic dysfunction and increased RV end-diastolic pressure, a R-L atrial shunt will maintain preload to the left ventricle and therefore cardiac output. Patients may be desaturated initially following surgery because of this shunting. As RV compliance and function improve, the amount of shunt decreases and both antegrade pulmonary blood flow and arterial oxygen saturation increase.

Arrhythmias following repair include heart block, ventricular ectopy, and junctional ectopic tachycardia. It is important to maintain sinus rhythm to avoid additional diastolic dysfunction and an increase in end-diastolic pressure. Atrioventricular pacing may be necessary for heart block. Complete right bundle branch block is typical on the postoperative ECG.

Most patients recover systolic ventricular function postoperatively. However, there is a small group of patients, especially those repaired at older ages, in whom significant ventricular dysfunction remains. Pulmonary valve insufficiency may contribute to residual ventricular systolic dysfunction [267]. The most common cause of systolic dysfunction immediately after repair of TOF is a residual or unrecognized additional VSD which causes a volume load on the left ventricle and pressure load on the hypertrophied right ventricle, leading to right ventricular failure and poor cardiac output [268,269]. A residual VSD combined with a residual right ventricular outflow obstruction is particularly deleterious. Suprasystemic pressure may occur in the right ventricle particularly if the PAs are hypoplastic or stenotic. In some cases, this can be ameliorated by partially opening the VSD to allow an intracardiac R-L ventricular shunt. This shunt unloads the compromised right ventricle but results in systemic hypoxemia.

Anesthetic considerations after right ventricle outflow reconstruction

Reconstruction of the RVOT may lead to significant problems that affect RV function and the risk for arrhythmias over time. While most of the long-term outcome data pertain to patients

following TOF repair, similar complications and risks are also likely for those who have undergone an extensive RV outflow reconstruction, such as placement of a conduit from the right ventricle to the pulmonary artery for correction of pulmonary atresia or truncus arteriosus, and the Rastelli procedure for transposition of the great arteries with pulmonary stenosis.

Complete surgical repair of TOF has been successfully performed for over 40 years, with recent studies reporting a 30–35-year actuarial survival of about 85%. Many patients report leading relatively normal lives, but RV dysfunction may progress after repair and may only be evident on exercise stress testing or echocardiography. Continued evaluation is necessary because these patients have an increased risk of ventricular dysrhythmias and late sudden death. Factors that may adversely affect long-term survival include older age at initial repair, initial palliative procedures, and residual chronic pressure and/or volume load such as from pulmonary insufficiency or stenosis [270,271]. A spectrum of problems may develop, ranging from a dilated RV with systolic dysfunction to diastolic dysfunction from a poorly compliant RV (Table 27.11). These problems need to be thoroughly evaluated preoperatively.

Both RV and LV systolic dysfunction secondary to a residual volume load from pulmonary regurgitation after tetralogy repair are predictors of late morbidity [270,271]. There is also an association between RV dilation from pulmonary regurgitation and the risk of ventricular tachycardia (VT) and sudden death [272]. The consequences of chronic pulmonary regurgitation are reflected by cardiomegaly on chest x-ray, an increase in RV EDV by echocardiography, and on exercise testing as a reduction in anaerobic threshold, maximal exercise performance, and endurance [273]. Preoperative exercise testing may provide some insight into hemodynamic reserves. Patients who have significant pulmonary regurgitation and reduced RV function are at potential risk of a fall in cardiac output during anesthesia, particularly as positive pressure ventilation may increase RV afterload and the amount of pulmonary regurgitation. Once again, it is difficult to predict those patients who are more likely to have instability during anesthesia for non-cardiac surgery; nor is it possible to formulate a "recipe" for anesthesia that will be suited to all patients.

Table 27.11 Long-term follow-up considerations after tetralogy of Fallot repair: right ventricular function

Circumstance	Clinical
Systolic dysfunction: "non-restrictive"	RV dilation: cardiomegaly Significant pulmonary regurgitation Volume overload: ↑ RVEDV, ↓ RV ejection fraction ↓ Maximal exercise capacity and endurance ↑ Risk for ventricular arrhythmias and possibly sudden death
Diastolic dysfunction: "restrictive"	↓ RV compliance: cardiomegaly less likely Limited pulmonary regurgitation ↑ RVEDP, contractility maintained Improved exercise capacity Lower risk for ventricular dysrhythmias

RV, right ventricle; RVEDP, right ventricle end-diastolic pressure; RVEDV, right ventricle end-diastolic volume; ↑, increased; ↓, decreased.

Some patients have restrictive physiology or diastolic dysfunction secondary to reduced ventricular compliance. These patients usually do not have cardiomegaly and demonstrate better exercise tolerance, and the risk for ventricular dysrhythmias is possibly decreased. Although the RV is hypertrophied, function is generally well preserved on echocardiography with minimal pulmonary regurgitation [273].

The incidence of significant RV outflow obstruction developing over time is low. Residual obstruction contributes to early mortality within the first year after surgery, but is well tolerated in the long term. A gradient more than 40 mmHg across the RV outflow is uncommon and the pressure ratio between the RV and LV is usually less than 0.5. The gradient may become more significant with time, but as the progression is usually slow, RV dysfunction occurs late.

A wide variation in the incidence of ventricular ectopy has been reported in numerous follow-up studies, including up to 15% of patients on routine ECG and up to 75% of patients on Holter monitor. Multiple risk factors including an older age at repair, residual hemodynamic abnormalities, and duration of follow-up have all been considered important [194,259,272]. In common with these factors is probable myocardial injury and fibrosis from chronic pressure and volume overload, and cyanosis. While ventricular ectopy is common in asymptomatic patients during ambulatory ECG Holter monitoring and exercise stress testing, it is often low grade and has not identified those patients at risk for sudden death. Electrophysiological induction of sustained VT, especially when monomorphic, is suggestive of the presence of a reentrant arrhythmic pathway [274]. Although dependent on the stimulation protocol used to induce VT, the presence of monomorphic VT in a symptomatic patient with syncope and palpitations is significant and indicates treatment with radiofrequency ablation, surgical cryoablation, antiarrhythmic drugs, or placement of an implantable cardioversion-defibrillator (ICD) [194,249,263]. The risk for ventricular dysrhythmias during anesthesia is unknown. While preoperative prophylaxis with antiarrhythmic drugs is not recommended, a means of external defibrillation and pacing must be readily available.

Tetralogy of Fallot with absent pulmonary valve

The absence of a functioning pulmonary valve gives rise to *in utero* pulmonary regurgitation resulting in the aneurysmal dilation of the main and branch pulmonary arteries. Tracheobronchial compression can result such that the pathophysiology of TOF is complicated by symptoms of an anterior mediastinal mass. These patients are usually positioned on their sides even when mechanically ventilated. Prior to repair, the patient is kept in the lateral position and returned supine immediately prior to incision and CPB is intiated expeditiously.

Pulmonary atresia

Pathophysiology

The intracardiac anatomy of TOF with pulmonary atresia is similar to that of simple TOF, but the RVOT is atretic. All systemic venous return moves right to left across the VSD. Therefore, complete mixing of pulmonary and systemic venous return occurs in the left ventricle and aorta, producing arterial hypoxemia. When antegrade flow is established from

the right ventricle into the main pulmonary artery by a reparative procedure, the L-R shunt via collateral flow will impose a diastolic load on the left ventricle. Preoperative occlusion of these collateral vessels can be accomplished by interventional techniques in the cardiac catheterization laboratory but may leave the child more cyanotic in the hours before operation. The most effective temporizing therapy is to reduce oxygen consumption (e.g. anesthesia, mechanical ventilation) and to increase the systemic perfusion pressure across other systemic-to-pulmonary communications.

Atresia of the pulmonary valve or main pulmonary artery forms a spectrum of cardiac defects, the management of which depends on the extent of atresia, size of the RV and tricuspid valve, presence of a VSD and collateral vessels, surface area of the pulmonary vascular bed, and coronary artery anatomy. At birth, pulmonary blood flow is derived either from a PDA or from other aortopulmonary collateral blood vessels. These collaterals, which arise from the descending aorta and supply both lungs, may be extensive. The RV is usually hypertrophied, and a restrictive physiology is common during initial postoperative recovery.

Critical pulmonary stenosis may exist with a variable degree of hypoplasia of the right ventricle, tricuspid valve, and pulmonary artery. There is no VSD. A pinhole orifice is present in the pulmonic valve, but the right ventricle is generally less hypoplastic than with pulmonary atresia. A fixed obligatory shunt of all systemic venous return occurs from the right to the left atrium, where blood mixes completely with pulmonary venous blood. Some blood may flow into the right ventricle, but because there is no outlet, blood regurgitates back across the tricuspid valve and eventually reaches the left atrium and left ventricle. Pulmonary blood flow is derived exclusively or predominantly from a PDA. These patients usually do not have extensive aortopulmonary collateral blood flow; consequently, they often become cyanotic when the PDA closes after birth. Critical pulmonary valve stenosis can be effectively treated by balloon dilation in the catheterization laboratory. Antegrade flow across the RV outflow may not improve immediately, but gradually increases over days as RV compliance improves.

Pulmonary valve atresia or short-segment main pulmonary artery atresia, with a VSD and normal-sized tricuspid valve, RV, and branch pulmonary arteries, is completely repaired in the neonate, usually involving placement of a pericardial patch to reconstruct the outflow tract. If there is long-segment pulmonary artery atresia, a homograft conduit is necessary to reconstruct the RV outflow. Conduits may be extrinsically compressed or kinked at the time of sternal closure, causing partial RV outflow obstruction or direct compression of a coronary artery leading to ischemia.

Patients with pulmonary atresia, a VSD, and small RV and tricuspid valve may not tolerate a complete initial repair. The RV may be unable to cope with the entire cardiac output, resulting in a low output state and RV failure (see later). Alternative management strategies therefore include initial palliation with a shunt and/or RV outflow patch to improve pulmonary blood flow, or a repair of the outflow tract with fenestration of the VSD patch to enable a R-L shunt at that level. Two-ventricle repair may ultimately be limited by growth of the tricuspid valve. If the right ventricle subsequently grows, the shunt and the patent foramen ovale ASD and VSD can be closed surgically.

Patients with pulmonary atresia and an intact ventricular septum usually have a small RV and tricuspid valve, which in general makes them unsuitable for a two-ventricle repair in the long term. Initial palliation with an aortopulmonary shunt is necessary; reconstruction of the RV outflow with a pericardial patch or conduit may also be considered if the RV is of a sufficient size such that a two-ventricle repair could be considered. Prior to surgery, the coronary anatomy should be determined, usually by cardiac catheterization. A large conal branch or aberrant left coronary artery across the RVOT may restrict the size of a ventriculotomy and placement of a patch or conduit. Patients with pulmonary atresia, a hypoplastic RV, and intact ventricular septum may have numerous fistulous connections between the small hypertensive RV cavity and the coronary circulation [275,276]. A significant proportion of the myocardium may therefore be dependent upon coronary perfusion directly from the RV. If, in addition, there is proximal coronary artery stenosis or even atresia restricting coronary perfusion from the aortic root, then decompression of the RV following reconstruction of the RVOT can lead to myocardial infarction.

Severe pulmonary atresia may be associated with a hypoplastic RV and diminutive pulmonary arteries that are not suitable for primary repair [277]. A palliative procedure with a B-T or central shunt is usually necessary at first to improve pulmonary blood flow, followed by staged single-ventricle repair (see section "Anesthetic considerations for patients following a Fontan procedure"). Multiple aortopulmonary collateral arteries may be present, supplying some or all segments of the lung. They can be associated with a large L-R shunt, contributing to volume overload and pulmonary hypertension. RV to diminutive pulmonary artery continuity is established in the operating room. Larger collateral vessels supplying significant portions of the lung can be anastomosed or unifocalized to the native pulmonary arteries, with the ultimate aim being to establish full antegrade pulmonary blood flow. Smaller vessels to some segments of lung can be coiled in the cardiac catheterization laboratory, provided there is antegrade flow from the native pulmonary arteries to those lung segments. Cyanosis may occur after collateral vessels are occluded in the cardiac catheterization laboratory. Therapy is aimed at lowering PVR and improving pulmonary blood flow.

It is important to establish early antegrade flow from the right ventricle to the pulmonary artery when pulmonary arteries are diminutive to promote growth and establish a pathway to the pulmonary arteries for subsequent balloon dilation. A B-T shunt may be necessary to provide sufficient pulmonary blood flow if the pulmonary arteries and right ventricle are small. Initially, the VSD can be left open, and postoperative management of cyanosis or CHF will be determined by the size of and the resistance offered by the pulmonary circuit.

Postoperatively, fully saturated hemoglobin in the aorta with elevated pulmonary artery oxygen saturation and left atrial pressure can signify a L-R shunt through a developing VSD. This will produce a volume load on the left ventricle which, if not tolerated, may require VSD closure or revision. When the patient is not fully saturated in the aorta but is suffering from a volume-loaded left ventricle with low cardiac output and high left atrial pressure postoperatively, excessive

systemic-to-pulmonary collateral flow may be the cause, and occlusion of the vessels in the catheterization laboratory or immediate reoperation may be necessary.

Anesthetic management

Anesthetic management of patients with pulmonary atresia is similar to that for TOF, but hypercyanotic spells related to indundibular spasm do not occur. Maintaining the patency of the ductus for the perioperative treatment of neonates with pulmonary atresia and critical pulmonary stenosis is essential. If the right ventricle is sufficiently well developed and the main pulmonary artery is present, it may be possible to perform a pulmonary valvotomy and provide adequate pulmonary blood flow without a supplemental systemic-to-pulmonary artery shunt. The goal of therapy is to improve oxygenation and decrease right ventricular afterload. Because the underdeveloped right ventricle is non-compliant and requires high filling pressures, there may be substantial R-L shunting through the foramen ovale, making these infants hypoxemic during the immediate postoperative period. With growth and improved compliance of the right ventricle, the R-L shunting diminishes and the infant's oxygenation improves substantially. If hypoxemia persists, a PGE1 infusion should be started to increase pulmonary blood flow through the ductus arteriosus while arrangements are made to surgically create a pulmonary-to-systemic artery shunt.

In patients with long-segment pulmonary atresia, the need for a conduit to bridge the gap between the right ventricle and the pulmonary artery complicates the repair. Again, right ventricular failure may occur postoperatively, especially when there is a residual VSD or an outflow obstruction. The conduit may obstruct acutely during chest closure, further elevating pressure in the right ventricle.

After the VSD is closed and blood flow is from the right ventricle to the pulmonary arteries, there may be excessive pulmonary blood flow (Qp/Qs >1) owing to the combined flow into the pulmonary arteries from the right ventricle and from aortopulmonary collaterals. If this occurs, the patient develops CHF and requires intraoperative inotropic support of the heart and an extended period of postoperative mechanical ventilation. With large collateral flows, the pulse pressure is large and diastolic pressure low. The patients may require surgery to ligate the collateral vessels or embolization in the catheterization laboratory.

Anesthetic considerations after repair

Patients with TOF and pulmonary atresia are subject to the same late problems and complications as patients with TOF alone. In addition, they may develop progressive conduit obstruction after surgery.

Tricuspid atresia

Pathology

In this condition, an imperforate tricuspid valve and hypoplasia of the right ventricle are present, often accompanied by a VSD of variable size and by pulmoniary stenosis (Fig. 27.24). A fixed obligatory shunt of all systemic venous return occurs from the right atrium through the patent foramen ovale or ASD into the left atrium, where complete mixing takes place. The degree of hypoxemia depends on the amount of pulmonary blood flow, which is regulated by the severity of the pulmonary stenosis. The common presentation is characterized by significant hypoxemia caused by the decreased pulmonary blood flow induced by either a restrictive VSD or a severe pulmonary stenosis.

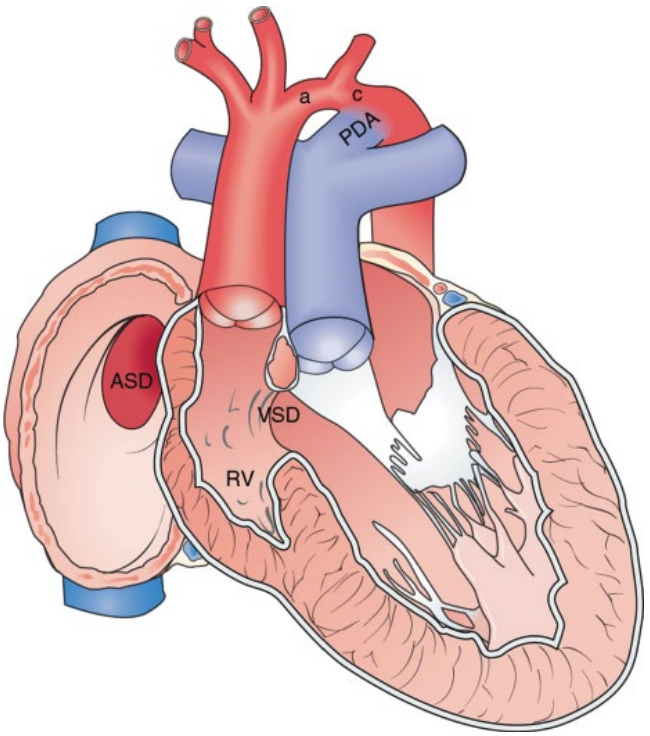

Figure 27.24 Tricuspid atresia. A plate-like obstruction exists in place of the tricuspid valve. This variant is type IIc (see text for details): transposition of the great vessels with no pulmonary stenosis. ASD, atrial septal defect; VSD, ventricular septal defect; RV, right ventricle; PDA, patent ductus arteriosus; a, hypoplastic transverse aortic arch; c, coarctation of the aorta. *Source*: Reproduced from Andropoulos and Gottlieb [359] with permission of Elsevier.

Anesthetic management

The reparative operation of choice for tricuspid atresia is a modified Fontan procedure, but a palliative procedure may initially be required to improve pulmonary blood flow. A pulmonary artery band may be needed if the pulmonary blood flow is increased, or a shunt may have to be created for the severely hypoxemic child with decreased pulmonary blood flow. The anesthetic management and complications are those discussed in the sections on shunts, banding, and modified Fontan procedures (see earlier in this chapter). Complications of chronic hypoxemia and cyanosis are also present.

Transposition of the great arteries

Pathophysiology

With transposition of the great arteries, the right ventricle gives rise to the aorta (Fig. 27.25). Transposition physiology is characterized by pulmonary artery saturation that is greater than aortic saturation. Almost 50% of patients with this anomaly have a VSD, and some of them have a variable degree of subpulmonary stenosis (Fig. 27.25). Oxygenated pulmonary venous blood returns to the left atrium and is recirculated to the pulmonary artery without reaching the systemic

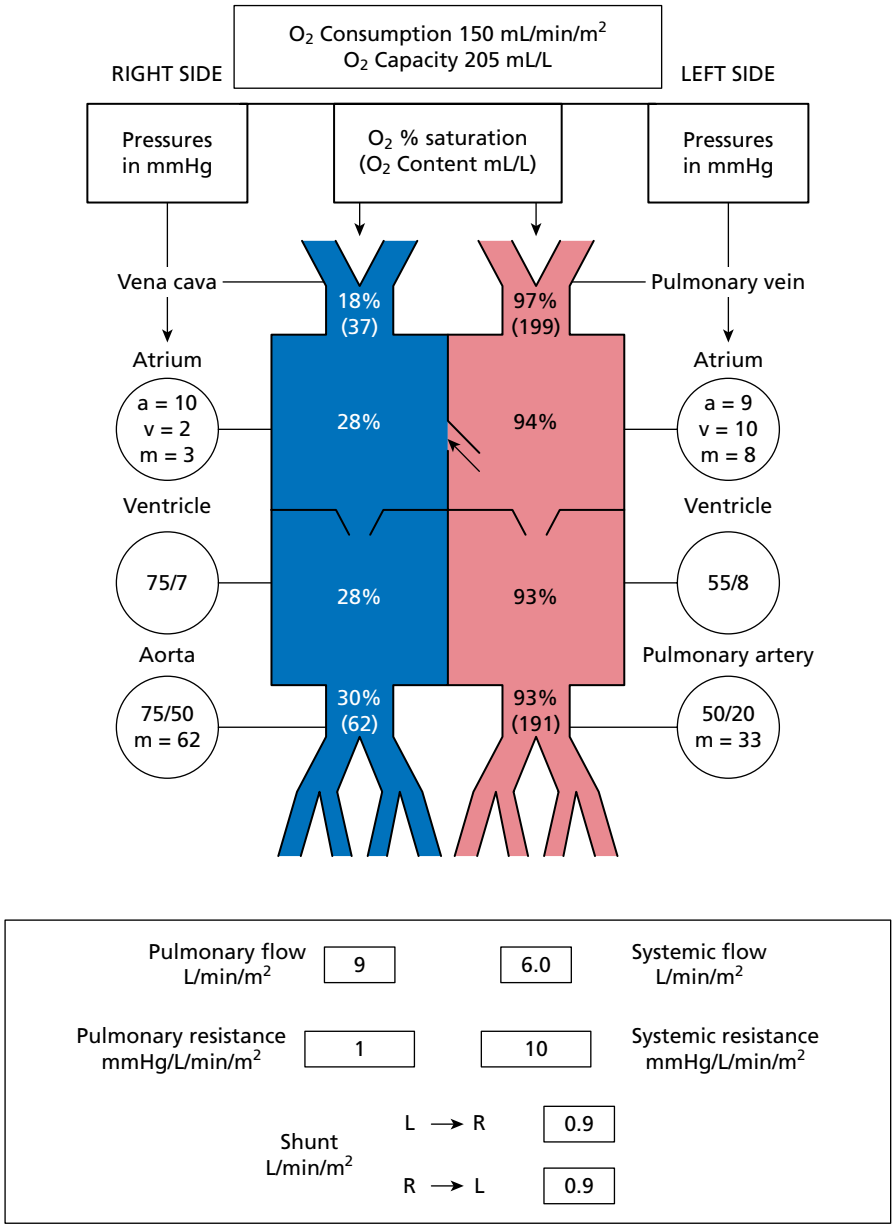

Figure 27.25 Catheterization findings in a patient with d-transposition of the great arteries and restricted pulmonary flow. a, arterial pressure; m, mean pressure; v, venous pressure. *Source*: Reproduced from Nadas and Fyler [357] with permission of Elsevier.

circulation. Similarly, systemic venous blood returns to the right atrium and ventricle and is ejected into the aorta again. This arrangement is incompatible with life unless there is some mixing of pulmonary and systemic venous blood via a patent ductus arteriosus or an opening in the atrial or ventricular septum at birth. The physiological disturbance in these patients is one of inadequate mixing of pulmonary and systemic blood rather than one of inadequate pulmonary blood flow.

Mixing of blood at the atrial level can be improved by balloon atrial septostomy. If dangerous levels of hypoxemia persist after the septostomy and metabolic acidosis ensues, an infusion of PGE1 can maintain the patency of the ductus arteriosus, increase pulmonary blood flow (by increasing L-R shunting across the PDA), and thereby increase the volume of oxygenated blood entering the left atrium. The volume-overloaded left atrium is likely to shunt part of its contents into the right atrium and thereby improve the oxygen saturation of aortic blood. Unlike the kinetics with other lesions, increased shunting of blood during anesthesia improves arterial oxygen saturation before correction of the transposition.

Depending on the particular anatomy and the presence of a VSD or pulmonary stenosis, one of three corrective procedures is used. The intraoperative and postoperative problems encountered differ with each type of procedure.

Atrial baffle procedure (Mustard and Senning)

An atrial-level partition or baffle is created to redirect pulmonary venous blood across the tricuspid valve to the right ventricle and thus to the aorta [278]. Systemic venous return is directed across the atrial septum to the mitral valve, into the left ventricle, and out into the pulmonary artery. Although the pulmonary and systemic circuits are then connected serially instead of in parallel, this arrangement leaves the patient with

a morphological right ventricle and tricupsid valve in continuity with the aorta. Thus, the morphological right ventricle must work against systemic arterial pressure and resistance.

One problem with atrial baffles is that they can obstruct systemic and pulmonary venous return [279]. When this occurs, the patient manifests signs and symptoms of systemic venous obstruction, as evidenced by SVC syndrome or other signs of systemic venous hypertension. When the pulmonary venous pathway is obstructed, pulmonary venous hypertension may be manifested by respiratory failure, poor gas exchange, and pulmonary edema (seen on chest radiograph). Severe pulmonary venous obstruction is manifested in the operating room by the presence of copious amounts of bloody fluid in the endotracheal tube, low cardiac output, and frequently poor oxygenation. Residual interatrial shunts also may cause intra- or postoperative hypoxemia. Long-term rhythm disturbances, along with functional and long-term limitations of the morphological right ventricle and atrioventricular valve in the systemic position have made this operation nearly obsolete. The Mustard and Senning procedures have not been performed regularly since the 1980s, but rare anatomical variants may require this approach, and adults with these repairs may present for cardiac or non-cardiac procedures.

Arterial switch procedure

The arterial switch operation (ASO) to correct dextro-transposition of the great arteries (d-TGA) is one of the major advances in congenital heart surgery over the past 40 years. Jatene and others explored whether anatomical correction of this lesion by dividing both great arteries and reattaching them to the opposite, anatomically correct, ventricle, would improve survival [280,281]. This procedure is now performed in virtually all patients who do not have outflow tract obstruction. It requires excision and reimplantation of the coronary arteries to the neo-aorta (formerly the proximal main pulmonary artery). Virtually all coronary artery patterns are amenable to the ASO (Fig. 27.26).

The success of the arterial switch procedure depends on maintaining adequate function of the morphological left ventricle before repair and successful transfer of the coronary arteries to the pulmonary artery. Anatomical correction of transposition of the great vessels is done during the neonatal period when PVR (afterload of the morphological left ventricle) and left ventricular pressures are still high, preserving the function of both ventricles. Left ventricular mass decreases progressively after birth as the PVR falls. If left ventricular function is misjudged preoperatively, the child may develop severe left ventricular failure postoperatively and require inotropic support and afterload reduction to provide normal cardiac output.

Infants with d-TGA who are more than a few weeks of age and have an intact ventricular septum may have decreased left ventricular pressure and mass. In such cases, the left ventricle may not tolerate the work required to perfuse the systemic vessels. Banding the pulmonary artery increases the afterload of the left ventricle and prepares it to function as a systemic ventricle by increasing and remodeling ventricular muscle mass. Pulmonary blood flow might need to be augemented with a modified B-T shunt if banding results in unacceptable cyanosis. The ASO can usually be accomplished 1 week later after hypertrophy and hyperplasia of the ventricle have occurred [282]. However, during this interval, these patients are cyanotic, with a volume-loaded right ventricle and a pressure-loaded left ventricle, and they may require considerable pharmacological support [283]. Infants with d-TGA and a non-restrictive VSD have a left ventricle that is

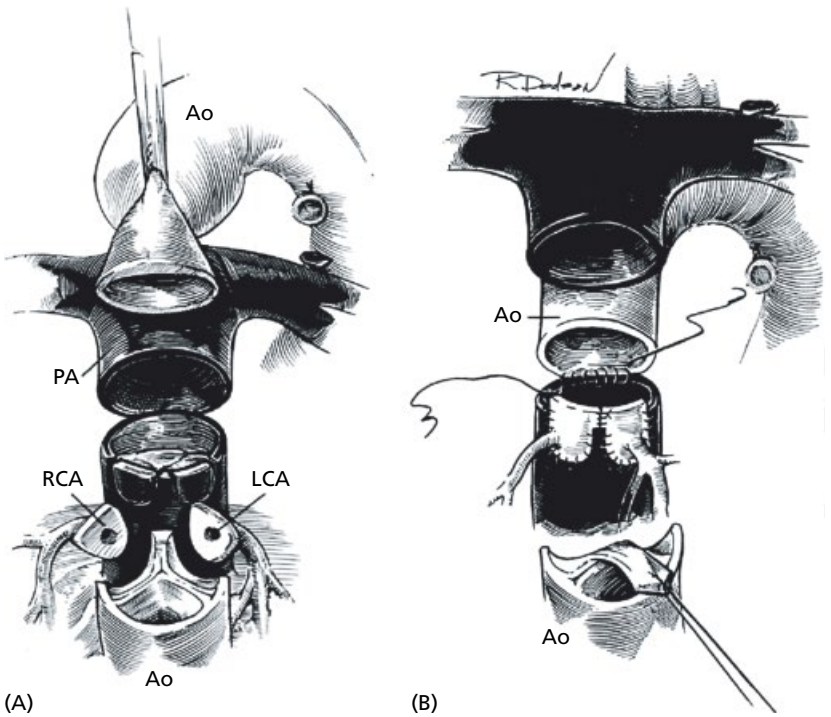

Figure 27.26 Arterial switch operation. (A) The aorta (Ao) and pulmonary artery (PA) are transected and translocated. accustomed to high pressure and may tolerate the increase in workload after the arterial switch operation at any age.

In experienced centers, the incidence of mortality for neonatal repair for d-TGA is now less than 3% and may be less than 2% for most anatomical arrangements of coronary arteries if the aortic arch is normal [284–286]. Midterm follow-up of these patients shows excellent outcome. Alternative operations are reserved almost exclusively for patients with particularly difficult coronary anatomy or pulmonic (neo-aortic) stenosis.

Myocardial ischemia or infarction may occur after mobilization and reimplantation of the coronary arteries, especially if they are stretched or twisted. This may occur if the left atrium becomes distended. Inotropic support, maintenance of coronary perfusion pressures, control of heart rate, and treatment with vasodilators may be particularly useful, as in adult patients with myocardial ischemia. Postoperative bleeding and tamponade occur more commonly with this operation because there are multiple arterial anastomoses.

Ventricular switch (Rastelli procedure)

Patients with a large VSD and severe subpulmonary stenosis can have the VSD closed obliquely to direct left ventricular flow to the aorta. The pulmonary valve is oversewn and the right ventricle connected to the pulmonary artery with a conduit [287]. Complications of the Rastelli procedure include obstruction of left ventricular outflow due to narrowing of the subaortic region by the VSD patch. The conduit also may obstruct during or after the immediate postoperative period. There is a small but significant incidence of heart block in these patients, which can be a difficult postoperative problem. In order to reduce the incidence of these complications, alternative surgical procedures involving biventricular outflow tract reconstruction such as aortic root translocation (Nikaidoh) and réparation à l'etage ventriculaire (the REV or Lecompte procedure) have been developed and modified [288,289].

Anesthetic considerations after repair

Patients who have a morphological right ventricle remaining as the systemic ventricle (as in patients who underwent an atrial switch procedures) have a physiologically corrected but anatomically incorrect functional two-ventricle repair. Actuarial survival figures at 20 years have been quoted up to 80%, but significant long-term functional deterioration is likely with increasing risk of right heart failure, sudden death, and dysrhythmias [290–293]. This situation is evidenced by systemic (right) ventricular dysfunction and tricuspid valve regurgitation long after the repair [294,295].

The development of arrhythmias later in life continues to be a problem following atrial switch procedures. There is a progressive postoperative increase in the incidence of non-sinus rhythm following both the Mustard and Senning operations. Actuarial analysis of several series revealed that by 10 years postoperation, only about 60–70% of patients will be in sinus rhythm at rest and by 20 years this will decrease to 40–50% [296–300]. In one series, only 7% of patients who underwent a Senning procedure for d-TGA with VSD were in sinus rhythmn at 15 years [290]. The majority of patients not in sinus rhythm will be in a junctional rhythm without the necessity for a pacemaker. Atrial flutter is present in 8% of patients at 5 years and in 27% at 20 years [300]. Late development of atrial flutter/fibrillation may be a surrogate marker for ventricular dysfunction and as such may put the patient at risk for VT and sudden death [301].

The exercise response of patients who have undergone an atrial switch procedure is abnormal with RV dysfunction, chronotrophic impairment, failure to augment ventricular filling and stroke volume, deconditioning, and impaired lung function all playing a role. Failure to augment ventricular filling is the consequence of diastolic pathology and poor atrial transport across reconstructed intra-atrial pathways [302–305].

Postoperative concerns of the ASO include the long-term patency and growth potential of the reimplanted coronary arteries. Fortunately, these problems have not materialized on a large scale. The overwhelming majority (95%) of patients have normal-sized, patent coronary arteries. A more recent study of a large cohort demonstrated that the incidence of adverse cardiovascular events was 93% at 25 years [306]. Patients with complex preoperative coronary anatomy are at increased risk of late occlusion [307].

After repair, the native pulmonary valve becomes the neo-aortic valve. Aortic insufficiency occurs in approximately 50% of patients at long-term follow-up with the majority (93%) graded as trivial or mild [294,308]. Time has shown aortic insufficiency to be a rare source of morbidity or indication for reoperation following the ASO [284,285].

In contrast to the atrial switch procedures, electrophysiological abnormalities are uncommon after the ASO. The most common abnormalities noted at midterm and long-term follow-up are rare asymptomatic atrial and ventricular premature beats [308–310].

Supravalvar pulmonary artery stenosis was an early complication, but is now less common with surgical techniques that extensively mobilize, augment, and reconstruct the pulmonary arteries. The incidence of supravalvular stenosis severe enough to require reoperation (generally a gradient greater than 50–60 mmHg) is approximately 10% [284,285]. There continue to be refinements in surgical technique to further reduce the incidence of this complication [311].

Assessment of myocardial performance using echocardiography, cardiac catheterization, and exercise testing following the ASO has demonstrated function identical to age-matched controls [312]. Based upon the currently available clinical, functional, and hemodynamic data, a patient who has undergone a previous ASO with no evidence of subsequent problems should be treated as for any patient with a structurally normal heart when presenting for non-cardiac surgery.

Total anomalous pulmonary venous connection

Pathophysiology

Patients with total anomalous pulmonary venous connection are cyanotic and have pulmonary veins connected to a systemic vein. The venous connection may be above the level of the heart (e.g. to the SVC, innominate, or azygos vein), directly to the right atrium, or below the level of the heart and the diaphragm (e.g. to the hepatic veins) (Fig. 27.27). Patients with this anomaly must have a patent foramen ovale or an ASD that allows blood flow to the left side of the heart. A subset of patients may have varying degrees of pulmonary venous obstruction.

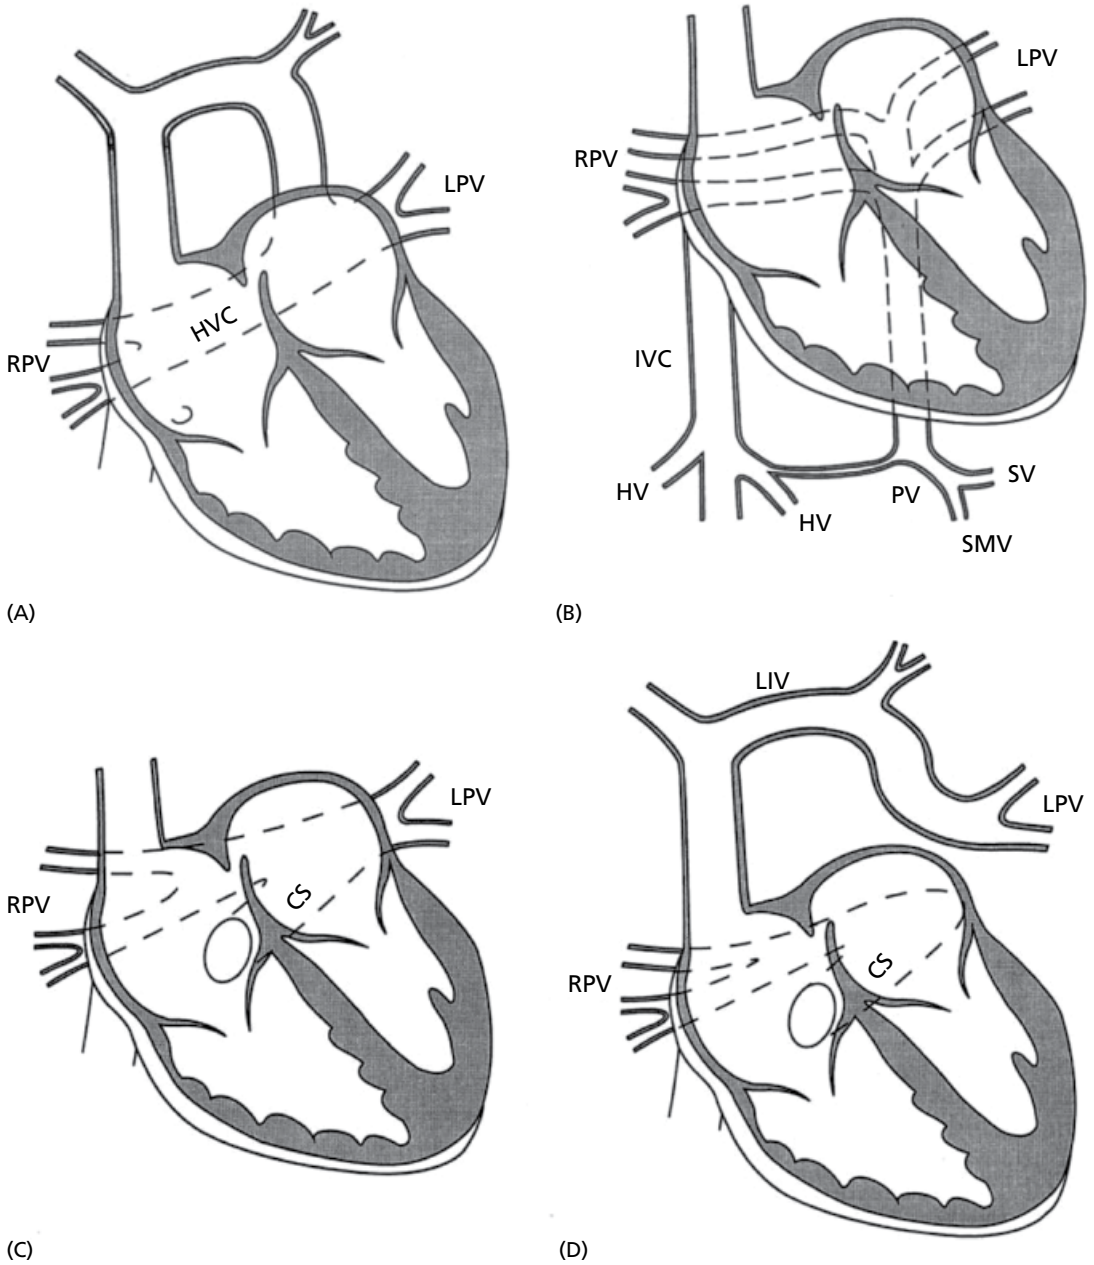

Figure 27.27 Four major subtypes of total anomalous pulmonary venous return (see text for further explanation): (A) supracardiac, (B) infracardiac, (C) cardiac, and (D) mixed. RPV, right pulmonary vein; HVC, horizontal pulmonary venous confluence; LPV, left pulmonary vein; CS, coronary sinus; IVC, inferior vena cava; HV, hepatic vein; PV, portal vein; SMV, superior mesenteric vein; SV, splenic vein; LIV, left innominate vein. *Source*: Reproduced from Allen et al [361] with permission of Wolters Kluwer.

This anatomical arrangement provides complete mixing of all systemic and pulmonary venous blood in the right atrium. The mixed venous blood is partially shunted across the atrial communication to the left arium and systemic circulation. Most of this right atrial blood passes through the right ventricle into the pulmonary artery, which increases pulmonary blood flow. If pulmonary venous return is significantly inhibited, there is increased pulmonary venous congestion and decreased pulmonary blood flow.

Anesthetic management

These patients may be very ill, with hypoxemia, severe pulmonary edema, and pulmonary artery hypertension. Patients are resuscitated with mechanical ventilation, use of PEEP, and inotropic support, and then undergo early surgical intervention to relieve the pulmonary venous obstruction. Although the patients are hypoxemic, their primary pathology is caused by obstructed venous return from the lungs. Therapy that increases pulmonary blood flow (e.g. PGE1) must be avoided. Surgical repair of total anomalous pulmonary venous connection requires attachment or redirection of the pulmonary venous confluence to the left atrium [313].

Intraoperative and postoperative problems are often related to residual or recurrent stenosis of the pulmonary veins. The pulmonary vascular bed is highly reactive in patients who had pulmonary venous hypertension preoperatively. This reactivity may produce high pulmonary artery pressures and poor right ventricular function after bypass and during the

early postoperative period. Anesthetic management of these patients after completion of the repair should emphasize inotropic support of the right ventricle, avoidance of myocardial depressant drugs, and minimization of pulmonary vascular resistance. Early extubation of the trachea is usually not feasible. Mechanical ventilation with hyperventilation and other postoperative therapy to decrease PVR are required. Use of inhaled nitric oxide has been particularly useful in this population.

Anesthetic considerations after repair

Other than the potential for late development of recurrent pulmonary venous obstruction, these patients generally do well and have good cardiovascular reserve once recovery from the surgery is complete [314]. The size of the pulmonary veins at birth may be a predictor of late complications with recurrent pulmonary vein stenosis [315].

Atrial septal defects

Pathophysiology

There are three anatomical varieties of ASD (Fig. 27.28). The most common is the secundum ASD, which is a deficit in the septum primum, the membrane that usually covers the region of the foramen ovale. The ASD primum is a deficit of the inferior portion of the atrial septum (endocardial cushion) and is usually accompanied by a cleft in the anterior leaflet of the mitral valve. Sinus venosus defects are located near the junction of the right atrium and the superior or inferior vena cava and are are frequently associated with a partial anomalous pulmonary venous connection where the two right-sided veins connect directly to the SVC.

ASDs are functionally characterized as simple L-R shunts that cause a low-pressure volume load to the right ventricle. Pulmonary blood flow is increased, but not enough to make these patients symptomatic during early childhood. Later in life, the left ventricle becomes less compliant and the left atrial pressure increases. Left-to-right shunting across the ASD and volume loading increase and symptoms of CHF may occur. Rarely does the long-standing increase in pulmonary blood flow cause development of precapillary pulmonary hypertension.

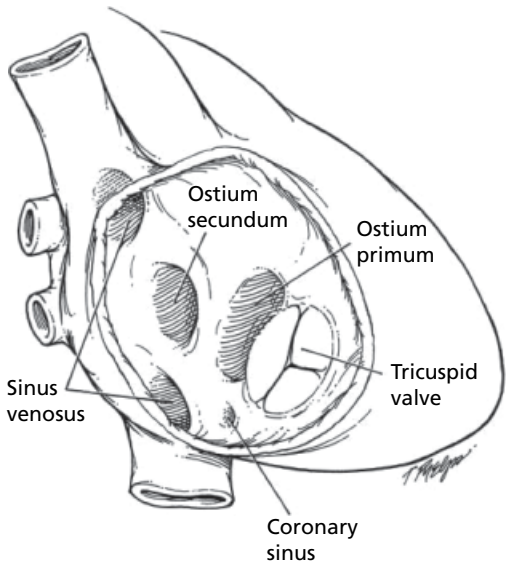

Figure 27.28 Types of atrial septal defects. *Source*: Reproduced from Redmond and Lodge [362] with permission of Elsevier.

Anesthetic management

Secundum ASDs can sometimes be closed using a minimally invasive transcatheter device in the catheterization laboratory. Large or multiple defects, as well as those with inadequate atrial borders to anchor a transcatheter device, require direct closure using sutures or a patch made of autologous or synthetic material. Sinus venosus defects associated with partial anomalous pulmonary venous connection require a more extensive patch that also directs the partial anomalous pulmonary venous return into the left atrium.

Patients with ASDs are usually easy to manage in the prebypass period and short bypass times make the patient amenable to early tracheal extubation in the ICU or operating room. Cardiovascular function and reserve are usually normal in the postoperative period, and inotropic support is rarely required. Atrial arrhythmias, including atrial flutter and atrial fibrillation, are unusual. Mitral regurgitation may occur in patients who have undergone repair of an ASD primum. Residual ASDs are uncommon, but occasionally failure to recognize partial anomalous pulmonary venous return results in a residual L-R shunt.

Ventricular septal defects

Pathophysiology

Defects in the ventricular septum occur at several locations in the muscular partition dividing the ventricles (Fig. 27.29). Simple shunting occurs across the ventricular septum. The magnitude of pulmonary blood flow is determined by the size of the VSD and the PVR (Fig. 27.30) [316]. With a non-restrictive defect, high left ventricular flows and pressures are transmitted to the pulmonary artery. Therefore, surgical repair is indicated within the first 2 years of life to prevent the progression of pulmonary vascular occlusive disease. In patients with established pulmonary vascular disease, the pulmonary arteriolar changes may not recede when the defect is closed. The growth and development of the pulmonary vascular bed are significant factors in the patient's ability to normalize pulmonary vascular hemodynamics after surgery [317]. When PVR approaches or exceeds systemic vascular resistance, R-L shunting occurs through the VSD and patients develop progressive hypoxemia (Eisenmenger syndrome) [318,319]. Closing the VSD in this circumstance may require management of acute right heart failure.

Anesthetic management

The defects are closed during CPB. The most common septal defect, the membranous defect, is frequently repaired through a right atriotomy and the tricuspid valve. However, lesions in the inferior apical muscular septum or those high in the ventricular outflow tract may require a left or right ventriculotomy. If so, the postoperative ventricular function may be impaired.

Before repair, measures that decrease PVR may appreciably increase L-R shunting in patients with a non-restrictive defect and may increase the degree of CHF. Postoperative right or left ventricular failure may be a manifestation of the preoperative status of the myocardium, a result of the ventriculotomy

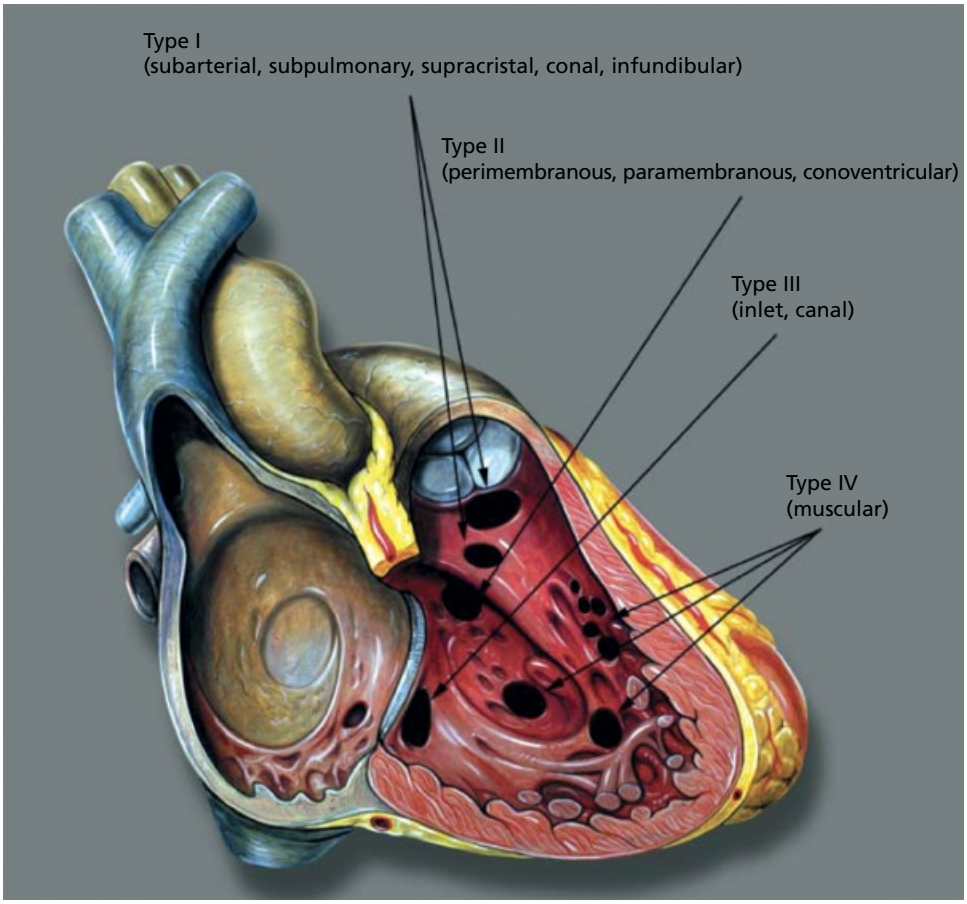

Figure 27.29 Types of ventricular septal defect. *Source*: https://commons.wikimedia.org/wiki/File:Heart_right_vsd.jpg. Licensed under CCBY 2.5.

and CPB, or both. Small infants who fail to thrive, who are malnourished, and who have significant CHF preoperatively may have excessive lung water and may require prolonged mechanical ventilation postoperatively. Such infants may have limited intraoperative tolerance for anesthetics that depress the myocardium or for maneuvers that increase pulmonary blood flow.

Persistent CHF and an audible murmur postoperatively, evidence of low cardiac output, or the need for extensive inotropic support intraoperatively suggest that a residual or previously unrecognized VSD is continuing to place a volume and pressure load on the ventricles. When PVR is increased preoperatively, the increase in right ventricular afterload caused by closure of the VSD may be poorly tolerated, leading to the need for inotropic support of the heart and measures to decrease PVR. Occasionally, ventricular outflow tract obstruction is caused by placement of the septal patch. Aortic regurgitation caused by prolapse of one of the aortic valve cusps can develop in subaortic or subpulmonic VSDs. In addition, heart block may occur after closure of VSDs with a patch. A pacemaker may be needed to maintain an adequate heart rate and cardiac output.

Anesthetic considerations after repair

Most patients regain normal myocardial function after repair, particularly when the VSD is repaired early. Residual VSDs, outflow tract obstruction, and heart block are known postoperative complications that will prolong recovery. A small percentage of patients, especially those who have had a large defect repaired late in childhood, will have persistent ventricular dysfunction and pulmonary hypertension.

Atrioventricular canal defects

Pathophysiology

The endocardial cushion defect, complete common AV canal, consists of defects in the atrial and ventricular septa and the AV valvular tissue. All four chambers communicate and share a single common AV valve. The atrial and ventricular shunts communicate volume and systemic pressures to the right ventricle and pulmonary artery. The ventricular shunt orifice is usually non-restrictive (simple shunt); therefore, PVR governs the degree of excess pulmonary blood flow. Mitral regurgitation and direct left ventricular-to-right atrial shunting may further contribute to atrial hypertension and total L-R shunting.

Anesthetic management

Surgical repair of this lesion consists of division of the common AV valve and closure of the atrial and ventricular septal defect with a single patch, modified single-patch, or two-patch technique [320]. In addition, the mitral valve (and sometimes the tricuspid valve) requires suture approximation and resuspension of the separated portions.

Preoperatively, these patients have large L-R shunts with excessive pulmonary blood flow that may progress to CHF with the eventual development of pulmonary hypertension. Myocardial depressants and therapies that decrease PVR may

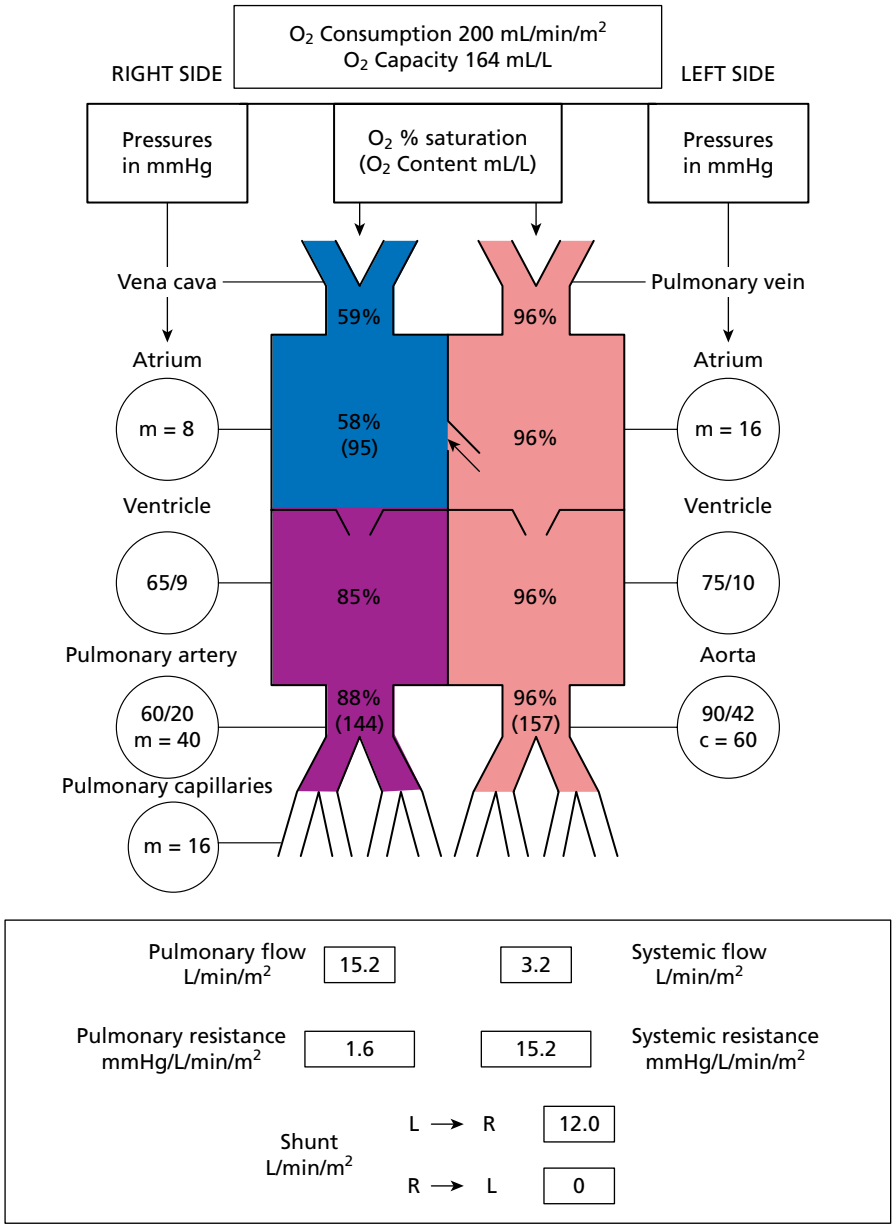

Figure 27.30 Catheterization findings in a patient with a VSD and pulmonary artery hypertension. m, mean pressure. *Source*: Reproduced from Nadas and Fyler [357] with permission of Elsevier.

be poorly tolerated. Some patients, especially older children, may have obstructive pulmonary vascular disease. All of the potential complications of ASD and VSD closures are seen in these patients. In addition, the mitral valve may be regurgitant [321]. Inotropic support for the failing heart, afterload reduction for mitral regurgitation, and measures to decrease PVR may be required intraoperatively and following repair [322].

Patients with Down syndrome frequently have an associated complete AV canal defect. Prolonged ventilatory support and therapies to decrease PVR following repair are sometimes necessary as these patients may have reactive airways and pulmonary vascular beds. The usual perioperative concerns of patients with Down syndrome exist, including macroglossia, upper airway obstruction, and difficult vascular access, but Down syndrome is not a risk factor for cardiac mortality, and early postoperative problems in Down syndrome patients are non-cardiac [323].

Patent ductus arteriosus

Pathophysiology

The ductus arteriosus is a fetal vascular communication between the main pulmonary artery at its bifurcation and the descending aorta below the origin of the left subclavian artery. When patent, it provides a simple shunt between the systemic and pulmonary arteries. The magnitude and direction of flow between the systemic and pulmonary vessels are determined by the relative resistances to flow in the two vascular beds and the diameter (resistance) of the ductus itself. Pulmonary blood flow is excessive and there is a large volume load on the left heart when the ductus is non-restrictive and the PVR is low. Pulmonary steal occurs when blood flows to the low-resistance lungs during systole and diastole at the expense of perfusing the systemic tissue beds. In addition, overcirculated lungs and elevated left atrial pressure increase the work of breathing.

Anesthetic management

Although the PDA of premature infants can often be closed medically with indomethacin or ibuprofen, contraindications to the use of these agents (e.g. intracranial hemorrhage, renal dysfunction, and hyperbilirubinemia) may require that the defect be closed surgically [324]. Thoracotomy and surgical ligation of the ductus arteriosus is the standard approach in infants and children, but some centers now occlude the ductus with a percutaneously inserted coil or occlusion device [325] or by using video-assisted thoracoscopic surgery (VATS) [326]. Advantages of VATS compared with open thoracotomy include decreased postoperative pain, shorter hospital stay, and decreased incidence of chest wall deformity [327].

Healthy asymptomatic patients can emerge from anesthesia in the operating room, but premature infants with severe lung disease may require mechanical ventilation for protracted periods of time after ligation of the ductus arteriosus. Fentanyl, a muscle relaxant, oxygen, and air constitute a common anesthetic regimen for this procedure in these sick premature infants. Anesthetic management of the premature infant in the operating room requires special considerations of gas exchange, hemodynamic performance, temperature regulation, metabolism, and drug and oxygen toxicity. Thoracotomy and lung retraction usually decrease lung compliance and increase oxygen and ventilatory requirements. A transient rise in systemic blood pressure with ligation of the ductus arteriosus may increase left ventricular afterload or elevate cerebral perfusion pressure, potentially precipitating heart failure or an intracranial hemorrhage in a premature infant. Inadvertent ligation of the left pulmonary artery or descending aorta has occurred because the ductus arteriosus is often the same size as the descending aorta.

Ligation of an isolated ductus arteriosus generally results in a decrement in left ventricular efficiency within 24 h due to the marked increase in afterload but recovers to preoperative levels after 2–4 days.

Truncus arteriosus

Pathophysiology

Truncus arteriosus is characterized by failure of the embryonic truncus to separate normally into the two great arteries, resulting in a single great artery that leaves the heart and gives rise to the coronary, pulmonary, and systemic circulations (Fig. 27.31). The truncus straddles a large VSD and receives blood from both ventricles.

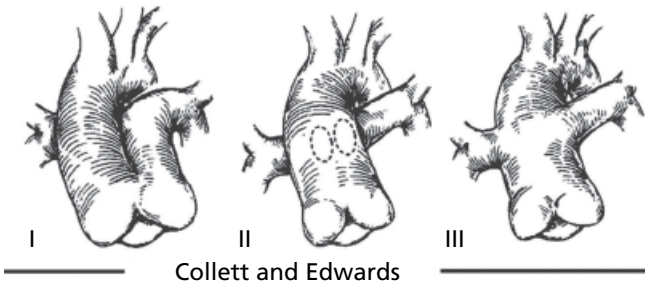

Figure 27.31 Truncus arteriosus – Collett and Edwards classification. In type I, the main pulmonary artery arises from the truncus (70% of patients). In type II, there are separate left and right pulmonary artery origins from the posterior truncus (30%). In type III, there are separate left and right pulomary artery origins from the lateral truncus (<1%). *Source*: Reproduced from Jacobs [363] with permission of Elsevier.

There is complete mixing of systemic and pulmonary venous blood in the single great artery, causing mild hypoxemia. One or two pulmonary arteries may originate from the ascending truncus with orifices that are seldom restrictive. The resulting simple shunt produces excessive pulmonary blood flow early in life as the pulmonary vascular resistance decreases, and pulmonary steal may develop compromising systemic blood flow. Net systemic oxygen transport decreases and lactic acidosis develops. Children with truncus arteriosus are at risk for developing early pulmonary vascular obstructive disease. Regurgitation of blood through the truncal valve may place an additional volume load on the ventricles [328].

Anesthetic management

Complete repair of this lesion should be performed in the neonatal period before the development of irreversible pulmonary vascular changes. The VSD is closed with a synthetic patch and the pulmonary arteries are detached from the truncus. Continuity is established between the right ventricle and the pulmonary arteries with a valved conduit. The truncal systemic valve may require valvuloplasty if a significant amount of blood regurgitates through it.

Anesthetic management centers around control of pulmonary blood flow and supporting ventricular function. Pulmonary blood flow may increase further with induction of anesthesia, hyperventilation, alkalosis, and oxygen administration, resulting in hypotension, decreased coronary perfusion, and acute ventricular failure. If measures to increase PVR do not decrease pulmonary flow, occlusion of one branch of the pulmonary artery with a tourniquet limits pulmonary flow and restores systemic perfusion pressure until CPB can be instituted. These patients are frequently in high-output CHF so myocardial depressants should be used with caution.

Persistent pulmonary artery hypertension and right ventricular failure may need to be addressed following the repair. Aggressive measures should be taken to normalize myocardial function and lower the PVR. A residual VSD adds an additional volume and pressure load on both ventricles and should be suspected in patients with poor hemodynamics and oxygenation after repair. Truncal valve regurgitation or stenosis may induce left ventricular failure early during the postoperative period.

Anesthetic considerations after repair

Obstruction of the pulmonary conduit and accompanying right ventricular hypertension may occur early or late during the postoperative course. The late development of truncal (systemic) valve regurgitation is possible, as is residual pulmonary hypertension, particularly in patients who underwent repair later in infancy or childhood.

Coarctation of the aorta

Pathophysiology

Patients with coarctation of the aorta have a narrowing of the descending aorta near the insertion of the ductus arteriosus into the aorta (Fig. 27.32). Coarctation of the aorta is sometimes associated with hypoplasia of the aortic isthmus proximal to the coarctation. Aortic and mitral valve abnormalities, as well as VSDs, may also be present.

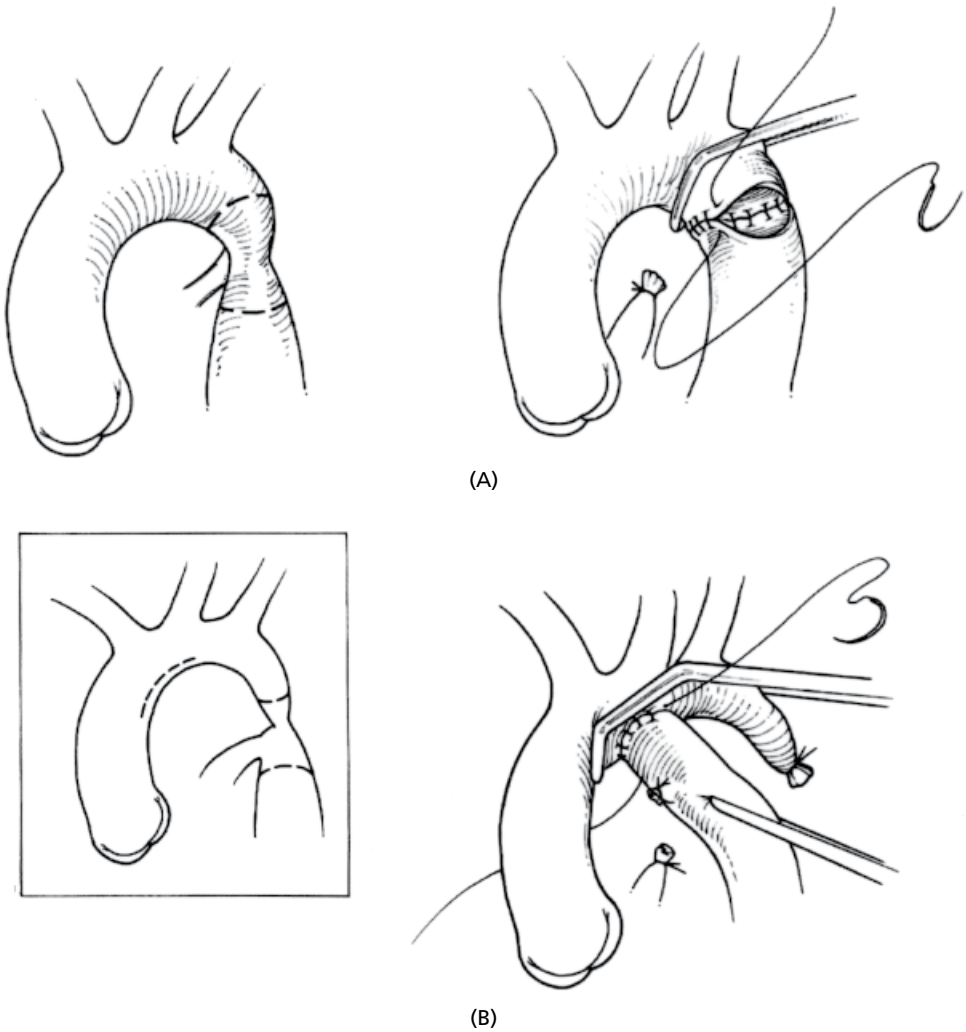

Figure 27.32 Two surgical approaches for repair of coarctation of the aorta. (A) Resection of coarctation with end-to-end anastomosis. (B) End-to-side or aortic arch advancement technique. *Source*: Reproduced from Chang et al [364] with permission of Wolters Kluwer.

Inadequate systemic perfusion caused by obstruction of blood flow in the descending aorta causes profound metabolic acidosis. Increases in left ventricular afterload are usually poorly tolerated by the neonatal heart, and elevated left ventricular end-diastolic pressure may cause pulmonary artery hypertension. Systemic flow distal to the coarctation is provided by right-to-left flow from the right ventricle and pulmonary artery through the ductus arteriosus. Maintaining or re-establishing duct flow can be accomplished with PGE1 infusion, which also reduces the left ventricular afterload.

Less severe coarctation of the aorta may be compensated for by the development of collateral circulation to the lower body and by increasing left ventricular muscle mass. Upper extremity hypertension and left ventricular hypertrophy noted later in childhood may be the only manifestation of the coarctation.

Anesthetic management

The optimal treatment for neonates, infants, and children with aorta coarctation is usually complete excision of the area of coarctation and surrounding ductal tissue with end-to-end anastomosis (Fig. 27.32A). Alternatively, a reverse subclavian patch repair can be undertaken. In this technique, the left subclavian artery is ligated and transected with the proximal portion of the artery used as a flap to augment the area of coarctation. Following this procedure, left arm pulses will be weak or absent. This technique is no longer used in modern surgical practice; an aortic arch advancement technique where the descending thoracic aorta is anastomosed to the underside of the aortic arch is an effective technique (Fig 27.32B). Dacron patch aortoplasty following resection of the posterior coarctation ridge has also been used, but this technique is associated with late development of hypertension and aneurysm formation as compared with end-to-end anastomosis [329].

All approaches require 10–25 min of aortic cross-clamping above and below the area of coarctation. Acidosis, hypertension, and spinal cord ischemia can occur during this period. Paraplegia is an extremely rare but tragic complication of the procedure. Upper body hypertension may compromise left ventricular function and decrease cardiac output, especially to the lower body, and must be treated. If the elevated arterial pressure in the head is transmitted to the cerebrospinal fluid (CSF), the CSF pressure may be elevated. Elevated pressures are transmitted to the CSF below the level of the coarctation so net spinal cord perfusion pressure is decreased [330]. Alternatively, if upper body hypertension is overtreated with vasodilators during cross-clamping of the aorta, the arterial pressure may be inadequate in the vasodilated lower half of the body, which is supplied by collaterals. If this occurs, spinal

cord or renal ischemia may result. Development of abdominal pain and bowel ischemia during the postoperative period may be related to insufficient flow in the mesenteric artery

These complications are not so much related to changes in proximal aortic pressure or distal CSF pressure as they are to distal perfusion pressures, adequacy of arterial collaterals, and duration of cross-clamping. Monitoring of arterial pressures in the lower extremities may be helpful but impractical during the cross-clamp period. Hyperthermia to 38°C and 40°C during cross-clamping is associated with an increased incidence of paraplegia and transient renal failure [331]. Therefore, mild hypothermia (32–34°C) is used in some centers during aortic cross-clamping as a possible prophylaxis for these rare but tragic problems.

Rebound hypertension after the cross-clamp is removed and later when the patient emerges from the anesthetic may be problematic. The etiology of this persistent hypertension is multifactorial. Reduced compliance of the left ventricle in systole, as well as stiffness of the perfused arteries, have been implicated [332]. Propranolol and hydralazine may be useful for treating moderate forms of postoperative hypertension, the more severe forms are best treated with sodium nitroprusside and esmolol during the first few hours after surgery.

The geometry of the aortic arch following coarctation and distal aortic arch repair is also a determinant of subsequent upper body vascular responses, pulse wave velocity, and left ventricular mass. Anatomy with a high arch height to width ratio (Gothic arch) is associated with impaired vascular response, increased pulse wave velocity, central aortic stiffness, and increased LV mass as compared to anatomy with a lower arch height to width ratio (Crenel and normal Romanesque arch anatomy) [333,334]. Abnormalities in baroreceptor reflexes and in the renin–angiotensin–aldosterone system have also been implicated as factors in persistent hypertension following successful coarctation repair. Recent evidence suggests that abnormalities in cardiovascular reflexes are already present in neonates with coarctation prior to repair [335–337].

Anesthetic considerations after repair

Persistent hypertension and left ventricular hypertrophy may be problems for anesthetic management in as many as one-third of patients after adequate repair of coarctation of the aorta [338]. If the left subclavian artery was used for the repair, the left arm cannot be used for accurate blood pressure measurements. Restenosis of the coarctation is routinely balloon dilated in the interventional catheterization laboratory.

Interrupted aortic arch

Pathophysiology

In some patients, the aorta is completely interrupted at one or more points along the aortic arch (Fig. 27.33). A PDA and VSD are nearly always present. Flow distal to the aortic interruption is supplied entirely by blood shunted right to left through the ductus arteriosus with L-R flow through the VSD. The L-R shunt through the VSD may cause excessive pulmonary blood flow and respiratory insufficiency. In addition, left ventricular outflow obstruction may be present. Ductal closure eliminates blood flow to the lower body and leads to metabolic acidosis. Patency of the ductus arteriosus is re-established with PGE1.

Anesthetic management

Repair of this lesion in neonates consists of patch closure of the VSD and a direct anastomosis of the descending aorta to the underside of the transverse arch. Alternatively, a palliative approach may be taken where the aortic arch is repaired, the pulmonary artery is banded, and the VSD is closed when the patient has grown. In the presence of significant left ventricular outflow tract obstruction, alternative procedures such as a Ross–Konno or Yasui procedure are considered [339].

The introduction of PGE1 has substantially improved the preoperative resuscitation and perioperative morbidity, and the PGE1 infusion should be continued until CPB is initiated. The residual effects of protracted poor perfusion distal to the interruption may complicate the intra- and postoperative course of these patients. Circulatory problems after CPB that require inotropic support may be caused by a significant residual VSD, by obstruction of blood flow in the aorta, or by subaortic stenosis aggravated by the VSD closure and a narrow subaortic region.

Late problems are related to obstruction of the descending aorta with subsequent growth of the child. These problems are similar to those seen with coarctation of the aorta. Subaortic stenosis may also develop and presents considerable surgical challenges to adequate relief of obstruction.

Critical aortic stenosis

Pathophysiology

The aortic valves in patients with critical aortic stenosis are thickened and rigid and have some degree of fusion of the valvar commissures. Patients have various degrees of fusion of the valvular commissures. In the newborn, the valve appears amorphous. There also may be evidence of endocardial

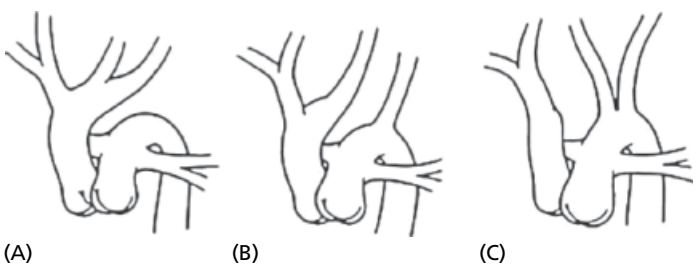

Figure 27.33 Interrupted aortic arch. (A) Type A: interruption between the left subclavian artery and the ductus arteriosus. (B) Type B: interruption between the left carotid and left subclavian arteries. (C) Type C: interruption at the proximal aortic arch between the innominate and left carotid arteries. *Source*: Reproduced from Chang et al [364] with permission of Wolters Kluwer.

fibroelastosis of the left ventricle and functional or anatomical abnormalities of the mitral valve.

Left ventricular outflow tract obstruction is poorly tolerated in the neonate because it causes left ventricular failure, poor systemic perfusion, hypotension, and pulmonary congestion. Myocardial perfusion is often borderline because the coronary perfusion pressure is relatively low and intraventricular pressure is high. Ventricular fibrillation may occur with surgical manipulation of the heart. In severe cases of criticial aortic stenosis, systemic blood flow may be partly supported from the right ventricle by R-L flow through the ductus arteriosus, provided that there is atrial septal communication. Stabilization of the patient's condition can be aided by infusion of PGE1 to increase systemic perfusion.

Anesthetic management

The treatment options for isolated critical aortic stenosis in the neonate are percutaneous balloon angioplasty and surgical valvotomy [340]. Myocardial depressants and rapid heart rates are poorly tolerated during either procedure. A defibrillator should be available for immediate use. Preoperative resuscitation and optimization of the left ventricle is imperative. Inadequate relief of the obstruction and persistence of left ventricular failure can complicate and prolong the postprocedure course. Residual stenosis or other added hemodynamic burdens further reduce myocardial performance. Mitral regurgitation may continue intraoperatively, and aortic regurgitation may occur after the valvotomy. Myocardial ischemia is not generally a problem after valvotomy. If the obstruction is adequately relieved, afterload reduction and inotropic agents may improve the poor myocardial function often evident postoperatively, especially when there is some degree of aortic regurgitation. In some patients, associated hypoplasia of the left ventricle or mitral valve may inhibit recovery and dictate a therapeutic approach to hypoplastic left heart.

Hypoplastic left heart syndrome

Pathophysiology

Hypoplastic left heart syndrome (HLHS) is the most severe form of obstructive left heart lesion and results in single-ventricle physiology (Fig. 27.34). There is an anatomical spectrum of disease. In its most severe and common presentation there is atresia or marked hypoplasia of the aortic and mitral valves with critical underdevelopment of the left atrium, left ventricle, and ascending aorta. A 1 or 2 mm ascending aorta gives rise to the coronary circulation and the head vessels before converging with the ductus arteriosus, where the aorta becomes larger and supplies the circulation to the lower body. Pulmonary venous return arrives in the diminutive left atrium and cannot cross the atretic mitral valve; therefore, it is directed to the right atrium and right ventricle, where common mixing occurs with the systemic venous return and all blood is ejected into the pulmonary artery. Systemic blood flow is then supplied from the pulmonary artery, right to left, across the PDA. As the PDA constricts in the neonatal period, systemic blood flow decreases and all ventricular output is directed to the lungs. The Qp/Qs ratio approaches infinity as Qs nears zero. Therefore, one has the paradoxical presentation of high PO_2 (70–150 mmHg) and profound metabolic acidosis. When the ductus arteriosus is reopened with PGE1, systemic perfusion is re-established, the acidosis resolves, and the PO_2 returns to the 40–60 mmHg range, representative of a Qp/Qs ratio of between 1 and 2.

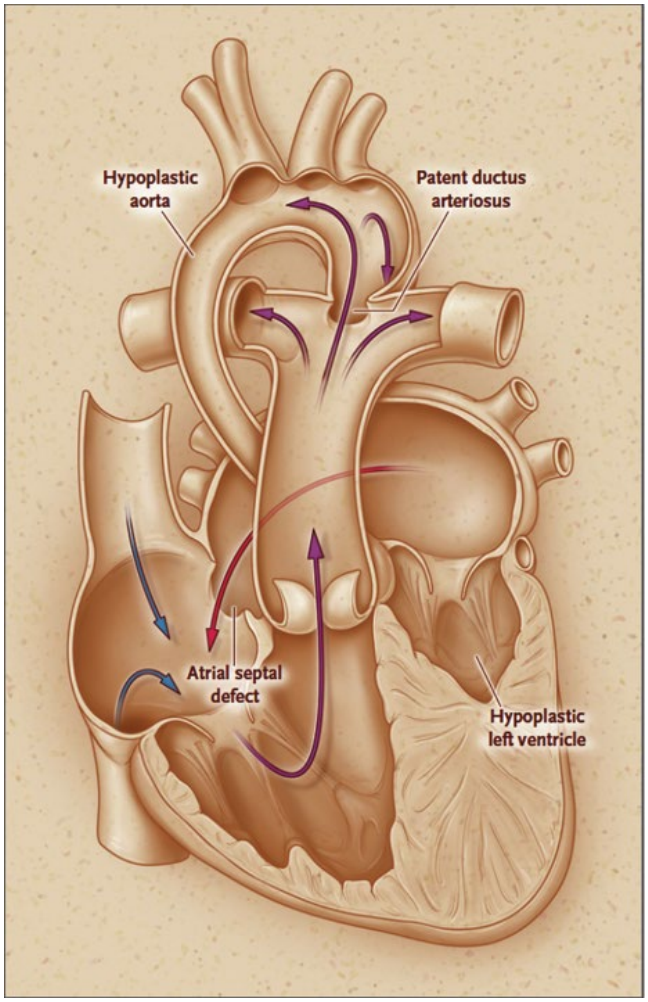

Figure 27.34 Hypoplastic left heart syndrome (HLHS). HLHS involves a single right systemic ventricle. Oxygenated blood from the pulmonary veins enters the left atrium, passes through an atrial septal defect to the right atrium, where it mixes with systemic venous blood returning through the vena cavae. The blood passes into the right ventricle, and is ejected out of the pulmonary artery. From the pulmonary artery, a portion of the blood flows to the lungs, and a portion of the blood flows through the patent ductus arteriosus to supply the lower body through the descending aorta, and the upper body, brain, and coronary arteries via retrograde blood flow. In cases of aortic atresia, there is no antegrade blood flow across the aortic valve; in severe aortic stenosis there is a minimal level of antegrade flow. *Source*: Reproduced from Ohye et al [344] with permission of NEJM.

HLHS is a uniformly fatal disease if left untreated and debate continues over staged palliation versus neonatal transplantation versus comfort care [341–343]. The results of surgical management vary between institutions, and are clearly dependent upon expertise and experience, as well as the clinical condition of the neonate at presentation and degree of hypoplasia of left heart structures [344]. In recent years, the trend has continued toward stage I palliation, where the hypoplastic aorta is reconstructed using the pulmonary valve and artery, and pulmonary blood flow is created using a systemic-to-pulonary artery shunt, or RV to PA conduit (Fig. 27.35) [344]. The stage I palliation for HLHS has now become the most commonly performed neonatal surgery in

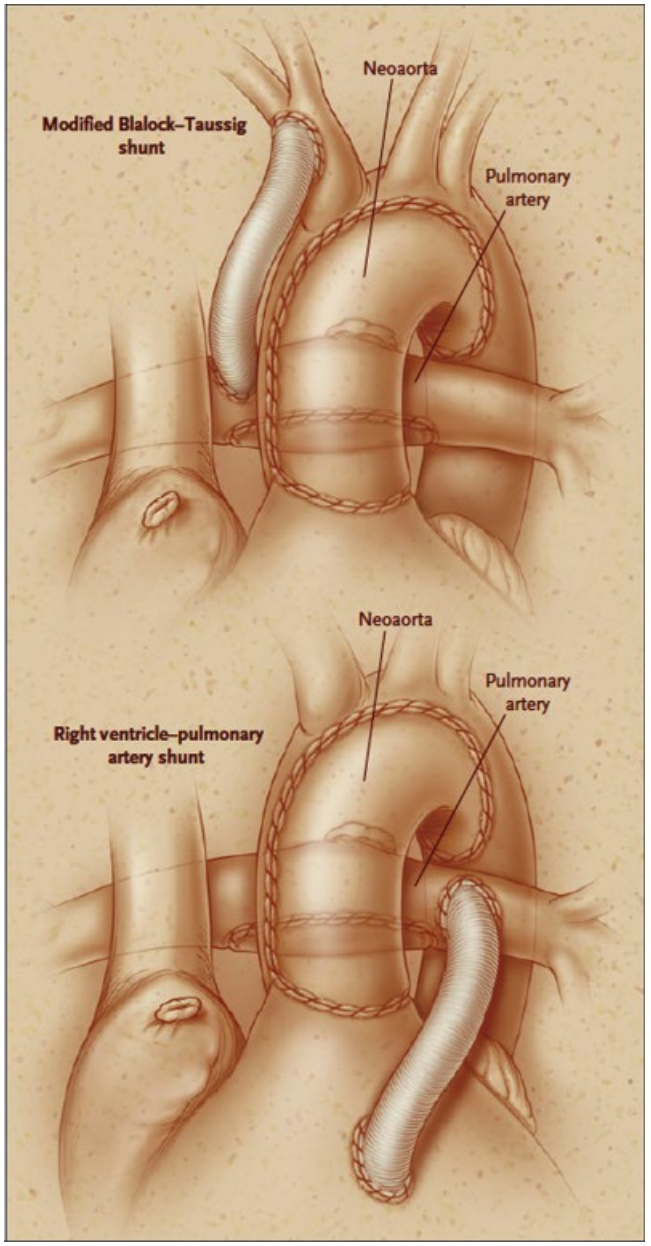

Figure 27.35 The Norwood stage I palliation with modified Blalock–Taussig shunt (A) or right ventricle-to-pulmonary artery shunt (B). *Source*: Reproduced from Ohye et al. [344] with permission of NEJM.

the Society for Thoracic Surgeons' Congenital Heart Surgery database of over 115 congenital heart surgery programs, mostly in the USA and Canada, accounting for 11.2% of neonatal operations in 2013–2016. Immediate postoperative survival is now over 80% in most centers [345].

Anesthetic management

Adequate preoperative resuscitation with PGE1 and correction of metabolic acidosis and end-organ dysfunction is crucial to the anesthetic preparation and management of patients with HLHS. Resuscutation is facilitated by judicious use of inotropic agents, which can optimize cardiac output and blood flow to systemic organs. Delays in surgical intervention will result in a gradual reduction in pulmonary vascular resistance over days, with excessive pulmonary blood flow and inadequate systemic perfusion.

The surgical palliative approach to this lesion currently entails three operations, with the goal of having a reconstructed aortic arch and Fontan type of circulation for single-ventricle physiology in as early as the first 2–3 years of life. In the first stage of the reconstruction (Norwood operation), the pulmonary artery is transected at the bifurcation and an anastomosis is performed to the ascending aorta, which has been surgically incised so that the aortic and pulmonary arterial confluences arise together from the single right ventricle as the neo-aorta, which is extended into the remaining native aorta using homograft material. Pulmonary blood flow is established with either a 3.5 or 4 mm modified B-T shunt or a 5 or 6 mm unvalved RV–PA conduit (Sano shunt). The atrial septum is excised to ensure free flow of pulmonary venous return over to the tricuspid valve. In addition to HLHS, the Norwood operation is also used to repair other complex single-ventricle defects with systemic outflow obstruction or hypoplasia [346,347].

The anesthetic considerations are the same as those outlined in detail for patients with single-ventricle physiology. The intraoperative and postoperative management requires careful manipulation of PVR and SVR to provide adequate but not excessive pulmonary blood flow and oxygen delivery while maintaining sufficient systemic and coronary artery perfusion. The precarious nature of the coronary os, which may be extremely small and closely approximated to the suture lines, means that even small variations in hemodynamics may compromise myocardial blood flow. Myocardial depressants are poorly tolerated, and ventricular failure and tricuspid (systemic) valve regurgitation can inhibit recovery.

The physiology of the modified B-T shunt and the RV–PA conduit as a source of pulmonary blood flow differs. A B-T shunt carries systemic arterial blood in systole and diastole to the pulmonary circulation, where an RV–PA conduit carries blood from the RV to the pulmonary circulation before it has entered the systemic arterial circulation (much like a double-outlet RV). As a result, for a given cardiac output and Qp/Qs, the pulse pressure is narrower and the aortic diastolic blood pressure is higher in patients with an RV–PA conduit. The higher diastolic blood pressure obtained with the RV–PA conduit shunt may provide better cerebral, coronary, and splanchnic perfusion. However, the RV–PA conduit requires creation of a small right ventriculotomy. The long-term functional consequences of this ventriculotomy in the systemic ventricle are unknown. The RV–PA conduit is usually valveless, resulting in some pulmonary insufficiency. The volume load on the RV induced by this is small and probably offset by the fact that RV–PA conduit patients have a slightly lower Qp/Qs and volume load than modified B-T shunt patients.

After CPB in the Norwood palliation procedure, the PVR may be transiently elevated and the B-T shunt or RV–PA conduit may not be adequate to sustain pulmonary blood flow and achieve adequate oxygenation without hyperventilation with 100% oxygen, alkalosis, and inotropic support to support systemic blood pressue. PVR usually falls in minutes to hours, myocardical function is restored, and pulmonary blood flow may become excessive. Hypoventilation with room air and the use of systemic vasodilators are not always effective at reversing the pulmonary steal phenomenon in this circumstance. More drastic measures, such as ventilation with hypoxic gas mixtures or ventilation with added CO_2, have

been advocated by some centers but have largely been abandoned over the years due to a lack of efficacy and deleterious effects on the distribution of blood flow away from the splanchnic bed [348–350].

The stage 1 hybrid procedure for HLHS is an alternative to the Norwood stage 1 procedure. The procedure (Fig. 27.36) involves off-pump placement of a bare metallic stent in the ductus arteriosus, bilateral pulmonary artery banding, and dilation/stenting of the intra-atrial septum. The hybrid procedure does not require CPB and the associated use of either DHCA or ACP in the neonatal period. This procedure must be done in a location that provides full cardiac catheterization infrastructure, including biplane cardio-angiography, in a sterile operating room environment. Whether hybrid strategies should be applied to select subsets of patients and whether they are a lower risk alternative to Norwood operations overall remains to be determined [351,352]. The balloon atrial septostomy is generally performed prior to discharge from the hospital unless there is obstruction of pulmonary venous blood delivery to the right ventricle and pulmonary venous hypertension detected earlier. The physiological burden associated with CPB and DHCA or ACP avoided in the first stage is then incurred at the time of the comprehensive stage 2 procedure (bidirectional Glenn shunt, Stansel anastomosis, aortic arch reconstruction, and definitive atrial septectomy) performed at 3–6 months of age.

KEY POINTS: SPECIFIC LESIONS AND PROCEDURES

- In the past several decades emphasis on complete repair of congenital heart defects in early infancy, where possible, has changed the congenital heart surgery population dramatically
- The neonatal arterial switch operation for transposition of the great arteries, and stage I palliation for hypoplastic left heart syndrome, together comprise about 20% of neonatal congenital heart surgeries
- Single-ventricle patients comprise almost 20% of patients having congenital heart surgery; almost all of these will undergo three stages of repair: neonatal surgery, bidirectional cavopulmonary connection at 3–6 months, and Fontan completion at 2–4 years of age
- Older children, teenagers, and adults with CHD who had previous operations with older approaches are increasingly presenting for subsequent surgery to revise or repair residual defects

CASE STUDY

The patient is a term 3-month-old male weighing 4.0 kg s/p stage I palliation on day 3 of life for HLHS with mitral and aortic atresia. He presents now for percutaneous endoscopic gastrostomy tube placement. The parents request that a circumcision be performed during the same anesthetic. The patient is poorly tolerant of oral feeds, has demonstrated poor weight gain and somatic growth (25th percentile for height and weight), and has medically managed gastroesophageal reflux. Oral medications are: 0.5 baby aspirin qd, furosemide 8 mg tid, digoxin 0.02 mg bid, captopril 1 mg tid, and ranitidine 8 mg bid.

Echocardiogram done 1 week ago reveals a patent Damus–Kaye–Stansel (DKS) anastomosis, non-restrictive atrial septum, a patent right modified Blalock–Taussig shunt without pulmonary stenoses, and a narrowed aorta at the junction of the isthmus and descending aorta with a peak Doppler-derived gradient of 30 mmHg without evidence of continuous flow in the abdominal aorta. There is mild to moderate tricuspid regurgitation and mild to moderate global right ventricular dysfunction.

Blood pressure is 70/30 mmHg in the left arm, heart rate is 165 bpm in sinus rhythm, and the SaO_2 is 75% on room air. Chest x-ray reveals an enlarged cardiac silhouette with some increase in pulmonary vascular markings.

Questions

1. What is your assessment of this child's cardiovascular status? What is the significance of the tricuspid regurgitation and right ventricular dysfunction in the setting of residual arch obstruction? What is the likely mechanism of the tricuspid regurgitation (TR)? Are the increased pulmonary vascular markings due to ventricular dysfunction, a high Qp/Qs or both?
2. Could better medical management of this child's heart failure obviate the need for a feeding tube?
3. Should this infant undergo an arch dilation in the cardiac catheterization laboratory prior to the proposed surgery?

Should this patient be considered for an early bidirectional Glenn as a means of decreasing the volume load on his RV and improving the TR?

4. Which a.m. medications will you have the parents give and which if any should be held? Is this infant an appropriate a.m. admission case or should he be admitted the night prior to surgery? Is the ICU necessary postoperatively?
5. What premedication will you administer? How will you induce and maintain anesthesia? What monitoring is necessary?

Induction of anesthesia proceeds smoothly and the anesthesia is maintained with remifentanil 0.5 μg/kg/min and isoflurane 0.7% in 100% O_2. During introduction of the endoscope ST segment depression is noted in V_5. Blood pressure is 60/25 mmHg, heart rate is 170 bpm, end-tidal CO_2 is 35 mmHg, and SaO_2 is 75%.

Questions

6. How will you adjust the ventilator (rate, tidal volume, PEEP, FiO_2)?
7. Is a fluid bolus warranted? Should inotropic support be initiated? Which inotrope?
8. How will you assess the adequacy of systemic oxygen delivery?
9. What is the mechanism of myocardial ischemia?
10. Once hemodynamics are stabilized and the ischemia resolves, should the case continue?

Discussion

The primary goal in the management of patients with single-ventricle physiology is optimization of systemic oxygen delivery and perfusion pressure. This is necessary if end-organ (myocardial, renal, hepatic, splanchnic) dysfunction and failure are to be prevented. This goal is achieved by balancing the systemic and pulmonary circulations. The term "balanced circulation" is used because both laboratory and clinical investigations have demonstrated that maximal systemic oxygen delivery (the product of systemic oxygen content and systemic blood flow) is achieved for a given single-ventricle output when Qp/Qs is at or just below 1:1. This relationship is illustrated in the graphs (Figs 27.37–27.41). Increases in Qp/Qs in excess of 1:1 are associated with a progressive decrease in systemic oxygen delivery because the subsequent increase in systemic oxygen content is more than offset by the progressive decrease in systemic blood flow (Fig. 27.37). Decreases in Qp/Qs just below 1:1 are associated with a precipitous decrease in systemic oxygen delivery because the subsequent increase in systemic blood flow is more than offset by the dramatic decrease in systemic oxygen content.

Since Qp/Qs is not a readily measurable parameter in a clinical setting, pulse oximetry is commonly used as a surrogate method of assessing the extent to which a balanced circulation exists. An arterial saturation of 75–80% is felt to be indicative of a balanced circulation (Fig. 27.38). It is important to point out, however, that an arterial saturation of 75–80% is indicative of a Qp/Qs at or near 1:1 only if the pulmonary venous saturation is 95–100% and the mixed

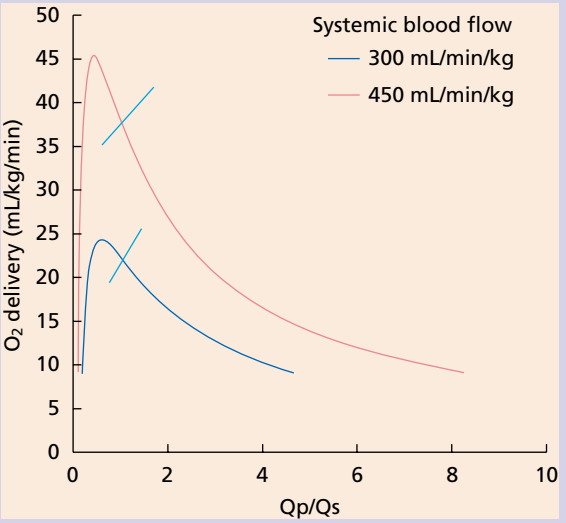

Figure 27.37 Pulmonary/systemic blood flow ratio versus systemic oxygen delivery.

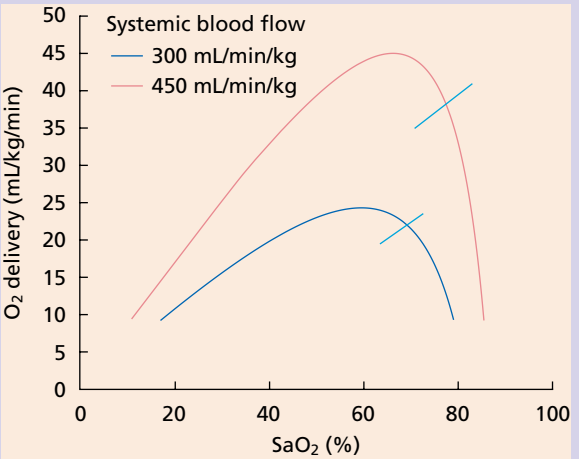

Figure 27.38 Systemic arterial oxygen saturation (SaO_2) versus systemic oxygen delivery.

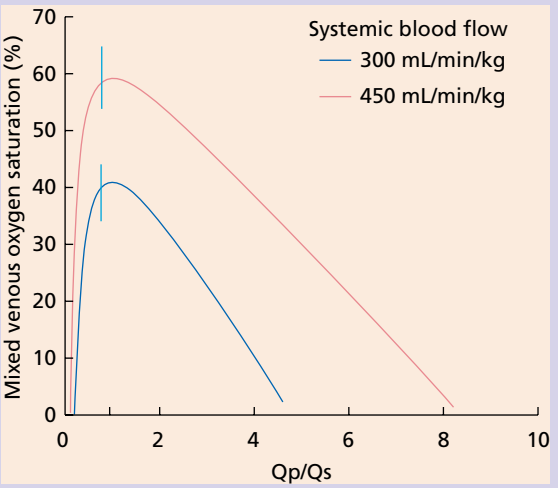

Figure 27.39 Pulmonary/systemic blood flow ratio versus mixed venous oxygen saturation (Ssvc%).

venous (SVC) saturation is 55–60% (Fig. 27.39). In fact, based on these assumptions, the equation used to calculate Qp/Qs in patients with univentricular physiology (SaO_2 – $SsvcO_2$)/$SpvO_2$ – SaO_2) can be simplified to: 25/(95 – SaO_2). In this simplified equation, $SpvO_2$ is assumed to be 95% and the AV O_2 saturation difference is assumed to 25%. Use of this simplified equation requires that the FIO_2 be at or near 21% in order that the dissolved O_2 content of the pulmonary venous blood can be ignored and an $SpvO_2$ of 95% used. Unfortunately, an arterial saturation of 75–80% can exist at the extremes of Qp/Qs depending on pulmonary and systemic venous saturation (Fig. 27.40). Specifically, in the presence of a high Qp/Qs it is possible for there to be inadequate systemic oxygen delivery (systemic venous desaturation, a wide AV O_2 difference, metabolic acidosis) in the presence of what is considered to be an adequate arterial saturation of 75–80%. In addition, clinically unrecognized episodes of pulmonary venous desaturation ($SpvO_2$ <90%) further confound assessment of Qp/Qs based on SaO_2.

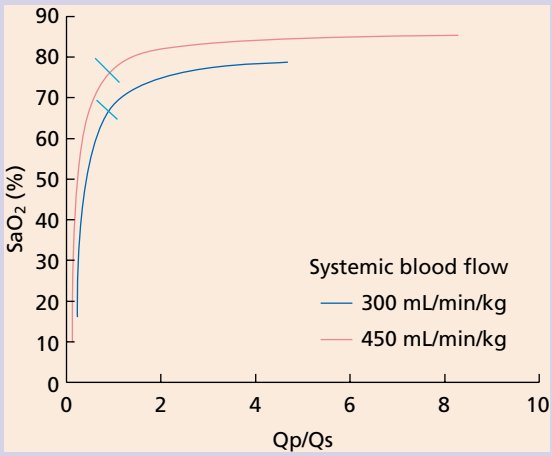

Figure 27.40 Pulmonary/systemic blood flow ratio versus systemic arterial oxygen saturation (SaO_2).

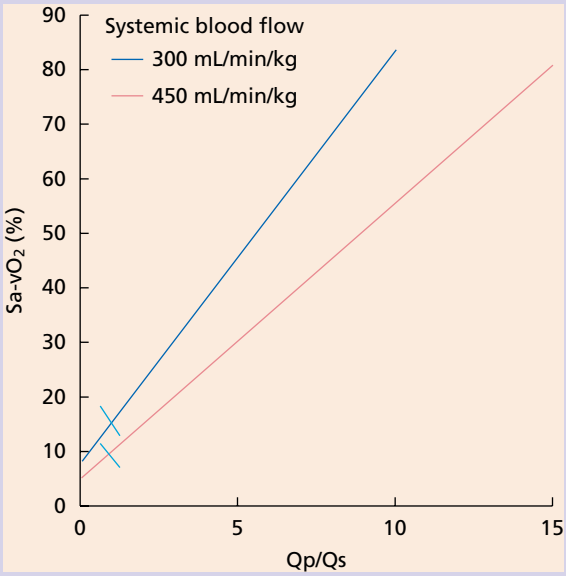

Figure 27.41 Pulmonary/systemic blood flow ratio versus arteriovenous oxygen difference (Sa-vO_2).

Mathematical modeling of univentricular physiology reveals that systemic O_2 delivery is a complex function of cardiac output (CO), pulmonary venous O_2 content, systemic O_2 consumption, and Qp/Qs. In fact, SaO_2 correlates poorly with Qp/Qs and the measurement of $SpvO_2$ and $SsvcO_2$ substantially improves estimation of Qp/Qs. Regression analysis demonstrates that SaO_2 accounts for 8% of the error in estimating Qp/Qs while $SsvcO_2$ and $SpvO_2$ contribute 48% and 44%, respectively. The figures illustrate the effect of CO (systemic blood flow 450 mL/min/kg versus 300 mL/min/kg) on O_2 delivery, SvO_2, SaO_2, and Sa-vO_2 as Qp/Qs varies with $SpvO_2$ = 95% and O_2 consumption = 9 mL/min/kg. It is clear that while SaO_2 remains satisfactory over a wide range of Qp/Qs, O_2 delivery and $SsvcO_2$ decrease precipitously outside a narrow range of Qp/Qs near 1.0. By the time a SaO_2 of 80% is reached, O_2 delivery is precipitously on the decline. Furthermore, Sa-vO_2 increases linearly with increasing Qp/Qs. Any combination of variables that produces a $SsvcO_2$ <30% is likely to result in the development of anaerobic metabolism. It is also clear that a higher CO allows maintenance of satisfactory O_2 delivery and $SsvcO_2$ over a wider range of Qp/Qs.

Debate continues as to the most efficacious method of manipulating the balance of SVR and PVR. Methods to elevate PVR include use of inspired N_2 to reduce alveolar O_2, use of intentional alveolar hypoventilation to achieve mild hypercarbia and a slightly acidotic pH, or use of inspired CO_2 to achieve mild hypercarbia and a slightly acidotic pH while maintaining normal minute ventilation.

Patients with congenital heart disease are more at risk for the development of subendocardial ischemia than is commonly appreciated. In some congenital lesions, abnormalities in the coronary circulation predispose to the development of myocardial ischemia but in many others ischemia occurs in the presence of normal coronary arteries secondary to myocardial oxygen supply/demand imbalance.

Subendocardial perfusion is largely determined by coronary perfusion pressure, that is the mean aortic diastolic pressure minus the ventricular end-diastolic pressure. In addition, the time interval available for perfusion (predominantly diastole) is critical. As a result, the relationship between heart rate, diastolic blood pressure, and ventricular end-diastolic pressure will determine whether subendocardial ischemia occurs.

- Aortic diastolic pressure that is normally low in neonates and infants is further compromised in single -ventricle physiology lesions because these lesions promote diastolic run-off of aortic blood into the lower resistance pulmonary circuit.
- Subendocardial pressure is elevated and subendocardial perfusion is compromised in the presence of an elevated ventricular end-diastolic pressure. Elevated ventricular end-diastolic pressure occurs as the result of the ventricular volume overload, which accompanies single-ventricle lesions, lesions with a high Qp/Qs, and regurgitant atrioventricular and semi-lunar valve lesions.

- The duration of diastole diminishes geometrically as heart rate increases while the duration of systole remains relatively constant. As a direct consequence of this, the time available for diastolic coronary artery perfusion, or diastolic perfusion time, falls geometrically as heart rate increases. Consequently, a higher diastolic pressure is necessary to maintain subendocardial perfusion at higher heart rates. The obvious corollary is that subendocardial perfusion is more likely to be maintained in the presence of a low diastolic blood pressure if the heart rate is slower. In an infant with HLHS and an aortic diastolic pressure of 25 mmHg, a heart rate of 130–140 bpm may well be tolerated without evidence of subendocardial ischemia whereas it is unlikely that a heart rate of 170–180 bpm will be tolerated at the same diastolic pressure.

J Thorac Cardiovasc Surg 2008; 135: 355–60. A very important large modern study demonstrating that hematocrit above 25% on bypass improves neurodevelopmental outcomes in infants.

342 Ohye RG, Schranz D, D'Udekem Y. Current therapy for hypoplastic left heart syndrome and related single ventricle lesions. Circulation 2016; 134: 1265–79. This is the best, most current summary of the results of the Single Ventricle Reconstruction (SVR) Trial. While the transplant-free survival of neonates randomized to modified Blalock–Taussig shunt versus Sano shunts is similiar 6 years out there are nuanced differences between the groups which are comprehensively summarized here.

344 Ohye RG, Sleeper LA, Mahony L, et al. Comparison of shunt types in the Norwood procedure for single-ventricle lesions. N Engl J Med 2010; 362: 1980–92. An important multicentered study comparing outcomes of the classic Blalock–Taussig shunt Norwood operation with the right ventricle to pulmonary artery conduit Norwood operation, demonstrating a lower rate of death or transplantation at age 12 months with the RV–PA conduit.

CHAPTER 28

Anesthesia for Non-cardiac Surgery in Patients with Congenital Heart Disease

Erin A. Gottlieb

Texas Center for Pediatric and Congenital Heart Disease, Dell Children's Hospital, Austin, TX, USA

Department of Surgery and Perioperative Care, Dell Medical School,

The University of Texas at Austin, Austin, TX, USA

Introduction

The incidence of congenital heart disease (CHD) in the USA is eight per 1000 live births, and it is estimated that congenital heart defects affect a minimum of 40,000 infants in the USA per year [1]. Major non-cardiac anomalies are found in approximately 25% of newborns with CHD [2]. Patients with CHD have an increased risk of anesthetic morbidity and mortality. Recognition of high-risk lesions, a thorough understanding of the anatomy and physiology of congenital heart lesions, and the ability to develop a detailed perioperative management plan are important to achieve the best possible anesthetic outcomes.

This chapter presents the anesthetic/perioperative management of lesions associated with the highest risk of perioperative morbidity and mortality, as well as management of patients who have undergone repair of CHD who are undergoing non-cardiac surgery. Procedural or operative conditions such as laparoscopy, otolaryngological airway assessment, and diagnostic imaging requiring anesthesia or sedation are also considered. Logistical concerns surrounding care of this complex population including risk stratification, anesthetic care providers, location, and current recommendations for bacterial endocarditis prophylaxis are reviewed.

Congenital heart disease and perioperative risk

Patients with CHD undergoing procedures requiring anesthesia are at an increased risk of perioperative morbidity and mortality. According to the Pediatric Perioperative Cardiac Arrest (POCA) Registry data, 34% of anesthesia-related pediatric cardiac arrests occurred in patients with heart disease. In addition, the mortality associated with perioperative pediatric cardiac arrest was higher in patients with cardiac disease (33% versus 23%) [3]. The increased risk of anesthetizing children with CHD exists in all anesthetizing locations including cardiac operating rooms, the cardiac catheterization laboratory, general operating rooms and procedural suites, and radiology locations [4–7].

Published data demonstrate that certain cardiac diagnoses are at higher risk of perioperative morbidity and mortality. Recognition of such patients and careful planning is essential for decreasing the anesthetic risk. Cardiac diagnoses demonstrated to be at higher risk include a single functional ventricle, left-to-right shunt lesions, left ventricular outflow tract obstruction, cardiomyopathy, and pulmonary hypertension (Table 28.1) [3,8,9]. The likelihood of mortality after perioperative cardiac arrest is also associated with diagnosis, with the highest mortality seen in patients with aortic stenosis (62%) and cardiomyopathy (50%) [3].

Young age is also a risk factor for perioperative morbidity and mortality in cardiac patients undergoing non-cardiac surgery. The POCA Registry data suggest that children less than 2 years of age are at higher risk [3]. Baum et al report a two-fold increase in mortality in neonates and infants with cardiac disease undergoing non-cardiac surgery [4].

As the patient groups at higher risk for perioperative morbidity and mortality undergo better definition, risk stratification scores and strategies are being developed to predict anesthetic risk in children with cardiac disease undergoing non-cardiac procedures. The purpose of risk stratification is to aid in determining in what locations patients should be cared for, what anesthesiologist training and experience is appropriate, the location of postanesthetic care, and occasionally whether the risks of the anesthetic and procedure outweigh the benefits [10–13].

It is also important to note that the number of adults with CHD has increased dramatically. It is estimated that there were 800,000 adults living with congenital heart defects in the

Gregory's Pediatric Anesthesia, Sixth Edition. Edited by Dean B. Andropoulos and George A. Gregory.

Table 28.1 Cardiac lesions conferring greatest mortality and morbidity risk with anesthesia

Cardiac lesion	Pathophysiological considerations	Anesthetic goals	Risk of cardiac arrest with anesthesia	Reference
Suprasystemic pulmonary artery hypertension	Calecholamine release from light anesthesia, hypercarbia, hypoxemia, acidosis, or systemic hypotension lead to elevated pulmonary artery pressure, right ventricular failure, low cardiac output, and hypoxemia	Maintain oxygenation, ventilation, coronary perfusion pressure, and adequate depth of anesthesia, and administer pulmonary vasodilators including nitric oxide	1.1–5.7% of anesthetics in severe pulmonary hypertension	[9]
Left ventricular outflow tract obstruction: subvalvar, valvar, or supravalvar aortic stenosis (e.g. Williams syndrome)	Tachycardia, hypovolemia, systemic hypotension, excessive myocardial depression, or hypercontractility reduce stroke volume, lead to coronary ischaemia, and low cardiac output	Maintain ventricular filling, systemic vascular resistance, normal to slow heart rate, and normal myocardial contractility	16% of POCA Registry	[2]
Infant with single functional ventricle and systemic to pulmonary artery shunt	Systemic and pulmonary output both ejected by single functional ventricle; pulmonary-to-systemic vascular resistance ratio determines systemic cardiac output	Avoid hyperoxygenation/ hyperventilation and maintain ventricular function	19% of POCA Registry	[2]
Dilated cardiomyopathy	Very increased ventricular volume, ejection fraction 5–25%, cardiac output maintained by near normal stroke volume and tachycardia, very limited reserve for decreased systemic vascular resistance, contractility, and preload	Avoid any decrease in myocardial contractility; maintain preload and systemic vascular resistance	13% of POCA Registry; 1.7% of anesthetics with dilated cardiomyopathy	[2,13]

USA in 2000 [1]. Adults with CHD are also at higher risk of perioperative morbidity and mortality when undergoing non-cardiac surgery, and it is often challenging to determine the best location and care team for delivery of optimal care in this patient group. Adults with CHD may be cared for in adult hospitals lacking anesthesiologists, cardiologists, and intensivists with expertise in CHD. Alternatively, these adult patients may be cared for in pediatric hospitals with expertise in CHD, but without access to adult specialists [14–17]. Ideally, these patients should be cared for in an adult hospital with an adult CHD team.

KEY POINTS: CHD AND PERIOPERATIVE RISK

- Recognizing high-risk patients is key to decreasing morbidity and mortality; it allows care at the right place with the right resources
- Cardiac lesions associated with cardiac arrest include left-to-right shunt lesions, left ventricular outflow tract obstruction, single ventricle lesions, and cardiomyopathy
- Pulmonary hypertension is also associated with perioperative morbidity and mortality, especially systemic or suprasystemic pulmonary hypertension

High-risk lesions

Left-to-right shunt

Left-to-right shunt lesions can occur at the atrial level, the ventricular level, and the level of the great arteries (Fig. 28.1). Although patients with left-to-right shunt lesions have been reported to have the highest percentage of perioperative cardiac arrest, they also have the lowest mortality after perioperative cardiac arrest [3]. The ratio of pulmonary to systemic blood flow (Qp:Qs) is often used to describe the magnitude of a left-to-right shunt. Patients with a high Qp:Qs are often described as "overcirculated," meaning they have excessive pulmonary blood flow.

In any patient with a communication between the left and right sides of the heart, meticulous care should be taken to avoid the introduction of air bubbles into the circulation. Air bubbles can cross into the systemic circulation and enter the coronary arteries causing ischemia, or go to the brain causing a stroke.

Atrial septal defects are usually not hemodynamically significant, and patients can tolerate them for many years. The degree of shunting depends on the difference between right and left atrial pressures. Over many years, the increased flow in the right heart may lead to pulmonary hypertension; this typically does not occur until the patient is over 40–50 years of age.

Ventricular septal defects (VSDs) vary in clinical significance according to size. Small, pressure-restrictive VSDs are usually not hemodynamically significant. Large or multiple VSDs can be hemodynamically significant due to the large amount of flow through the defects. These VSDs present early in life and are associated with signs of congestive heart failure from excessive pulmonary blood flow. These patients are often classified as "failing to thrive," with poor growth due to the high energy expenditure with increased total cardiac output and work of breathing from pulmonary overcirculation.

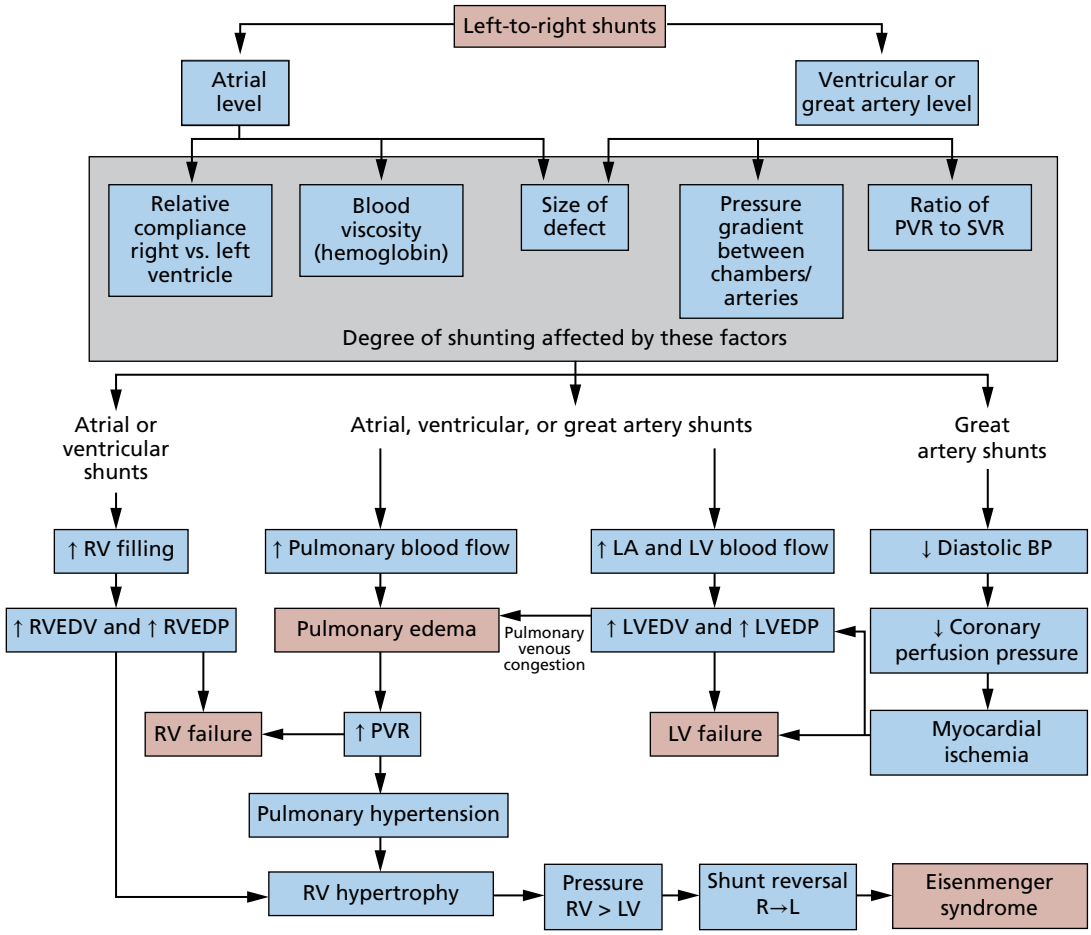

Figure 28.1 Pathophysiology of left-to-right shunting lesions. The flow diagram depicts factors that affect left-to-right shunting at the atrial, ventricular, and great artery level and the pathophysiology produced by these shunts. A large shunt will result in left ventricle (LV) failure, right ventricle (RV) failure, and pulmonary edema. Increased pulmonary blood flow and pulmonary artery pressures lead to pulmonary hypertension and eventually Eisenmenger syndrome. These final common outcomes are highlighted in bold lettering. See text for detailed discussion. BP, blood pressure; LA, left atrium; LVEDP, left ventricular end-diastolic pressure; LVEDV, left ventricular end-diastolic volume; PVR, pulmonary vascular resistance; RVEDP, right ventricular end-diastolic pressure; RVEDV, right ventricular end-diastolic volume; SVR, systemic vascular resistance.

These infants are underweight and experience diaphoresis and fatigue with feeding. They are often managed with diuretics prior to repair of the VSD. When these patients present for non-cardiac procedures, recognition of the degree of pulmonary overcirculation is important, and interventions to control pulmonary blood flow are instituted. To limit Qp:Qs in patients with pulmonary overcirculation, maneuvers to increase pulmonary vascular resistance should be undertaken. These include using a low fraction of inspired oxygen (FiO_2) and avoiding hyperventilation. Maintaining a low FiO_2 <0.30 and end-tidal CO_2 of 40–45 mmHg is sufficient for many patients.

Left-to-right shunts at the level of the great arteries include truncus arteriosus, aortopulmonary window, and patent ductus arteriosus (PDA). Patients with truncus arteriosus and aortopulmonary window are usually repaired in the early neonatal period because of severe pulmonary overcirculation, but they can require non-cardiac surgery before the cardiac repair. The Qp:Qs in these patients needs to be managed carefully. Unregulated pulmonary blood flow can lead to systemic hypoperfusion, coronary ischemia, and cardiac arrest. Care should be taken to increase pulmonary vascular resistance (PVR) and decrease Qp:Qs by avoiding high FiO_2 and hyperventilation. If the PVR is well maintained and diastolic hypotension persists, vasopressin or phenylephrine can increase diastolic blood pressure and avoid coronary ischemia. In addition, increasing the hematocrit to 40–45% can improve the pathophysiology by increasing the viscosity of the blood and decreasing the pulmonary blood flow. Although it is not an option during most non-cardiac procedures, the placement of a temporary pulmonary artery band can mechanically improve hemodynamics by restricting the pulmonary blood flow.

KEY POINTS: LEFT-TO-RIGHT SHUNT

- Left-to-right shunt lesions can be at the level of the atria, the ventricles, or the great arteries
- Patients with left-to-right shunt lesions at the level of the great arteries are at risk for developing diastolic hypotension and myocardial ischemia
- Maneuvers to increase pulmonary vascular resistance include using a low FiO_2 and hypoventilation to a $PaCO_2$ of 40–50 mmHg

Left ventricular outflow tract obstruction

There are a number of disease states, lesions, and syndromes that are associated with left ventricular outflow tract obstruction (LVOTO). They are characterized by obstruction at the subaortic, aortic valve, or supravalvar aortic levels. In some instances, such as Shone complex, the obstruction to left ventricular outflow occurs at multiple levels. According to the data from the POCA Registry, 16% of the perioperative cardiac arrests in children with heart disease were in children with left ventricular obstructive lesions [3]. Unfortunately, patients with this diagnosis are notoriously difficult to resuscitate; aortic stenosis patients with perioperative cardiac arrest had a mortality of 62%. The etiology of most cardiac arrests in patients with LVOTO is myocardial ischemia due to the imbalance between myocardial oxygen supply and demand. Thus, with the known difficulty in resuscitating patients with these lesions, the best approach is to avoid cardiac arrest and to have a plan in place if an arrest occurs.

Subaortic stenosis can be an isolated lesion or can exist as part of multilevel LVOTO or with another lesion such as complete atrioventricular (AV) canal. The interventricular septum can also cause dynamic LVOTO in systole in hypertrophic obstructive cardiomyopathy (HOCM). Aortic stenosis occurs at the level of the valve, and can be categorized as mild, moderate, severe, or critical depending on the pressure gradient across the valve.

Supravalvar aortic stenosis (SVAS) related to elastin arteriopathy can present as part of a syndrome (Williams syndrome), familial and non-syndromic, or sporadic cases. All varieties can be associated with sudden death and cardiac arrest in the perioperative period. Patients with Williams syndrome have a distinctive appearance and personality, and have an aptitude for music. Cardiac manifestations of elastin arteriopathies include SVAS, peripheral pulmonary stenosis, and coronary artery abnormalities. There are multiple case reports and series describing cardiac arrest related to anesthesia in patients with SVAS [18–20], and it is important that every pediatric anesthesiologist understands the pathophysiology of the disease and the causes of cardiac arrest. The tenuous balance between myocardial oxygen supply and demand is easily upset with the effects of anesthesia and surgery [21]. Due to coronary abnormalities and the loss of aortic distensibility due to reduced elastin, myocardial oxygen supply is already marginal in many SVAS patients. The decrease in systemic vascular resistance (SVR) associated with anesthetics such as propofol and inhalational agents reduces the coronary perfusion pressure that is necessary to maintain oxygen supply to the at-risk ventricles that are hypertrophied, with high end-diastolic pressures and high myocardial oxygen demand. It should be noted that surgical factors such as blood loss can also upset this tenuous balance. Hemodynamic effects associated with the procedure can lead to cardiac arrest. For example, anaphylaxis related to contrast for computed tomography imaging has been reported as the cause of cardiac arrest (and death) in a patient with Williams syndrome [22]. The hemodynamic effects associated with laparoscopy have also been implicated as a cause of cardiac arrest in this patient population. The decrease in afterload and preload associated with the release of pneumoperitoneum can lead to myocardial ischemia and arrest in patients with SVAS [23]. Steps to reduce the impact of the hemodynamic change, such as an intentional slow release of the pneumoperitoneum, should be considered. Anticipation of and preparation for procedure-related changes in afterload and preload can prevent morbidity in these patients.

Matissoff et al developed a risk assessment tool to guide perioperative care of patients with Williams syndrome (Table 28.2) [24], and Collins et al have provided a very complete review of and strategies for reducing periprocedural risk [25]. These recommendations should likely be applied to all patients with elastin arteriopathy and supravalvar aortic stenosis.

Prevention of cardiac arrest is critically important because if cardiac arrest occurs, resuscitation is difficult. Of note, the availability of extracorporeal membrane oxygenation (ECMO) support has decreased the mortality associated with perioperative cardiac arrest in patients with LVOTO. For this reason, it is suggested that anesthesia and sedation of patients with significant LVOTO should be performed at institutions where rapid cannulation for ECMO is possible [26].

KEY POINTS: LEFT VENTRICULAR OUTFLOW TRACT OBSTRUCTION

- Patients with LVOTO are not candidates for office-based anesthesia or ambulatory surgical centers
- Prolonged preoperative fasting should be avoided as it can lead to instability on induction; intravenous fluids should be started if the patient cannot take clear fluids
- Goals for induction include maintaining SVR and avoiding tachycardia
- It is difficult to resuscitate patients with LVOTO after cardiac arrest

Table 28.2 Classification of risks of Williams syndrome

Low risk	Moderate risk	High risk
Normal ECG	Mild stenosis of a branch of the pulmonary artery	Severe SVAS (>40 mmHg)
Normal echocardiogram	Hypertension	Symptoms or ECG signs consistent with ischemia
Minimal extracardiac anomalies	Mild-to-moderate SVAS (<40 mmHg)	Coronary disease demonstrated in imaging
	Other mild cardiac anomalies (e.g. ventricular septal defect)	Severe left ventricular hypertrophy
	Repaired SVAS or SVPS without residual gradients	Biventicular outflow tract disease
	Mild left venticular hypertrophy	Prolonged QTc on ECG
	Mild to moderate SVPS in isolation	
	Significant extracardiac disease such as difficult airway or severe gastroesophageal reflux	

ECG, electrocardiogram; SVAS, supravalvar aortic stenosis; SVPS, supravalvar pulmonary stenosis.

Single ventricle lesions

Patients with single ventricle (SV) physiology are another group of pediatric patients with cardiac disease who are at an increased risk of morbidity and mortality when undergoing non-cardiac procedures. According to the data from the POCA Registry, SV lesions made up 19% of the congenital heart lesions associated with a perioperative cardiac arrest [3]. It is also clear that the stage of SV palliation is an important consideration. Of the 24 SV patients experiencing cardiac arrest, 17 had not yet undergone the second stage procedure for SV palliation (bidirectional Glenn operation or superior cavopulmonary anastomosis). Two had undergone the Glenn operation, and five patients had undergone the third stage procedure (Fontan operation or total cavopulmonary anastomosis). Christensen et al reported a 15% incidence of adverse events in patients with hypoplastic left heart syndrome (all stages included) undergoing non-cardiac surgery. Of note, those who were pre-superior cavopulmonary anastomosis (pre-SCPA) had a 40% incidence of instability [27]. In a retrospective study of pre-SCPA SV patients undergoing non-cardiac surgery, Brown et al reported an 11.8% incidence of major adverse events [28]. To reduce the perioperative risk, the anesthesiologist providing care for patients with a SV lesion should have a thorough understanding of each stage of palliation, the ability to plan an appropriate anesthetic, and the capacity to rapidly assess and treat hemodynamic instability. These patients may need a non-cardiac procedure at any stage, from just after birth to after the Fontan operation, or anytime in between.

Prior to surgical/catheter-based procedure

Lesions with single ventricle physiology include tricuspid atresia, pulmonary atresia, double-inlet left ventricle, unbalanced atrioventricular canal defect, hypoplastic left heart syndrome (HLHS), and double-outlet right ventricle. After birth, the sources of systemic and pulmonary blood flow should be determined. Lesions with aortic obstruction like HLHS may require prostaglandin E1 (PGE1) to maintain ductal patency for systemic blood flow. Others like pulmonary atresia require PGE1 to maintain ductal patency for pulmonary blood flow. Other lesions may have unrestricted systemic and pulmonary blood flow [29].

Patients with a SV lesion who require anesthesia for a non-cardiac procedure prior to addressing the cardiac disease are at substantial risk of morbidity and mortality. The types of procedures that may need to be addressed at this time include tracheo-esophageal fistula/esophageal atresia (TEF/EA), congenital diaphragmatic hernia, anal atresia, intestinal atresia, myelomeningocele repair, colostomy, exploratory laparotomy for necrotizing enterocolitis, and others. Although good outcomes have been reported [30,31], there are also many reports of adverse outcomes with patients not surviving to cardiac repair [32–35]. In patients with CHD undergoing TEF/EA repair, those with PDA-dependent lesions had a 57% chance of not surviving compared with 10% in patients with non-PDA-dependent lesions. Of note, all of the patients with TEF/EA without CHD survived [32]. Among SV patients with congenital diaphragmatic hernia, only 16% survived to discharge and only 5% had their cardiac disease addressed [33].

Anesthetic care for patients with a SV lesion for non-cardiac surgery requires preparation and anticipation of instability. Because this is a diverse group of lesions, it is imperative to understand the cardiac anatomy. For patients with PDA-dependent lesions, the PGE1 infusion must be continued intraoperatively. For most procedures, general anesthesia is required, although regional anesthesia has been described [35]. Many of these patients have excessive pulmonary blood flow (high Qp:Qs), which can be exacerbated by intubating the trachea and controlling ventilation. A reasonable goal for most SV patients for oxygenation is a pulse oximeter reading of 85%. To avoid pulmonary overcirculation, PVR should be increased by achieving a FiO_2 as low as possible, while allowing the end-tidal CO_2 to increase to 40–45 mmHg. This maneuver will reduce pulmonary blood flow and augment systemic blood flow. Not uncommonly, despite these maneuvers, the peripheral oxygen saturation (SpO_2) is still in the mid-90% range, and the systemic blood pressure is low. In patients with PDA-dependent pulmonary blood flow, the diastolic blood pressure maybe extremely low due to diastolic run-off. Hypotension, especially diastolic hypotension, can lead to myocardial ischemia. It is helpful to monitor the invasive arterial blood pressure, cerebral and somatic oximetry by near-infrared spectroscopy (NIRS), and the electrocardiogram with ST segment monitoring. If the blood pressure and NIRS are low despite efforts to increase PVR with low FiO_2 and hypoventilation, other steps can be taken. Packed red blood cell transfusion to a hematocrit of 40–45% will increase oxygen-carrying capacity and blood viscosity, which can decrease left-to-right shunt flow. In addition, an infusion of vasopressin (0.01–0.02 units/kg/h), epinephrine (0.02–0.04 μg/kg/min), or calcium chloride (10 mg/kg/h) will increase systemic blood pressure. Arterial blood gases and lactate levels should be assessed frequently to manage oxygenation, ventilation, and systemic perfusion. Postoperative disposition in an intensive care unit (ICU) is almost always required, and a conservative approach to postoperative ventilation, by not extubating the trachea in the operating room, is often prudent.

After first palliative procedure

Many of these patients will require a cardiac intervention in the neonatal period. Patients with HLHS are managed with an operative stage I palliation (Norwood operation) with the creation of either a Blalock–Taussig (B-T) shunt (systemic arterial to pulmonary artery) or a Sano shunt (right ventricle to pulmonary artery conduit) or the hybrid procedure for HLHS, which includes a PDA stent, bilateral pulmonary artery bands, and an atrial septal stent (Fig. 28.2) [36]. Patients with PDA-dependent pulmonary blood flow (e.g. pulmonary atresia) will need a stable source of pulmonary blood flow, either a surgical systemic to pulmonary artery shunt (e.g. modified B-T shunt or central aortopulmonary shunt) or a PDA stent placed percutaneously in the cardiac catheterization laboratory. Patients with PDA stents, central shunts, or B-T shunts are at risk for coronary hypoperfusion from diastolic run-off into the pulmonary circulation. For this reason, the physiology is fragile and can easily be perturbed. Other patients with unrestricted pulmonary blood flow may require a pulmonary artery band placement in the operating room to help reduce pulmonary blood flow until the second stage procedure [29,37].

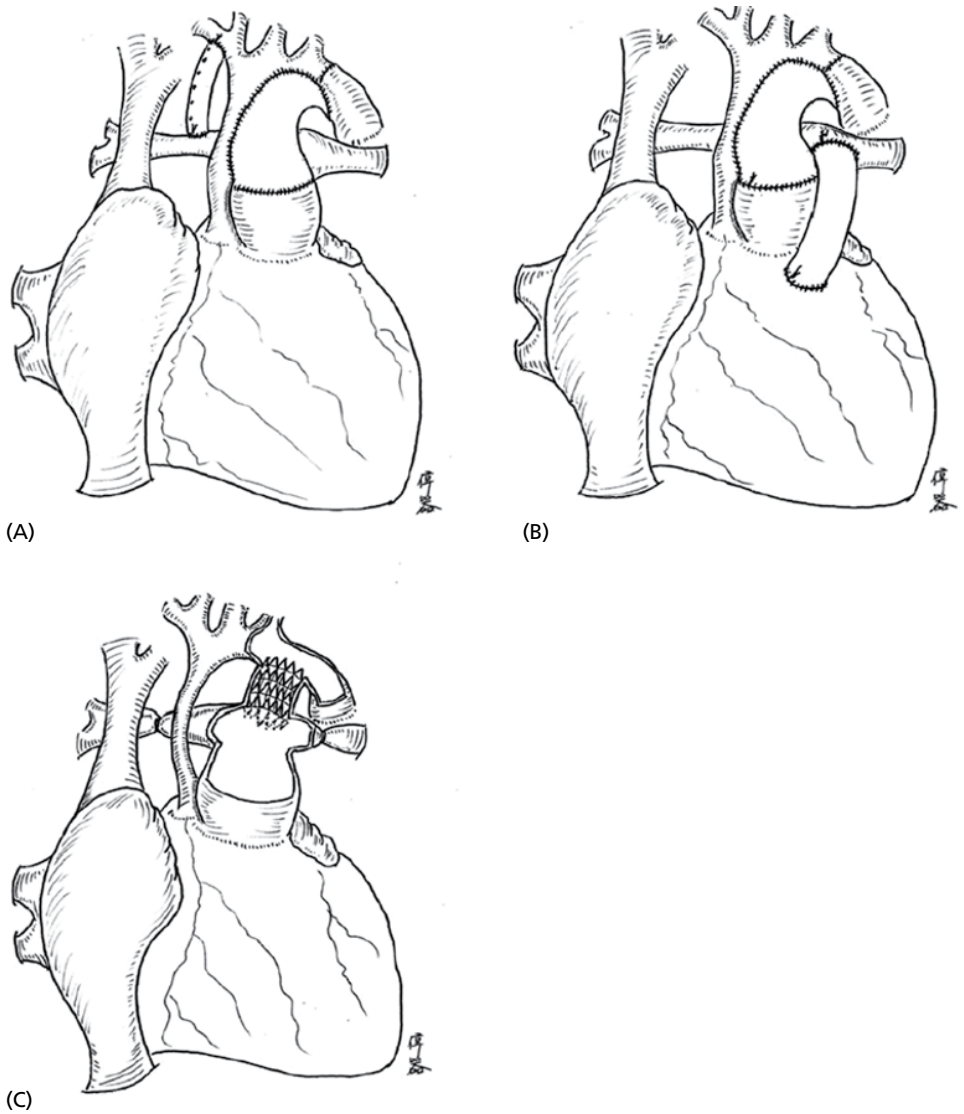

Figure 28.2 Hypoplastic left heart syndrome following the Norwood operation. (A) A demonstration of the standard Norwood procedure, with a right modified Blalock–Taussig shunt from the right subclavian artery to the right pulmonary artery. (B) A representation of the modified Norwood procedure where a right ventricle to pulmonary artery conduit (so-called "Sano") is placed to provide pulmonary blood flow. (C) A representation of the hybrid Norwood, wherein the pulmonary blood flow is controlled with bilateral restricting bands, and the ductus arteriosus is stented to provide unobstructed systemic blood flow. *Source*: Reproduced from Petit [36] with permission of John Wiley and Sons.

The patient with a shunt or PDA stent has a fragile physiology and may need to undergo non-cardiac surgery or imaging prior to the superior cavopulmonary anastomosis operation. Many agree that elective procedures should be postponed until after the SCPA operation due to increased stability of the circulation [27,29,37,38] and the removal of shunt/ductal occlusion as a risk factor [39]. These patients are at risk for periprocedural complications including heomodynamic instability and cardiac arrest [27–29,37,40–43].

Anticipation of and preparation for hemodynamic instability, coronary steal, and/or acute shunt or PDA stent occlusion will reduce these risks. Preoperative strategies include encouraging clear fluid ingestion until 2 h prior to the procedure or even hospital admission the evening before the procedure for an observed nil per os period with intravenous fluid administration [5,37]. Preoperative angiotensin-converting enzyme inhibitors have been associated with hypotension at anesthesia induction, and some institutions discontinue these drugs for 24 h preoperatively [28,41]. Management strategies for these patients undergoing non-cardiac procedures that have been successful include maintaining the hematocrit at 40–45%, monitoring invasive arterial pressure, increasing PVR by decreasing minute ventilation and allowing the $PaCO_2$ to increase, using the minimum FiO_2 to maintain baseline oxygen saturations, checking frequent arterial blood gases, monitoring NIRS, using low insufflation pressures (8–12 mmHg) with laparoscopic procedures, postoperative mechanical ventilation, and recovering the patient in the ICU [29,40,44,45]. In the event of excessive pulmonary blood flow and diastolic hypotension with possible myocardial ischemia, infusions of vasopressin, epinephrine, and calcium should be prepared [29,40].

Acute shunt or PDA stent occlusion is catastrophic and can occur during non-cardiac procedures and imaging [46]. Signs of partial or total occlusion include worsening hypoxemia despite supplemental oxygen administration, expansion of

the intravascular volume, and increasing systemic blood pressure. End-tidal CO_2 levels may drop precipitously as well. Cardiac arrest may follow and immediate resuscitation should commence. The lungs should be auscultated to exclude right mainstem bronchial intubation or another cause of decreased ventilation, and auscultation for the shunt or PDA stent murmur should occur immediately. At the same time, rapid echocardiographic assessment of the shunt or duct should be performed; an interventional cardiologist should be summoned for consideration of therapy in the cardiac catheterization lab for angioplasty, stent placement, or thrombolytic administration; and a surgeon should be called for the possibility of shunt revision or ECMO [47–49]. A systemic heparin bolus of 100 units/kg may be given, and systemic thrombolytic therapy may be considered [50]. Predisposing factors for shunt occlusion include preoperative dehydration, elevated hematocrit, and hypotension [39,48].

The HLHS patient with a right ventricle (RV) to pulmonary artery conduit may be less vulnerable to hemodynamic instability and shunt occlusion than the patient with a B-T shunt, but the same preanesthetic preparations should be made. Patients with a pulmonary artery band often have a fixed pulmonary blood flow, and overcirculation may be impossible. However, ventricular function must be maintained. Peripheral oxygen saturations of 80–90% are appropriate [37]. It should be noted that ECMO has been used as a rescue in multiple cases of cardiac arrest or severe hemodynamic instability in infants with CHD undergoing non-cardiac surgery [28,42,43,46,49,50]. When a palliated neonate experiences cardiac arrest, ECMO activation should be considered early, i.e. after 5–10 min if spontaneous circulation has not been restored. Without the availability of ECMO, many of the patients in these case reports would have expired.

After second stage palliation

The next stage of palliation for the SV lesion is the creation of a bidirectional Glenn shunt or SCPA (Fig. 28.3) [36]. After this intervention, pulmonary blood flow is supplied by the superior vena cava. Compared with the condition in which pulmonary blood flow is supplied by a stented PDA, B-T shunt, central shunt, or RV to pulmonary artery conduit, the ventricle is partially volume unloaded, and the risk of coronary hypoperfusion is greatly reduced. This stage is often considered the optimal for non-cardiac surgery because the threat of coronary hypoperfusion is reduced, the ventricular volume overload is reduced, and the venous blood from the lower half of the body returns directly to the atrium, maintaining preload if pulmonary blood flow decreases [27,29,37,38]. In addition, the risk of catastrophic shunt/PDA stent occlusion is no longer present [39]. However, the increased resiliency of this circulation compared with that of the pre-SCPA circulation should not result in complacency on the part of the anesthesiologist. These patients still have only one functional ventricle, and they remain cyanotic with oxygen saturations usually in the 75–85% range. The echocardiogram should be reviewed preoperatively with attention to ventricular function and the presence of AV valve regurgitation. Depressed ventricular function and AV valve regurgitation are concerning and increase the risk of anesthetic complications. Cardiac catheterization data can provide information about the PVR and SCPA anatomy. Baseline oxygen saturation should be noted.

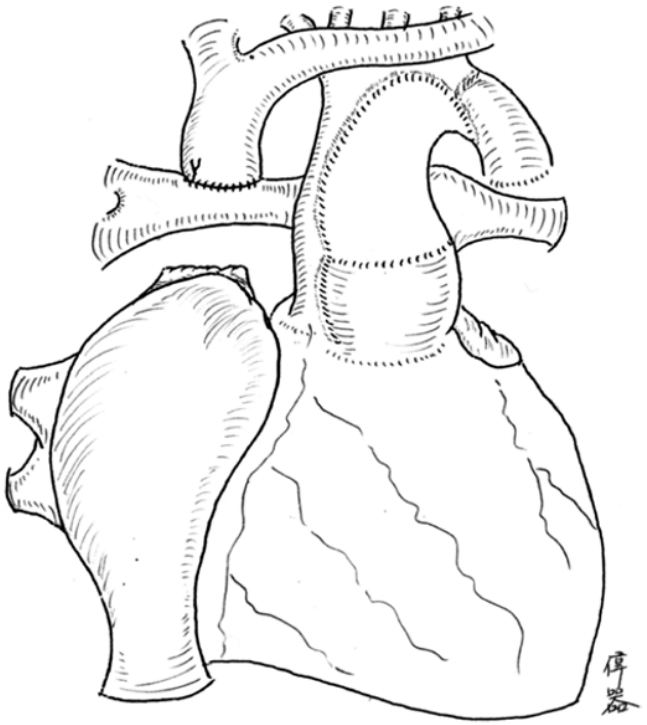

Figure 28.3 The bidirectional Glenn (superior cavopulmonary anastomosis) operation – a superior cavopulmonary connection. *Source*: Reproduced from Petit [36] with permission of John Wiley and Sons.

Hemodynamic goals when providing anesthesia for patients with a SCPA circulation involve maintaining a normal blood pressure and avoiding increases in PVR that can be associated with agitation, pain, and extreme hypoventilation. The delivery of higher oxygen concentrations is not harmful in this population, as the susceptibility to diastolic steal with coronary ischemia is not a factor. The cerebral-pulmonary–cardiac circulation is especially important in younger patients with this physiology, and a $PaCO_2$ of 40–45 mmHg allows sufficient cerebral blood flow, which then perfuses the lungs to be oxygenated. Hyperventilation is counterproductive as it decreases cerebral blood flow and therefore pulmonary blood flow, resulting in hypoxemia [27,29,37]. Ventricular function should be maintained, and these patients' tracheas are often extubated at the end of the procedure [38]. Postoperative ICU monitoring for patients with this circulation and normal cardiac function is not required.

Patients with SCPA circulation with depressed myocardial function and AV valve regurgitation should be monitored very closely. Instability should be anticipated. Inotropic and vasopressor support should be available, and if the function is extremely poor it may be prudent to initiate inotropic support prior to the induction of anesthesia. Invasive blood pressure and NIRS monitoring may be helpful. These patients are high risk; postoperative ventilation should be considered, and postoperative ICU monitoring is advised.

After third stage palliation

The third stage of SV palliation is the Fontan operation (total cavopulmonary anastomosis) (Fig. 28.4). After this procedure all systemic venous return flows directly to the pulmonary

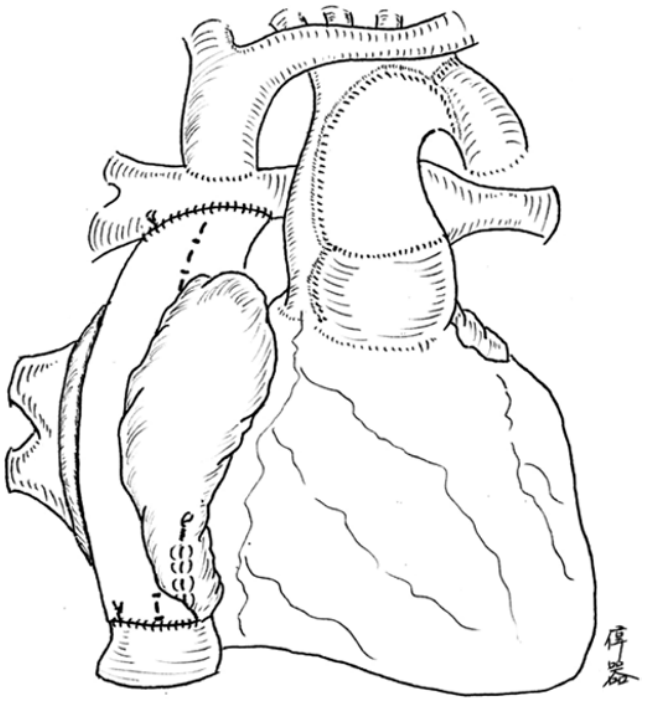

Figure 28.4 Fontan operation. *Source*: Reproduced from Petit [36] with permission of John Wiley and Sons.

arteries [36]; therefore, pulmonary blood flow is passive. An optimal Fontan circulation requires adequate preload with a central venous pressure of approximately 15 mmHg, a low PVR, a non-regurgitant AV valve, and a normal ventricular ejection fraction. These patients are at a higher risk of arrhythmia, especially those with a lateral tunnel or atriopulmonary Fontan (Fig. 28.5). Decreases in central venous pressure caused by venodilation from vasodilators or decreased sympathetic tone, acute blood loss, or dehydration are not well tolerated [29,51]. For this reason, prolonged fasting prior to induction of anesthesia should be avoided. At some centers, patients are intravascular volume loaded prior to induction [29,52], and intravenous fluid volume should be available. Others use vasopressor or low-dose inotropic support to lessen the risk of hypotension, and avoid large volume administration [29,53]. Increases in PVR are also poorly tolerated, and maintaining a normal $PaCO_2$ is recommended. Pharmacological means to decrease the PVR including inhaled prostacyclin analogs and milrinone have been described [54,55]. Depressed ventricular function may require inotropic support intraoperatively. Positive pressure ventilation worsens systemic venous return and may decrease stroke volume and cardiac output in the Fontan circulation [56]; however, the manipulation of ventilatory parameters to achieve appropriate gas exchange at the lowest mean airway pressure can minimize this effect [51]. On the other hand, increasing PVR

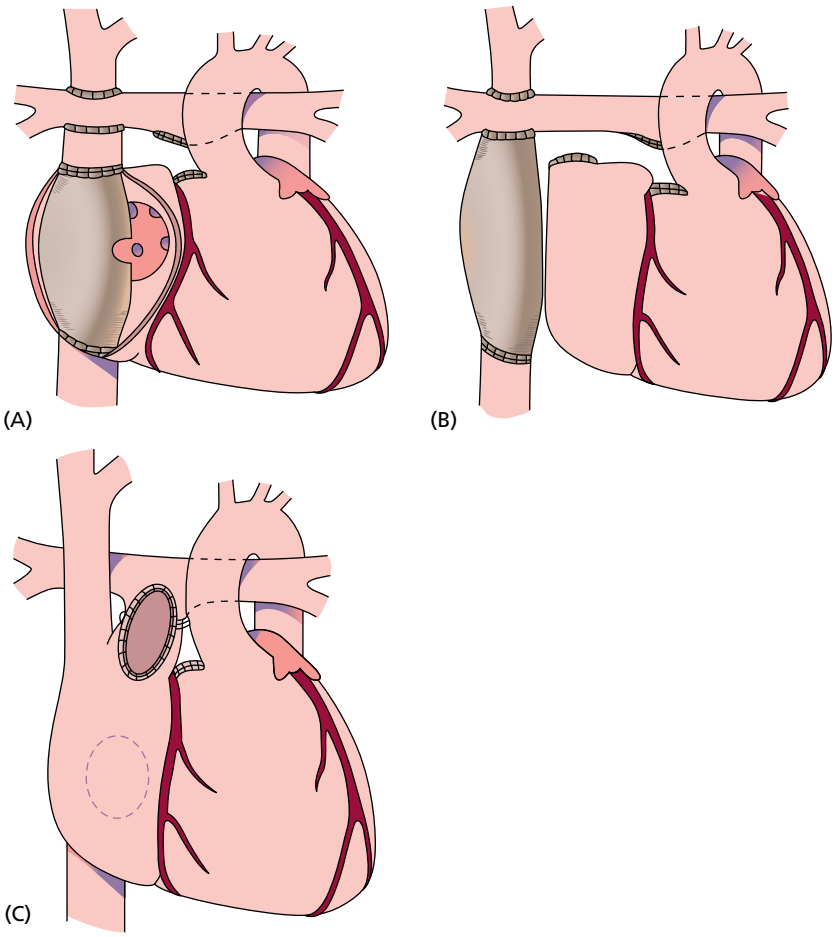

Figure 28.5 Fontan configurations for cases with (A) lateral tunnel Fontan, (B) extracardiac Fontan, and (C) atriopulmonary connection Fontan. *Source*: Reproduced from Yuki et al [29] with permission of Japanese Society of Anesthesiologists.

from ineffective ventilation can also reduce venous return to the systemic ventricle and reduce cardiac output.

In the Fontan circulation, inadequate pulmonary blood flow results in a decrease in systemic ventricular filling, reducing cardiac output. Sometimes, a fenestration may be created between the Fontan baffle and the atrium to allow systemic ventricular filling in the event of an increase in PVR. If there is no fenestration, the patient should not be cyanotic. With a fenestration, the oxygen saturation will vary based on the magnitude of the right-to-left shunt.

The Fontan circulation is the third stage of SV palliation, but it is by no means a repair. Patients with a Fontan circulation may develop depressed myocardial function, AV valve regurgitation, arrhythmias, thromboembolic events, protein-losing enteropathy, cirrhosis, lower extremity edema, plastic bronchitis, and other sequelae [57]. Many will require additional cardiac surgery including heart transplantation. When evaluating these patients prior to surgery, these conditions should be assessed.

As they age, SV patients will undergo non-cardiac procedures and may present for obstetric management. It is important to have a plan for optimizing hemodynamic status and avoiding complications intraoperatively. Intravenous fluids in adequate amounts, vasopressors, and inotropes should be immediately available. A defibrillator should be in the room with appropriately sized pads to treat arrhythmia. Patients with pacemakers and implanted defibrillators should have their devices interrogated; the patient's underlying cardiac rhythm should also be understood. These devices often should have their defibrillation function disabled, and pacing mode converted to asynchronous because of interference with their function by electrocautery. Advice and recommendations of the patient's cardiologist should be sought.

Monitoring for SV patients may include the use of an arterial catheter, a central venous catheter (which will be measuring Fontan pressure, not atrial pressure), and transesophageal echocardiography to assess ventricular filling and AV valve function. Cardiopulmonary resuscitation (CPR) is often not effective with a Fontan circulation, and ECMO is often complicated by anatomy. However, Jolley et al report improved outcome when patients are placed on ECMO before CPR is necessary [51].

They are many reports of non-cardiac surgery in patients with a Fontan circulation. In the largest series, Rabbitts et al reviewed 39 anesthetics in 31 patients with Fontan circulation who had non-cardiac surgery. A perioperative complication occurred in 31% of the operations, and one patient died postoperatively. A low preoperative ejection fraction (less than 30%) was associated with serious adverse outcomes (dialysis and death) [54]. Another predictor of periprocedural complications in adult Fontan patients is baseline cyanosis, which can be a marker for increased PVR, depressed ventricular function, or increased right-to-left shunting [58]. Laparoscopy has been successfully performed in these patients. Low insufflation pressures (8–12 mmHg) are recommended, and hypercarbia should be avoided [52,59].

There are several reports of scoliosis repair in the SV population [60–64]. Generally, invasive arterial and venous pressure monitoring are recommended, with some groups advocating transesophageal echocardiography. High venous pressure is necessary for pulmonary blood flow, but it also increases the risk of bleeding, as does abnormal baseline coagulation in these patients. Controlled hypotension to decrease blood loss is not recommended. The blood loss for scoliosis repair in the Fontan patient is larger than normal. Cell salvage and antifibrinolyic therapy should be employed [60–64]. Craniotomy for electrocorticography and seizure ablation in this population is also reported [65,66], as is craniotomy for pial synangiosis and evacuation of hematoma [53]. The intracranial vascular anatomy is also abnormal, and increased bleeding is described [53,65].

Interestingly, there are multiple reports of pheochromocytoma in the Fontan population as well. All of the patients received invasive arterial blood pressure monitoring, and most also had placement of central venous catheters. All but one was performed via open approach, and one was performed laparoscopically. An epidural catheter was placed in one patient. As this is a case in which there are multiple opportunities for hypertension and hypotension, invasive arterial blood pressure monitoring was very helpful, and vasopressors, inotropes, and vasodilators were required for most cases [55,67–69].

KEY POINTS: SINGLE VENTRICLE LESIONS

- Unpalliated neonates are at high risk for overcirculation during non-cardiac procedures, and measures to increase PVR should be employed
- Patients with a systemic to pulmonary artery shunt or PDA stent are at risk for diastolic hypotension and myocardial ischemia; they are also at risk for catastrophic stent or ductal occlusion
- Bidirectional Glenn circulation is considered the most resilient because the ventricle is unloaded and cardiac output does not rely completely on pulmonary blood flow
- Pulmonary blood flow in a patient with Fontan circulation is dependent on the transpulmonary gradient (systemic venous pressure – the left ventricular end-diastolic pressure)

Pulmonary hypertension

Pulmonary hypertension (PH) is a known risk factor for anesthetic morbidity and mortality in adults and in children [8,70,71]. In a retrospective review of 101,885 anesthetics, van der Griend et al reported an increase in anesthesia-related mortality in children with heart disease and especially those with pulmonary hypertension. In fact, 50% of the anesthesia-related deaths were in patients with PH [8]. In a retrospective review of children with PH undergoing cardiac catheterization or non-cardiac surgery, the severity of PH was also associated with increased anesthetic risk – with patients with suprasystemic pulmonary artery pressures eight times more likely to have a major complication compared with those patients with subsystemic pulmonary artery pressures [9]. Taylor et al reported an incremental increase in all complications including death with increasing severity of PH (Table 28.3) in pediatric patients undergoing procedures not involving cardiopulmonary bypass [72]. Bernier et al reported not only increased risk with severe PH, but also an association between the type of procedure and

Table 28.3 Risk of complications with degree of pulmonary hypertension

	Minor complications	Major complications	Death
Subsystemic PHT	6/188 (3.2%)	3/188 (1.6%)	1/188 (0.5%)
Systemic PHT	2/50 (4%)	2/50 (4%)	1/50 (2.0%)
Suprasystemic PHT	3/25 (12%)	4/25 (16.0%)	1/25 (4.0%)

risk of a major event, with thoracic procedures being at an increased risk [73]. Symptoms at presentation may correlate with severity of disease; patients with complaints of chest pain, syncope, and dizziness were found to be at highest risk of instability and cardiac arrest [74].

PH is defined as a mean pulmonary artery pressure greater than 25 mmHg at rest, or greater than 30 mmHg during exercise. The cause of PH may be idiopathic or associated with other conditions, including CHD, disorders of the respiratory system, and many others [75,76]. A distinction should be made between precapillary PH and postcapillary PH. Postcapillary PH is due to increased pulmonary venous pressure such as that found in pulmonary vein stenosis or left heart dysfunction or obstruction [77,78]. Heart disease associated with postcapillary PH includes pulmonary vein obstruction or stenosis and conditions associated with chronic increased left atrial pressure like cardiomyopathy, coarctation of the aorta, HLHS with restrictive atrial septum, Shone complex, mitral stenosis, supravalvar mitral ring, or cor triatriatum [76]. Precapillary PH is associated with a pulmonary capillary wedge pressure (PCWP) of less than 15 mmHg (idiopathic pulmonary hypertension and intrinsic lung disease or hypoplasia), and postcapillary PH is associated with a PCWP of >15 mmHg [77]. Treatment strategies differ between the two types of PH. Before cardiac repair in patients with postcapillary etiology, therapy to decrease pulmonary resistance may result in increased pulmonary blood flow in the face of a fixed downstream obstruction, and pulmonary edema with worsening gas exchange[77,78].

Preprocedural assessment should be directed at determining the severity of the PH. Symptoms of PH may include dyspnea on exertion, reduced exercise tolerance, orthopnea, atypical chest pain, hemoptysis, cyanosis, and syncope [76,78]. Syncope is an especially concerning symptom. The echocardiographic exam should be reviewed. Findings of PH include a tricuspid regurgitation Doppler velocity of greater than 2.5 m/s or an estimated systolic pulmonary artery pressure that is greater than 50% of the systemic systolic blood pressure. It is also informative to assess at the degree of dilation and the function of the RV. A poorly contractile, massively dilated RV that causes interventricular septal bowing and compression of the left ventricle is a sign of severe pulmonary hypertension (Fig. 28.6). A decompressive shunt, such as an atrial septal defect, may also be encountered. This "pop-off" can serve to preserve cardiac output by allowing the right-to-left shunting of blood to fill the left heart during a pulmonary hypertensive crisis [72,78]. Cardiac catheterization data should also be reviewed. A PVR of >3 Wood units is indicative of PH [77]. Information regarding the etiology of the PH can also be sought; increased PCWP and/or left arterial pressure suggests postcapillary causes.

Figure 28.6 Transthoracic echocardiographic apical four-chamber view of pulmonary hypertension in systole. Note the severely dilated right ventricle, bowing of the intraventricular septum right to left, and compression of the left ventricle due to suprasystemic pulmonary artery and right ventricular pressure.

Patients may be taking medications for PH, or they may be untreated. Unfortunately, many patients who present for cardiac catheterization to evaluate newly diagnosed PH are untreated. Therapy for PH may include the endothelin antagonist bosentan, a calcium channel blocker such as diltiazem, phosphodiasterase-3 inhibitors such as milrinone, phosphodiesterase-5 inhibitors such as sildenafil, home oxygen, inhaled nitric oxide, or a prostacyclin analog (treprostinil (intravenous or subcutaneous), epoprostanol (intravenous), iloprost (inhaled), or beraprost (oral)) [72]. Some studies suggest that there is a decreased risk of adverse events when patients are receiving treatment preoperatively [73,79,80], but others suggest that this is not necessarily the case [72].

The key to avoiding an adverse event when caring for patients with PH is to minimize increases in PVR, maintain myocardial contractility, and to maintain systemic blood pressure, so that coronary perfusion is not compromised. To minimize increases in PVR, hypoxemia, hypercarbia, acidosis, and noxious stimuli without an appropriate anesthetic plane should be avoided. In addition, the prompt recognition and treatment of a pulmonary hypertensive crisis is critical. A pulmonary hypertensive crisis is characterized by an acute increase in PVR, decrease in systemic arterial blood pressure,

and RV failure (Fig. 28.7). Treatment consists of medications and maneuvers to decrease PVR. The systemic blood pressure should be supported, and cardiac contractility preserved [81]. Box 28.1 summarizes options for treatment.

When caring for patients with postcapillary pulmonary hypertension, left heart physiology should be optimized while maintaining right heart contractility and coronary perfusion [77]. In some cases such as pulmonary vein stenosis or cor triatriatum, left heart physiology cannot really be optimized, and focus should be on the right heart.

PVR can be decreased by increasing the FiO_2, hyperventilation, treating acidosis, blunting the response to noxious stimuli, and administering rescue pulmonary vasodilators such as inhaled nitric oxide or aerosolized iloprost. The possibility of hypoventilation with obstruction in an uninstrumented airway, a poorly seated supraglottic airway device, or an occluded endotracheal tube should be explored and corrected. Inhaled nitric oxide and iloprost are both effective pulmonary vasodilators [82–84]. These agents are delivered directly to the pulmonary circulation and do not cause significant systemic effects. Both drugs require specialized equipment. Inhaled nitric oxide can be delivered continuously or via a pulsing system (Fig. 28.8). Iloprost is delivered via a nebulizer, and a specialized adaptor that fits into the ventilator circuit is required (Fig. 28.9). Iloprost is not associated with rebound increases in PVR after discontinuation, as is the case with inhaled nitric oxide. However, the amount of drug that reaches the alveolus with a nebulizer in an anesthesia ventilation circuit may not be consistent [83]. There is some question about whether a combination of inhaled nitric oxide and iloprost is more potent than either agent alone, and some

evidence of synergy between the two classes of drugs in animals and children [85–89].

Maintenance of SVR in patients with PH is important, and is a critical goal in the treatment of a pulmonary hypertensive crisis. In the patient without PH, right ventricular perfusion and myocardial supply compared with demand are ample, as opposed to the situation in the left ventricle. For example, the RV is normally perfused throughout the cardiac cycle, unlike the left ventricle which is perfused during diastole. When the RV is doing increased pressure work, as is the case with PH, RV perfusion becomes phasic as is seen in the left ventricle, with flow only during diastole. During a pulmonary hypertensive crisis, when RV afterload increases acutely, systemic blood pressure decreases. This can be due to decreased blood flow across the pulmonary bed with a resultant decrease in left heart filling, as well as a change in left ventricular geometry secondary to the compression of the left ventricle by the RV. This decrease in blood pressure occurs at the same time that the myocardial oxygen demand of the RV increases, and this situation often results in RV ischemia, worsened myocardial function, decreased pulmonary blood flow and left heart filling, and cardiac arrest [81]. Pharmacological means of increasing the systemic blood pressure include phenylephrine, norepinephrine, and vasopressin. There is evidence that both phenylephrine and norepinephrine increase systemic and pulmonary vascular resistance, while vasopressin increases SVR without increasing PVR [90]. A benefit of norepinephrine is the β-adrenergic receptor-mediated increase in contractility that can be helpful during acute RV dysfunction [91].

Maintaining or improving RV contractility is also important in avoiding adverse events in patients with PH and for treating pulmonary hypertensive crises. Epinephrine infusion can both increase SVR and provide inotropic support to the RV. Milrinone can also improve RV contractility, but a decrease in SVR with this drug should be anticipated. In the event of a pulmonary hypertensive crisis, epinephrine is the inotrope of choice for resuscitation [91].

Diligent case preparation when caring for this high-risk group cannot be overemphasized. Chau et al stress the importance of preoperative multidisciplinary discussion [77]. The anesthesiologist, pulmonologist, cardiologist, intensivist, and surgeon or proceduralist should be involved. Plans should be made for postoperative recovery in the ICU, if indicated, and the possibility of extracorporeal support should be discussed. Pulmonary vasodilator therapy should be continued. The patient should not be kept fasting without intravenous fluids for an extended period. Elective cases should be scheduled during normal working hours, so that subspecialty and emergency consultation and assistance are readily available. All providers should be familiar with PH, the risks involved, and the plan if a cardiac arrest or other adverse event occurs. Before starting the procedure, all necessary equipment should be immediately available, because delays in procuring equipment after the patient is anesthetized can lead to unnecessary opportunities for the patient to suffer an adverse outcome [77,79].

When providing anesthesia for patients with PH, especially those with systemic or suprasystemic pulmonary artery pressures, the anesthesiologist should anticipate instability and a pulmonary hypertensive crisis. Care should be taken to avoid hypoxemia and hypercarbia. Pulmonary vasodilators should be readily available. Because both inhaled nitric oxide and iloprost require special equipment, their use should be anticipated, and the equipment readied. Some groups advocate starting inhaled nitric oxide preinduction and continuing it intraoperatively and postoperatively [78]. Others advocate a preoperative iloprost nebulizer treatment [91]. Infusions of epinephrine, vasopressin or norepinephrine, and milrinone should be prepared. Some anesthesiologists will start infusions prior to induction [91]. Invasive arterial and central venous pressure monitoring may be helpful. Children rarely tolerate placement of invasive catheters prior to induction.

All classes of anesthetic drugs have been used in patients with PH. Anesthetic drugs should be selected to maintain myocardial contractility and to avoid decreases in SVR. For this reason, propofol or high concentrations of inhalational agent are often avoided [78,79]. A thorough understanding of the physiology associated with PH should be helpful in selecting an anesthetic plan.

KEY POINTS: PULMONARY HYPERTENSION

- Patients with systemic or suprasystemic pulmonary artery pressure are at high risk for perioperative cardiac arrest
- Treatment of pulmonary hypertensive crisis involves decreasing PVR, maintaining or improving RV contractility, and increasing SVR to maintain coronary perfusion
- Strategies to decrease PVR include high FiO_2, hyperventilation, inhaled nitric oxide, prostacyclin analogs, and phosphodiesterase inhibitors
- A distinction should be made between precapillary and postcapillary etiology of the PH as treatment differs

Cardiomyopathy

Patients with cardiomyopathy are another group with heart disease at high risk of perioperative morbidity and mortality. Cardiomyopathy accounted for 13% of the perioperative cardiac arrests in patients with heart disease in the 2011 report from the POCA Registry, and 50% of the patients with

cardiomyopathy who suffered cardiac arrest died as a result of the arrest [3]. In a study by Tabib et al, of the 12 pediatric patients who had unexpected perioperative sudden death, 75% had an undiagnosed cardiomyopathy [92]. An understanding of the different cardiomyopathy subtypes and subtype-specific perioperative management goals is important for decreasing perioperative risk and improving the rate of successful resuscitation after cardiac arrest [93].

The World Health Organization classifies cardiomyopathies into four basic categories: dilated cardiomyopathy (DCM), hypertrophic cardiomyopathy (HCM), restrictive cardiomyopathy (RCM), and arrhythmogenic right ventricular dysplasia (ARVD). The European Society of Cardiology added a fifth unclassified category that included 'left ventricular noncompaction' (LVNC) [94]. Many cardiomyopathies are acquired such as acute myocarditis and those from anthracycline exposure after cancer therapy, or are associated with genetic diseases or syndromes (Table 28.4) [95].

Dilated cardiomyopathy

The most common pediatric cardiomyopathy in children is DCM, accounting for 50% of pediatric cardiomyopathy [96]. Most DCM in children is idiopathic or due to myocarditis, but it can also be associated with neuromuscular disorders, inborn errors of metabolism, or familial predisposition [97]. An important differential diagnosis in infants is anomalous origin of the left coronary artery from the pulmonary artery (ALCAPA), which results in chronic myocardial ischemia as PVR decreases after birth, and presentation may be indistinguishable from DCM. Echocardiography can usually establish the diagnosis of ALCAPA.

DCM is associated with ventricular dilation and depressed function. Infants can present with signs of heart failure including sweating or tiring with feeds, failure to thrive, or decreased activity. Older patients may present with decreased exercise tolerance, abdominal pain, or chest pain. Unfortunately, many early signs are unnoticeable or non-specific, and patients often present with syncope, shock, or cardiac arrest.

On echocardiogram, the ejection fraction (normal >50%) or fractional shortening (normal >35%) indicates the degree of ventricular dysfunction (Fig. 28.10) [98]. The severity of dysfunction is associated with worse perioperative morbidity and mortality. In a retrospective study from Kipps et al, 83% of all complications in patients with cardiomyopathy undergoing non-cardiac surgery occurred in patients with severe myocardial dysfunction, as did the one mortality in the study [99]. This study also found an association between increased anesthetic duration and complications. Strategies to maximize good anesthetic outcomes include a plan for postoperative ICU admission, invasive arterial monitoring to facilitate prompt recognition and treatment of hemodynamic instability, and early administration of vasoactive and inotropic medications [99].

Other important preoperative information includes a history of medications that the patient is taking. Some DCM patients are receiving chronic intravenous milrinone therapy for inotropic support and afterload reduction. Common medications include diuretics, angiotensin-converting enzyme

inhibitors, and β-blockers. A chest radiograph may reveal pulmonary edema or cardiomegaly that may affect ventilation. Other patients may have a biventricular pacemaker that has been placed for cardiac resynchronization therapy, and perioperative device management may be necessary. An increasing number of patients with DCM are now receiving mechanical support with left or biventricular support devices, all of which require anticoagulation. A preoperative discussion with the patient's cardiologist is helpful to determine if the patient's status is optimized or if there have been changes in condition. Preoperative planning for postoperative ICU disposition should also be determined. In addition, ECMO and cardiac transplant candidacy should be part of the multidisciplinary discussion, especially in patients with severe myocardial dysfunction. The benefit of the procedure should also be carefully weighed against the risks associated with the anesthetic [100].

The anesthetic management of the patient with dilated cardiomyopathy should focus on maintaining an adequate coronary perfusion pressure, maintaining adequate preload, avoiding tachycardia, maintaining cardiac contractility, and keeping SVR relatively low so that the severely depressed ventricle can eject [101]. Hemodynamic instability with induction of anesthesia should be anticipated. Because these patients are often receiving diuretic therapy and are nil per os, the hemodynamic response to vasodilation and/or a decrease in myocardial contractility related to anesthetic induction may be pronounced [100]. In fact, according to the largest review of patients with cardiomyopathy undergoing anesthetics, hypotension and/or bradycardia were reported to be the most common causes of arrest on induction of anesthesia [102]. For this reason, emergency drugs and vasoactive agents should be immediately available. For patients with severely depressed myocardial function, initiating low-dose inotropic infusions before induction (e.g. epinephrine 0.02–0.03 μg/kg/min) can be effective in preventing hypotension and low cardiac output. In addition, the placement of a preinduction or peri-induction arterial line can be helpful in this situation.

The selection of induction agent(s) is based on the severity of ventricular dysfunction and on the experience/preference of the anesthesiologist, with the goal of avoiding excessive vasodilation and myocardial depression. The use of midazolam, fentanyl, ketamine, etomidate, propofol, sevoflurane, sodium thiopental, and combinations of these drugs have all been described [99,102]. It is, however, important that the medications be carefully titrated to effect. When these drugs are administered, the patient's circulation time should be considered, and an extended time may be observed until induction occurs. High-concentration sevoflurane or large doses of propofol or sodium thiopental are not tolerated. Ketamine is often selected for its sympathomimetic properties, but it can be a direct myocardial depressant in patients in catecholamine-depleted states. Etomidate has the benefit of preserving myocardial function in DCM patients, but it is associated with adrenal suppression even after a single dose [95].

Hypotension can lead to decreased myocardial perfusion pressure, ischemia, further depressed function, decreased cardiac output, and cardiac arrest. For this reason, hypotension should be anticipated and treated early. Invasive blood pressure monitoring can lead to early recognition and treatment. Inotropic support with milrinone or low-dose epinephrine can be helpful, and vasopressor support with low-dose vasopressin or phenylephrine can counteract the vasodilation associated with the anesthetic and help maintain an adequate myocardial perfusion pressure. However, the ventricle with severe dysfunction will not tolerate excessive SVR.

Hypertrophic cardiomyopathy

According to the Pediatric Cardiomyopathy Registry, HCM comprises 42% of pediatric cardiomyopathies. Most cases are idiopathic or familial, but many are related to inborn errors of metabolism or associated with genetic syndromes. HCM is a leading cause of death in young people [95]. HCM is characterized by marked ventricular hypertrophy, which can be uniform or asymmetrical and focal. Left ventricular hypertrophy leads to a decrease in LV compliance, reduced filling and stroke volume, a propensity for subendocardial ischemia due to the thick ventricular wall, and an increase in myocardial oxygen consumption. Asymmetrical septal hypertrophy results in dynamic LVOTO, and focal hypertrophy can lead to myocardial bridges (present in 28% of patients with HCM) [103].

The hypertrophic ventricle with dynamic LVOTO is a condition with fragile physiology. Myocardial oxygen supply is limited due to the thickened myocardium and occasionally due to the presence of a myocardial bridge, which can decrease the amount of blood flow through the affected coronary artery during diastole. Myocardial oxygen demand is increased due to the hypertrophy of the ventricle. This delicate balance can be upset by normal patient activity. Tachycardia, for example, increases myocardial oxygen demand at the same time that it decreases myocardial oxygen supply by decreasing the time spent in diastole. Significant LVOTO that occurs with exercise can exacerbate the problem by decreasing the systolic and diastolic blood pressure. This can lead to ischemia and sudden cardiac death from dysrhythmia.

Patients with HCM are prescribed exercise restrictions, and they are often treated with β-antagonists, which slow the heart rate and increase the time spent in diastole, improving filling during diastole, and decreasing contractility, limiting LVOTO. Patients with arrhythmias may require automatic internal cardiac defibrillator placement, and some patients require a ventricular septal myectomy to improve symptoms [95,101].

Preoperative assessment should include an echocardiogram (Fig. 28.11). When reviewing the echocardiogram, it is important not to rely on the ejection fraction or fractional shortening alone for indices of the degree of LVOTO. These indices are often normal in patients with HCM. More important in HCM is the thickness of the left ventricle. The two-dimensional left ventricle mass index is reported in grams per meter squared, and it can be very useful to assess the degree of hypertrophy in comparison with normal values [104]. Another method to express the left ventricle thickness is the Z-score – one Z-score is one standard deviation above or below a size- or age-specific population mean for a given parameter [105]. An electrocardiogram (ECG) should be obtained and examined for signs of ischemia, and history of dysrhythmia, syncope, or aborted sudden death should be investigated.

The hemodynamic goals when anesthetizing a patient with HCM should be to maintain ventricular preload, maintain SVR (coronary perfusion pressure), avoid tachycardia, and avoid increasing LVOTO. LVOTO is increased with tachycardia, endogenous or exogenous catecholamine exposure, and hypovolemia. Tachydysrhythmias and specifically rhythms without an atrial contraction (atrial fibrillation, atrial flutter) are poorly tolerated due to poor filling of a non-compliant left ventricle.

Preoperative planning for postoperative ICU disposition should be determined. In addition, ECMO and transplant candidacy should be part of the multidisciplinary discussion, especially in patients with severe dysfunction. The benefit of the procedure should be carefully weighed against the risks associated with the anesthetic [100]. Due to the propensity for sudden death and poorly tolerated dysrhythmias, appropriately sized defibrillation pads or paddles should be available. Emergency drugs should be prepared, and infusions of esmolol and a vasoconstrictor (typically phenylephrine or vasopressin) should be ready for administration. The placement of a preinduction or peri-induction arterial catheter should be considered.

The primary goals for anesthesia induction with LVOTO are to maintain SVR and avoid tachycardia. This can be accomplished with a number of agents including midazolam, fentanyl, etomidate, ketamine, propofol, sodium thiopental, and sevoflurane, but they must be titrated in slowly and carefully. Caution should be taken when using propofol, sodium thiopental, and sevoflurane as these drugs are associated with a decrease in preload and SVR. Decreases in blood pressure should be treated quickly with a bolus of phenylephrine or vasopressin to avoid ischemia and cardiac arrest. Infusions of these vasoconstrictor can be very effective. An esmolol infusion can be initiated to improve coronary perfusion and filling and to decrease LVOTO. These vasoactive agents may also be needed throughout the anesthetic to maintain stability.

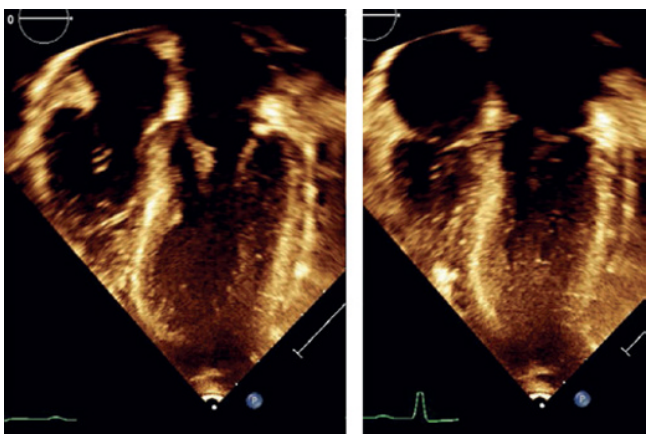

Figure 28.11 Transthoracic echocardiogram of hypertrophic cardiomyopathy. Both images are subcostal four-chamber views demonstrating a very thickened left ventricular free wall and interventricular septum, which causes left ventricular outflow tract obstruction. *Source*: Reproduced from Lee et al [98] with permission of Wolters Kluwer.

Pompe's disease, glycogen storage disease type II, is associated with HCM in early infancy. This disease was uniformly fatal until 1995, when enzyme replacement therapy (ERT) became available. With the advent of ERT, these high-risk patients often require multiple anesthetics for central line placement and for multiple muscle biopsies to follow the response to the enzyme replacement. The only cardiac arrest in the series of 13 anesthetics reported by Ing et al was shortly after an inhaled induction with sevoflurane followed by a continuous infusion of propofol for maintenance. The cardiac arrest was attributed to myocardial depression from the inhaled agent and hypotension from a propofol-induced decrease in SVR and hypovolemia [104].

It also should be noted that the sympathectomy associated with neuraxial anesthesia may also lead to ischemia and cardiac arrest in LVOTO patients. Some authorities discourage the use of spinal anesthesia in patients with hypertrophic obstructive cardiomyopathy [106]. However, if the sympathectomy associated with neuraxial anesthesia is anticipated and treated, spinal anesthesia can be performed safely [107]. Subsequent to these case reports there have been additional reports of successful epidural and spinal anesthetics. Although there are no reports in the pediatric literature, neuraxial anesthesia can be performed successfully with careful maintenance of preload and SVR.

As with any anesthetic, unexpected intraoperative events in patients with LVOTO can occur, such as anaphylaxis. Yee et al reported the case of an adult with HCM who suffered an anaphylactic reaction soon after induction. Unfortunately, the hypotension and tachycardia associated with the reaction can quickly cause a cardiac arrest in a patient with HCM. In addition, epinephrine, usually given to inhibit mast cell degranulation, cause bronchodilation, and support the blood pressure, is not a drug that is well-tolerated in HCM. The authors describe a long, unsuccessful resuscitation that ultimately resulted in emergent cannulation for bypass [108].

Postoperatively, it is also important that the patient with HCM maintains preload. Inadequate oral intake, fluid shifts, bleeding, or postoperative nausea and vomiting can lead to hypovolemia which in turn can lead to increased LVOTO, hypotension, ischemia, and cardiac arrest. Postoperative monitoring and level of care should reflect this serious potential risk.

Restrictive cardiomyopathy

Restrictive cardiomyopathy comprises 2–5% of all pediatric cardiomyopathies. This cardiomyopathy is associated with endomyocardial fibrosis, decreased myocardial compliance, and poor ventricular filling. Over time, increased left ventricular end-diastolic pressure leads to increased left atrial pressure, increased pulmonary venous pressure, and increased PVR.

Patients with RCM often present late with signs of reactive airway disease, decreased exercise tolerance, syncope, or thromboembolism, and by the time of presentation, PVR is already 10–15 Woods units/m^2 [93,98,101,109]. Echocardiographic findings associated with RCM include small non-compliant ventricles and massively dilated atria (Fig. 28.12) [98].

Hemodynamic goals when anesthetizing a patient with RCM are chosen with the aim of preserving cardiac output. Neither tachycardia nor bradycardia is well tolerated in these patients. Tachycardia leads to poor filling with a non-compliant ventricle, and bradycardia leads to a decrease in cardiac output due to a relatively fixed stroke volume. Preload and contractility should be maintained. Care should be taken to avoid further increases in PVR, and in the presence of increased PVR, afterload should be maintained (see earlier section on PH) [93,101].

Arrhythmogenic right ventricular dysplasia/cardiomyopathy

Arrhythmogenic right ventricular dysplasia/cardiomyopathy (ARVD/C) is an uncommon type of cardiomyopathy. It is associated with the fibrofatty infiltration of the right ventricle, arrhythmias and abnormal electrocardiographic findings, right ventricular failure, and occasionally biventricular failure [101]. This condition is associated with unexplained and unanticipated perioperative death. In a series of 50 autopsies performed on patients who suffered unexplained perioperative death, 36% were found to have ARVD/C. These patients were undergoing uncomplicated procedures. Four of these patients experienced cardiac arrest on induction of anesthesia, nine arrested during the procedure, and five arrested within 2 h of the surgery [92]. There are additional case reports of patients who suffered cardiac arrest and died perioperatively who were also found to have ARVD/C on autopsy [110–112]. For this reason, it is important to have an understanding of the disease and its course.

The clinical presentation of ARVD/C is often related to arrhythmia or ventricular failure. Common presentations include palpitations, syncope, atypical chest pain, dyspnea, right ventricular failure, arrhythmia, or sudden cardiac death. The four phases of ARVD/C include: (1) the "concealed" phase with subtle right ventricular abnormalities; (2) "overt arrhythmia" with symptomatic ventricular arrhythmias; (3) isolated right heart failure; and (4) biventricular failure that can mimic dilated cardiomyopathy [113].

Electrocardiographic findings in patients with ARVD/C include sinus rhythm with a QRS >110 ms in lead V1, an epsilon wave which is a terminal deflection within or at the end of the QRS in leads V1–V3, T-wave inversion in leads V1–V3, complete or incomplete right bundle branch block (RBBB), or in the absence of RBBB, selective prolongation of the QRS in leads V1–V3 compared with V6 (Fig. 28.13) [114].

Therapy for ARVD/C includes treatment of arrhythmia and treatment for cardiac failure. Arrhythmia can be treated with pharmacological antiarrhythmics, commonly sotalol or

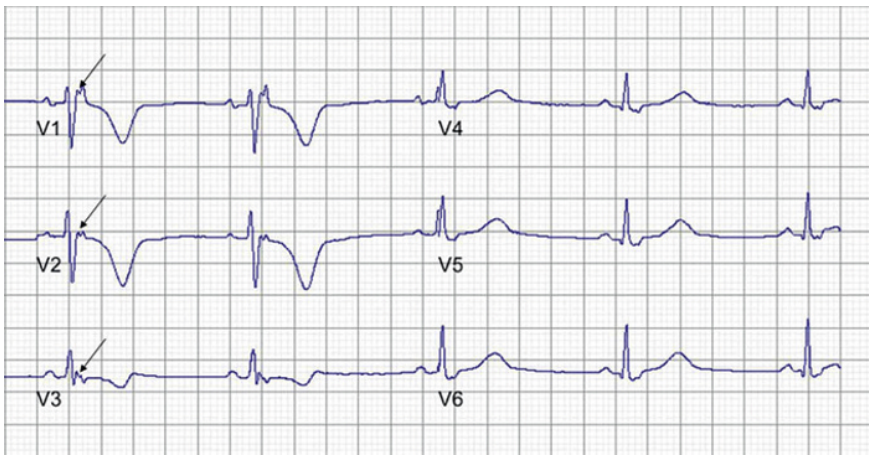

Figure 28.13 ECG in arrhythmogenic right ventricular dysplasia/cardiomyopathy. The precordial leads of an ECG are shown from a 44-year-old woman that were recorded during regular sinus rhythm, with an epsilon wave (arrow) in leads V1–V3. The ECG shows a right bundle branch block pattern. *Source*: Reproduced from Kies et al [114] with permission of Elsevier.

amiodarone. Catheter ablation can be used for patients with inducible, monomorphic ventricular tachycardia, and placement of an automatic implantable cardiac defibrillator is reserved for those at high risk for unstable ventricular tachycardia [115]. Right ventricular exclusion surgery during which a total cavopulmonary anastomosis (Fontan) is constructed and the right ventricular wall is resected has also been described [116–118]. Exercise restriction is also a component of therapy [119]. Heart transplantation is indicated for intractable arrhythmias or end-stage cardiac failure [115].

As ARVD/C may be clinically silent, special attention should be given to a history of syncope, family history of sudden cardiac death or heart failure, as well as the preoperative ECG. The presence of findings associated with ARVD/C may indicate the need for an echocardiogram.

In patients with known ARVD/C, successful anesthetics have been reported [120,121]. All antiarrhythmics should be continued in the perioperative period. In addition, appropriate defibrillator pads should be available. Strategies for improving anesthetic outcome also include the avoidance of adrenergic agents including epinephrine, noxious stimuli and sympathetic stimulation, and large doses of bupivacaine. For patients with ventricular dysfunction, transesophageal echocardiography and invasive arterial blood pressure monitoring may be helpful. Pulmonary artery catheters are relatively contraindicated due to the arrhythmogenic potential and possible perforation of the abnormal ventricular wall [101,115,122]. The avoidance of the tachycardia associated with pancuronium or excessive anticholinergic administered with reversal of neuromuscular blockade may also be considered [101]. Implanted pacemakers/defibrillators should be interrogated, and managed with the input of the patient's cardiologist.

KEY POINTS: CARDIOMYOPATHY

- The anesthesiologist should be familiar with the different types of cardiomyopathies, and know their anesthetic implications
- Anesthetic induction with dilated cardiomyopathy should focus on maintaining contractility and an adequate coronary perfusion pressure
- Goals for the induction of the patient with hypertrophic cardiomyopathy include maintaining SVR and avoiding tachycardia

Special scenarios

Anesthesia and sedation for diagnostic imaging

Patients with cardiovascular disease often require magnetic resonance imaging (MRI) and computed tomography (CT) examinations for diagnosis and planning, and many patients require anesthesia or sedation to obtain these studies. As in other anesthetizing locations, these patients are at a higher risk of adverse events [5,123]. Hypotension, cardiac arrest, tachyarrhythmias, and shunt occlusion have all been described [5,46,123,124]. However, with careful preparation and planning, some of the risks can be reduced [124,125].

The MRI and CT scanners are often located in a remote location from the operating rooms. This often leaves the anesthesiologist without additional assistance if the patient becomes unstable. This risk can be mitigated by assigning two anesthesiologists to the case for high-risk patients, if possible [124]. Other strategies include anesthetic induction and intubation in the ICU, an operating room, or a procedure room that is in close – to skilled assistance or a surgical team before traveling to a remote location. For ICU patients, a full hand-off report should take place and in some cases the ICU team may be available to transport with the anesthesia care team for high-risk patients, as the risk of adverse events is higher in hospitalized patients and those requiring general anesthesia [123]. Some institutions are building MRI suites into their heart centers so the location is no longer remote.

The MRI environment is often cold, and access to the patient is limited once they are positioned under the MRI coil and in the bore of the scanner. The physiological monitor is the primary contact with the patient, although remote cameras are now in use in many MRI suites. The anesthesiologist is often in the control room with the technologist during the scan, quite far from the patient. When two anesthesia care providers are present, one can be in the room with the patient, adjusting the anesthetic and monitoring more closely, while the other confers with the technologist and the radiologist about the scan and need for breath holding, heart rate control, and other maneuvers to improve image quality [124]. It is possible to monitor invasive arterial and central venous pressures during MRI, although one must confirm that the pressure monitoring cables for the MRI monitor is compatible with the patient transducers from the ICU.

Current disadvantages of cardiac MRI are the multiple sequences that are often necessary, and requirements for breath holding and signal averaging over a few cardiac cycles to reduce motion artifacts due to respiration, which necessitate general anesthesia for younger children [126]. Fortunately, faster acquisition techniques, ECG-gated signal acquisition, and reconstruction strategies are being developed that can decrease scanning times from 60 to 10 min and obviate the requirement for breath holding [127].

Dynamic contrast-enhanced lymphatic angiography is also being employed in patients with SV physiology to identify lymphatic abnormalities suitable for catheter intervention [126]. This study involves the injection of gadolinium into inguinal lymph nodes, with MRI image acquisition. This technique can be used to guide percutaneous thoracic duct embolization to treat chylous effusion or embolization of pulmonary lymphatic vessels to treat plastic bronchitis [128].

CT is often used for imaging the heart and extracardiac vessels, and airway. Because of the brevity of the scan (often 30 s to 2–3 min), many patients do not require anesthesia or sedation for CT imaging. Unfortunately, CT involves ionizing radiation. Newer scanners with higher gantry rotation speeds, helical scanning, and multiple dectectors decrease scan times and lower the radiation dose [129]. When anesthetic risk is high, CT without sedation may yield similar information as MRI. CT alone is not without risk, however. A serious reaction to intravenous contrast can result in cardiac arrest in a patient with fragile physiology [22]. CT for coronary angiography can require general anesthesia, heart rate control, and breath holding for image clarity in patients who have higher heart

rates (>120 bpm) and who are unable to suspend respiration. Prior discussion with the radiologist is advised, so that the requirements for successful images are met.

There are some misconceptions about diagnostic imaging and cardiac patients. First, many ordering physicians are not aware that the patient may require general anesthesia for the study, and they do not have a concept of the risk associated with anesthetizing these patients. For high-risk patients, it is worth a discussion with the ordering physician and the radiologist to determine if the risk of the anesthetic outweighs the benefit of the test, or if there is another test (e.g. CT, echocardiography) that will yield the same or similar information without requiring anesthesia. In addition, the risk for an anesthetic for imaging in high-risk patients is not less because it is "only" an MRI. For SV patients with systemic to pulmonary artery shunt or equivalent, admission to the hospital for intravenous fluids preoperatively is described to decrease the risk of instability on induction or shunt occlusion and the risk of prolonged fasting with an at-risk circulation [5,46]. Similar considerations should be given to other at-risk physiology such as LVOTO, HCM, or unrepaired tetralogy of Fallot. Postanesthetic care should be guided by the patient's physiology, not by the procedure performed [40]. At Texas Children's Hospital, outpatient SV patients are admitted for recovery in the heart center recovery unit for a planned 6–8 h of observation, instead of the radiology postanesthesia care unit. After a prolonged observed recovery period, it is determined whether the patient can be discharged home or should be admitted to the hospital for ongoing monitoring.

Anesthetic options for diagnostic imaging vary. Some older patients do well with midazolam only. Others prefer light sedation and MRI-compatible video goggles ("midazolam and a movie"). Options for general anesthesia or deep sedation include propofol infusion or propofol-ketamine infusion. General anesthesia with an inhalational agent is also a possibility, either with a supraglottic airway device or endotracheal tube. The potential need for breath holds should be discussed with the radiologist before anesthetizing the patient. Techniques for breath holding include the use of muscle relaxant, hyperventilation before the breath hold, or a bolus of propofol. Patient physiology should be considered when selecting a technique for breath holding, as hyperventilation can lead to coronary hypoperfusion via steal in shunted patients. In addition, propofol boluses in patients with other high-risk lesions can lead to hypotension, ischemia, and cardiac arrest.

Strategies to avoid sedation have both the benefit of avoiding the anesthetic risk associated with cardiac disease and avoiding the potential for anesthetic neurotoxicity [130]. "Feed, swaddle, and sleep" techniques where the patient is fasted for 4 h, fed by the caregiver, swaddled, and placed in a vacuum bag immobilizer can be used successfully in neonates and infants up until 6 months [131,132]. Of course, care should be taken when fasting vulnerable patients. Certified Child Life Specialists (CCLSs) are often able to help allay anxiety regarding the scan, and with the use of mock scanners, toy scanners, video goggles, and other modalities, many more children are able to avoid anesthesia or sedation (Table 28.5) [133–135]. These strategies involve the collaborative efforts of the radiologist, anesthesiologist, technologist, CCLS, and the family [135]. The scan should be planned by the radiologist to prioritize the sequences that answer the clinical question, in the event that the patient is unable to complete the scan [131]. They may also use new techniques in acquisition and processing and optimize MRI protocols to decrease the amount of time on the scanner [136].

KEY POINTS: ANESTHESIA AND SEDATION FOR DIAGNOSTIC IMAGING

- The MRI and CT scanners are located in remote locations in many hospitals; this necessitates careful preparation and planning when caring for high-risk patients
- Dynamic contrast-enhanced lymphatic angiography is being used to map lymphatic circulation and to plan interventions in patients with single ventricle physiology
- General anesthesia and sedation for imaging carries the same risk as for other procedures; it is not "just an MRI"
- Discussion with the radiologist regarding the requirements for successful imaging including breath holds or heart rate control should take place prior to the anesthetic

Table 28.5 Alternatives to pediatric sedation in magnetic resonance (MR) imaging preparation

Alternative	Definition	Most effective age range*
Mock scanner	Replica of MR imaging unit used for practice with a child before an MR examination	3–8 years
MR-compatible audiovisual system	MR-safe headphones and goggles allow the child to watch a movie during the scan	3–10 years
Feed–sleep manipulation	Keeping the child awake during the day, with examinations scheduled at night; fasting until just before the examination; melatonin administration	Neonates to 4 years
Play therapy	Child life specialist/play specialist conducts play sessions with the child for examination preparation	4–12 years
Incubators/immobilizers	The infant is placed in a Med-Vac vacuum bag for immobilization and sleep promotion or in an MR-compatible incubator with built-in head coil for sleep promotion	Neonates
Photo diary	Before the appointment, the family receives a photo diary to read to the child explaining the MR imaging procedure	7–12 years
Sucrose solution	An oral sucrose solution is placed on a pacifier and given to the infant for preprocedural calming	Neonates
Guided imagery	The child listens to a relaxation audiorecording with guided imagery during the examination	4–8 years

Anesthesia for airway procedures

Airway procedures are quite common in patients with CHD due to congenital or acquired airway abnormalities. In fact, in a retrospective study of 162 neonates undergoing bronchoscopy at a tertiary care center, 30.2% of the neonates had cardiac defects. The common findings in these patients included abnormal bronchi, bronchomalacia, tracheal stenosis, complete tracheal rings, and vascular rings [137]. Direct laryngoscopy and bronchoscopy can be diagnostic, and it can also be therapeutic (to remove mucous plugs or clots, dilate the trachea, laser treatment of subglottic stenosis, or remove bronchial casts).

Patients undergoing cardiac surgery are also at risk for subglottic stenosis and vocal fold immobility. This may be due to coexisting syndromes that can be associated with subglottic narrowing such as trisomy 21 or velocardiofacial syndrome [138,139] or it may be related to hypoperfusion and mucosal injury due to the CHD or repair in association with prolonged tracheal intubation [140–143]. Recurrent laryngeal nerve injury is a well-known complication of surgery on the aortic arch and its branches. Kruse et al report a 0.7% incidence of subglottic stenosis in infants and children undergoing heart surgery with bypass; subglottic stenosis was associated with younger age, prolonged bypass time, and prolonged mechanical ventilation [144]. Balloon dilation laryngoplasty (BDL) is one treatment for subglottic stenosis that can help avoid tracheostomy placement (Fig. 28.14). Collins et al report the use of BDL on patients with subglottic stenosis and CHD. In four of five patients, the need for tracheostomy was avoided, with only one patient requiring tracheostomy and laryngotracheal resection [143]. Laser treatment of subglottic stenosis requires adhering to all necessary precautions such as utilizing the lowest possible FiO_2, eye protection for patient and providers, wet towels around the face and head of the patient, and preparations to address an airway fire. Chapter 34 reviews laser bronchoscopy and laryngoscopy in detail.

Another described use of direct laryngoscopy and rigid bronchoscopy in the population with CHD is for the evaluation and treatment of plastic bronchitis, usually in patients with Fontan physiology. Plastic bronchitis usually presents with coughing and respiratory distress. Rigid bronchoscopy and removal of the proteinaceous bronchial cast is the treatment (Fig. 28.15). In a case series of three patients with Fontan physiology and plastic bronchitis, one recovered fully after one bronchoscopy, and two required

multiple bronchoscopic procedures over a week with ECMO support for oxygenation [145].

Providing anesthetic care for an airway procedure in patients with CHD can be challenging due to the physiology of the cardiac lesion and the procedural requirements. Direct laryngoscopy and bronchoscopy requires a deep plane of anesthesia, as it is quite stimulating. Topical anesthesia in the form of atomized or nebulized local anesthetic is very effective; attention must be paid to not exceed the maximum tolerated doses of local anesthetic. For some indications, it is important that the patient be spontaneously ventilating, as well. At other times, the patient will need periods of apnea. Prior to anesthetizing the patient, it is important to have a discussion with the otolaryngologist about what conditions are needed for the study. It is also necessary to communicate how those conditions may or may not be possible with the patient's cardiorespiratory needs. In addition, it should be verified that all equipment needed for the procedure is in the operating room and assembled (e.g. the bronchoscope components) prior to anesthetizing the patient.

The importance of PVR has been discussed throughout this chapter for many lesions. It is especially important in unpalliated or unrepaired patients, patients with shunt or ductal stent physiology, and patients with Fontan physiology. During the anesthetic for an airway procedure, PVR changes considerably. Often prior to the laryngoscopy, the patient is preoxygenated at the same time that the anesthetic is deepened. This may increase risk for systemic and coronary hypoperfusion from increased pulmonary blood flow. Then, during the procedure, the patient may hypoventilate or become apneic with an associated increase in PVR and decrease in pulmonary blood flow. Planning for and recognition of extremes in PVR is essential in maintaining stability. Overzealous preoxygenation can result in myocardial ischemia and cardiac arrest, so it should be approached with caution and close attention paid to the systemic blood pressure and ST segment changes on ECG. Extended laryngoscopy and bronchoscopy can result in rapid desaturation and a precipitous decrease in pulmonary blood flow. The patient may not be able to tolerate long periods of apnea. Ventilation by facemask or endotracheal tube may be necessary between visualizations to allow the patient time to resaturate and ventilate. Effective communication with the otolaryngologist is essential.

Patients with Fontan physiology are also at risk for instability with airway examination due to dependence on passive pulmonary blood flow to maintain cardiac output. Increases in PVR with long periods of apnea may result in a decrease in filling of the systemic ventricle and a decrease in cardiac output. Instability may require volume resuscitation, inotropic support, limitation of apnea, and even ECMO support [145].

Laryngoscopic and bronchoscopic examinations in patients with pulmonary hypertension can lead to a pulmonary hypertensive crisis and cardiac arrest. Any increase in PVR that is associated with hypoventilation, apnea, hypoxemia, or inadequate anesthesia during laryngoscopy can lead to prompt right heart failure and cardiac arrest. Multidisciplinary discussion should take place prior to this type of procedure, and careful preparations should be made to prevent and treat pulmonary hypertensive crisis and cardiac arrest.

It is also challenging to provide a deep anesthetic in this patient population. As noted above, topical anesthesia provided by the surgeon is very effective in limiting the need for a deep plane of anesthesia. Many patients have depressed cardiac function or physiology that does not tolerate a significant decrease in SVR. There is no ideal anesthetic for these types of procedures. Caution should be taken when delivering high-concentration inhalational agent or propofol to these patients. Ketamine or remifentanil can be useful adjuncts. Anesthetic agents should be carefully titrated, and resuscitative medications should be readily available.

It is also important to note that airway manipulation by the anesthesiologist and care team may also result in the same perturbations in PVR and SVR. Limiting the duration of laryngoscopy and awareness of the PVR and SVR are critically important. Cardiac arrest during laryngoscopy has been reported [28].

KEY POINTS: ANESTHESIA FOR AIRWAY PROCEDURES

- Communication between the otolaryngologist and the anesthesiologist is imprtant for sharing information about the planned procedure and how the patient's physiology will need to be managed
- Pulmonary vascular resistance can rapidly increase during an airway examination; pausing to oxygenate and ventilate may be required
- Patients with Fontan physiology can require direct laryngoscopy and bronchoscopy for the removal of bronchial casts

Anesthesia for laparoscopic surgery

Laparoscopic surgery in children can result in shorter length of hospital stay, better pain control, and shorter time to feeding tolerance compared with open procedures [146–149]. There are several small series reporting the safe management of laparoscopic fundoplication and gastrostomy tube placement in pediatric patients with cardiac disease [44,45,150,151], and two recent cohort studies using data from the American College of Surgeons' National Surgical Quality Improvement Program – Pediatrics ' report some benefits of laparoscopic approaches including a shorter postoperative length of stay [152,153], fewer complications [152], and fewer transfusions [153] compared with the open approach in patients with CHD. However, in patients with major or severe CHD, the laparoscopic approach was comparable to the open approach in terms of morbidity and mortality [153]. There is also evidence that the severity of the CHD correlates with morbidity and mortality after laparoscopic procedures [154]. Concerns remain regarding the effects of insufflation and pneumoperitoneum on patients with reduced cardiorespiratory reserve [154,155].

Laparoscopic surgery requires the creation of a pneumoperitoneum by insufflating carbon dioxide into the abdomen. In healthy children, insufflation to 6 and 12 mmHg results in increases in SVR and mean arterial pressure. Insufflation to 12 mmHg is also associated with a decrease in

cardiac index of 13% and a decrease in left ventricular systolic function on echocardiography. This suggests that patients with impaired cardiovascular reserve may not tolerate the change in intra-abdominal pressure. In addition, the release of the pneumoperitoneum at the end of the procedure may result in a decrease in SVR and mean arterial pressure [156]. An increase in intra-abdominal pressure during laparascopy can affect ventilation, causing atelectasis, reducing functional residual capacity, and increasing intrathoracic pressure and mean airway pressure. Absorption of CO_2 into the blood can also result in hypercarbia and an increase in PVR. Carbon dioxide embolism may also occur limiting pulmonary blood flow or resulting in paradoxical embolism [52].

Due to concerns about reflux, aspiration, and failure to thrive, patients who are between the first and second stages of SV palliation are often scheduled for laparoscopic fundoplication and gastrostomy tube placement. Insufflation-related decreases in SVR, mean arterial pressure, cardiac index, and systolic function that healthy children tolerate quite easily may result in hemodynamic instability and cardiac arrest. Increases in CO_2 absorption can lead to increases in PVR. High PVR coupled with decreased systemic pressure can result in reduced flow through a systemic-to-pulmonary shunt, shunt thrombosis, and cardiac arrest [44,157,158].

Although these serious sequelae can occur, the successful management of such patients is possible. First, insufflation pressures should be limited to 8–12 mmHg. Invasive arterial pressure monitoring is helpful for rapid recognition and treatment of hemodynamic instability with volume or vasoactive infusion to improve blood pressure or cardiac function. Arterial blood gases should be analyzed frequently, and ventilation should be adjusted based on the $PaCO_2$ [44,45]. End-tidal CO_2 is not a reliable reflection of $PaCO_2$ in SV patients undergoing laparoscopic surgery [157]. Extubation usually takes place within 24 h after the procedure, and most patients should be monitored postoperatively in an ICU [44,45]. A standardized perioperative management strategy is helpful for providing a framework for better outcomes.

Laparoscopic surgery in patients with Fontan physiology may also be a challenge. The combination of the effects of positive pressure ventilation and insufflation of the abdomen may affect the transpulmonary gradient that promotes pulmonary blood flow in the patient with Fontan physiology. The transpulmonary gradient is the difference between the central venous pressure and the left ventricular end-diastolic pressure (LVEDP). Decreases in central venous pressure that can be seen with tracheal intubation, positive pressure ventilation, and venodilation with anesthetic induction and airway management, and increases in LVEDP that can be seen with insufflation (increased systemic arterial pressure, decreased cardiac index, and decrease contractility), may significantly decrease the amount of pulmonary blood flow and systemic ventricular filling in the patient with Fontan physiology. In addition, CO_2 absorption may increase the PVR, further limiting pulmonary blood flow and systemic ventricular filling. Carbon dioxide embolus may also be poorly tolerated, and paradoxical embolus through a fenestration remains a concern [52,59].

Although challenging, laparoscopic procedures in patients with Fontan physiology have been described. Preservation of a reasonable transpulmonary gradient by augmenting preload, minimizing high ventilator pressures, preserving myocardial contractility, and keeping insufflation pressures below 12 mmHg is advised. Invasive arterial blood pressure monitoring is helpful for recognition and treatment of hemodynamic compromise [52,59]. Arterial blood gas monitoring ($PaCO_2$) may be used to guide the management of ventilation and PVR. Intraoperative transesophageal echocardiography can also help guide management. Resumption of spontaneous ventilation and extubation at the end of the procedure preserves the transpulmonary gradient, pulmonary blood flow, and cardiac output. Postoperative disposition in the ICU may be indicated.

Patients with other cardiac lesions may have derangements in physiology with laparoscopic procedures. Patients who require a higher mean arterial blood pressure for coronary perfusion include those with LVOTO, coronary abnormalities, and HCM. These patients may tolerate insufflation quite well as it increases SVR and mean arterial pressure. However, the decrease in these indices with the release in the pneumoperitoneum may result in sudden coronary insufficiency and cardiac arrest [23]. These changes should be anticipated, release of the pneumonperitoneum should be slow and gradual, and concurrent treatment of the SVR should be considered.

KEY POINTS: LAPAROSCOPIC SURGERY

- Laparoscopic procedures can be successfully performed in patients with CHD; an understanding of the patient anatomy and physiology is important
- Insufflation pressures should be limited to 8–12 mmHg in patients with CHD
- The hemodynamic effects of insufflation include an increase in systemic vascular resistance, a decrease in cardiac output, and a decrease in contractility; the release of the pneumoperitoneum has the opposite effects

Antibiotic prophylaxis for infective endocarditis

Patients with CHD are at risk for infective endocarditis. Approximately 35–60% of children with IE have CHD [159]. Rushani et al reported that the children with CHD who were found to be at higher risk of infective endocarditis include cyanotic CHD lesions, left-sided lesions, and endocardial cushion defects, and that the relative risk of developing infective endocarditis is elevated during the 6 months (the length of time it takes prosthetic material to endothelialize) after cardiac surgery and in children <3 years of age [160].

The American Heart Association (AHA) guidelines for the prevention of infective endocarditis were updated in 2007 to restrict the groups of patients for whom antibiotic

prophylaxis was indicated before invasive procedures. The revision in the guidelines were due the fact that: (1) infective endocarditis is more likely to result from random bacteremia, not bacteremia related to a medical procedure; (2) prophylaxis probably prevents an exceedingly small number of cases of infective endocarditis; (3) the risk of antibiotic-associated adverse events exceeds the benefit of prophylaxis; and (4) maintenance of good oral health is more effective at reducing the incidence of bacteremia from daily activities than prophylaxis for dental procedures is for reducing infective endocarditis. The high-risk groups who should receive antibiotic prophylaxis for infective endocarditis are displayed in Box 28.2. Antibiotic regimens for dental procedures are displayed in Table 28.6. For patients undergoing respiratory tract procedures that involve the incision of the respiratory tract mucosa, prophylaxis should be given. For patients undergoing genitourinary or gastrointestinal procedures, infective endocarditis prophylaxis is not recommended. However, if the patient already has a genitourinary or gastrointestinal tract infection, it is reasonable to include an agent that is active against enterococci. Patients with the conditions in Box 28.2 with infected skin, skin structures, or musculoskeletal tissue might also receive antibiotic coverage against staphylococci and β-hemolytic streptococci [161].

Box 28.2: Cardiac conditions associated with the highest risk of adverse outcome from endocarditis for which prophylaxis with dental procedures is reasonable

- Prosthetic cardiac valve or prosthetic material used for cardiac valve repair
- Previous infective endocarditis
- Congenital heart disease (CHD):*
  Unrepaired cyanotic CHD, including palliative shunts and conduits
  Completely repaired congenital heart defect with prosthetic material or device, whether placed by surgery or by catheter intervention, during the first 6 months after the procedure†
  Repaired CHD with residual defects at the site or adjacent to the site of a prosthetic patch or prosthetic device (which inhibit endothelialization)
- Cardiac transplantation recipients who develop cardiac valvulopathy

*Except for the conditions listed above, antibiotic prophylaxis is no longer recommended for any other form of CHD.
†Prophylaxis is reasonable because endothelialization of prosthetic material occurs within 6 months after the procedure.

KEY POINTS: ANTIBIOTIC PROPHYLAXIS FOR INFECTIVE ENDOCARDITIS

- Good oral hygiene is required for the prevention of infective endocarditis
- The risk of developing infective endocarditis is elevated during the 6 months after cardiac surgery; it takes 6 months for prosthetic material to endothelialize
- The 2007 AHA guidelines restricted the groups of patients for whom antibiotic prophylaxis is required before dental procedures

Table 28.6 Antibiotic regimens for dental procedures

Situation	Agent	Regimen: single dose 30–60 min before procedure	
		Adults	Children
Oral	Amoxicillin	2 g	50 mg/kg
Unable to take oral medication	Ampicillin	2 g IM or IV	50 mg/kg IM or IV
	OR		
	Cefazolin or ceftriaxone		
		1 g IM or IV	50 mg/kg IM or IV
Allergic to penicillins or ampicillin – oral	Cephalexin*†	2 g	50 mg/kg
	OR		
	Clindamycin		
	OR		
	Azithromycin or clarithromycin		
		600 mg	20 mg/kg
		500 mg	15 mg/kg
Allergic to penicillins or ampicillin and unable to take oral medication	Cefazolin or ceftriaxone†	1 g IM or IV	50 mg/kg IM or IV
	OR		
	Clindamycin		
		600 mg IM or IV	20 mg/kg IM or IV

* Or other first- or second-generation oral cephalosporin in equivalent adult or pediatric dosage.
† Cephalosporins should not be used in an individual with a history of anaphylaxis, angioedema, or urticaria with penicillins or ampicillin.

Perioperative planning

Multidisciplinary discussion

The care of the patient with cardiac disease undergoing a noncardiac procedure is a collaborative effort involving the cardiologist, cardiac surgeon, anesthesiologist, intensivist, pulmonologist (if applicable), and the proceduralist (surgeon, radiologist, gastroenterologist, etc.). This group should confer about perioperative planning including preprocedural and postprocedural disposition, determination of ECMO candidacy, and arrangement for ECMO availability. In addition, concerns about the risks, benefits, and timing of the procedure should take place.

Preoperative concerns

Many of these fragile patients do not tolerate a long fasting time due to concerns about hypovolemia and instability on induction of anesthesia. It has been discussed previously in this chapter that patients who are between the first and second stages of SV palliation (pre-SCPA) are at risk for instability, shunt thrombosis, and death [5,46]. Patients with LVOTO are also at a higher risk of instability and cardiac arrest on induction of anesthesia, and care should be taken to prevent hypovolemia. It is recommended that these patients are encouraged to drink clear fluids until 2 h prior to the anesthetic, and hospital admission prior to the procedure for management of the fasting period and intravenous fluids should be a serious consideration for high-risk patients. Procedures should also be scheduled early in the day to minimize fasting time. Angiotensin-converting enzyme inhibitors and diuretics should be held prior to the procedure. Antiarrhythmic medications and β-blockers should be continued.

Postoperative disposition

Before the procedure, the postoperative disposition of the patient should be planned. For high-risk physiology, an ICU bed should be requested. For other patients, a regular ward bed should suffice. High-risk patients rarely undergo outpatient procedures. If discharge home is considered, patients should be observed for at least 6–8 h after the procedure. Only if the patient is fully recovered from the effects of anesthesia, with intravascular volume status optimized, and hemodynamic parameters, respiration, and oxygen saturation at baseline without supplemental oxygen, should discharge home be allowed.

Anesthesiologist selection

These patients should be cared for by anesthesiologists who have a thorough understanding of the anatomy and physiology of CHD and who feel comfortable managing them. This may include pediatric anesthesiologists, pediatric cardiac anesthesiologists, and pediatric anesthesiologists with consultation with a pediatric cardiac anesthesiologist. Some pediatric programs have guidelines that specify which patients are assigned a pediatric cardiac anesthesiologist, such as preoperative and pre-SCPA SV patients. Institutional requirements vary widely.

Location and time of day

In general, high-risk cardiac patients should not be anesthetized in office settings or in ambulatory surgical centers where there is no access to invasive monitoring, subspecialty pediatric care, intensive care, and ECMO support. For some high-risk patients, procedures in remote locations like the gastroenterology suite may be moved to an operating room where more equipment, resources, and personnel are available. These patients should ideally be scheduled during regular daytime working hours, and as early in the day as possible.

Consent

Preoperative discussion with the parent or guardian should include the anesthetic plan, the risks associated with the procedure, and the implications of the cardiac disease. Discussion of interventions if the patient is unstable or has a cardiac arrest may be appropriate, e.g. ECMO support. The family should be given ample time to ask questions, and it is possible that multiple disciplines should be involved.

Preparedness and chance

A keen understanding of the anatomy, physiology, and "pitfalls" of each cardiac lesion is necessary. Having a plan for the management of predicted intraoperative issues, like hypotension in a shunted SV undergoing MRI or cardiac arrest during induction in a patient with Williams syndrome, is very important. The entire operating room team should be briefed on the patient's disease and potential intraoperative events prior to proceeding to the procedure room. It can also be helpful to review cognitive aids for the treatment of common dysrhythmias and events prior to induction in a patient with a history of them.

Unexpected events occur in patients with cardiac disease. Anaphylaxis can occur. Hemodynamic and physiological changes due to the operative procedure can result in cardiac arrest. Paradoxical air or CO_2 embolus can lead to coronary ischemia. A patient can experience sudden catastrophic blood loss. Tools such as cognitive aids, point-of-care ultrasound, and transesophageal echocardiography can aid in diagnosis and treatment.

Unfortunately, undiagnosed patients with cardiac disease can present for anesthetic care. It is important to take a history and listen carefully for symptoms of decreased exercise tolerance or heart failure, to review the vital signs, and to auscultate the heart and lungs. Causes of intraoperative instability should include undiagnosed cardiac disease, and an understanding of how to treat high-risk lesions can be helpful.

KEY POINTS: PERIOPERATIVE PLANNING

- Multidisciplinary planning is useful for discussing the risks and benefits for a given procedure
- ECMO candidacy should be determined before proceeding to the operating room
- Fasting times should be minimized and/or intravenous fluids should be given to avoid hypovolemia in patients with fragile physiology

CASE STUDY

In the weekly heart center multidisciplinary planning conference, a 2-month-old girl weighing 3.6 kg with hypoplastic left heart syndrome (HLHS) who is status post Norwood stage I palliation with a right modified BT shunt, is presented for an open gastrostomy due to difficulty with oral feeds and failure to thrive. In attendance are representatives from cardiology, cardiac surgery, critical care, anesthesiology, and general surgery. All agreed that although the patient had not had her superior cavopulmonary anastomosis operation, she was not growing well and met indications for gastrostomy tube placement.

The infant was born at full term and had a prenatal diagnosis of HLHS. She underwent the Norwood stage I palliation at 7 days of age after an uneventful preoperative course during which ductal patency was maintained with prostaglandin E1. The stage I palliation went well. A right ventricle to pulmonary artery conduit (Sano shunt) was planned, but coronary anatomy precluded its placement, and a right modified Blalock–Taussig shunt was placed instead. The baby had been extubated and was being cared for in the ICU. She had a heart rate of 138 bpm, a non-invasive blood pressure of 66/30 mmHg on the left arm, SpO_2 of 89%, and temperature of 37.1°C. She was NPO and receiving 5% dextrose in 0.25 normal saline at a 14.4 mL/h. Her medications included aspirin, ranitidine, and enalapril. Physical examination revealed that the lungs were clear to ausculation and a shunt murmur was present. Echocardiogram findings included minimal atrioventricular valve regurgitation and mildly depressed right ventricular function. A 22 G peripheral IV was present on the right forearm, and there was a neonatal PICC line in the right saphenous vein. After discussing the anesthesia plan and obtaining consent from the family, the patient was transported to the operating room.

Routine monitors were applied. Her heart rate was 144 bpm with normal sinus rhythm. The non-invasive blood pressure measured on the left arm was 74/40 mmHg, and the pulse oximeter reading was 93% on room air. Anesthesia was induced with midazolam 0.4 mg, fentanyl 10 µg, and low-concentration sevoflurane in a mixture of air/oxygen (FiO_2 0.5). After loss of consciousness, neuromuscular blockade was achieved with 0.4 mg of vecuronium. The trachea was intubated orally with a 3.5 cuffed endotracheal tube. After intubation, the heart rate was 130 bpm, the blood pressure was 60/25 mmHg, and the SpO_2 was 97%. The FiO_2 was decreased to 0.21, and ventilation was adjusted to an $ETCO_2$ of 45 mmHg. Sevoflurane was reduced to 0.6% inspired concentration. A left radial arterial line was placed with ultrasound guidance. Arterial blood gas results were pH 7.32/$PaCO_2$ 49 mmHg/PaO_2 46 mmHg/lactate 0.9 mmoL/base excess –5.2 with a hematocrit of 32%.

As the patient was being prepped for surgery, the heart rate increased to 155 bpm, the arterial blood pressure decreased to 44/21 mmHg, and the SpO_2 was 90% (FiO_2 of 0.21). ECG ST segments in multiple leads were unchanged from baseline. Infusions of epinephrine 0.02 µg/kg/min, vasopressin 0.02 units/kg/h, and calcium chloride 10 mg/kg/h were started via the neonatal PICC line. A packed red blood cell transfusion of 10 mL/kg was given. With these interventions, blood pressure increased to 62/30 mmHg. For the remainder of the procedure, anesthesia was maintained with 1.4% sevoflurane in air, and the patient received a total of 10 µg/kg of fentanyl (including induction). Local anesthetic infiltration of the would by the surgeon, and intravenous acetaminophen 15 mg/kg were administered for analgesia. The patient was transported back to the ICU in a stable condition where her trachea was extubated on postoperative day 1.

This case illustrates a number of points presented in this chapter. First, patients with high-risk anatomy must be identified preoperatively. In this case, a multidisciplinary group discussed the risks and benefits associated with the procedure and decided to proceed. With a preoperative oxygen saturation of 89% it could be inferred that the patient had slightly generous pulmonary blood flow. Indeed, after induction and intubation, the patient's systemic blood pressure was low, especially the diastolic pressure, placing the patient at risk for myocardial ischemia. Interventions were taken to restore a normal blood pressure including increasing PVR by decreasing the FiO_2 and reducing minute ventilation to achieve a $PaCO_2$ of approximately 45 mmHg, transfusing red blood cells to increase the hematocrit to 40–45% and using medications (epinephrine, vasopressin, calcium) to augment blood pressure. At the end of the case, the patient was transferred with her trachea intubated to the ICU, avoiding immediate postoperative hemodynamic and respiratory instability.

This large cohort study using NSQIP-P data demonstrated significantly higher morbidity and mortality in children with major or severe CHD undergoing laparoscopic procedures compared with children without CHD. Of note, children with minor CHD also experienced significantly higher postoperative complications than those without CHD.

CHAPTER 29
Anesthesia for Spinal Surgery in Children

Joseph D. Tobias
Department of Anesthesiology and Pain Medicine, Nationwide Children's Hospital, and The Ohio State University, Columbus, OH, USA

Introduction

Procedures involving the vertebral bodies and spinal column represent one of the most common of the major orthopedic surgeries in the pediatric-aged patient. Spinal deformities requiring orthopedic surgical intervention may be the result of congenital, acquired, or traumatic conditions. They may be related to primary defects of the vertebral column (hemivertebrae), neuromuscular conditions (muscular dystrophy, cerebral palsy), or neoplastic, infectious, or therapy-related problems (surgical resection of oncological processes or radiation). Regardless of the cause, during surgical procedures to correct spinal deformities, there are several potential factors that may result in morbidity or even mortality, including associated co-morbid disease processes, patient positioning, blood loss, and neurological damage from surgical distraction of the spinal cord or instrumentation. The most recent data from the Pediatric Perioperative Cardiac Arrest (POCA) Registry in the pediatric-aged patient demonstrate that cardiovascular causes of cardiac arrest are most common (41%), with hypovolemia from blood loss and hyperkalemia from transfusion being the most common causes of cardiovascular deterioration leading to cardiac arrest [1]. These issues occurred most commonly during either craniofacial reconstruction or spinal surgery [1]. Beyond the patient with idiopathic scoliosis, the perioperative risk is further compounded by the fact that many patients presenting for spinal surgery have a higher American Society of Anethesiologists (ASA) physical classification (III versus I or II) with associated neuromuscular disorders, including muscular dystrophy or spinal muscular atrophy and pre-existing central nervous system (CNS) involvement, including cerebral palsy, seizure disorders, and meningomyelocele. Furthermore, the chronic care required by such patients may result in problems related to vascular access. To limit perioperative morbidity and mortality, these patients should be approached in a standardized fashion, which includes a preoperative evaluation for the identification of co-morbid features, design of the intraoperative anesthetic plan with attention to monitoring of neurological function with motor and somatosensory-evoked potentials, patient positioning, maintenance of normothermia, techniques to limit the need for homologous transfusion, and control of coagulation function during large volume transfusions. The postoperative regimen should include maintenance of hemodynamic and respiratory function as well as the provision of postoperative analgesia.

Surgical procedures on the pediatric spine may involve one or several vertebral levels with an incision at any level of the vertebral column (cervical, thoracic, lumbar, sacral). Further variations include the surgical approach, which may be anterior, posterior, or in the case of thoracic and lumbar spine procedures, a combined anterior–posterior (AP) approach. A majority of the procedures performed in the pediatric-aged patient involve long segment surgery on the thoracic and lumbar spine related to either neuromuscular or idiopathic scoliosis. The following chapter reviews the developmental and gross anatomy of the spine; details the more common surgical procedures; outlines preoperative assessment; discusses intraoperative anesthetic care, including methods to limit the need for homologous blood transfusion, and spinal cord monitoring; and provides options for postoperative care, including pain management.

Developmental and gross anatomy of the spine

Overview

The spine can be divided into four regions corresponding to four natural spinal curves: cervical, thoracic, lumbar, and sacral. These naturally occurring spinal curves are either kyphotic or lordotic. The "normal" spine has thoracic and sacral kyphosis with corresponding cervical and lumbar lordosis. The lordotic curvature of the cervical neck and of the

Gregory's Pediatric Anesthesia, Sixth Edition. Edited by Dean B. Andropoulos and George A. Gregory.

lumbar spine develops as a response to weight bearing. As an infant gains strength in the posterior neck muscles, the cervical spine develops a lordotic curve to support the head. At approximately 12 months of age, the lumbar spine develops a lordotic curve as a result of upright walking. Cervical and lumbar lordoses are considered secondary curves due to their development dependent on weight bearing. Their purpose is to keep the spine balanced and to reduce the workload on the posterior spinal musculature. Thoracic and sacral kyphosis are considered to be primary curves. Normal cervical lordosis ranges typically from 20° to 40° while lumbar lordosis ranges between 30° and 50°. Acceptable thoracic kyphosis curvature is 20–50°. Medically, there is a broad range of acceptable sacral curvatures since the sacral segments (S1–5) are fused in a kyphotic angle.

Abnormal curvatures of the spine include both scoliosis and excessive kyphosis [2,3]. Scoliosis is a complex three-dimensional deformity that involves changes in the coronal, sagittal, and axial alignment of the spine [2,3]. The structural changes include wedging of the vertebral body; rotation of the vertebral body to the convex side of the curve; and deformities of the posterior elements. These structural changes are greatest at the apex of the curve. The pedicle is shortened and thickened, the lamina is heavier, and the spinous process is deviated toward the concave aspect of the curve. The vertebral body becomes wedge shaped and thicker on the concave aspect of the curve as a result of the compressive forces during spinal growth. On the convex side, the vertebral body becomes thinner since it is expanded. The transverse processes approach the sagittal plane on the convex side and are closer to the concave side in the frontal plane. Rib prominence is often noticed on the convex side of the curve. This is due to the rotation of the thoracic vertebra. These spinal structural and rib alterations result in an asymmetrical thoracic cavity and may compromise respiratory function, leading to restrictive lung disease.

There are several potential etiologies for scoliosis [2,3]. Congenital scoliosis describes a failure of formation or failure of segmentation of the vertebrae. Neuromuscular scoliosis may be caused by cerebral palsy, primary muscular involvement (muscular dystrophy), myelomeningocele, poliomyelitis, and other disease affecting the muscle or nervous systems. Idiopathic scoliosis is by far the most common of all scoliosis and is classified according to age of development. Syndromes associated with development of a scoliotic spine include Marfan syndrome, neurofibromatosis, and bone dysphasia.

Abnormal kyphosis is a spinal deformity that is usually classified as either postural kyphosis, congenital kyphosis, or Scheuermann kyphosis. Postural kyphosis, otherwise known as round-back deformity, is a flexible spinal deformity that generally responds to non-operative treatments. Less common, yet more serious, is congenital kyphosis. Surgery is usually recommended with a congenital kyphosis diagnosis given its rapid rate of progression at 5–7° per year and the potential for neurological compromise related to spinal cord compression. Congenital kyphosis, similar to congenital scoliosis, is known to be caused by either a failure of part or all of the vertebral body to form or a failure of segmentation of part or all of the vertebral body.

Scheuermann kyphosis may affect the thoracic, thoracolumbar, and/or lumbar spine. Although several possible etiologies, including hormonal, nutritional, traumatic, vascular, and genetic causes, have been suggested, no definitive etiology for thoracic and thoracolumbar Scheuermann disease has been defined. Trauma is the usual causative factor of lumbar Scheuermann kyphosis. All three Scheuermann kyphosis variations clinically result in rigidity of the affected area. Using a standard radiograph, the diagnostic criteria includes ≥5° of wedging in at least three adjacent vertebrae in a lateral radiograph. Additionally, the vertebral endplates are irregular and the disk plates are narrowed. Schmorl nodes, the result of a herniated disk protruding through the weakened endplate, are often visible on x-ray. Depending on the symptoms and the degree of the curve, treatment includes both non-operative and operative modalities. A curve that is ≥75–80° generally warrants surgical intervention.

Spinal nerves and cord

There are 31 pairs of spinal nerves: eight cervical; 12 thoracic, five lumbar, five sacral, and one coccygeal. The first cervical root exits between the skull and C1 while the 8th cervical nerve root exits between C7 and T1. Thereafter, all nerve roots exit at the same level as their corresponding vertebrae. However, the nerve roots branch from the spinal cord higher than their actual exit point through the intervertebral foramen as the growth of the vertebral column exceeds that of the spinal cord [4]. Therefore, the spinal nerve travels in a caudad direction adjacent to the spinal cord prior to exiting through the vertebral foramen.

The neural tube is crucial in embryonic development of the CNS, including the spinal cord and the spinal nerves [5]. The neural tube becomes the CNS and the neural crest forms the majority of the peripheral nervous system. As the neural tube closes, the neural crest cells migrate between the neural tube and the somite. These neural crest cells form the peripheral nervous system, Schwann cells, and melanocytes. The neural tube becomes the spinal cord, the brain, and the peripheral afferent nerves and preganglionic fibers of the autonomic nervous system.

While the neural tube closes, the dorsal region separates into two halves, the alar and basal laminae, referred to as the roof and floor plates. The alar plate becomes the sensory pathways, or dorsal columns, whereas the basal plates develop into the motor pathways. The motor pathways or the ventral horn neurons develop axons that form the ventral roots. The axons of the ganglion cells form central processes, which become the dorsal roots and peripheral processes that end in sensory organelles. Motor neurons develop capabilities before sensory nerves, and autonomic nerve function is established last.

Upon gross dissection, one can identify that the motor fibers are located on the anterior side of the spinal cord with the sensory fibers on the posterior side. A group of motor fibers are referred to as ventral roots (anterior roots) while a collection of sensory fibers comprise the dorsal root (posterior root). The sensory nerves have an accumulation of cell bodies outside of the spinal cord known as the dorsal root ganglia, which contain the nuclei of the sensory (afferent) nerves. Directly lateral to the ganglia, the anterior and posterior (ventral and dorsal) nerve roots join to form a common spinal nerve surrounded by a dural sheath. This point is where the peripheral

nerve begins. Immediately after formation the nerve divides into a small dorsal (posterior) ramus and a much larger ventral (anterior) primary ramus. The posterior primary rami innervate a column of muscles on either side of the vertebral canal and a narrow strip of overlying skin. All of the other muscle and skin is supplied by the anterior primary rami, which form the cervical, brachial, lumbar, and sacral plexuses and the intercostal nerves.

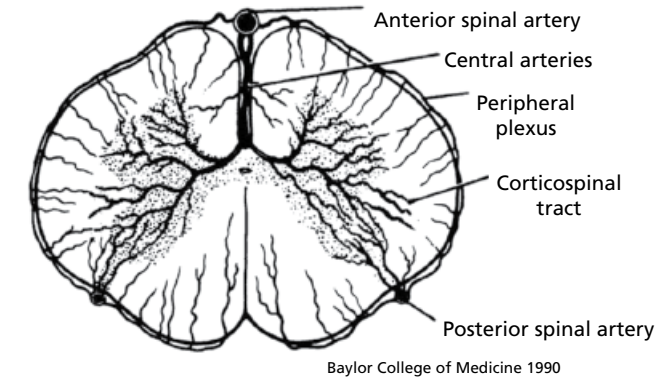
Additional gross dissection will provide a view of the multiple layers of the spinal cord. Protection of the spinal cord is provided by three layers of meninges including the dura mater, arachnoid, and pia mater. The dura mater, constructed of connective tissue, is the most external layer, gray in color, and is typically easily identified within the spinal canal. A thin subdural space separates the dura mater from the next layer, the arachnoid. This middle layer provides much of the vascular supply. Between the arachnoid layer and the deepest layer, the pia mater, lies the subarachnoid space which houses the cerebrospinal fluid (CSF). The CSF protects the spinal nerves by providing fluid which acts as a shock absorber. The pia mater is closely adherent to the spinal cord and the individual nerve roots. Similar to the arachnoid layer, the pia layer is highly vascularized, providing additional blood supply to the nerves.

The spinal cord extends from the foramen magnum to L1–4 depending on the age of the patient. With growth and development, the caudal end of the cord moves from its initial position of L3–4 in infancy to its adult level of L1. The end of the spinal cord terminates as the conus medularis and, below this, the thick flexible dural sac contains the spinal nerves collectively known as the cauda equina. Within the cauda equina, is the filum terminale, which extends from the conus medularis to the coccyx. The filum terminale acts as an anchor to keep the lower spinal cord in its normal shape and position.

Vascular components

Circulation to the spinal cord is provided by multiple arteries and arteriolar branches (Fig. 29.1) [6–9]. The anterior arterial trunk and the two posterior lateral trunks are important suppliers of blood to the cervical, thoracic, and lumbar cord. All of these arteries arise from the vertebral arteries. Radicular arteries of the spinal cord assist these longitudinal arterial pathways. There are up to 17 radicular arteries anteriorly, and as many as 25 posteriorly. The thoracic and lumbar radicular arteries are supplied by the aorta whereas the vertebral arteries supply the majority of the radicular arteries in the cervical spine. The blood supply of the thoracic spine is more tenuous than the cervical or lumbar spine, especially at the T4–9 watershed area, which is more prone to ischemic injury. The artery of Adamkiewicz provides significant circulation to the lumbar section of the spinal cord. It is usually on the left side, located at the level of T9–11. It is the largest of the radicular arteries that supply the spinal cord by anastomosing with the anterior (longitudinal) spinal artery. Injury to the artery of Adamkiewicz from trauma or during surgical procedures can result in devastating ischemia of the lower spinal cord and paraplegia.

A pair of segmental arteries, arising from the aorta, are present at every vertebral level providing blood flow to the extraspinal and intraspinal structures. The segmental arteries



(A)

(B) Reproduced from Connolly et al [8] with permission of Elsevier.

divide into many branches at the intervertebral foramen. A second network of segmental arteries lies within the spinal canal in the loose connective tissue of the extradural space. This second anastomotic network provides an alternative

pathway of arterial blood flow ensuring adequate spinal cord circulation after ligation of the segmental arteries during surgery.

Bony components

The surrounding, outer layer of the vertebrae consists of cortical bone, which is dense, solid bone tissue made of compact Haversian systems. Within the vertebra lies cancellous bone, a porous, loosely connected bone. Cancellous or trabecular bone is weaker and more susceptible to disease and loss of bone density than cortical bone. Together, these two types of bone (trabecular and cortical) form the vertebral body, which has the shape of a thin ring with an hour-glass shape. The outer cortical bone extends above and below the superior and inferior ends of the vertebrae to form rims. The pedicles, consisting of dense cortical bone surrounding a medullary canal, are two short, rounded processes that extend posteriorly from the lateral margin of the dorsal surface of the vertebral body. The anterior third of the pedicle and the vertebral body together are referred to as an anterior arch (Fig. 29.2) [10].

The posterior arch, which directly attaches laterally to the anterior arch, includes the laminae, the processes (spinous process, transverse process, superior particular process), and the posterior two-thirds of the pedicles. The laminae are two flat plates of bone extending medially from the pedicles to form the posterior wall of the vertebral foramen. The part of the lamina located between the superior and inferior articular processes is called the pars interarticularis. Spondylolysis is a term used to refer to a defect in the pars, most commonly at the L5 level.

The three spinal processes are projections of bony tissue that are the insertion site for tendons and ligaments. Specifically, two inferior and two superior articular processes extend from the junction of the pedicles and laminae. These inferior articular processes meet with the superior articular processes to form facet joints. The facet joints are surrounded by a capsular membrane containing synovial fluid that, along with the intervertebral disk, provides mobility of the spine. Additionally, two transverse processes (one on each side of the pedicles), extend laterally and provide an attachment point for ligaments and tendons. A single spinous process arises posteriorly from the junction of the two laminae, again providing an attachment point for ligaments and tendons and serving as a lever for motion of the vertebrae.

Additional bony components include the endplate and apophyseal ring. Endplates are located superiorly and inferiorly within the rim of each vertebral body. Each endplate consists of a cartilaginous external layer and a bony internal layer and provides vascular nutrition to the avascular intervertebral disk. These endplates also serve as a growth ring, predominately in height, for the vertebral body. The endplates are closed by 17–18 years of age. The apophyge ring of cortical bone surrounds the vertebral body below portions of the endplate. Surgically, it is important to leave as much of the bony endplate intact as possible, thus preventing subsidence of the device into the soft cancellous bone. The endplate is well vascularized, offering an excellent site for a fusion graft. The apophyseal ring is an ideal site for interbody fusion devices.

KEY POINTS: DEVELOPMENTAL AND GROSS ANATOMY OF THE SPINE

- Lumbar lordosis of the spine develops at about 12 months of age due to upright walking, cervical lordosis starts developing by about 4 years and is complete by adolescence
- The three types of scoliosis are congenital, neuromuscular, and idiopathic
- Motor fibers are on the anterior side of the spinal cord, sensory fibers are posterior
- The blood supply of the thoracic spine is more tenuous than the cervical or lumbar spine, especially at the T4–9 watershed area
- The artery of Adamkiewicz at T9–11 provides significant circulation to the lumbar section of the spinal cord

Surgical procedures on the pediatric spine

Scoliosis is a lateral and rotational deformity of the vertebral column. Its etiology is most commonly idiopathic (60–70%), neuromuscular, or related to congenital bony deformities (Table 29.1) [11–14]. Adolescent idiopathic scoliosis has an incidence of 1–3% in children aged 10–16 years. Most of these patients can be managed with conservative therapy, e.g. observation or bracing. Congenital scoliosis is diagnosed at birth and results from vertebral or costal maldevelopment, and occurs in approximately one of every 1000 live births. Neuromuscular scoliosis results from a number of disorders, with muscular dystrophy and cerebral palsy among the most common etiologies [14].

Other less common etiologies for scoliosis include post-traumatic injuries and therapy-related ones (previous surgical procedure or radiation for oncological diseases). Idiopathic scoliosis is more common in females with a female:male ratio of 3–4:1. The timing or need for surgery is based on the Cobb angle. The Cobb angle is calculated by identification of the most affected vertebra in the curve also known as the apical vertebra (Fig. 29.3). The apical vertebra is the vertebral body that has the greatest rotation and displacement from its ideal alignment. The top and bottom vertebrae of the curved or scoliotic segment are identified. These vertebrae have the most tilt, but the least amount of rotation and displacement. They are located above and below the apical vertebra, respectively. On the radiograph, a line is drawn along the edge of these two vertebrae and extended out. On the top vertebrae, the line starts on the top, is drawn along the top edge, and slopes downward according to the angle of the vertebra. On the bottom vertebra, the line is drawn along the bottom edge in an upward direction. Perpendicular lines are then drawn from both lines so that they meet each other at the level of the apical vertebra. The Cobb angle is the angle formed by these two intersecting perpendicular lines. Treatment modalities are based on the Cobb angle. If the Cobb angle is ≤15°, follow-up visits are scheduled to monitor the progression of the scoliosis. Bracing is generally indicated for a Cobb angle of 20–40°, while surgical intervention is indicated when the Cobb angle

Table 29.1 Scoliosis classification and associated conditions

Scoliosis classification	Associated conditions
Idiopathic	Infantile (0–3 years) Juvenile (4–10 years) Adolescent (>10 years)
Congenital	Bony deformity Neural tube defects
Neuromuscular	Cerebral palsy Poliomyelitis Muscular dystrophy Spinal muscular atrophy Neurofibromatosis

(A) (B)

Figure 29.3 Radiographs showing the determination of the Cobb angle.

is greater than 40° in the lumbar spine or greater than 50° in the thoracic spine. Although some correction of the curve may be feasible, the primary goal of surgical treatment is to stop progression of the curve. Without intervention, progression of the scoliosis will invariably lead to physical deformity with a negative self-image, physical pain, functional limitations, and cardiopulmonary dysfunction. The latter includes the development of progressive restrictive lung disease and respiratory insufficiency which may result in severe morbidity (chronic hypoxemia and hypercarbia) and eventual death from cor pulmonale.

Decision regarding the surgical approach and surgical therapy include the age of the patient, the underlying cause of the spinal deformity, and the severity of the curve. A patient with neuromuscular scoliosis may be surgically treated with a posterior procedure or may require an anterior spinal release followed by posterior fusion if the deformity is more severe to gain better correction. Although idiopathic scoliosis has been most commonly treated by a posterior approach (Fig. 29.4), in some centers an anterior approach with instrumentation is being used for idiopathic scoliosis (Fig. 29.5) [15,16]. The underlying diagnosis, curve magnitude, and the patient's age are all important factors when determining the type of procedure.

One issue that affects the timing of surgery is that the fused segments will no longer grow. As such, complete surgical correction with fusion is undertaken only when spinal growth is nearly complete, generally at ≥12–14 years of age. When surgical treatment is necessary for the juvenile idiopathic scoliosis patient, non-segmental posterior spinal instrumentation without fusion is used (i.e. growing rods) (Fig. 29.6A) [17]. This approach serves to allow correction of the scoliosis without decortication of bone and fusion of numerous vertebral segments. Therefore, normal growth will continue. During the growing rod procedure, specific vertebral levels are decorticated and fused in an attempt to allow for correction of the curvature with normal growth of the remaining spine. In general, the convex sides are decorticated and fused so that the concave sides straighten out with the ensuring growth of the vertebral bodies. Patients undergoing growing rod procedures will require repeated operative intervention at 4–6-month intervals to adjust the growing rods (Fig. 29.6B) [17]. To obviate the need for repeated procedures for adjustment and lengthening of the growing rods, which is performed under general anesthesia, new instrumentation with magnetic rods, otherwise known as magnet-driven growth rods (Fig. 29.7A, B) [17]. These devices allow lengthening of the rod with the child awake without a skin incision and the need for general anesthesia (Fig. 29.7C) [17–19]. Following periodic adjustments of the growing rods, the definitive posterior spinal fusion procedure with instrumentation is performed once growth of the vertebral column has ceased. This approach is used most commonly in patients with bony congenital anomalies or muscular dystrophies that result in the early onset (birth to 10 years of age) of scoliosis.

Another recent approach for scoliosis surgery in growing children is the vertical expandable prosthetic titanium rib (VEPTR) (Fig. 29.8) [17]. This system was originally designed to treat thoracic insufficiency syndrome caused by congenital spine and chest wall deformities, such as missing ribs in vertebral, anal, cardiac, tracheoesophageal renal and limb (VACTERL) syndrome, or Jeune syndrome. The VEPTR is positioned around the ribs, and can be expanded during subsequent less invasive surgical procedures. The VEPTR can also correct associated scoliosis as the device is expanded. A second VEPTR device may be attached to the spine, or pelvis, depending on the deformity.

Anterior surgery for scoliosis

Although idiopathic scoliosis has generally been treated via a posterior approach with posterior spinal fusion, anterior approaches have been developed more recently [15,16]. Advocates of the anterior approach believe that successful correction of the curve can be achieved while limiting the extent of the fusion, thereby maintaining flexibility and mobility of the spine. The approach addresses the higher curve and depends on the natural regression of the lower curve which is generally compensatory for the higher pathological curve. This approach is usually used for patients with idiopathic, non-neuromuscular scoliosis. The anterior approach can be performed through an open standard incision (thoracotomy)

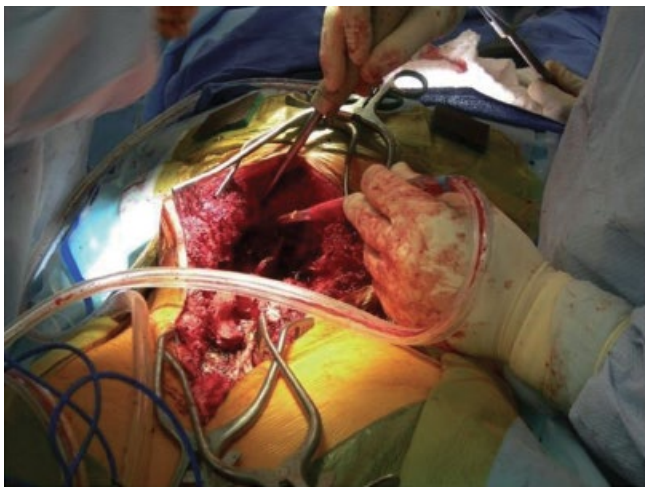

Figure 29.4 Standard long vertical posterior incision for instrumentation and correction of scoliosis.

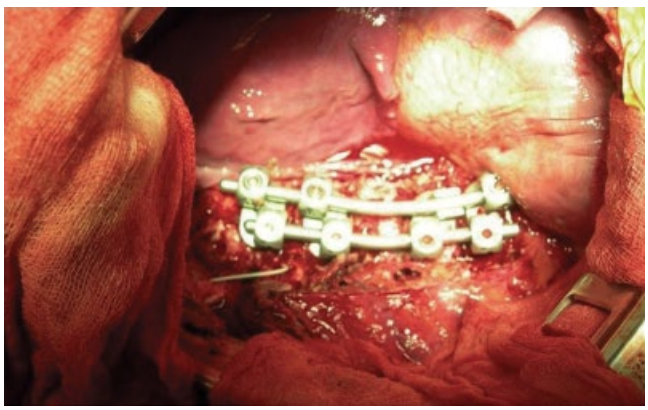

Figure 29.5 Anterior approach for surgical exposure and instrumentation in the treatment of scoliosis. With the use of one-lung ventilation, the surgeon's access to the anterolateral aspect of the thoracic and lumbar vertebral bodies can be facilitated.

or more recently via a mini-thoracotomy using minimally invasive thoracoscopic techniques.

For the anterior approach, the patient is placed in the lateral decubitus position with the operating table flexed. The upper arm is moved forward and rotated away from the posterior portion of the spine. An axillary roll is placed to minimize pressure on the brachial plexus and the vasculature structures. Depending on the level of scoliosis (thoracic versus lumbar), entry into the thoracic cavity may be required. When the thoracic cavity is entered, the use of one-lung ventilation (OLV) may greatly facilitate the surgeon's access to the anterior spine for open procedures and is generally routinely used and necessary during minimally invasive approaches. Following skin incision, access to the spine is achieved through the bed of the convex 5th rib for visualization of T5–12, or via the bed of the 10th rib for access to the thoracolumbar spine. The initial incision extends anteriorly to the lateral border of the rectus sheath with its length determined by the number of levels required to be exposed. The rib to be excised corresponds to the most superior vertebral body requiring exposure. For example, with a T6–12 anterior fusion, the 5th rib is excised. The costal cartilage is split anteriorly which can later serve as a landmark for closure. Once the spine is exposed, retractors are positioned to protect the lung tissue and peritoneum. The surgeon can now access the vertebral disk or vertebral body with the caveat that segmental vertebral vessels (artery and vein) are present at each level. When necessary, these vessels can be ligated as vascular compromise of the spinal cord after ligation is uncommon, even if several segmental vessels are ligated.

Video-assisted thoracoscopic surgery

Video-assisted thoracoscopic surgery (VATS) techniques have also been incorporated into the surgical treatment of scoliosis. As with other types of VATS procedures, specialized surgical equipment is necessary including the scope, light sources, cameras, flexible portals, monitors, and specific instrumentation. For the successful completion of such procedures, OLV is generally mandatory to allow for adequate visualization of the spine (see section "Intraoperative anesthetic care"). Contraindications to this approach include the inability to

tolerate OLV, severe respiratory insufficiency, high airway pressures with positive pressure ventilation, and previous thoracotomy which may result in adhesions, thereby limiting surgical access and the ability to obtain lung deflation during OLV. Positioning and preparation are generally the same as for the open, anterior approach. The surgical landmarks for trocar and instrument placement include the scapular border, 12th rib, and iliac crest.

The first portal is placed at or near the T6–7 interspace in the posterior axillary line. After surgical incision, dissection continues with electrocautery through the intercostal muscle to enter the thoracic cavity. Once adequate lung deflation is

ensured, flexible ports are inserted in the intercostal spaces with a trocar. A blunt-tipped needle is placed adjacent to the thoracic spine and a roentgenogram is obtained to confirm the disk spaces intraoperatively. The parietal pleura is completely resected without ligation of the segmental thoracic vessels. The disks and endplates are then removed. After the necessary discectomies are completed, rib grafts are harvested through the portal sites. Prior to closure, a chest tube is placed through the most posterior inferior portal. The pleura may be closed or left open. The chest tube is connected to water seal and the anesthesiologist tests for an air leak in the reinflated lung. Potential perioperative issues include bleeding, damage to the lung tissue, dural tears, lymphatic injury, and sympathetic dysfunction on the operative side. If hemostasis cannot be obtained or visualization is not optimal, conversion to an open anterior approach may be required. Postoperatively, pulmonary problems may occur within the deflated lung leading to recurrent atelectasis.

Posterior surgery for scoliosis

Over the past 20 years, the surgical approach to scoliosis has changed with advancements in segmental posterior spinal instrumentation. As such, correction of both sagittal and coronal plane spinal deformities has improved compared with older systems such as the Harrington rods. The posterior surgical approach with instrumentation uses the spinous processes, the pedicles, the facets, and the laminae to control the alignment of the vertebral bodies with laminar hooks, pedicle hooks, pedicle screws, facet screws, and wires.

For the classic posterior approach, the patient is placed prone on an appropriate spinal frame with the abdomen hanging freely to avoid compression of the intra-abdominal portion of the inferior vena cava. This prevents increased intra-abdominal pressure thereby decreasing venous pressure with decompression of the epidural veins to limit venous bleeding. It also prevents an increase in intra-abdomianl

pressure that may interfere with diaphragmatic movement. Traditionally a Hall frame or more recently a Jackson table is used to support the patient in this position (Fig. 29.9). The patient's face should be well padded without pressure on the eyes (see later for an expanded discussion of postoperative visual compromise) (Fig. 29.10). The patient's back is completely draped with exposure to the entire spine and the iliac crest for harvesting of the bone graft. A midline incision over the spinous processes is made, followed by splitting the apophysis and subperiosteal dissection to expose the spine laterally to the transverse processes. Placement of a blunt needle is followed by confirmation of the appropriate vertebral body using either fluoroscopy or plain radiography. After a facetectomy and wide posterior release at each level, the instrumentation is placed. The surgeon inserts pedicle hooks, pedicle screws, laminar hooks, and sublaminar wires at the vertebral levels requiring surgical correction of the scoliosis. The first rod is placed on the concave side of the curve and rotated to correct the spinal deformity. This represents a key moment during the instrumentation procedure as alterations in spinal cord perfusion may occur during correction of the curvature with distraction of the spinal cord and its associated perfusion. Changes during neuromonitoring may occur at any point during the surgical procedure, but are most common during this portion of the surgery. Once correction is maintained with the first rod, the second rod is placed. Cross-links are added, allowing an increase in torsional stiffness of the rod's construct. Decortication of the posterior elements prepares the spine for fusion. The placement of the bone graft completes the procedure and is followed by a layered closure of the muscles, fascia, and skin.

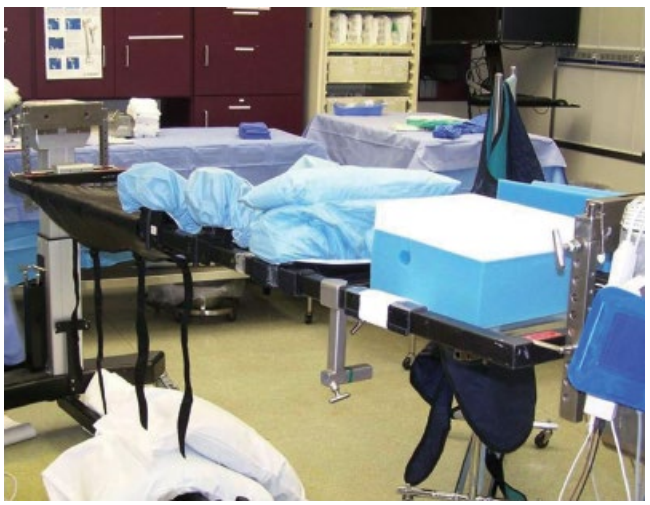

Figure 29.9 Jackson table for positioning of patients in the prone position for posterior spinal fusion.

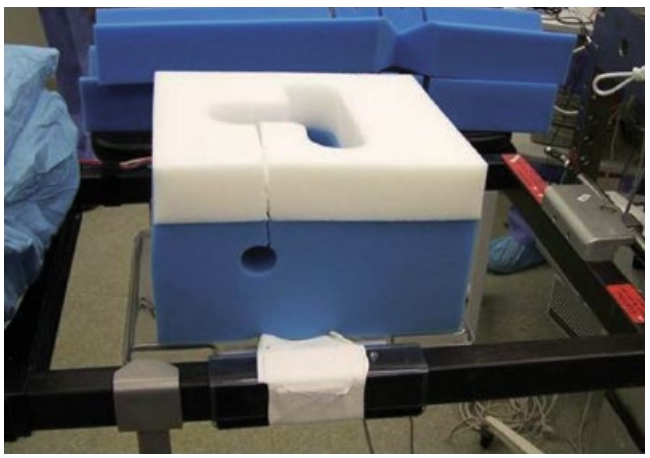

Figure 29.10 Specialized cushion or pillow used for positioning on the Jackson table. When applied appropriately, the pillow should eliminate pressure points on the face or eyes. The endotracheal tube can be brought out the side hole of the pillow or through the bottom of the pillow.

KEY POINTS: SURGICAL PROCEDURES ON THE PEDIATRIC SPINE

- Surgical intervention is indicated when the Cobb angle is greater than 40° in the lumbar spine or 50° in the thoracic spine
- Special techniques for the growing spine are used before skeletal maturity, i.e. growing rods, magnetic adjustment rods, and vertical expandable titanium ribs
- An anterior approach to the spine may correct the curve while limiting the extent of the fusion, thereby maintaining flexibility and mobility
- Open thoracotomy or video-assisted thoracoscopic approaches can be used for anterior spine fusion
- Posterior spine fusion is the most common approach, and advances in instrumentation have led to improved outcomes

Preoperative and intraoperative care

Preoperative evaluation

The initial step in the perioperative care of pediatric patients presenting for spinal surgery is the preoperative evaluation to identify co-morbid features that may impact their perioperative care and to maximize the patient's preoperative state in the hopes of preventing perioperative complications. Of primary importance when evaluating children and adolescents for spine surgery is the impact of the disease process on airway management and cervical spine stability. Cervical spine stability is the spine's ability to resist displacement under normal physiological loads. Patients presenting for cervical spine surgery, especially the trauma patient, should be assumed to have an unstable cervical spine or the potential for subluxation during flexion or extension of the neck, which can result in spinal cord compromise [20,21]. Cervical spine issues and any resultant instability may be related to a traumatic event or a congenital syndrome with cervical spine involvement such as trisomy 21, achondroplasia, or other more uncommon craniofacial syndromes, such as Pfeiffer, Aperts, or Crouzon syndrome [22–25]. Subluxation and upper cervical intervertebral fusions have been reported in 30% of patients with Pfeiffer syndrome, and odontoid hypoplasia with the risk of C1–2 subluxation has been reported in patients with Crouzon syndrome and the mucopolysaccharidoses [23,24]. Ligamentous laxity and the potential for cervical subluxation is also present in patients with trisomy 21 [25].

Patients with achondroplasia may have associated stenosis of the foramen magnum, which may also impact airway management strategies and intraoperative positioning. Foramen magnum stenosis results from hypertrophy of the bony margins of the foramen magnum and can lead to narrowing of the cervical spinal canal with compression of the cervical spinal cord or medulla. In children with achondroplasia, who manifest neurological or respiratory symptoms related to foramen magnum stenosis, the diameter of the foramen magnum has been shown to be more than 3 standard deviations from the mean for age-matched controls of normal stature.

Even in the absence of associated syndromes, cervical spine involvement from scoliosis or kyphosis may limit normal cervical spine movement thereby leading to difficulties with tracheal intubation or positioning for the subsequent surgical procedure. Given these issues, as time permits, an evaluation of the cervical spine may be indicated as part of the preoperative work-up in such patients. Preoperative evaluation for cervical spine abnormalities includes a physical examination with questioning regarding the presence of neck pain and an evaluation of neck movement (flexion, extension, and lateral rotation). This is supplemented with radiograph examination (flexion/extension films) or computed tomography scanning when historical or clinical findings are noted. If potential issues are identified during the evaluation process, various approaches to tracheal intubation are available, which can be performed in either the anesthetized, sedated, or awake state [20,21].

Patients with craniofacial syndromes may also have midface anatomical issues that impact on airway management, including ease of bag-valve-mask ventilation and tracheal intubation [22,23]. Common features of many of the craniofacial syndromes include micrognathia, microstomia, midface (maxillary) hypoplasia, and lip/palatal abnormalities. Glossal hypertrophy may be present in neuromuscular conditions or in association with trisomy 21. Although beyond the scope of this chapter, identification of potential difficulties with direct laryngoscopy and tracheal intubation should prompt alternative approaches to the airway including indirect videolaryngoscopy or fiberoptic techniques. Additionally, there should be ready access to the equipment required for management of a difficult airway including various sizes of laryngeal mask airways or a similar type of supraglottic device. Chapter 16 presents a thorough discussion of management of the difficult pediatric airway.

Another situation faced by the anesthesiologist that impacts perioperative airway management is the patient with an *in situ* tracheostomy requiring airway management and prone positioning for spinal surgery. Although there have been some suggestions regarding strategies to manage a tracheostomy in the perioperative period, including use of an existing tracheostomy, exchange to a cuffed tracheostomy, placement of an endotracheal tube through the tracheostomy stoma, or use of standard orotracheal intubation, there are no definitive consensus guidelines available [26]. Although the presence of a tracheostomy initially may facilitate airway management, positioning and other intraoperative issues may affect airway patency. Most importantly, if a standard tracheostomy tube is used, given its rigidity, traction from the anesthesia circuit may cause posterior displacement of its lumen with occlusion against the tracheal wall, especially in patients with scoliosis or kyphosis, which may affect airway anatomy and integrity [27,28]. Such problems can generally be avoided by exchanging the tracheostomy tube for an appropriately sized armored tracheal tube. Use of the armored tube may avoid positional changes related to traction on the tube due to the weight of the anesthesia circuit. After exchange for the tracheostomy tube, the armored tracheal tube can be secured in place using a suture to the neck or the anterior chest wall. Given that the tracheostomy site enters the trachea closer to the carina than standard tracheal intubation techniques, careful placement and auscultation of bilateral breath sounds is necessary to avoid endobronchial intubation. Appropriate positioning of the tracheal tube should be confirmed in the neutral position and with the neck flexed.

Following the evaluation of the airway and cervical spine, the preoperative examination follows a sequential organ system approach. Co-morbidities of the central and peripheral nervous and muscular systems may be a frequent feature in the pediatric patient presenting for spine surgery. These may include cerebral palsy, seizure disorders, static encephalopathy, or associated neuromuscular conditions. The preoperative assessment and documentation of neurological and neuromuscular function will help in the identification of perioperative injuries related to the surgical procedure or positioning and aid in differentiating these from pre-existing conditions. During the preoperative evaluation, therapeutic serum anticonvulsant concentrations should be documented and the parents instructed to give the usual anticonvulsant medications on the morning of surgery regardless of other nil per os instructions [29]. If morning doses are missed, these can be given in the preoperative holding area prior to anesthetic care. Although many of the newer medications have long half-lives, ongoing perioperative dosing is recommended to maintain therapeutic plasma concentrations. Intraoperatively, conversion to intravenous administration is available for several anticonvulsant medications so that therapeutic levels are maintained perioperatively. Postoperatively, dosing can be switched back to the oral route when the patient's status permits or alternative routes of delivery (intravenous or rectal) may be used. Chronic anticonvulsant therapy leads to the induction of hepatic enzymes thereby altering the pharmacokinetics and pharmacodynamics of several medications, including neuromuscular blocking agents (NMBAs). Increasing the intraoperative doses of NMBAs and certain intravenous anesthetic induction agents may be necessary with concomitant anticonvulsant therapy [30–32]. A second factor affecting dosing of NMBAs is the fact that many anticonvulsant agents have weak neuromuscular blocking properties, leading to the upregulation of acetylcholine receptors. Therefore, increased dosing requirements may be seen even for agents such as *cis*-atracurium which are not dependent on hepatic metabolism for their elimination.

Developmental delay, visual impairment, and hearing disturbances may present a major challenge in the communication with and assessment of the patient during the perioperative period. Some degree of intellectual impairment is noted in 30–50% of patients with Duchenne muscular dystrophy and in a greater percentage of patients with cerebral palsy and other syndromic conditions. Many of these patients will have heightened perioperative anxiety and fear which may be mitigated by premedication or parental presence

during the induction phase. In addition to limiting preoperative cooperation and understanding, these issues may be particularly problematic during the postoperative period when pain assessment may be difficult (see later).

Depending on the degree of scoliosis and the presence of co-morbid disease processes, there may be some degree of preoperative compromise of respiratory function from restrictive lung disease. Progressive scoliosis results in a restrictive defect with a decrease in the vital capacity, total lung capacity, and forced expiratory volume with no change in residual volume. The decrease is greater in patients with congenital or infantile scoliosis when compared with adolescent scoliosis [33,34]. The severity of respiratory impairment is related to the angle of the scoliosis, the number of vertebral levels involved, the cephalad level of the scoliosis, and the loss of the normal thoracic kyphosis. Respiratory compromise is worse in younger patients and those with infantile or congenital scoliosis. Muirhead and Conner noted that there was a moderate or severe ventilation defect (40–59% predicted for age) in 14 of 41 children with either infantile or congenital scoliosis compared with only four of the 51 adolescents with idiopathic scoliosis [33]. However, unlike the adult population, the impact of moderate degrees of respiratory compromise is generally limited. In the previous study, there was no requirement for postoperative respiratory support in patients with a preoperative vital capacity ≥40% predicted for age. The effect of the surgical procedure on postoperative respiratory function is dependent on the surgical approach and the type of surgery. Surgical procedures involving the thorax (anterior spinal fusion) lead to a reduction in lung function at 3 months with a return to preoperative values by 2 years, while the standard posterior approach leads to improved respiratory function at both 3 months and 2 years [34,35].

Of even greater concern for the preoperative evaluation of patients with neuromuscular disorders is the ability to determine the degree of respiratory compromise that contraindicates scoliosis surgery. Given its greater impact on respiratory function, this need is greater if an anterior approach is chosen when compared to a standard posterior approach. In the adult population, it has been suggested that prolonged postoperative mechanical ventilation is likely to be required in patients with a reduction of the forced vital capacity (FVC) or the forced expiratory volume in 1 second (FEV_1) to less than 40% predicted. However, as there are generally fewer co-morbid features in children, such as associated cardiac disease, when compared with adults, it is likely that the same criteria used to predict postoperative respiratory function in adults should not necessarily be applied to pediatric-aged patients. The lack of predictive power of preoperative pulmonary function testing in children has been previously demonstrated in a cohort of pediatric oncology patients requiring repeated thoracotomy for excision of metastatic disease [36]. After 32 thoracotomies in 19 pediatric oncology patients, there was a consistent decrease in pulmonary function test (PFT) values with a decrease in the FVC (% predicted for age) from 68 ± 3.6% to 60 ± 2.4% ($p < 0.01$) and the FEV_1 from 69 ± 4.2% to 60 ± 3.8% ($p < 0.01$); there was no permanent morbidity noted even in patients with decreased preoperative respiratory function. Five of the patients had severe preoperative decreases in pulmonary function (≤40% predicted for age). Although the incidence of morbidity defined as postoperative ventilation, supplemental oxygen for more than 12 h, or persistent air leak was three of five in this group versus three of 20 in patients with mild or moderate lung disease (PFT 60–80% predicted for age), there was no postoperative mortality and no need for prolonged mechanical ventilation. Similar data were also reported in a cohort of 45 adolescents with Duchenne muscular dystrophy and compromised respiratory function [37]. Twenty patients had a preoperative FVC ≤30% predicted for age. Despite the low FVC, there was no statistically significant difference in several postoperative variables including the duration of postoperative tracheal intubation, duration of bi-level positive airway pressure (BiPAP) support, total time with ventilator assistance, and inpatient stay. However, there were significant cardiorespiratory complications noted in both groups demonstrating that this is a high-risk population with the potential for perioperative complications. Five patients (25%) with an FVC ≤30% had complications, including adult respiratory distress syndrome (ARDS), respiratory tract infections, and the need for a tracheostomy, while four (16%) with a preoperative FVC ≥30% also had complications. The one death in the cohort was in a patient with an FVC of 18% who initially had an uncomplicated postoperative course, but went on to develop ARDS.

Although the majority of patients presenting for spinal surgery without co-morbid conditions (idiopathic scoliosis) will not require postoperative mechanical ventilation, factors such as co-morbid conditions, intraoperative blood loss, and surgical duration may mandate the option of providing a short period of postoperative mechanical ventilation to ensure patient safety. In addition to respiratory function, airway issues may necessitate postoperative mechanical ventilation. Prolonged procedures in the prone position may result in airway or lingual edema thereby necessitating postoperative tracheal intubation. Almenrader and Patel reviewed their 18-month experience in a cohort of 42 patients with non-idiopathic scoliosis [38]. In their series, 23.8% of patients required postoperative mechanical ventilation. Consistent with the data of Harper et al [37], they noted that patients with Duchenne muscular dystrophy and those with a preoperative FVC ≤30% were more likely to require postoperative respiratory support (40% in their series). The authors suggested the use of non-invasive ventilator techniques to ease the transition from mechanical to spontaneous ventilation. The use of non-invasive ventilation including BiPAP can greatly facilitate the ability to rapidly provide tracheal extubation during the immediate postoperative period [39]. This pathway was the result of a cooperative effort between healthcare providers from pediatric anesthesiology, pediatric intensive care unit (ICU) medicine, pediatric pulmonology, and respiratory care.

In addition to respiratory issues in patients undergoing scoliosis surgery, perioperative morbidity and mortality may also be related to secondary cardiac involvement. Myocardial dysfunction in this group of patients may be related to the primary disease process such as muscular dystrophy or less commonly due to chronic hypoxemia from restrictive lung disease and associated cor pulmonale. The latter is uncommon as scoliosis is frequently addressed prior to the development of chronic cardiovascular effects. More

commonly, various neuromuscular conditions such as the muscular dystrophies or myotonic dystrophies may lead to myocardial involvement with alterations in the contractile function or conduction abnormalities. Of these conditions, Duchenne muscular dystrophy is the most common disorder, with an incidence of one in 3300 male births [40]. Although skeletal muscle involvement with weakness predominates as the major clinical feature of this disorder, as these patients enter the second and the third decades of life, progressive myocardial involvement leads to impaired myocardial contractility, conduction disturbances, and arrhythmias. The potential impact of this disorder on perioperative morbidity and even mortality cannot be ignored as the literature has demonstrated a significantly increased risk during anesthetic care in these patients [41]. Sethna et al reported intraoperative cardiac arrest and death in two of 25 patients requiring anesthetic care during various surgical procedures [41]. Given the potential for associated myocardial involvement, preoperative evaluation should include transthoracic echocardiography and a 12-lead electrocardiogram (ECG). It has also been suggested that the combination of a preoperative chest x-ray and ECG can be used to screen for the presence of myocardial dysfunction 42]. Although Clendenin et al noted that an abnormality on the chest x-ray (increased cardiac silhouette) and abnormal findings on the ECG was predictive in 81% of their 255 patients, echocardiography remains the gold standard [42].

A second group that tends to be increasing in the spinal surgery population are those with associated congenital heart disease. In this group of patients, especially those with residual lesions or single ventricle physiology, preoperative assessment is of paramount importance to guide intraoperative care. When myocardial dysfunction is identified, additional intraoperative monitoring (transesophageal echocardiography) with consultation from pediatric cardiology may be required. Furthermore, close observation during positioning is suggested as the condition of these patients may deteriorate rapidly with the institution of positive pressure ventilation or when turned prone due to changes in venous return or increased intrathoracic pressure. Furthermore, once cardiovascular deterioration occurs, successful resuscitation may be more problematic than in patients without co-morbid cardiac involvement.

The period of preoperative evaluation and preparation of the patient is also an essential time to institute measures to limit allogeneic blood product needs. Simple measures include identification and treatment of anemia prior to elective spinal surgery. In the adult population, age greater than 50 years, preoperative hemoglobin less than 12 g/dL, fusion of more than two levels, and transpedicular osteotomy have been identified as independent risk factors for the need for perioperative transfusion [43]. Routine screening for preoperative anemia and its treatment, many times with nothing more than supplemental iron, may prevent the need for perioperative transfusion. Such interventions are particularly important in patients with poor nutritional status or in adolescent females following menarche. Although treatment with oral iron is generally effective, a more rapid response within 2–3 weeks can be obtained with intravenous iron therapy [44]. The latter is more costly and associated with a higher incidence of adverse effects. As such, the risk:benefit ratio must be closely evaluated.

More aggressive and more expensive preoperative blood avoidance techniques may include the administration of erythropoietin to augment preoperative autologous donation or the success of intraoperative isovolemic hemodilution (see section "Intraoperative anesthetic care"). Issues with erythropoietin include, most importantly, its cost and the lack of reimbursement from most insurance companies when it is used in this clinical setting. Furthermore, there are varying reports of its efficacy in the literature with some studies showing no benefit, variations in dosing regimens, the need for weekly visits with laboratory measurement of hemoglobin and subcutaneous injections, as well as the potential to increase the incidence of postoperative deep vein thrombotic events. In a retrospective analysis of 178 pediatric patients undergoing spinal surgery, homologous transfusions were administered to 30.6% of patients who did not receive erythropoietin versus only 17.5% of those who did ($p < 0.05$) [45]. In a subgroup analysis of the patients with idiopathic scoliosis, the need for homologous transfusion was 3.9% in those receiving erythropoietin versus 23.5% of those who did not ($p = 0.006$). However, subsequent work from the same investigators demonstrated no benefit of preoperative erythropoietin in limiting the need for allogeneic transfusion in a cohort of 61 patients with neuromuscular scoliosis [46]. Other investigators have suggested the efficacy of erythropoietin when used in combination with an autologous blood donation strategy [47]. Although such techniques are feasible in the pediatric population, given the need for repeated phlebotomy and laboratory analysis with the inherent time, cost, and needle-stick pain, there has been a significant decrease in interest in the use of preoperative autologous blood donation. Furthermore, as a clerical error remains the most common cause identified for death related to blood transfusion, the inherent safety of autologous transfusion may not be clinically different from allogeneic transfusion, especially in the pediatric population. The prothrombotic potential of erythropoietin deserves consideration when deciding on its role in perioperative blood avoidance. In the adult, population, Stowell et al reported a higher incidence of deep vein thrombosis of 4.7% versus 2.1% in a cohort of 680 adults [48].

Patients presenting for major orthopedic surgery may have co-morbid conditions or nutritional conditions that affect coagulation function. The chronic administration of anticonvulsant agents, including phenytoin and carbamazepime, may adversely affect coagulation function. Nutritional issues and poor intake of vitamin K may result in a low levels of vitamin K-dependent coagulation factors resulting in preoperative coagulation dysfunction. Preoperative screening of coagulation function and simple measures such as the administration of vitamin K (oral or intramuscular) may alleviate such problems. Patients with chronic orthopedic problems and pain frequently use non-steroidal anti-inflammatory drugs (NSAIDs). Although acetylsalicylic acid irreversibly inhibits cyclo-oxygenase and platelet function for the life of the platelet, NSAIDs result in reversible inhibition of platelet function that is dependent on the plasma concentration and hence the half-life of the NSAID. Discontinuation of most NSAIDs for 2–5 days prior to surgery will allow for the return of normal platelet function.

KEY POINTS: PREOPERATIVE EVALUATION

- Thorough evaluation, particularly of airway and cervical spine stability in neuromuscular and congenital spine patients, is essential
- All preoperative medications for pulmonary, neurological, and cardiac disease are generally continued through the day of surgery. Most NSAIDs should be discontinued 2–5 days preoperatively
- Neuromuscular spine patients often have respiratory compromise; but even those with FEV_1 <40% predicted may have an uncomplicated postoperative course
- Cardiac involvement for neuromuscular spine patients may include cardiomyopathy in Duchenne muscular dystrophy, or congenital heart disease including single-ventricle patients
- Erythropoietin therapy or autologous blood collection may lessen the need for intraoperative blood transfusion, but with the complexity of these procedures and increasing safety of allogeneic transfusion, they are infrequently used

Premedication, anesthetic induction, and positioning

Various agents or combinations may be required preoperatively in patients undergoing spinal surgery. Premedication regimens may include:

- High-flow nebulization of albuterol and an anticholinergic agent such as ipratroprium in patients with airway reactivity.
- Topical or aerosolized administration of lidocaine if a fiberoptic intubation is planned due to a difficult airway scenario.
- Gastrointestinal prophylaxis in patients at risk for gastroesophageal reflux and aspiration may include agents to increase gastric pH, such as H_2 antagonists, proton pump inhibitors, or oral non-particulate antacids and motility agents such as metoclopramide to decrease to gastric volume.
- Dexamethasone for patients with airway reactivity and to decrease postoperative nausea and vomiting.
- An anticholinergic agent such as glycopyrrolate or atropine to dry secretions, blunt cholinergic-mediated airway reactivity, and to prevent bradycardia during laryngoscopy.
- Hydrocortisone if patients are chronically receiving corticosteroids. Such therapy is frequently used in patients with Duchenne muscular dystrophy given data suggesting their ability to slow progression of the disease [49].
- An anxiolytic agent, such as oral midazolam, in patients without intravenous access or intravenous midazolam in those with pre-existing IV access.

Following premedication, the patient is transported to the operating room and routine ASA monitors are placed. From the start of anesthetic care, attention should be directed at the maintenance of normothermia. Hypothermia is particularly common and may occur rapidly in patients with cerebral palsy and failure to thrive who may have limited body fat. Patients with static encephalopathy and related conditions may have abnormal central control of temperature thereby placing them at further risk of hypothermia. In addition to other physiological effects, perioperative hypothermia has been shown to be a key factor in increasing intraoperative blood loss during major surgical procedures [50,51]. The maintenance of normothermia includes preoperative warming of the patient using forced-air devices, keeping the operating room warmed until the patient is positioned and covered, warming intravenous fluids, blood, and blood products, and the intraoperative use of forced-air warming devices. Some type of invasive continuous monitoring of core temperature should be used. This can be either nasopharyngeal, esophageal, or bladder. The availability of Foley catheters with a built-in temperature probe provides an easy and accurate means of intraoperative temperature monitoring.

The technique and medications used for the induction of anesthesia should be guided by the patient's co-morbid conditions, the assessment of the ease of tracheal intubation, as well as the patient's preference and/or demographics (age and cognitive function). For anterior or posterior spinal surgery, a reinforced endotracheal tube (ETT) may be used to prevent inadvertent airway occlusion during surgical dissection and/or extreme neck flexion (Fig. 29.11). During prolonged cases with significant neck flexion, there may be a risk for non-reinforced ETTs to warm, bend, and obstruct if they are held in a flexed position over a protracted period of time. The time-honored practice of using uncuffed ETTs in patients less than 6–8 years of age has recently changed with a transition to the use of cuffed ETTs in patients of all ages [52]. Once the ETT is secured in place, a gauze roll is placed in the mouth to prevent biting during motor evoked potential stimulation (see later).

When considering agents for anesthetic induction, several options are available for the induction and maintenance of anesthesia in patients with stable cardiovascular function. In the absence of intravenous access, anesthetic induction can be carried out by the inhalation of an incremental concentration of sevoflurane in oxygen or oxygen and nitrous oxide. Alternatively, a peripheral intravenous cannula can be painlessly placed following 2–3 min of breathing 50–70% nitrous oxide. In patients with previously established intravenous access, several of the commonly used intravenous induction agents are suitable. If there is a plan for tracheal extubation in the operating room or

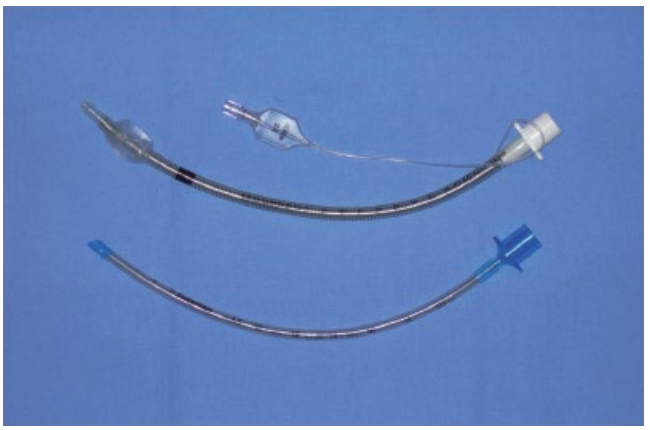

Figure 29.11 Wire reinforced endotracheal tube to prevent kinking during prone positioning with head flexion or for placement through a tracheostomy stoma.

immediately postoperatively, propofol may provide a more rapid awakening and a better recovery profile during the immediate postoperative period than induction with barbiturates such as thiopental. The latter are rarely if ever used for intravenous induction in the United States. Although its effect on adrenal function has led to the suggestion that its use should be re-evaluated, etomidate may still be an appropriate choice for anesthetic induction in patients with diminished myocardial function [53,54].

Once adequate bag-mask ventilation has been demonstrated, inhalation or an intravenous induction technique can be followed by the administration of a non-depolarizing neuromuscular blocking agent (NMBA). Succinylcholine is contraindicated in patients with various neurological and myopathic conditions given the potential for rhabdomyolysis, hyperkalemia, and cardiac arrest. Similar problems with succinylcholine may occur in patients within 48–72 h following a spinal cord injury. In the absence of concerns of a difficult airway, tracheal intubation can be facilitated with an intermediate-acting (vecuronium, rocuronium, *cis*-atracurium, atracurium) or short-acting (mivacurium) non-depolarizing NMBA [55]. The dosing of these agents should be titrated using train-of-four monitoring, especially in patients with Duchenne muscular dystrophy and other myopathies, as even a single dose for tracheal intubation of an intermediate-acting NMBA may result in a prolonged duration of neuromuscular blockade. When motor-evoked potentials (MEPs) are being used to monitor spinal cord function, a single, small dose of a non-depolarizing NMBA (rocuronium 0.3–0.4 mg/kg) can be used to facilitate tracheal intubation as its effects will generally dissipate prior to the need to initiate MEP monitoring after the patient is turned prone. In rare circumstances, the new reversal agent, sugammadex, can be used when the duration of effect of either vecuronium or rocuronium interferes with the need for MEP monitoring [56,57].

After the airway is secured, adequate intravenous access and invasive cardiovascular monitoring are obtained as indicated. Several factors may be responsible for hemodynamic changes during spinal surgery in pediatric patients, including co-morbid conditions, positioning on the operating room table, and blood loss. In general, for major spinal surgical procedures, two large-bore peripheral intravenous cannulae are placed for the rapid administration of fluids, blood, and blood products. Additional invasive hemodynamic monitoring with an arterial cannula and central venous access may be obtained depending on the patient's condition and the surgical expertise. In experienced hands, blood loss is generally minimal in patients with idiopathic scoliosis (400–600 mL) thereby eliminating the need for central venous access. Additionally, the accuracy of central venous pressure monitoring in the prone position has been questioned, thereby limiting its clinical utility [58]. In our clinical practice, central venous access is not routinely obtained during spinal surgery. Its use is limited to those patients who may have difficulties with peripheral vascular access postoperatively, when the use of specific vasoactive agents is anticipated or when central venous saturation monitoring is planned. Ultrasound imaging has been shown to be helpful if obtaining peripheral venous and arterial access is problematic, especially in patients with a history of previous difficulties with vascular access [59].

Once appropriate vascular access and monitoring has been established, the patient is then positioned on the operating room table. Patient positioning will be dependent on the specific type of surgery, with either prone positioning for posterior spinal fusion or lateral positioning if an anterior approach is chosen. If the cervical spine and upper thoracic vertebrae are included in the surgical field, neutral positioning of the head is required. Alternatively, for posterior spinal fusion that does not involve the lower cervical or high thoracic area or isolated lumbar surgery, the patient can be positioned prone and the head turned to the side, thereby limiting the potential for pressure points on the eyes and face. Regardless of the positioning, careful padding of pressure points is needed since these procedures may last up to 10–12 h. Positioning should minimize the venous pressure at the surgical site to reduce bleeding. This is done by using specialized operating room tables, placing rolls under the chest and pelvis to keep the abdomen free, and by reverse Trendelenburg positioning. Mild reverse Trendelenburg positioning also helps limit the development of dependent edema in the face, tongue, and upper airway and limits the increase in intraocular pressure (IOP) which may occur with prone positioning. A specialized frame (Wilson frame) or operating room table (Jackson table) is generally used to position the patient, and to decrease venous pressure and surgical bleeding (see Fig. 29.9). The Jackson table with longitudinal bolsters has been shown to have the least effect on reducing cardiovascular performance [60]. Keeping the abdomen free also facilitates mechanical ventilation by preventing limitation of diaphragmatic movement.

A major concern during surgical procedures in the prone position is the occurrence of postoperative visual impairment or blindness [61]. Increased IOP with prone positioning has been postulated to be one of the contributing factors for this rare, but devastating, complication of blindness following prone surgical procedures [62–64]. In a cohort of 20 adults undergoing surgery in the prone position, IOP was 19 ± 1 mmHg in the awake state, which decreased to 13 ± 1 mmHg in the supine position after the induction of anesthesia, but then increased to 40 ± 2 mmHg after 320 ± 107 min in the prone position. Although various etiologies may be responsible for postoperative visual loss (POVL), no unifying theory (ischemic, thrombotic, oncotic, and embolic) has been accepted or can explain all of the events. Given the devastating consequences and potential medicolegal implications of this phenomenon, the Postoperative Visual Loss Registry was established in 1999 in an attempt to determine factors associated with POVL [65]. In the registry, the authors reviewed 93 voluntarily reported cases of POVL following spinal surgery and noted that when considering the 83 cases of ischemic optic neuropathy, blood loss greater than 1000 mL and surgical duration ≥ 6 h were present in 96% of the cases. Owing to the concerns over POVL, controlled hypotension to limit intraoperative blood loss is not routinely employed in the adult population.

For anterior procedures, the patient can be positioned in the lateral position and a thoracotomy performed to gain access to the vertebral column. Alternatively, there is increasing experience with the use of thoracoscopic approaches for such procedures. Regardless of the approach (open thoracotomy or thoracoscopy), OLV can greatly enhance the surgeon's view of the surgical field.

KEY POINTS: PREMEDICATION, ANESTHETIC INDUCTION, AND POSITIONING

- Premedication considerations include midazolam for anxiolysis, continuing respiratory and neurological medications, stress dose corticosteroids as indicated, anticholinergic drugs to dry secretions as indicated, and long-acting analgesics such as methadone or clonidine
- The difficult airway should be anticipated and all necessary preparations made in advance with equipment and additional personnel available during induction
- A reinforced tracheal tube may be needed to ensure a patent airway in the prone position or extreme neck flexion
- Arterial cannulation is usually performed, central venous cannulation is used as indicated, and secure large-bore peripheral intravenous access is essential

One-lung ventilation for anterior approaches

Options for OLV include a tracheal double-lumen tube (DLT), a bronchial blocker, or selective mainstem intubation [66–68]. The smallest, commercially available DLT in most countries is 26 Fr, thereby allowing its use in patients who are 8–10 years of age. Advantages of a tracheal DLT include rapid placement, easy separation of the lungs, complete deflation of the operative lung, improved pulmonary toilet with access for suctioning of both lungs, the ability to rapidly switch to two-lung ventilation if needed, and the feasibility of administering continuous positive airway pressure (CPAP) or oxygen insufflation to the operative lung should this become necessary to improve oxygenation. In patients whose size precludes the use of a DLT, the bronchus on the operative side can be occluded with a balloon-tipped catheter that is placed using fiberoptic bronchoscopic guidance. Several different devices can be used as bronchial blockers including a Fogarty embolectomy catheter, atrio-septostomy catheter, pulmonary artery catheter, the Arndt endobronchial blocker (Cook Critical Care, Birmingham, IN, USA), and the Univent tracheal tube (Fuji Systems, Tokyo, Japan). Devices with a central channel provide the advantage of allowing some degree of suctioning through the channel, not to clear the lung of secretions as the channel is too small for that purpose, but rather to deflate the operative lung and improve surgical visualization or for the insufflation of oxygen and the application of CPAP. Without the central channel, air or gas cannot exit from the lung once the balloon is inflated; therefore the lung may not deflate totally and may obscure surgical visualization. The final option for lung separation is selective endobronchial intubation. The major disadvantage of selective mainstem intubation is that it is not possible to quickly change from OLV to two-lung ventilation as this requires repositioning the ETT from the mainstem bronchus into the trachea and vice versa. Additionally, with movement of the ETT, inadvertent extubation may occur, which may be particularly problematic for the patient in the lateral decubitus position. Placement into the right mainstem bronchus can generally be accomplished blindly while left-sided placement requires guidance with a fiberoptic bronchoscope because of the different anatomical orientation of the left and right mainstem bronchi. See Chapter 26 for additional discussion of one-lung ventilation.

Techniques to limit homologous transfusion

There is a growing body of evidence demonstrating the potential adverse effects of the administration of allogeneic blood and blood products [69–73]. These adverse effects include the transmission of infectious diseases, immunosuppression, transfusion-related acute lung injury, hemolytic and non-hemolytic transfusion reactions, transfusion-associated circulatory overload, and graft-versus-host disease. Of specific concern during the performance of major orthopedic surgical procedures is accumulating data demonstrating the association and potential causative role of allogeneic blood product use in postoperative infectious complications [70,71]. The primary focus on techniques to limit perioperative transfusion remains the appropriate preoperative preparation of the patient as well as attention to basic intraoperative tenets of pediatric anesthesiology, such as patient positioning and maintenance of normothermia. The general perioperative considerations that have a major impact on the perioperative need for allogeneic blood products include optimization of preoperative hemoglobin and coagulation function with avoidance of NSAIDs preoperatively as well as attention to intraoperative anesthetic technique including choice of fluid for intraoperative resuscitation and fluid therapy, proper patient positioning, and maintenance of normothermia [74,75]. The use of preoperative erythropoietin may be costly and not reimbursed by most insurance companies when it is used as a means of increasing the hematocrit to limit perioperative transfusion therapy. Furthermore, as weekly visits are needed for hemoglobin checks and injections, it is time-consuming and therefore generally reserved for specific circumstances where avoidance of allogeneic transfusions is mandated, such as the Jehovah witness patient [76]. On the other hand, an extremely simple and cost-effective measure is the identification of preoperative anemia, which may be prevalent in girls who have started their menstrual cycle. In many circumstances, treatment of anemia can be accomplished with nothing more than oral iron therapy.

While the exact clinical impact is questionable, laboratory tests demonstrate that the choice of intraoperative fluid administration affects coagulation function, including platelet function. During acute normovolemic hemodilution, intraoperative phlebotomy is performed and the removed blood is replaced with crystalloids or colloids. The removal of 10–15 mL/kg of whole blood followed by the administration of crystalloid results in the dilution of proteins with anticoagulation functions, such as antithrombin III. This results in increased coagulation [77]. Replacement of blood with albumin- or gelatin-based solutions have no effect or may actually improve coagulation function, while either medium or high molecular weight hydroxyethyl starches, because of their effects on von Willebrand factor, adversely affect coagulation function, in particular platelet function [78].

Limitation of perioperative blood and administration of blood products can also be achieved by acceptance of the tenet that there is no universal trigger for the administration

of blood products [79,80]. In the absence of co-morbid diseases that compromise end-organ oxygenation or limit the compensatory mechanisms for anemia, hemoglobin levels down to 7 g/dL are generally well tolerated. In a recent prospective trial in the adult ICU population, a restrictive strategy for the administration of blood (blood administered only for a hemoglobin less than 7 g/dL), no difference in outcome was noticed when compared to a liberal transfusion protocol (blood administered for a hemoglobin less than 10 g/dL) [80]. In the less critically ill patients and in those less than 55 years of age, there was a statistically significant improvement in 30-day mortality in the restrictive transfusion group.

Outside of the preoperative phase, there are several additional techniques or medications that may have a role in limiting perioperative allogeneic blood transfusions during spinal surgery:

- Autologous transfusion therapy including:
  a. Preoperative donation with the use of erythropoietin.
  b. Intraoperative collection using acute normovolemic hemodilution.
- Intraoperative and postoperative blood salvage.
- Pharmacological manipulation of the coagulation cascade with:
  a. Antifibrinolytic agents (ε-aminocaproic acid or tranexamic acid).
  b. Procoagulant agents including desmopressin (DDAVP) and recombinant factor VIIa (rFVIIa).
- Controlled hypotension.

The goal of performing pediatric spine surgery without the use of allogeneic blood products is best accomplished by combining several of these techniques [81]. Use of these techniques depends on the co-morbidities of the patient, the type of surgery, and the likelihood of the need for allogeneic transfusions. During spinal surgery, factors that increase the likelihood of needing allogeneic transfusions include the number of vertebral bodies fused and the presence of neuromuscular scoliosis [82,83]. Depending on the expertise of the surgeon, it may be that surgery for idiopathic scoliosis can be performed with few if any of these techniques, while several or all may be required for neuromuscular scoliosis.

Preoperative donation

Although preoperative donation of autologous blood was first suggested by Fantus in 1937 when he founded the first blood bank in the United States, the technique did not gain clinical popularity until the 1980s. Advantages that have been cited of preoperative donation include a reduction of exposure to allogeneic blood, the availability of blood for patients with rare phenotypes, reduction of blood shortages, and avoidance of transfusion-induced immunosuppression [84]. In individual cases, patients who refuse transfusions based on religious beliefs may accept autologous donation, although most will refuse it once the blood is separated from the body.

There are no contraindications to the autologous donation based on the patient's weight or age. Patients who weigh more than 50 kg, can generally donate a standard unit of blood, whereas patients weighing less donate proportionately smaller volumes based on their weight and the presenting hemoglobin or hematocrit. Prior to donation, the hematocrit should be more than 33%. All patients enrolled in an autologous donation program should be on replacement iron therapy to augment erythropoiesis [85]. Cost and scheduling concerns aside, the efficacy of red blood cell production can be augmented by the administration of erythropoietin. Specific contraindications to autologous blood donation are similar to those for the donation of blood for allogeneic use. In general, patients with end-organ disease or limitations of the compensatory mechanisms that maintain tissue oxygen delivery during anemia are not candidates.

Donations are generally made no more often than once a week with the last unit donated at least 5–7 days prior to surgery to allow plasma proteins to restore intravascular volume and to allow ample time for adequate erythropoiesis so that the patient is not anemic upon arrival in the operating room. Although this technique has been endorsed as the easiest means of avoiding allogeneic transfusions, its use has decreased significantly over the past 5–10 years. Concerns regarding the use of autologous blood include the lack of universal screening of these units for infectious diseases with the potential to have an infected unit of blood sitting in the blood bank. Additionally, as the primary event responsible for death following allogeneic blood administration is a clerical error and transfusion of the wrong blood product, autologous units can have the same incidence of this error as allogeneic units. Many of the units of autologous blood are never used. Therefore, they are wasted when there is no standardized policy and procedure for their routine screening and subsequent move into the allogeneic pool. Additional limitations include the cost involved, time constraints, as patients must return to the hospital several times before their operative procedure, and difficulties with vascular access in infants and children. In most centers, this practice has fallen out of favor and is no longer used.

Acute normovolemic hemodilution

Perhaps a more cost-effective and safer means of obtaining autologous blood is acute normovolemic hemodilution [86]. The technique involves the intraoperative removal of blood, generally after the induction of anesthesia and prior to the start of the surgical procedure. Blood is removed from a large-bore intravenous cannula, arterial cannula, or central line, and the volume withdrawn is replaced with colloid or crystalloid in a ratio of 1:3 to maintain normovolemia. The blood is collected in standard CPD-A (citrate phosphate dextrose with adenosine) blood bank bags until they are full (approximately 450–500 mL) or weighed to ensure that the appropriate amount of blood is removed. The amount of blood that can be safely removed is determined by the formula:

$$\text{Estimated blood volume} \times \left(\text{initial hematocrit} - \text{target hematocrit}\right) / \text{mean hematocrit}$$

The mean hematocrit is the average between the initial and the target hematocrit. The removed blood can kept at room temperature for up to 4 h to maintain the function of platelets and clotting factors, thereby providing a significant advantage over allogeneic blood and even predonated autologous blood. Intraoperatively, as needed, the blood is infused in the opposite order to that in which it was withdrawn so that the units with the highest hematocrit are saved until the end of the procedure when there is the least amount of bleeding. Compensatory physiological mechanisms to maintain tissue

oxygen delivery despite a decrease in hematocrit include a decrease in blood viscosity that results in increased venous return, peripheral vasodilation, increased cardiac output, and rightward shift of the oxyhemoglobin dissociation curve. Additionally, as oxygen delivery declines, oxygen extraction at the tissue level can increase to maintain adequate oxygen delivery to tissues [87].

Intraoperative blood salvage

Intraoperative blood salvage involves the collection of blood lost into the surgical field. The collected blood is anticoagulated, filtered for clots and debris, washed (with some devices), and then reinfused. There are three different techniques of intraoperative salvage. Semicontinuous flow devices were the first to be introduced and, although they are the most complex and labor intensive to use, are still the type used most commonly for intraoperative blood collection and reinfusion. The commercially available equipment consists of an aspiration and anticoagulation assembly, a reservoir (various sizes are available depending on the size of the patient), a centrifuge bowl, a waste bag, and tubing. A double-line aspiration set includes an anticoagulation line that permits either heparin or citrate to combine with the aspirated blood at a controlled rate. The anticoagulated blood is collected into a disposable reservoir containing a filter. The filtered blood is then pumped into a bowl, centrifuged, washed with saline, and pumped into a reinfusion bag. Most of the white blood cells, platelets, clotting factors, free plasma hemoglobin, and anticoagulant are removed in the washing process and eliminated in the waste bag. The process takes approximately 5–10 min resulting in a blood cell suspension with a hematocrit of 50–60%. Pediatric-specific devices are available that allow the processing of smaller volumes of blood.

The second type of intraoperative salvage uses a rigid canister with a sterile, disposable liner. Blood is aspirated from the wound and anticoagulant added in a manner similar to that of semicontinuous flow devices. The blood is collected in a rigid plastic reservoir containing a disposable liner. The blood can either be washed prior to infusion or reinfused without washing. Functioning platelets and coagulation factors are present if the blood is left unwashed; however, there is an increased risk for adverse effects due to cellular debris, free hemoglobin, and fragmented blood components. This type is rarely used in the perioperative setting.

The third type of collection is a single-use, self-contained rigid plastic reservoir that collects the shed blood. The anticoagulant (citrate) is placed in the container prior to use. This apparatus is most commonly used for postoperative blood collection and reinfusion. The surgical drains are connected to the canister, and every 4 h the canister is replaced and the blood reinfused. Coagulation factors and platelets are present in this blood as well. Adverse effects may occur as a result of cell fragmentation and the release of free hemoglobin.

Suggested indications for perioperative blood salvage include anticipated blood loss exceeding 20% of the patient's blood volume or a procedure during which more than 10% of patients require transfusion. Contraindications include situations in which there may be contamination of the collected blood with infectious or non-infectious agents (amniotic fluid, hemostatic agents such as topical thrombin, or protamine). Potential complications include air and fat embolism, hemolysis, pulmonary dysfunction, renal dysfunction, coagulopathy, hypocalcemia, and sepsis [88]. Coagulopathy may occur related to the initiation of disseminated intravascular coagulation due to improper technique and the infusion of blood cell fragments or the infusion of residual anticoagulant after washing [89]. Hemolysis may occur if the suction level is too high or if the aspiration method causes excessive mixing of air with blood. Free hemoglobin may be released during salvage and washing because of erythrocyte damage. Free hemoglobin levels exceeding 100–150 mg/dL may lead to hemoglobinuria and acute renal failure, as the binding capacity of haptoglobin is saturated and free hemoglobin is filtered in the renal tubules. Metabolic consequences of cell salvage may also be seen including a metabolic acidosis and alterations in electrolytes, such as magnesium, calcium, and potassium. Despite the list of potential complications and cost for the initial purchase of the machine and disposable items, the incidence of significant adverse effects is low and it represents an effective means of limiting the need for allogeneic transfusion [90].

Pharmacological manipulation of the coagulation cascade

Various agents have been used as prophylactic measures, even in patients with normal baseline coagulation function, to decrease intraoperative blood loss. Although these agents have been studied in well-designed prospective trials, the outcomes of the studies are, at times, conflicting. Another issue to consider with the administration of any agent that alters coagulation function is the potential to invoke a prothrombotic state with venous or arterial thrombotic complications.

1-Deamino-8-D-arginine vasopressin (DDAVP) is a synthetic analog of vasopressin initially used in the treatment of diabetes insipidus. Its hemostatic effects result from the release of factor VIII and von Willebrand factor (vWF) from endothelial cells. Factor VIII, a glycoprotein, accelerates the activation of factor X by factor IX, while vWF increases platelet adherence to vascular subendothelium, augments the formation of molecular bridges between platelets to increase aggregation, protects factor VIII in the plasma from proteolytic enzymes, and stimulates the synthesis of factor VIII. Although anecdotal reports have demonstrated its efficacy in augmenting coagulation function in various acquired and inherited forms of platelet dysfunction, prospective trials have failed to show an effect on blood loss during spinal surgery in pediatric patients [91]. Although routine use is not recommended and of limited utility, it may have a role in patients with specific defects of coagulation function or number.

ε-Aminocaproic acid (EACA) and tranexamic acid (TXA) are γ-amino carboxylic acid analogs of lysine that inhibit fibrinolysis by preventing the conversion of plasminogen to plasmin. They represent the agents that are used most commonly to manipulate the coagulation cascade to limit allogeneic transfusions during spinal surgery. In the plasma, plasminogen is activated by tissue plasminogen activator to form plasmin which cleaves fibrin, thereby preventing the formation of the fibrin mesh. This fibrinolytic system is a basic defense mechanism that prevents the excessive deposition of fibrin following the activation of the coagulation cascade. Plasmin can also hydrolyze activated factors V and VIII. EACA and TXA bind

to the lysine group that binds plasminogen and plasmin to fibrinogen, thus displacing these molecules from the fibrinogen surface and inhibiting fibrinolysis.

One of the issues with the use of agents such as EACA and TXA is that various dosing regimens have been reported in the literature and there remains significant variation in current clinical practice [92]. In general, both medications are administered as a loading dose followed by an infusion during the intraoperative period, with some studies continuing the infusion for a brief period of time into the postoperative course. Ninety percent of EACA is excreted in the urine within 4–6 h of administration. Although TXA is generally considered to be pharmacologically 7–10 times as potent as EACA, some studies have reported similar dosing regimens. Adverse effects of EACA or TXA may be related to the effect on coagulation function and the route of excretion. Since these agents are cleared by the kidneys, thrombosis of the kidneys, ureters, or lower urinary tract may occur if urological bleeding is present. Both EACA and TXA may be associated with hypotension during rapid intravenous administration. Seizures have been reported with TXA administration, most commonly during cardiac surgery; however, its use has not been restricted in patients with seizure disorders or those receiving anticonvulsant medications [93]. Given the limited adverse effect profile and general efficacy in the pediatric-aged patient, these agents are commonly used as a means of limiting intraoperative blood loss during spinal surgery [94,95]. In prospective, randomized trials, both EACA and TXA have been shown to decrease intraoperative blood loss during posterior spinal fusion in children and adolescents with either idiopathic or neuromuscular scoliosis [95–97]. As noted, dosing regimens vary greatly among the clinical trials with many centers, including our own, using a loading dose of 50 mg/kg followed by an infusion of 5 mg/kg/h [98].

Controlled hypotension

Controlled hypotension (deliberate or induced hypotension) may be defined as a deliberate reduction of systolic blood pressure to 80–90 mmHg, a reduction of mean arterial pressure (MAP) to 50–65 mmHg or a 30% reduction of baseline MAP. The latter is relevant for the pediatric-aged patient whose baseline MAP may be within the 50–65 mmHg range to start with. Although the primary premise for the use of controlled hypotension is to limit intraoperative blood loss, an additional benefit may be improved visualization of the surgical field and thereby shorter surgical times.

Advances in drug therapy have provided the clinician with several pharmacological options for controlled hypotension in pediatric-aged patients [99]. The agents available for controlled hypotension can be divided into those used by themselves (primary agents) and adjunctive or secondary agents which are used to limit the dose requirements and therefore the adverse effects of primary agents. Primary agents include regional anesthetic techniques (spinal and epidural anesthesia), the inhalational anesthetic agents (halothane, isoflurane, sevoflurane), the nitrovasodilators (sodium nitroprusside, nitroglycerin), prostaglandin E1, and adenosine. The calcium channel blockers and β-adrenergic antagonists have been used as both primary agents as well as adjuncts to other agents. Pharmacological agents used as adjuncts or secondary agents include the angiotensin-converting enzyme inhibitors and α-adrenergic agonists such as clonidine. When neurological monitoring is used (see next secton), the potential impact of the agent used for controlled hypotension must be considered.

Sodium nitroprusside (SNP) is one of the most commonly used agents for controlled hypotension [100]. It is a direct-acting, non-selective peripheral vasodilator that primarily dilates resistance vessels leading to venous pooling and decreased systemic vascular resistance. It has a rapid onset of action (approximately 30 s), a peak hypotensive effect within 2 min with a return of blood pressure to baseline values within 3 min of its discontinuation. SNP releases nitric oxide (formerly endothelial-derived relaxant factor), which activates guanylate cyclase leading to an increase in the intracellular concentration of cyclic guanosine monophosphate (cGMP). cGMP decreases the availability of intracellular calcium through one of two mechanisms: decreased release from the sarcoplasmic reticulum into smooth muscle or increased uptake by the sarcoplasmic reticulum. The net result is decreased free cytosolic calcium and vascular smooth muscle relaxation. Adverse effects include rebound hypertension, coronary steal, increased intracranial pressure, increased intrapulmonary shunt with ablation of hypoxic pulmonary vasoconstriction, platelet dysfunction, and cyanide/thiocyanate toxicity. Direct peripheral vasodilation also results in baroreceptor-mediated sympathetic responses with tachycardia and increased myocardial contractility. The renin–angiotensin system and sympathetic nervous system are also activated. The result is increased cardiac output which may offset the initial decrease in MAP. Plasma catecholamine and renin activity may remain elevated after discontinuation of SNP, resulting in rebound hypertension. The considerable expense of this drug in many areas has limited its use, with alternative drugs such as nicardipine in more common use.

Nicardipine is a calcium channel blocker of the dihyropyridine class that dilates the systemic, cerebral, and coronary vasculature with limited effects on myocardial contractility and stroke volume. Unlike SNP, nicardipine does have some intrinsic negative chronotropic effects which may limit the rebound tachycardia. Like other direct-acting vasodilators, nicardipine and the other calcium channel antagonists may increase intracranial pressure. Studies comparing SNP with nicardipine have demonstrated several potential advantages of nicardipine including fewer episodes of excessive hypotension, less rebound tachycardia, less activation of the rennin–angiotensin and sympathetic nervous systems, and, in some studies, decreased blood loss [101]. One disadvantage of nicardipine is that its effect is somewhat prolonged (20–30 min) following discontinuation of the infusion. More recently, a new dihydropyridine, clevidipine, has been added to the list of agents that may be used for intraoperative blood pressure control [102]. Although its hemodynamic effects are similar to those of nicardipine, it is metabolized by plasma and tissue esterases thereby resulting in a half-life of 2–3 min.

Although controlled hypotension is effective at reducing blood loss, care must be taken not to decrease blood pressure excessively due to the risk of spinal cord ischemia. Spinal cord monitoring must be carefully assessed for effects of hypotension, and the blood pressure increased if evoked potentials are decreased in the face of hypotension.

KEY POINTS: TECHNIQUES TO LIMIT HOMOLOGOUS TRANSFUSION

- Intraoperative techniques include acute normovolemic hemodilution, intraoperative and postoperative blood salvage, antifibrinolytic agents such as TXA and EACA, and procoagulants like DDAVP and recombinant factor VIIa
- Deliberate hypotension can be induced with anesthetic agents, sodium nitroprusside, nicardipine, or clevidipine. Care must be taken to not lower blood pressure excessively to avoid the risk of spinal cord ischemia

Spinal cord monitoring

Without electrophysiological monitoring, the incidence of neurological deficits following surgical procedures on the vertebral column may be as high as 3.7–6.9%. This can be decreased to less than 1% with appropriate monitoring [103]. In their guidelines on intraoperative monitoring, the American Academy of Neurology concluded that the evidence favors the use of monitoring as a safe and efficacious tool in clinical situations where there is a significant nervous system risk, provided its limitations are appreciated [103]. A recent meta-analysis of multimodality spinal cord monitoring for idiopathic scoliosis surgery included seven studies and 2052 patients [104]. Both somatosensory-evoked potentials (SSEPs) and transcranial MEPs were utilized and the incidence of neurological deficit was 0.93%. All 19 patients with neurological deficit had a neuromonitoring change in SSEP and/or transcranial MEP. No patient without neuromonitoring change had a deficit. The overall sensitivity for predicting neurological deficit when both modalities were utilized was 83%, specificity was 94%, positive predictive value 12%, and negative predictive value 99.8%. One of the major limitations is that animal studies have demonstrated a window of opportunity of less than 10 min from the time when a change in monitoring parameters is noted until permanent damage occurs. Additionally, when various techniques are used, such as SSEPs or MEPs, the anesthetic technique must be modified to facilitate processing of the signals.

In general, there are four techniques of intraoperative monitoring: (i) the ankle clonus test; (ii) the wake-up test; (iii) SSEPs; and (iv) MEPs. The ankle clonus test was the first to be used intraoperatively to assess spinal cord integrity [105]. During the normal awake state, descending inhibitory fibers prevent clonus in response to an ankle stretch. The reflex is also inhibited during deep levels of anesthesia. However, during emergence from anesthesia, inhibition of the central descending pathways allows ankle clonus to be elicited following dorsiflexion of the foot/ankle. If there has been damage to the spinal cord, flaccid paralysis will be present and no spinal reflexes can be elicited. To elicit ankle clonus, neuromuscular blockade must be reversed or absent and the patient is allowed to emerge from general anesthesia, as is done with a wake-up test. In most circumstances, the ankle clonus test can be elicited prior to the patient regaining consciousness and therefore at a deeper level of anesthesia than a true wake-up test [105]. The test is both extremely sensitive and specific; however, it does not provide a continuous monitor of spinal cord function and is present only at a specific depth of anesthesia.

The wake-up test was originally reported in the 1970s as a means of monitoring spinal cord integrity. The potential need for the technique should generally be included during the preoperative discussion with the patient. Details may include what the test entails, its purpose, timing during the procedure, and the fact that there may be some intraoperative recall during the period of time when the test is performed. Given the increased sophistication of neurophysiological monitoring techniques, the wake-up test is no longer routine, but is reserved for times when changes in MEPs or SSEPs are noted and do not respond to interventions. When a wake-up test is performed, neuromuscular blockade is reversed as needed and the depth of anesthesia decreased. The speed with which a patient will respond to verbal stimuli can be increased by the use of short-acting anesthetic agents (desflurane and remifentanil). When these agents are used, responsiveness and a successful wake-up test can generally be accomplished in less than 10 min after the surgeon's request. The use of reversal agents for opioids and benzodiazepines, although available, in clinical practice is not generally recommended as they may have prolonged effects that will interfere with the resumption of anesthesia after the wake-up test. However, if longer acting, high-potency opioids are used (sufentanil), the administration of naloxone may be necessary. The depth of anesthesia and the patient's awakening can also be judged by the use of neurophysiological or depth of anesthesia monitors. As the depth of anesthesia is decreased, one anesthesia provider stands at the head of the bed with one hand on the patient's head to limit the risk of sudden inadvertent movements that may dislodge the tracheal tube. The other hand is used to feel the patient's response to a verbal command to squeeze one's hand. When the patient reaches a light plane of anesthesia, a voluntary movement in the motor groups above the level of surgery (e.g. squeezing one's hand) is requested initially to ensure that the patient is awake enough to follow commands. This is then followed by a request to move the lower extremities to ensure that motor function is still intact. Once a positive response is achieved in the lower extremities, the depth of anesthesia is deepened by the bolus administration of propofol. The wake-up test entails certain risks including having an awake patient in the prone position on the operating room table. Inadvertent or sudden movements may result in patient injury, dislodgment of venous or arterial cannula, and hypertension with exacerbation of bleeding. Additionally, like the ankle clonus test, it provides only a single assessment of spinal cord integrity. In most centers, the wake-up test is used only when there are questionable findings on electrophysiological monitoring.

Electrophysiological monitors include both SSEPs and MEPs. SSEPs are monitored by stimulation of a distal nerve, generally in the leg (posterior tibial), and measuring the response at the cervical level and the central nervous system via standard electroencephalography electrodes. The pathways involved include the peripheral nerve, the dorsomedial columns (fasciculus gracilis and fasciculus cuneatus) of the spinal cord, and the cerebral cortex. SSEPs do not monitor anterior cord (motor) function. Given the close proximity of the tracts (motor and sensory) in the spinal cord, damage to the motor tracts generally results in damage to the sensory tracts making SSEPs a fairly reliable measure of motor function. However, given that the dorsomedial tracts and the

anterior aspect of the spinal cord do not share the same arterial supply, isolated damage to the motor tract with intact SSEPs has been reported.

Since SSEPs can be affected by anesthetic agents, baseline recordings are performed after an appropriate level of anesthesia has been achieved [106]. During the subsequent anesthetic care, effective monitoring is facilitated by maintaining a similar depth of anesthesia. While various agents have differing effects on the ability to obtain MEPs and SSEPs, it is most important to not maintain too deep a plane of anesthesia as this will invariably decrease the ability to obtain effective neurophysiological monitors. Given these concerns, we have found depth of anesthesia monitors very useful during neurophysiological monitoring, and suggest maintaining the bispectral index (BIS™, Medtronic Corp., Minneapolis, MN, USA) at 55–60 [107].

The variables measured for SSEPs include both the height of the response (amplitude) and the time it takes the response to travel from the periphery to the central nervous system (latency). Significant changes include a reduction in the amplitude of ≥50% or an increase in the latency of ≥10%. The potent inhalational anesthetic agents and nitrous oxide cause a decrease in the amplitude and an increase in the latency of SSEPs. However, acceptable monitoring can be achieved with 0.5 MAC (minimum alveolar concentration) of isoflurane, sevoflurane, or desflurane. Although practices vary from center to center, nitrous oxide is generally avoided. Intravenous anesthetic agents have been shown to have less of an effect on SSEPs, making a total intravenous anesthetic technique using propofol or midazolam combined with an opioid an effective technique. In general, either propofol or 0.5 MAC of an inhalational anesthetic agents can be combined with a continuous infusion of a potent synthetic opioid, either sufentanil or remifentanil. Neuromuscular blocking agents have no effect on SSEPs, but will obviously eliminate the ability to obtain MEPs [107]. When a volatile agent such as desflurane is chosen, a 0.5 MAC amount can be titrated using the BIS and incremental doses of a benzodiazepine (midazolam) administered as needed to ensure amnesia while allowing for a low enough desflurane concentration to allow for neurophysiological monitoring.

Due to the concern that there can be isolated motor damage with intact SSEPs, most centers monitor MEPs along with SSEPs. As with SSEPs, MEPs are affected by the type of anesthetic agent used. Various techniques have been recommended and there remains variation from center to center, but the anesthetic technique is generally the same as for SSEP monitoring. Dexmedetomidine has also been used during spinal surgery, given its ability to decrease requirements for inhalational anesthetic agents and propofol as well as its ability to decrease postoperative opioid requirements [108,109]. Provided that the depth of anesthesia is maintained, no change in MEPs or SSEPs have been reported with the use of dexmedetomidine as part of the intraoperative anesthetic care [109,110]. With MEP monitoring, the level of neuromuscular blockade must be kept stable with maintenance of one or two twitches of the train-of-four. Alternatively, as is our preference, neuromuscular blockade with a short-acting agent is used only for tracheal intubation and no neuromuscular blocking agents are used during the procedure. Regardless of the anesthetic technique used for these cases, a protocolized approach should be in place should there be loss of SSEPs or MEPs (Box 29.1). Two examples of abrupt loss of MEP signal, and the interventions employed, are presented in Fig. 29.12 [111]. A summary of anesthetic agents' effects on neuromonitoring parameters is presented in Table 29.2 [112].

Box 29.1: Treatment protocol for loss of neurophysiological monitors

- Consider any recent surgical correction and attempt to reverse it, including removal of distraction devices, wires, hardware, or pedicle screws
- The anesthesiologist should prepare for a wake-up test to confirm the MEP and SSEP findings if the following steps are not effective
- Discontinue controlled hypotension
- Increase MAP to ≥90 mmHg by:
  a. reducing the depth of anesthesia
  b. increasing intravascular volume by the administration of crystalloid or colloid
  c. administering a vasoactive agent (phenylephrine)
- Increase the hematocrit to a hemoglobin ≥8–10 g/dL
- Adjust mechanical ventilation parameters:
  a. increase oxygen concentration to 100%
  b. ensure normocarbia
- If the MEP or SSEP changes are not reversed, a wake-up test should be performed
- If there is a neurological deficit confirmed by the wake-up test:
  a. a spinal cord injury protocol should be instituted with consideration for the administration of methylprednisolone (30 mg/kg as a loading dose over 60 min followed by an infusion at 5.4 mg/kg every hour for the next 23 h)
  b. surgical consideration for removal of spinal hardware and instrumentation
  c. emergent radiological imaging (computed tomography or magnetic resonance) as clinical care allows

KEY POINTS: SPINAL CORD MONITORING

- There are four techniques of spinal cord monitoring: the ankle clonus test, the wake-up test, somatosensory-evoked potentials (SSEPs), and motor evoked potentials (MEPs)
- Monitoring of SSEPs and MEPs are standard care and together have high sensitivity and specificity for spinal cord ischemia detection
- The wake-up test is reserved for cases where neuromonitoring is persistently abnormal
- Volatile anesthetics and nitrous oxide have significant effects on SSEPs and MEPs and are avoided or used only in low concentrations
- An acute change in SSEPs or MEPs mandates timely response, including raising blood pressure and hemoglobin, ensuring normocarbia, decreasing depth of anesthesia, reversing surgical manipulaton like hardware placement or spine distraction, and use of the wake-up test if signals are not restored quickly

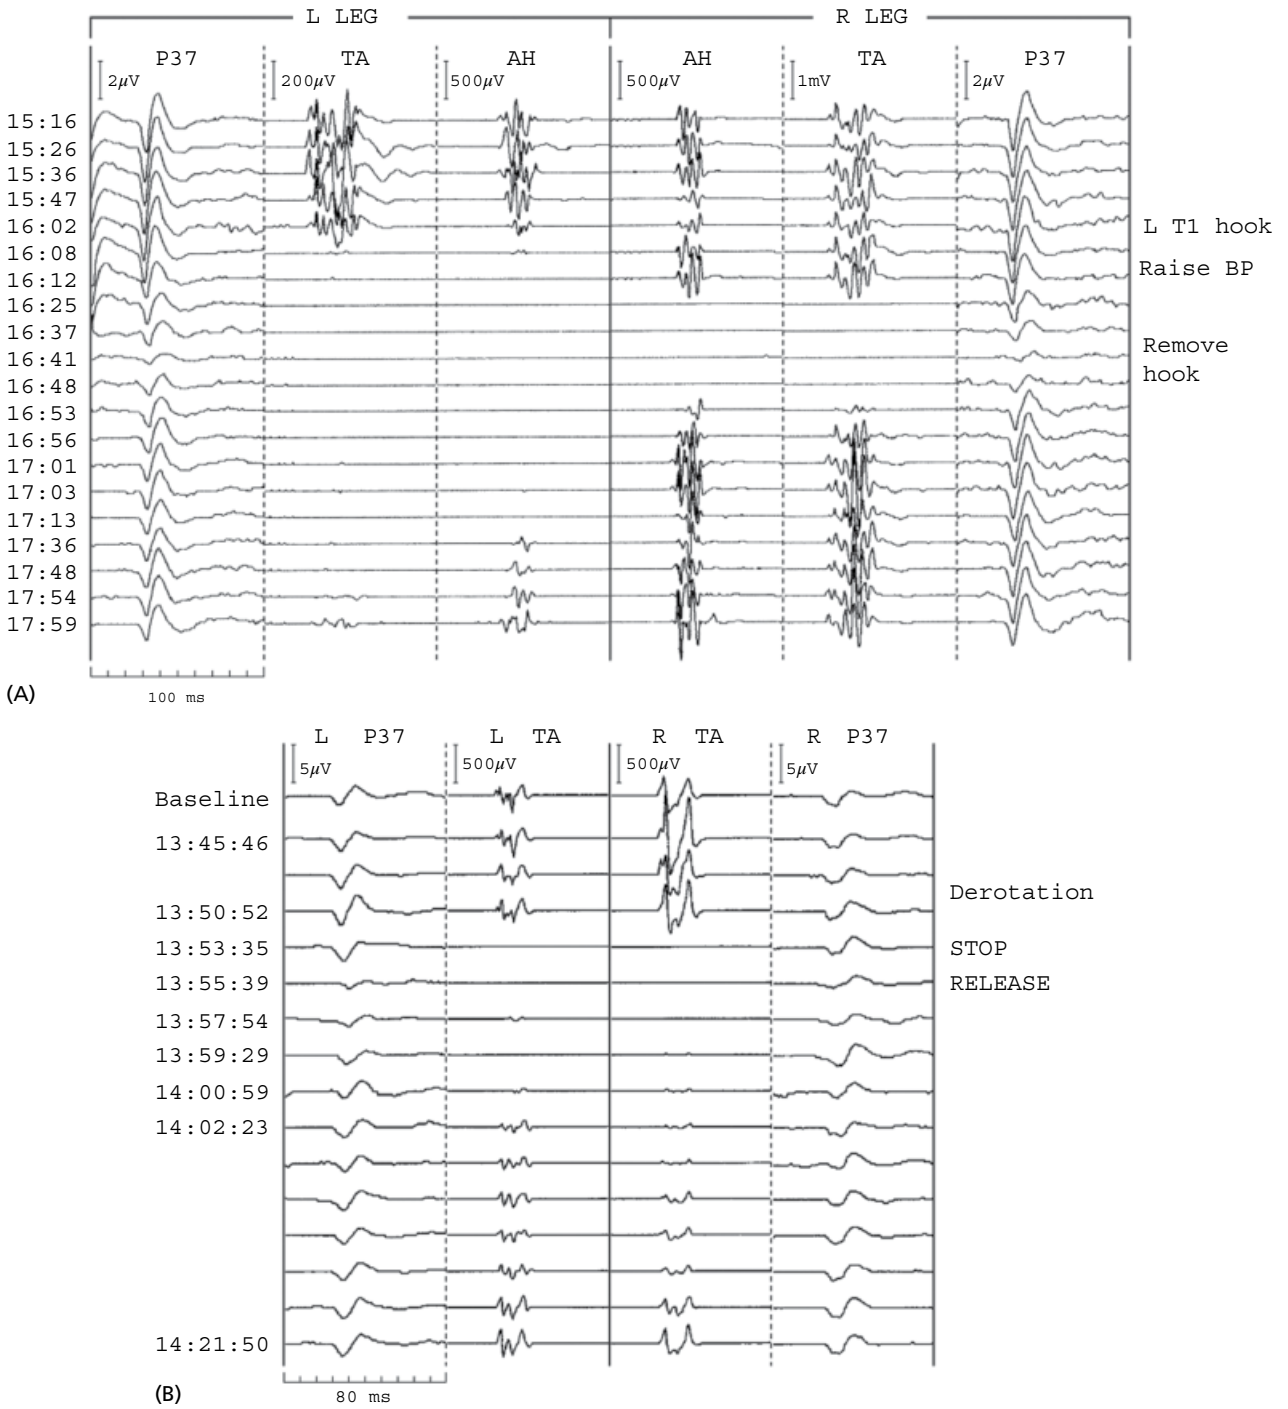

Figure 29.12 Two examples of intervention for MEP disappearance during scoliosis surgery. (A) Raising blood pressure (BP) had no beneficial effect on abrupt left leg MEP loss after sublaminar hook insertion. Instead, deterioration progressed to right leg MEP loss and bilateral SEP reduction. The hook was finally removed and evoked potential restoration followed, but left leg MEP absence was protracted (>40 min) and there was left leg paresis lasting a few days. Immediate hook removal might have been a more effective initial intervention. (B) Immediate instrumentation release without raising BP was quickly followed by restoration of abrupt bilateral leg MEP loss and subsequent SEP deterioration during derotation. There was no deficit. AH, abductor hallucis; P37, tibial nerve cortical SEP; TA, tibialis anterior. *Source*: Reproduced from Macdonald et al [111] with permission of Elsevier.

Intraoperative anesthetic care

Intraoperative anesthesia is generally best coordinated with the physicians and technicians providing intraoperative neurophysiological monitoring, as significant variations in preference vary from center to center. The techniques generally combine either a propofol infusion or a low dose inhalational anesthetic agent (0.5 MAC) with a potent synthetic opioid infusion (remifentanil or sufentanil). Some centers avoid inhalational anesthetics altogether, mandating a total intravenous anesthesia approach. As mentioned previously, dexmedetomidine may be added to the intraoperative regimen to limit the requirements for either propofol or the inhalational anesthetic agent. We have also found that these agents can be effectively titrated to achieve an acceptable level of blood

Table 29.2 Properties pertinent to neuromonitoring of commonly used anesthetic agents in major spine surgery

Drug name	Drug class	Effect on SSEPs	Effect on MEPs	Length of emergence	Approximate CST½ (min) at 2/4/6 h and B:GC for volatile agents	Clinical advantages relating to intraoperative neuromonitoring	Disadvantages
Propofol	GABA agonist	↓	↓	+++	15/20/30	Titratable, smooth emergence	Accumulation, slow wake-up
Etomidate	GABA agonist	↑↑	–	++	5/10/20	Titratable, hemodynamically stable	Adrenal suppression, PONV, myoclonus seizures
Midazolam	Benzodiazepine	↓	–	+++	40/60/65	Amnestic	Prolonged emergence
Ketamine	NMDA antagonist	↑	–/↓	+++	15/30/40	Analgesic, amnestic, sympathomimetic, hemodynamically stable	Hallucinations
Fentanyl	Opioid synthetic	–/↓	↓	+++	40/160/240	Analgesic	Accumulation, respiratory depression
Remifentanil	Opioid synthetic	–/↓	–/↓	+	7/7/7	Potent analgesic	Hyperalgesic effect after discontinuation
Sufentanil	Opioid synthetic	–/↓	↓	++	15/20/30	Potent analgesic	Respiratory depression
Dexmedetomidine	α_2-agonist	–/↓	–/↓	+++		Sedato-hypnotic with preserved respiratory drive, awake intubation	Bradycardia and heart block
Isoflurane	Inhalational	↓↓	↓↓↓	+++	1.4	Low cost	Reduced $CMRO_2$ of CNS
Sevoflurane	Inhalational	↓↓	↓↓	++	0.65	Mask induction	Emergence delirium
N_2O	Inhalational	↓↓	↓↓	+	0.47	Rapid elimination, analgesic effect	Synergistic effect on signal depression, PONV
Desflurane	Inhalational	↓↓	↓↓	+	0.42	Rapidly titratable, fast elimination	Emergence delirium, branchospasm
Rocuronium	NDMR	–	↓↓↓	N/A	N/A	Relatively short half-life and quick elimination after IOA with low doses	Interindividual variability of elimination, risk of residual NMB
Succinylcholine	Depolarizing muscle relaxant	–	↓↓↓	N/A	N/A	Rapid elimination after IOA	Contraindicated in MH and muscular dystrophies, pseudo-cholinesterase deficiency leads to long half-life

B:GC, b!ood:gas partition coefficient (the higher the value, the more agent is dissolved in blood and the longer it takes for the volatile anesthetic to be eliminated); $CMRO_2$, cerebral metabolic rate for oxygen; CNS, central nervous system; CST½, context sensitive half-time (elimination half-life as a function of duration of infusion); GABA, γ-aminobutyric acid; IOA, induction of anesthesia; MEPs, motor-evoked potentials; MH, malignant hyperthermia; NDMR, non-depolarizing muscle relaxant; NMB, neuromuscular blockade; PONV, postoperative nausea and vomiting; SSEPs, somatosensory evoked potentials.

pressure control to provide controlled hypotension with a limited need for supplemental antihypertensive agents. In most cases when remifentanil and dexmedetomidine infusions are used, controlled hypotension can be maintained with only an occasional need for intermittent doses of labetolol.

Although remifentanil is a frequent component of intraoperative care for spinal surgery, one issue that has been identified with its use is the development of acute opioid tolerance [113]. This may result in an increased opioid requirement during the postoperative period. Crawford et al investigated the effects of remifentanil on postoperative opioid requirements in a cohort of 30 adolescents undergoing posterior spinal fusion for the treatment of idiopathic scoliosis [114]. Cumulative morphine use during the first 24 postoperative hours was 30% greater in the group receiving remifentanil. Despite such observations, the mechanisms responsible for the postoperative hyperalgesia remain undefined. Although it has been attributed to effects of remifentanil at the N-methyl-D-aspartate receptor, the hyperalgesia is not blocked by the administration of ketamine [115]. Given the potential for hyperalgesia following the intraoperative use of remifentanil, several centers have incorporated a single intraoperative bolus dose of methadone at the start of the anesthetic regimen [116–118].

Another potential adjunct for the intraoperative anesthetic care of patients during spinal surgery is the inclusion of a magnesium infusion [119,120]. A magnesium infusion has been shown to decrease intraoperative anesthetic requirements for propofol, the need for inhalational anesthetic agents and neuromuscular blocking agents, effectively control hypotension, and even decrease postoperative opioid requirements. In a prospective trial of 61 children with cerebral palsy undergoing spinal fusion, patients were randomized to receive magnesium (50 mg/kg followed by an infusion of 15 mg/kg/h) or a saline placebo [121]. Postoperative analgesic requirements and pain scores were lower at 24 and 48 h in the group that had received magnesium. Our clinical practice suggests that care must be exercised with the administration of the bolus dose of magnesium, as we have anecdotally noticed significant changes in MEPs following the bolus dose.

Additional intraoperative considerations include alterations in care, which may affect postoperative surgical site infections (SSIs) and the treatment of acute intraoperative events. Although various factors are involved in the genesis of a SSI, recent data have focused on the potential beneficial impact of the intraoperative F_iO_2. As oxygen is required for neutrophil killing of bacteria, it has been postulated that increasing the inspired FiO_2 may decrease the incidence of SSIs. In a case–control study, Maragakis et al compared the intraoperative course of 104 adult patients with SSIs to a randomly selected control group [122]. Risk factors for SSI included an intraoperative FiO_2 of less than 0.5 (adjusted odds ratio 12, 95% confidence interval 4.5–33, $p < 0.001$).

Given the complexity of the surgical procedure, various unique intraoperative complications may occur. As there is extensive removal of cortical bone and placement of screws, intraoperative hemodynamic instability may occur related to emboli (air, bone marrow, or fat), blood loss, or even anaphylactoid reactions to thrombotic or other pharmacological agents [123,124]. Early recognition of such events is mandatory, as cessation of surgical manipulation and flooding the surgical field with saline may limit the impact of air embolism on hemodynamic status. In more extreme cases, resuscitation in the prone position may be necessary. Although flipping the patient may be an option, even rapid closure of the surgical wound and flipping can result in the loss of precious minutes of resuscitation. Several case reports and animal studies demonstrate that effective cardiopulmonary resuscitation (CPR) can be performed in the prone position [125]. The technique involves the placement of one hand over each scapula with compressions performed in a perpendicular motion toward the operating room table or floor. If the patient is on a specialized frame, the thoracic support underneath the patient will generally provide enough counter-pressure for effective changes in intrathoracic pressure. If the patient is on a frame where the chest and abdomen hang free, it may be necessary for another care provider to support the chest from underneath the table to allow for effective CPR.

KEY POINTS: INTRAOPERATIVE CARE

- Careful positioning is essential to avoid nerve and eye injuries, to avoid dislodgment of the endotracheal tube, and to enable the abdomen to hang free to reduce blood loss
- Remifentanil may lead to tachyphylaxis and increased postoperative pain; if used, then a long-acting opioid such as methadone can be given at the beginning of the case
- Postoperative visual loss is a rare but devastating complication of spine surgery; pressure on the globe, head down position, prolonged surgery with significant blood loss, and fluid administration are risk factors

Postoperative care including pain management

One of the keys to the successful care of the pediatric spine patient is to provide a smooth transition from the operating room to the ICU. This process begins with the preoperative preparation and education of the patient, preferably with a tour of the pediatric ICU. The patient should also be instructed regarding the correct use of incentive spirometry and patient-controlled analgesia (PCA) if the use of these devices is planned.

At the completion of the procedure, the majority of patients undergo tracheal extubation in the operating room. Given the prolonged prone positioning, lingual edema may be present and result in postoperative upper airway obstruction. Excessive lingual edema may mandate continuing mechanical ventilation into the postoperative period. When the cuff is deflated, an adequate airway leak should be present before tracheal extubation. An appropriate level of responsiveness should be obtained to allow for a neurological examination to demonstrate adequate upper and lower extremity function. In many institutions, idiopathic scoliosis patients are not routinely admitted to the pediatric ICU, but rather the inpatient ward. In such instances, a 2–4 h stay in the postanesthesia care unit is used to ensure hemodynamic respiratory stability.

Patients with co-morbid cardiac or respiratory disease are usually admitted to the pediatric ICU, and the decision to continue mechanical ventilation into the postoperative period is made on an individual basis. If there is any possibility for the use of postoperative mechanical ventilation or non-invasive respiratory support, this should be discussed preoperatively with the carers and the patient. The need for mechanical ventilation may be related to either the patient (neuromuscular disorder, preoperative pulmonary dysfunction) or the surgical procedure (blood loss of more than 1 blood volume). In specific cases, the best option may be to provide 2–4 h of postoperative mechanical ventilation to ensure cardiorespiratory stability, normal coagulation function, and correction of metabolic parameters. Once this is accomplished, the trachea can be extubated in the ICU setting. In patients with neuromuscular disorders, our practice is to consider tracheal extubation to a non-invasive ventilation technique (BiPAP). We have found that this may allow for rapid tracheal extubation following the procedure and yet limit the development of atelectasis or respiratory insufficiency.

Due to the significant length of the surgical incision and the degree of bony and soft tissue dissection required for such procedures, there may be significant postoperative pain. Effective analgesia is generally best provided using a multimodality approach, which includes analgesic agents, anxiolytic agents, and medications to control muscle spasms. Muscle spasms may be particularly problematic in patients with underlying cerebral palsy or neuromuscular disorders. Options for the provision of analgesia include the intravenous administration of medications and/or regional anesthetic techniques. For intravenous administration, we prefer the use of PCA. Although young patients or those with developmental disabilities may not be able to activate the device, nurse-controlled or parent-controlled analgesia may be provided. By using the device in this manner, the bedside nurse has ready access to a supply of opioid to provide an immediate dose to a patient who is in pain. Prior to instituting PCA, an appropriate level of analgesia must be achieved by the careful titration of opioid. This is generally done in the operating room at the completion of the surgical procedure. Once neurophysiological monitoring is completed, the remifentanil and propofol infusions are discontinued and desflurane or sevoflurane started to maintain the BIS at 50–60. After the onset of spontaneous ventilation, incremental doses of either hydromorphone (2–3 μg/kg) or morphine (20 μg/kg) are titrated based on the patient's respiratory rate. Once tracheal extubation is completed, additional complaints of pain are treated with additional bolus doses of opioid followed by the initiation of the PCA device to maintain analgesia. In patients who have received methadone as part of their intraoperative anesthetic technique, the PCA device is generally used in the bolus mode only without a continuous opioid infusion. Given the significant interpatient variability that may occur, age-appropriate pain scores as used to titrate the PCA doses up or down based on the patient's response.

To limit the total dose of opioid required and thereby opioid-related adverse effects, adjunctive agents can be used. There remains significant controversy regarding the potential adverse effects of NSAIDs on bone formation. Given these concerns, many centers choose not to use these agents following spinal surgery in children or at least to limit their use for the first 24 postoperative hours. Our preference is to administer intravenous acetaminophen every 4–6 h around the clock. Given the propensity of these patients to develop muscle spasms and the need, in some patients, to provide anxiolysis, benzodiazepines such as diazepam may be added to the postoperative regimen either as on an as needed basis or at fixed intervals. Alternatively, there may be a role for the α2-adrenergic agonists to provide anxiolysis as well as relief of muscle spasms. Given its limited effects on respiratory function and its ability to potentiate opioid-induced analgesia, dexmedetomidine may also have a role in the ICU setting to provide anxiolysis following major surgical procedures including spine surgery. The other class of agent that has gained popularity as an adjunct to opioid analgesia following spinal surgery are the γ-aminobutyric acid analogs such as gabapentin and pregabalin [126–129]. In a prospective study of 59 patients, 9–18 years of age, undergoing posterior spinal fusion, gabapentin significantly reduced total morphine consumption and pain scores in the postanesthesia care unit and on the first postoperative day [127]. In addition to working during the acute postoperative period, data from adult populations suggest more prolonged effects with decreased pain scores and improved functional outcomes 3 months after surgery [128].

Given successes in other surgical procedures, there is also significant interest in the potential use of regional anesthetic techniques as a means of controlling pain following spine surgery in children. Reports in the literature regarding the use of regional anesthesia following spine surgery have included several variations: (1) the dose of the medications used; (2) the route of delivery (intrathecal or epidural); (3) the mode of delivery (single dose, intermittent bolus dosing, or continuous infusion); (4) the number of catheters used (one versus two); (5) the medications infused (opioids or local anesthetics or both); (6) the opioid used (morphine, fentanyl, hydromorphone); (7) analgesic regimen of the control group if present (intermittent "as needed" morphine or PCA); (8) the type of surgery (short segment lumbar fusion, short segment laminectomy for dorsal rhizotomy, posterior spinal fusion, and anterior spinal fusion); and (9) the surgical approach (open versus thoracoscopic). The reader is referred to a review of the reports regarding the use of regional anesthetic techniques following spine surgery in pediatric-aged patients and a recent meta-analysis evaluating these techniques [130,131]. The evaluation of the efficacy of regional anesthetic techniques is clouded by the variation in the techniques, as previously outlined. Future trials are needed to determine the optimal postoperative analgesic regimens for these procedures.

KEY POINTS: POSTOPERATIVE CARE

- ICU care is frequently required after scoliosis surgery, particularly neuromuscular scoliosis. Patient preparation and through ICU hand-over of care are important for these complex patients
- Most patients are extubated in the operating room; however, for specific cases a 2–4 h period of mechanical ventilation may be prudent to ensure cardiorespiratory stability, normal coagulation function, and correction of metabolic parameters

- Extubation to BiPAP is appropriate for many neuromuscular spine patients with pulmonary involvement
- A multimodal analgesic approach, including opioid PCA, prevention of muscle spasm, and possible use of NSAIDs, α_2-adrenergic agonists, and γ-aminobutyric acid analogs is often required for pediatric spine surgery

Summary

There are many challenges facing the anesthesia provider during spine surgery in pediatric patients. As with any surgical procedure, patient care begins with a thorough preoperative evaluation to identify co-morbid features which are present in many of these patients. Although idiopathic scoliosis is still a common disease, many of these patients will have associated neurological or myopathic conditions that impact on anesthetic care. Intraoperative issues include techniques for airway management, vascular access, blood conservation techniques, patient positioning, intraoperative neurological monitoring, administration of blood and blood products, and maintenance of fluid and electrolyte homeostasis. There is also a need for a smooth transition to the postoperative period with ongoing monitoring to ensure stable cardiorespiratory function and an aggressive approach for the provision of effective postoperative analgesia.

CASE STUDY

A 14-year-old, 72 kg adolescent presented for posterior spinal fusion in the treatment of idiopathic scoliosis. His past medical history was unremarkable for co-morbid medical conditions or previous anesthetic care. Preoperative preparation included the administration of iron and two subcutaneous doses of erythropoietin. Preoperative coagulation function (PT, PTT, and INR) was within normal limits and the hemoglobin was 14.6 g/dL. The patient was held nil per os for 6 h and transported to the operating room where routine ASA monitors were placed. Core body temperature was monitored using a temperature probe incorporated into the Foley catheter. A gauze pad that had been rolled was placed in the mouth to prevent lingual damage from masseter muscle contraction during neurophysiological monitoring. Following the inhalation of nitrous oxide for 3 min, a large-bore peripheral intravenous cannula was placed followed by the intravenous administration of midazolam (2 mg) to provide anxiolysis. This was followed by anesthetic induction with 3 mg/kg of propofol and 5 μg/kg of fentanyl. Tracheal intubation was facilitated by rocuronium (0.4 mg/kg).

Following anesthetic induction, maintenance anesthesia consisted of desflurane (expired concentration 3–4%), intermittent doses of midazolam titrated to maintain the bispectral index at 50–60, and a remifentanil infusion at 0.1–0.3 μg/kg/min. To blunt the hyperalgesia related to remifentanil and provide postoperative analgesia, methadone (0.15 mg/kg) was administered. A second large-bore peripheral intravenous cannula and a radial arterial cannula were placed. Intraoperative monitoring with both somatosensory (SSEP) and motor (MEP) evoked potential monitoring was planned and the appropriate electrodes were placed over the extremities and scalp. A prone pillow was placed to prevent pressure to the eyes and face and the patient was turned prone onto a Jackson table. To facilitate SSEP and MEP monitoring, the concentration of desflurane was kept at 3–4%. No additional doses of a neuromuscular blocking agent were administered until the patient was turned prone and the first set of MEPs were obtained. The remifentanil was increased up to 0.3 μg/kg/min and a clevidipine infusion added as needed to maintain controlled hypotension with a MAP of 50–65 mmHg. Once positioned prone, a forced-air heating device was used to maintain normothermia. The antifibrinolytic agent, tranexamic acid, was administered as a bolus dose of 50 mg/kg followed by an infusion of 5 mg/kg/h until wound closure was started. Intraoperatively, blood salvage with a cell saver from the surgical suction devices was employed. With the desflurane–remifentanil technique, effective monitoring of SSEPs and MEPs was achieved. The technique was titrated to allow for a wake-up test or ankle clonus test should there be changes in neurophysiological monitoring that did not respond to the departmental protocol for loss of neurophysiological monitoring signals. Intraoperative arterial blood gas parameters and hemoglobin values were monitored.

The surgical hardware was placed without incident and the wound was closed. During wound closure, 400 mL of intraoperatively salvaged blood was washed and returned to the patient. Once monitoring of neurophysiological function was no longer indicated, the remifentanil infusion was discontinued with continuation of desflurane to maintain the BIS at 40–60. Once there was return of spontaneous ventilation, hydromorphone was administered in incremental bolus doses (0.1 mg) to achieve a respiratory rate of 8–12 breaths/min. Ondansetron (4 mg) and dexamethasone (4 mg) were administered to prevent postoperative nausea and vomiting. At completion of the surgical procedure, the desflurane was discontinued and the patient was turned supine.

Once there was eye opening and appropriate response to verbal commands, the patient's trachea was extubated. The patient was transported to the post-anesthesia care unit and then admitted to the inpatient orthopedic surgical ward for continued observation. Postoperative analgesia was provided by hydromorphone PCA with intravenous acetaminophen administered every 6 h. The hemoglobin value on postoperative day 1 was 11.6 g/dL. The remainder of the hospital course was unremarkable.

This case illustrates several of the basic tenets required for performance of anesthesia during spinal surgery. Of prime importance is tailoring of the anesthetic regimen to allow for effective monitoring of spinal cord function using SSEP and MEP modalities while ensuring the ability to achieve a rapid wake-up test in the event of changes. This generally includes

the comibed use of 0.5 MAC of desflurane and a synthetic opioid infusion (remifentanil or sufentanil). The desflurane is titrated up to 3–4% expired concentration to maintain the bispectral index at 50–60 with incremental doses of midazolam added if needed. During neurophysiological monitoring, if changes occur, immediate communication with the surgeon is necessary to allow for the reversal of any surgical intervention which may have resulted in these changes. This may include removal of recently placed hardware, wires, or pedical screws. In the event that the neurophysiological changes do not respond to surgical intervention or manipulations of hemodynamic parameters (increasing the blood pressure or the hemoglobin) and mechanical ventilation (increasing the inspired oxygen to 100% and ensuring normocarbia), the anesthesiologist must be ready to allow for a wake-up test. This will require a rapid decrease in the depth of anesthesia. A second component of anesthetic care during spinal surgery is the use of techniques to limit intraoperative blood loss, including basic maneuvers such as effective patient positioning to avoid abdominal compression and distention of epidural veins as well as maintenance of normothermia. Additional techniques may include isovolemic hemodilution, administration of an antifibrinolytic agent, intraoperative blood salvage, and controlled hypotension. The final component is the provision of effective postoperative analgesia with a multimodality approach including the use of patient-controlled analgesia and adjunctive agents (acetaminophen, NSAIDSs, dexmedetomidine, and gabapentin).

Review article that addresses various co-morbid genetic conditions and their impact on general anesthesia and procedural sedation with details on associated co-morbid conditions that may impact airway management.

37 Harper CM, Ambler G, Edge G. The prognostic value of preoperative predicted forced vital capacity in corrective spinal surgery for Duchenne's muscular dystrophy. Anaesthesia 2004; 59, 1160–2. In their cohort of 45 patients, 20 patients had a preoperative FVC ≤30% predicted for age. There was no statistically significant difference in several postoperative variables including the duration of postoperative tracheal intubation, duration of BiPAP support, total time with ventilator assistance, and inpatient stay. However, there were significant cardiorespiratory complications in both groups demonstrating that this is a high-risk population with the potential for perioperative complications. Five patients (25%) with an FVC ≤30% had complications including ARDS, respiratory tract infections, and the need for a tracheostomy, while four (16%) with a preoperative FVC ≥30% had complications. The one death in the cohort was in a patient with an FVC of 18% who initially had an uncomplicated postoperative course, but went on to develop ARDS.

Introduction

Medical progress has made organ transplantation an accepted therapeutic modality for treating a variety of diseases affecting various organ systems in infants and children. Improvements in immunosuppressive therapy, surgical techniques, and organ preservation have permitted utilization of transplantation in a greater number of patients, and pediatric patients in particular have benefited from the growth of transplantation. The scope and magnitude of various transplant procedures in infants and children with underlying organ system disease will continue to challenge anesthesiologists caring for these patients. In addition, as more children undergo transplantation, anesthesiologists must be prepared to care for them following transplantation, including the management of post-transplant complications and procedures.

Anesthetic management of these procedures requires understanding the physiological implications of organ failure, as well as specific requirements of the transplant procedure [1]. To facilitate this discussion, issues related to the anesthetic care of children undergoing liver, renal, heart, heart–lung, lung, and multivisceral transplantation will be discussed separately. In addition, other chapters describe anesthetic care of infants and children with specific organ dysfunction who require surgery.

Perioperative anesthetic management of solid organ transplant procedures has a number of similarities. Because of the logistic constraints involving donor organ procurement and admission of patients awaiting transplantation, there is limited time available to the anesthesia team for preparation. During this time, the patient must be admitted to the hospital and an updated history and physical examination and laboratory studies must be obtained. The short period of preparation usually limits the duration of nil per os (NPO) status for most children, which has implications for the anesthesiologist. Anesthetic preparation and planning must incorporate the magnitude of these procedures. Because several vascular anastomoses are required, there is significant potential for hemorrhage. Adequate vascular access, invasive monitoring, and availability of adequate quantities of blood products are

Gregory's Pediatric Anesthesia, Sixth Edition. Edited by Dean B. Andropoulos and George A. Gregory.

required. Given the severity of underlying diseases, the physiological alterations they cause, and the frequency of intraoperative changes in the patient's condition, arterial blood gas and pH, blood chemistry profiles, and other hematological tests often are required during transplant procedures. When new transplantation programs are established, anesthesia departments should take an active role in defining the requirements and availability of these ancillary services to help in the care of these patients. Because of the urgent or emergent nature of most transplant cases, the resources must be available to the anesthesia team on a 24 h, 7 days a week basis.

Care of organ donors after neurological death

Once brain death has been established in a donor, and suitability of the donor organs has been established, the emphasis for patient care is directed toward organ preservation by maintaining cardiac output and oxygen delivery. After placement of the organs according to the United Network for Organ Sharing (UNOS) waiting list criteria in the USA, coordination of the arrival of the harvesting teams is done by the local organ procurement agency, and an operating room time selected. The anesthesia team needs to ensure preservation of oxygen delivery to the harvested organs by maintaining adequate ventilation, cardiac output, hemoglobin, and blood pressure within target ranges. Diabetes insipidus is often present, requiring close attention to urine output and electrolytes, replacement of losses, and 1-deamino-8-D-arginine vasopressin (DDAVP) administration. Because of loss of sympathetic outflow from the central nervous system, hypotension and cardiovascular compromise are a constant possibility during the preparation for harvest. Close communication with the surgical team, or teams for multiple organ harvests, will assure optimal organ retrieval.

Brain-dead donors do not experience pain; however, they may experience hemodynamic changes from spinal cord reflexes with surgical incision and should be treated with inhalational anesthetics or opioids. After wide abdominal exposure, the retrieval team will ask for heparin (200–400 units/kg). Organs are generally removed according to their susceptibility to ischemia, with the heart first and the kidney last. After the heart, great vessels, and lungs are dissected out, and the donor aorta is cross-clamped, the heart is perfused with a preservation solution such as standard crystalloid cardioplegia or Celsior® to provide both cardioplegia and organ preservation. The organs are then placed in ice for transport at 4°C.

Donation after cardiac death

Because of the ongoing shortage of donors for all organs, the concept of organ donation after cardiac death (DCD) is advocated. Families may request organ donation after withdrawal of mechanical ventilatory support in patients who are otherwise suitable for donation, with an irreversible neurological injury, who do not have brainstem death.

This condition must be confirmed by the patient's physicians and agreed to by the patient's next of kin. In order to optimize organ retrieval, patients and families are typically taken to the operating room where ventilatory and circulatory support is withdrawn. A physician not involved with the organ procurement determines an irreversible cessation of cardiac and respiratory function, and the organ recovery takes place. As of 2007 in the USA, transplant centers and organ procurement organizations are required to have policies and procedures in place for this process. DCD increased the number of donors (adult and pediatric) by over 600 in 2006 [2]. Despite increasing the pool of potential donors (an estimated 6–20% of pediatric deaths could potentially be DCD donors), a recent review of pediatric organ donation after cardiac death indicated that very few organs from DCD donors are implanted into pediatric patients annually. For example, in 2010 there were 137 pediatric DCD donor organs, but only nine of these organs were transplanted into pediatric patients (three livers, five kidneys, and one heart) [3]. Ethical issues, potential physician conflicts of interest, logistical issues, and concerns over warm ischemia time all have limited the application of DCD procedures. Pediatric renal and liver transplant outcomes after cardiac death are comparable to those following transplant from brainstem deceased donors, with minimal data about heart and lung transplant outcomes.

Immunosuppression for pediatric solid organ transplantation

Review of the history of solid organ transplantation demonstrates that successful outcomes are impossible without effective immunosuppression. The aim of immunotherapy is to minimize the risk of rejection and drug toxicity. Currently, pediatric solid organ transplantation protocols for induction, maintenance, and desensitization vary widely between centers. Even single organ transplant groups are far from consensus on the ideal approach to immunosuppression [4]. A general strategy is depicted in Figure 30.1 [4]. Most transplant patients require indefinite maintenance therapy, although

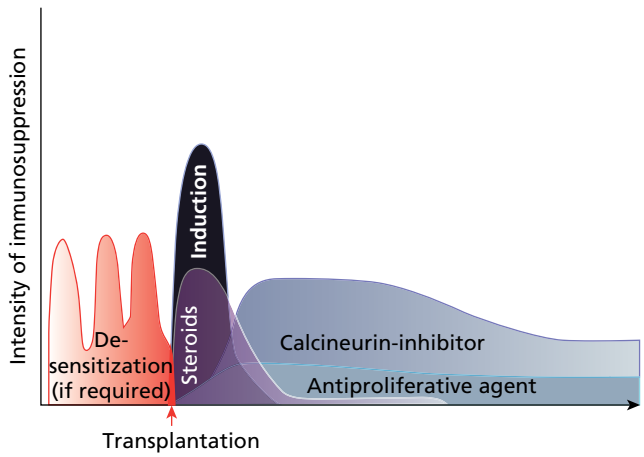

Figure 30.1 Time line showing the different approaches for immunosuppression in relation to the time of transplant. Pretransplant protocols are reserved for patients with specific risk factors (e.g. HLA sensitization or ABO-incompatible transplantation). Depending on the transplanted organ and center, the use of induction may or may not be part of the protocol. Furthermore, low-dose steroids may remain part of the maintenance therapy, supporting a regimen of one or two drugs of different classes. Additional treatments are used for treatment of rejection. *Source*: Reproduced from Urschel et al [4] with permission of Elsevier.

about 20% of pediatric liver transplant recipients and some kidney recipients have been successfully weaned from immunosuppression late after transplantation [5]. Figure 30.2 illustrates the cellular targets of immunosuppressive drugs, and commonly used drugs are detailed in Table 30.1 [4,6]. Discussion of individual agents is beyond the scope of this chapter and has been addressed recently [3,7–12].

It is important to monitor drug levels because co-existing disease and drug interactions can result in subtherapeutic or toxic drug effects. Nephrotoxic agents should be avoided even if renal function is normal. Cystic fibrosis patients have unreliable gastric absorption and hepatic clearance and are at risk for developing acute toxicity from oral medications like cyclosporine. Hepatic enzymes such as cytochrome P450 metabolize commonly used immunosuppressant drugs. Perioperative drugs (e.g. metoclopramide, amiodarone, antibiotics, barbiturates, phenytoin) may induce or inhibit cytochrome P450 and alter drug levels of calcineurin and mammalian target of rapamycin (mTOR) inhibitors. Newer immunosuppressant medications often do not include the liquid forms required for young children. Such liquid preparations must be compounded by local pharmacies and may have a short shelf-life, making them difficult to manage for patients not residing near a pediatric medical center. Moreover, absorption and pharmacokinetic data for infants and children often do not exist, often making dosing decisions in drugs that may have narrow therapeutic windows challenging [13].

Induction therapy

Induction immunotherapy is intense immunosuppression in the immediate perioperative phase of organ implantation to reduce the incidence of acute rejection in the early post-transplant phase [5,14,15]. Also, there are longer term benefits because chronic graft failure and decreased long-term survival correlate with the frequency of acute rejection. However,

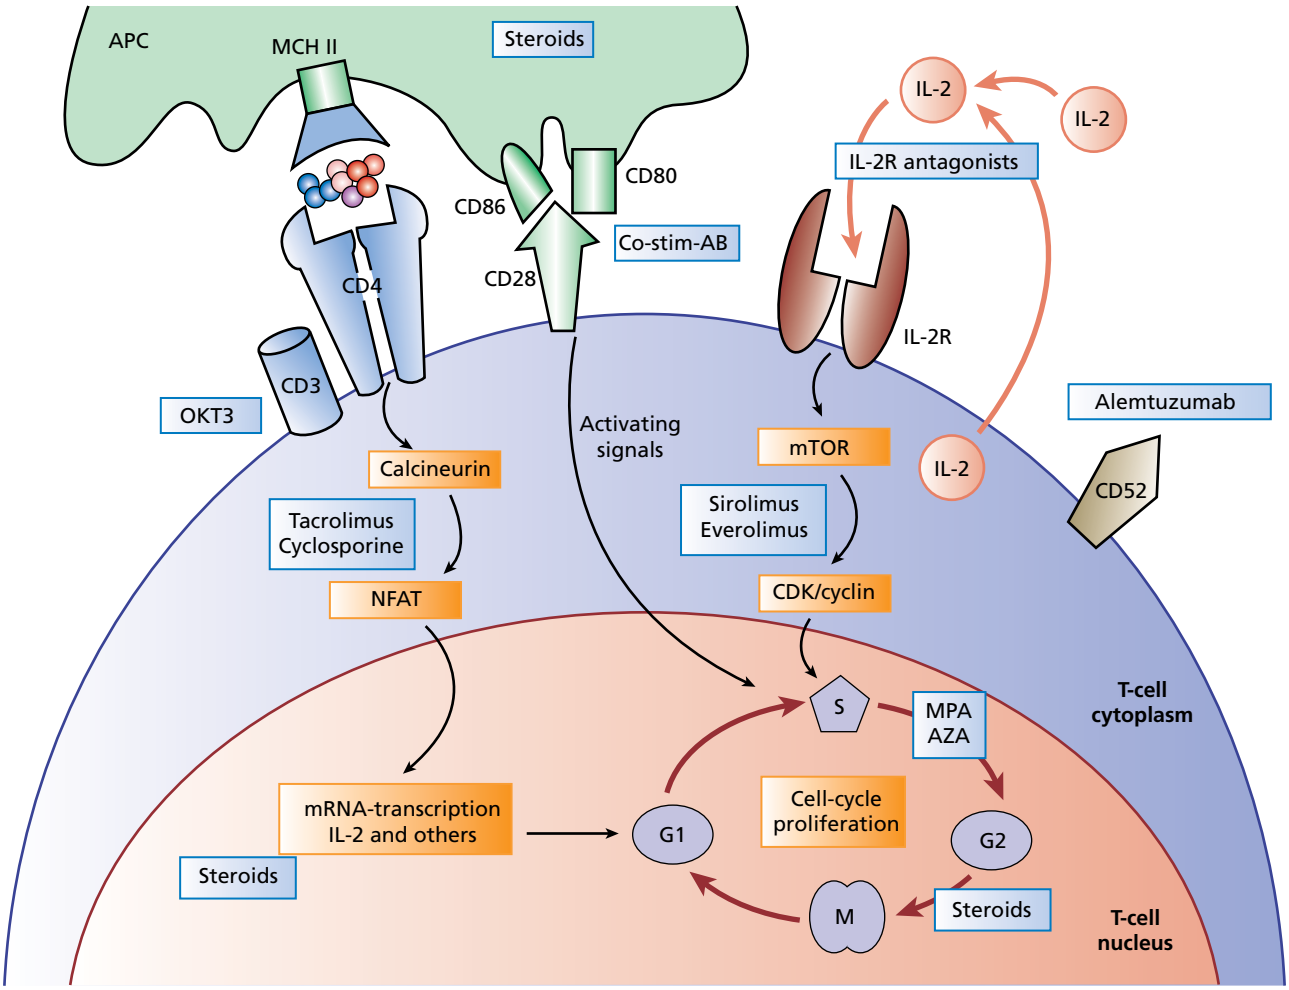

Figure 30.2 T-cell activation and proliferation results from presentation of a peptide fragment of the donor antigen in the major histocompatibility complex class II (MHC II) of the antigen-presenting cell (APC) and a co-signal from interaction from CD80/CD86 and CD28. This mechanism results in activation of calcineurin, which leads to production of interleukin-2 (IL-2). Autocrine stimulation by IL-2 results in cell proliferation by a pathway involving target of rapamycin (mTOR) and cyclin/cyclin-dependent kinase (CDK). Immunosuppressive agents exert their effects at a number of different targets to prevent T-cell proliferation. The CD80/CD86 and CD28 interaction is targeted by specific antibodies (Co-stim-AB) abatacept and belatacept. Basiliximab and daclizumab (IL-2R antagonists) target the receptor for IL-2, required for cell activation via mTOR, which is targeted by sirolimus and everolimus. Tacrolimus and cyclosporine interfere in the signal transduction from the T-cell receptor by inhibiting calcineurin nuclear factor of activated T-cells (NFAT). Mycophenolic acid (MPA), mycophenolate mofetil, and azathioprine (AZA) interfere in the cell cycle, preventing the T-cell as well as the B-cell from proliferation. Steroids target multiple sites in the interaction. Alemtuzumab and muronomab target specific lymphocytic surface structures to induce cytolysis; a similar principle is used for the antithymocyte globulins but with multiple targets on the surface. *Source*: Reproduced from Urschel et al [4] with permission of Elsevier.

Table 30.1 Immunosuppression therapies used in pediatric patients following organ transplantation

Drug class	Immunosuppression agents	Mechanism of action	Adverse effects
Calcineurin inhibitors	Tacrolimus	Calcineurin inhibitor blocking T-cell activation and proliferation	Nephrotoxicity, neurotoxicity, lymphomas and lymphoproliferative disease, cardiomyopathy, anemia, chronic diarrhea, onset of diabetes mellitus, electrolyte disturbances
	Cyclosporine	Interfering with activity and growth of T cells	Infection, malignancy, hypertension, dyslipidemia, post-transplant diabetes mellitus, renal failure, neurological effects, gingival hyperplasia, acne, hirsutism, hyperkalemia, hypomagnesemia
Mammalian target of rapamycin (mTOR) inhibitors	Sirolimus (rapamycin)	Binds to mTOR in T cells, suppressing T-cell proliferation by inhibiting progression from the G1 to S phase of the cell cycle	Hyperlipidemia, proteinuria, myelosuppression, poor wound healing, pneumonitis, hypersensitivity reactions
	Everolimus	A derivative of sirolimus with mechanism of action similar to sirolimus	Hypersensitivity reactions
Purine synthesis inhibitors	Mycophenolate mofetil	Targets an enzyme in the body called inosine monophosphate dehydrogenase that is important for the formation of DNA in cells	Gastrointestinal side-effects, neutropenia, opportunistic infections
	Azathioprine	Is converted into 6-mercaptopurine in the body where it blocks purine metabolism and DNA synthesis	Infection, malignancy, post-transplant diabetes mellitus, alopecia, nausea, vomiting, bone marrow suppression
	Cyclophosphamide	Cylotoxic effect on lymphocytes	Nausea, vomiting, bone marrow suppression, alopecia, joint pain, easy bruising and bleeding
Monoclonal antibodies	OKT3 (muromonab)	Binds to CD3 receptor (anti-CD3 monoclonal antibodies) of the T cell causing transient depletion of functional T cells from peripheral circulation	Cytokine release syndrome, opportunistic infections, post-transplant diabetes mellitus, gastrointestinal upset, bone marrow suppression, infusion-related reactions
	Basiliximab and daclizumab	Bind to the alpha chain of the IL-2 receptor (anti-CD25 antibodies) resulting in the inhibition of signal 3 of the T-cell activation pathway	Infection, malignancy, post-transplant diabetes mellitus, acute hypersensitivity reactions (rare)
	Rituximab	Anti-CD20 antibody that works by lowering the number of certain types of white blood cells (B cells) in the body	Severe infusion reaction, cardiac arrest, cytokine release syndrome, tumor lysis syndrome, causing acute renal failure, immune toxicity, malignancy, bowel obstruction and perforation
	Bebtacept (LEA29Y)	A fully human fusion protein with a binding affinity to CD86/CD80 on the antigen presenting cell, thus resulting in the blockade of T-cell activation	Anemia, diarrhea, urinary tract infection, peripheral edema, constipation, hypertension, pyrexia, graft dysfunction, cough, nausea, vomiting, headache, hypokalemia, hyperkalemia, leukopenia
	Eculizumab	A complete, humanized C5 monoclonal antibody that inhibits complement factor 5a, blocking terminal complement activation and the formation of membrane attack complexes	Life-threatening and fatal meningococcal infections, headache, and fever with nausea or vomiting
	Alefacept	It is thought to neutralize the effect of CD2-expressing T cells by complement-mediated lysis, interrupting the CD2 interaction with LFA-3, limiting helper T-cell adhesion to antigen-presenting cells, and disrupting effector T-cell receptor engagement with antigens and major histocompatibility complex molecules	Lymphopenia, malignancies, infections, hypersensitivity reactions, hepatic toxicity

(*Continued*)

Table 30.1 (Continued)

Drug class	Immunosuppression agents	Mechanism of action	Adverse effects
	Alemtuzumab (Campath-IH)	A monoclonal antibody targeting the CD52 antigen present on T and B lymphocytes, natural killer cells, and monocytes	Infection, malignancy, post-transplant diabetes mellitus, gastrointestinal effects
	Bortezomib	A proteasome inhibitor	Peripheral neuropathy, neutropenia, thrombocytopenia, gasrointestinal effects
Malononitrilamides	FK778(manitimus)	It inhibits both T-cell and B-cell functions by blocking *de novo* pyrimidine synthesis, inhibiting tyrosine kinase activity, and suppressing IgG and IgM antibody production	Anemia, angina pectoris, hyperlipidemia
Janus kinase inhibitors	Tofacitinib	These inhibit activity of the enzyme Janus kinase 3 (JAK3), by interfering with the JAK-STAT signaling pathway	Upper respiratory tract infections, diarrhea, headache
S1P-R agonists	FTY720 (fingolimod)	A sphingosine 1-phosphate receptor modulator. The exact mechanism is unknown, but is thought to work by reducing the immune system's attack on the central nervous system by retaining certain white blood cells (lymphocytes) in the lymph nodes	Bradycardia, encephalitis, macular edema
Polyclonal antibodies	Antithymocyte globulin	Causes depletion of T cells, modulation of various lymphocyte surface antigens, and interferes with the function of other immune effector cells	Cytokine-release syndrome, myelosuppression

the side-effects from induction agents are significant (polyclonal antibodies, opportunistic infections, post-transplant lymphoproliferative disorder, anaphylaxis, monoclonal antibodies, and hypersensitivity reactions). Induction therapy allows a delayed and gentle introduction of maintenance immunotherapy, thereby reducing the potential for harm (e.g. renal damage) from toxic drug concentrations [16,17].

Maintenance therapy

Steroids

Corticosteroids are used in most solid organ transplant protocols for induction, maintenance, and acute rejection. Their side-effects include hypertension, diabetes mellitus, osteopenia, poor wound healing, cataracts, emotional lability, hyperlipidemia, salt and water retention, Cushingoid habitus, weight gain, hirsutism, acne, and growth impairment. Steroid-free maintenance has been successfully achieved in liver, heart, and kidney but not lung transplantation [18–20].

Calcineurin inhibitors

Adult data comparing the two calcineurin inhibitors (CNIs) indicate that tacrolimus improved graft survival and prevented acute rejection more effectively than cyclosporine. Nephrotoxicity is an adverse side-effect common to both and is a major concern in pediatric solid organ transplant patients. Acute toxicity is dose dependent and can lead to chronic renal damage and transplantation. Renal-sparing strategies include the use of mycophenolic acid (MPA) and mTOR inhibitors. The side-effect profiles of CNI drugs are similar; generally hirsutism, hypertrichosis, gingival hyperplasia, hypertension, and hyperlipidemia are more likely with cyclosporine, and diabetes, tremor, peripheral neuropathy, alopecia, and gastrointestinal symptoms are commoner with tacrolimus. The seizures associated with CNI agents seem dose related and are thought to be due to ischemia from cerebral vasoconstriction. Autoimmune hemolytic anemia and leucopenia have been reported with both drugs, but may improve by switching to the other CNI.

Antiproliferative agents

The principle side-effect of azothioprine is bone marrow depression. Other concerns are an ultraviolet-dependent increase in skin cancers, pancreatitis, and hepatotoxicity. Azothioprine has largely been replaced by MPA-containing drugs such as mycophenolate mofetil (MMF), which have similar mechanisms of action but are more potent and have better efficacy [21]. The two main side-effects of MPA are gastrointestinal problems and marrow depression.

mTOR inhibitors

Mammalian target of rapamycin inhibitors such as sirolimus and everolimus cause an arrest in cell cycle and cell differentiation. Sirolimus inhibits vascular smooth muscle proliferation and hence may have a protective effect against coronary artery vasculopathy in cardiac allografts [22]. Adverse side-effects of mTOR inhibitors include renal dysfunction, hyperlipidemia (typically responds to statins), delayed wound healing, bone marrow suppression, ampthous ulcers, and systemic inflammatory response syndrome (e.g. pnuemonitis). The anti-CD20 monoclonal antibody rituximab may be added.

Acute rejection therapy

The usual first-line therapy is steroids, with the addition of polyclonal lymphocyte-depleting antibodies (antithymocyte globulin) in more severe cases of rejection. Maintenance immunosuppression might be switched from cyclosporine to tacrolimus. Antibody-mediated rejection is treated with plasmapheresis and IV immunoglobulin.

Newer agents

Normal immune tolerance to self-antigens involves central and peripheral mechanisms that potentially may be manipulated to allow recipient tolerance to alloantigens [23]. Anti-CD52 antibodies cause profound lymphocyte depletion and held promise as a tolerance-inducing agent but clinical studies to date are discouraging.

Abatacept and belatacept cause co-stimulation blockade of T-cell CD28 receptor binding to CD80/CD86 of the antigen-presenting cell and may allow less nephrotoxic maintenance regimens. Pediatric data are lacking.

KEY POINTS: IMMUNOSUPPRESSION FOR SOLID ORGAN TRANSPLANTATION

- Induction, maintenance, and desensitization protocols vary widely between centers; most transplant recipients receive indefinite maintenance therapy
- Induction immunotherapy is intense immunosuppression in the immediate perioperative phase of organ implantation to reduce the incidence of acute rejection in the early post-transplant phase
- The maintenance phase usually consists of corticosteroids, but many other agents such as calcineurin inhibitors, antiproliferative agents, mTOR inhibitors, and monoclonal antibodies may be used

Liver transplantation

Thomas E. Starzl performed the first human liver transplant in a 3-year-old child with biliary atresia in 1963. The attempt ended in failure from intraoperative hemorrhage, although Starzl performed the first successful liver transplant in a child in 1967. One-year survival after liver transplant remained below 50% until the introduction of cyclosporine in 1979. By 1983 pediatric liver transplantation was deemed the standard of care for hepatic failure or end-stage liver disease [24], and in 2002 the pediatric end-stage liver disease (PELD) and model for end-stage liver disease (MELD) scores were implemented to prioritize organ allocation to the sickest patients, rather than to those with the longest wait time, as had been the case. In addition, the PELD system conferred special status and protection to pediatric organs and recipients. Today pediatric liver transplantation is one of the most successful solid organ transplants. According to the US Organ Procurement and Transplantation Network (OPTN)/Scientific Registry of Transplant Recipients data, the 1-year patient survival rate is 88–94%, depending on the age at transplant [25]. The number of pediatric liver transplants per year has

remained steady in the last 10–15 years, averaging approximately 600 annually in the USA [25]. Currently, pediatric transplants account for about 10% of all liver transplants in the USA, and the majority of these transplants involve children less than 12 years of age. Liver transplantation is now performed on infants less than 3 months of age with graft survival and patient survival similar to that of older patients [26]. There is evidence that higher volume pediatric liver transplant centers (i.e. 10 or more transplants per year) have significantly lower wait list mortality, a higher likelihood of transplant, and higher survival at 5 and 10 years after transplant (91% and 89%, respectively) [27].

Indications

The indications and clinical characteristics for liver transplantation are listed in Table 30.2 [25]. Life-threatening complications secondary to hepatic failure or chronic end-stage liver disease are the primary indications for transplantation. Another indication is from progressive primary liver disease refractory to maximal medical management, before the development of life-threatening complications. A smaller number of liver transplants are performed for metabolic disease, in which liver replacement is curative, and for unresectable primary liver tumors. Fulminant hepatic failure is the indication for liver transplantation in approximately 11% of pediatric cases [28]. These children commonly present with rapidly developing life-threatening complications, and, therefore, the establishment of the underlying diagnosis is not always feasible. Approximately 13% of children undergo liver transplantation because of metabolic diseases [29–32], and these patients generally have excellent outcomes [31,33]. Pediatric patients with liver tumors represent a growing group of transplant recipients. Hepatoblastoma is the most common pediatric primary liver tumor. Resection in combination with systemic chemotherapy is the preferred method of treatment. If the tumor is unresectable after appropriate chemotherapy, transplantation may be offered if there has been a demonstrated response to therapy, even in the face of pulmonary metastases [34–36].

The MELD score (serum creatinine, bilirubin, sodium, and international normalized ratio (INR)) is calculated for patients age 12–17 years, and the PELD score (albumin, bilirubin, INR, growth failure, and age at listing) is used for patients under age 12 years.

Pathophysiology of end-stage liver disease

Patients with end-stage liver disease that results from many causes manifest similar pathophysiology (Table 30.3). The clinical manifestations of end-stage liver disease develop

Table 30.2 Clinical characteristics of pediatric liver transplant recipients, 2004–2006 and 2014–2016. Pediatric candidates aged 12–17years can be assigned model for end-stage liver disease (MELD) or pediatric end-stage liver disease (PELD) scores

Characteristic	2004–2006		2014–2016

Table 30.3 Pathophysiology of end-stage liver disease

Organ system	Common findings
Cardiovascular	Hyperdynamic circulation; increased cardiac output, decreased systemic vascular resistance, increased stroke volume and ejection fraction
	Expanded plasma volume
	Arteriovenous shunting
Pulmonary	Restrictive pulmonary function secondary to ascites
	Hypoxemia secondary to ventilation/perfusion mismatch, impaired hypoxic pulmonary vasoconstriction, intrapulmonary shunting
	Pulmonary hypertension
	Hepatopulmonary syndrome
Central nervous system	Encephalopathy
	Cerebral edema with fulminant hepatic failure
Gastrointestinal	Hepatic dysfunction: synthetic, metabolic, excretory aspects
	Portal hypertension (esophageal varices, portal hypertensive gastropathy)
	Delayed gastric emptying
Renal	Renal dysfunction from prerenal azotemia (secondary in diuretics)
Hematological	Elevated PT
	Thrombocytopenia
	Anemia
	Hypofibrinogenemia, dysfibrinogenemia
	Fibrinolysis
	Disseminated intravascular coagulation
Fluids, electrolytes, acid–base status	Intravascular volume depletion (secondary to diuretics)
	Hypokalemia, hyponatremia
	Metabolic alkalosis
	Metabolic acidosis (especially fulminant hepatic failure)

PT, prothrombin time.

from the loss of hepatocytes and resulting fibrosis. The loss of hepatocytes results in the development of coagulopathy, hypocholesterolemia, hypoalbuminemia, and encephalopathy. Hepatocellular injury results in fibrosis and destruction of the portal triad with increased resistance to liver blood flow leading to portal hypertension manifest by varices (esophageal, bowel), hemorrhoids, ascites, spontaneous bacterial peritonitis, splenomegaly with thrombocytopenia, and hepatic encephalopathy.

The cardiovascular system undergoes marked changes as the child develops cirrhosis and end-stage liver disease. Patients frequently have a hyperdynamic circulation, decreased systemic vascular resistance, increased cardiac output, and a slightly decreased arterial blood pressure. The pathophysiology producing peripheral vasodilation remains obscure, and the "humoral factor" theory is the most widely accepted explanation [37]. In cirrhosis, increased intrahepatic resistance induces portosystemic collateral formation, allowing gut-derived humoral substances (endocannabinoids and nitric oxide) to directly enter the systemic circulation without detoxification by the liver. The hyperdynamic circulation of the patient has important implications for the anesthesiologist, including a decreased sensitivity to catecholamines and vasoconstrictors, an increase in mixed venous oxygen saturation, with a decreased arteriovenous oxygen difference. Because of the vasodilated state, anesthetics may cause severe hypotension in this patient population.

Patients with end-stage liver disease also manifest significant changes in the pulmonary system and are frequently hypoxemic. Many patients with chronic liver disease have abnormal pulmonary mechanics and some degree of alveolar hypoventilation. The presence of ascites and increased infra-abdominal pressure alter the respiratory mechanics and often reduce functional residual capacity. Atelectasis produces ventilation/perfusion mismatch and is common in patients with ascites, hepatosplenomegaly, and/or pleural effusions. Hepatopulmonary syndrome is characterized by hypoxia from intrapulmonary arteriovenous shunting and intrapulmonary vascular dilation [38]. The diagnosis is predicated on either arterial hypoxia (PaO_2 <70 mmHg) or an alveolar–arterial gradient greater than 20 mmHg in the setting of pulmonary vascular dilation. Intrapulmonary vascular dilation can best be demonstrated on echocardiography or by macroaggregated albumin perfusion scan [39]. Again, the most likely explanation for the development of hepatopulmonary syndrome is related to systemic absorption of nitric oxide from the gut without detoxification in the liver. Supplemental oxygen therapy is the mainstay of supportive therapy and definitive treatment is liver transplantation. A case series of seven children with hepatopulmonary syndrome and severe hypoxemia were successfully transplanted and recovered from hepatopulmonary syndrome on average within 24 weeks of their liver transplant [40].

Portopulmonary hypertension (PPH) is defined as pulmonary artery hypertension (pulmonary systolic pressure ≥25 mmHg) in the setting of normal pulmonary capillary wedge pressure and portal hypertension [41]. The incidence of PPH is 0.2–0.7% in adults with cirrhosis and is present in 3–9% of adults undergoing liver transplantation [42]. The incidence in children is probably lower, and occurrences are limited to case reports and one case series. The signs and symptoms of PPH on presentation include a new heart murmur, dyspnea, and syncope. Echocardiography can diagnose pulmonary hypertension, and is one reason why routine screening of potential liver transplant candidates includes a baseline echocardiogram [43]. The largest retrospective review of 43 adult patients found mean pulmonary artery pressure (MPAP) to be predictive of outcome. Those patients with a MPAP <35 mmHg did not have increased mortality after orthotopic liver transplantation. In contrast, those with a MPAP of 35–45 mmHg had a mortality of 50%, and those with a MPAP >50 mmHg had 100% mortality [44]. Among children with PPH, early identification is essential. And if PPH is suggested by screening echocardiography, a cardiac catheterization should be performed to confirm the diagnosis, measure the pulmonary pressures, and assess the response to nitric oxide and epoprostenol. Children who respond to medical management may be candidates for liver transplantation [45]. Severe PPH is generally a contraindication for liver transplantation because of the high mortality.

Hepatic encephalopathy is a significant neurological complication of liver disease that may be acute, as seen in fulminant hepatic failure, or chronic. Table 30.4 presents the staging of hepatic encephalopathy [46]. Cerebral edema is a feature of both acute and chronic encephalopathy; however, it is more severe and happens more rapidly in acute hepatic encephalopathy commonly leading to increased intracranial pressure (ICP). The pathogenesis is thought to be due to hyperammonemia that more readily crosses the blood–brain barrier and will cause astrocytes to swell, leading to low-grade cerebral edema [47]. Blood ammonia levels develop from catabolism of endogenous protein and gastrointestinal absorption. Ammonia is formed when bacteria break down nitrogen-containing products in the gut which are then absorbed into the portal circulation. Therefore, blood ammonia levels increase from increased catabolism due to infection, increased gut absorption from high protein diets, and gastrointestinal bleeding and renal failure. Arterial ammonia levels over 200 μg/dL have been strongly correlated with cerebral herniation and death. Other factors that may contribute to cerebral edema include benzodiazepines, hyponatremia, and inflammatory cytokines. Management typically focuses on reducing gastrointestinal production and absorption of ammonia. Lactulose is often prescribed to create an osmotic diuresis and

Table 30.4 Classification of the severity of acute and chronic hepatic encephalopathy

Grade 0	Minimal hepatic encephalopathy, lack of detectable changes in personality or behavior; no asterixis
Grade 1	Trivial lack of awareness, shortened attention span, sleep disturbance, altered mood, slowing the ability to perform mental tasks; asterixis may be present
Grade 2	Lethargy or apathy, disorientation to time, amnesia of recent events, impaired simple computations, inappropriate behavior, slurred speech; asterixis is present
Grade 3	Somnolence, confusion, disorientation to place, bizarre behavior, clonus, nystagmus, positive Babinski sign; asterixis usually absent
Grade 4	Coma, lack of verbal, eye, and oral response to stimuli

Source: Reproduced from Zafirova and O'Connor [46] with permission of Wolters Kluwer.

to acidify the lumen of the gut to trap ammonia and minimize absorption, yet it has not been shown to improve survival [46]. Antibiotics (e.g. neomycin and metronidazole) are sometimes used to kill the gastrointestinal bacteria involved in metabolizing nitrogen products to ammonia.

As hepatic encephalopathy progresses, the child's ability to manage the airway should be carefully assessed. Children with grade 3 and 4 disease commonly require endotracheal intubation to protect their airway and to maintain oxygenation and ventilation. Increased ICP occurs in 38–81% of adult patients with fulminant hepatic failure [48] and brain computed tomography (CT) is recommended in those with grade 3–4 hepatic encephalopathy. Simple therapeutic measures, which can be performed on all patients, include elevation of the head of the bed to 30° and minimizing stimulation. Acute hyperventilation fails to reduce episodes of cerebral edema, and it does not delay onset of herniation [48]. ICP monitors may help to diagnose intracranial hypertension and optimize management, although their use remains controversial [49,50]. Non-randomized trials have shown no survival advantage. Medical management to reduce ICP includes intravenous administration of sodium thiopental or propofol to minimize stimulation and to directly reduce ICP. Mannitol can be administered if ICP remains increased. Hypothermia has also been used to treat increased ICP. In a trial of 14 patients with fulminant hepatic failure, ICP was significantly reduced by mild hypothermia to 32–33°C [49]. Corticosteroids have no role in this setting [51], and orthotopic liver transplantation remains the definitive treatment.

The gastrointestinal system undergoes many changes when patients have end-stage liver disease, including abnormal synthetic, metabolic, and excretory functions of the liver and portal hypertension. Complications of portal hypertension include: (1) altered hepatic and intestinal lymph flow and decreased plasma oncotic pressure, which facilitate the development of ascites; and (2) gastrointestinal bleeding from esophageal and gastric varices or from portal hypertensive gastropathy.

Renal failure commonly complicates acute and chronic liver disease in adults; however the incidence in children is considerably lower [52]. Renal insufficiency is common and may be caused by prerenal azotemia, acute tubular necrosis, or hepatorenal syndrome. Prerenal azotemia may develop from the use of diuretics, gastrointestinal bleeding, splanchnic pooling, and sepsis. Acute tubular necrosis develops when the kidney becomes ischemic from these same etiologies. Hepatorenal syndrome is characterized by renal insufficiency or failure in the setting of liver failure and portal hypertension. The pathophysiology of hepatorenal syndrome is thought to be secondary to intense renal vasoconstriction from activation of the renin–angiotensin, arginine–vasopressin, and sympathetic nervous systems [53]. However, hepatorenal syndrome presents as prerenal azotemia (increased creatinine, decreased urine sodium); a fluid challenge will not improve renal function. Rapid progression of renal failure from hepatorenal syndrome is classified as type 1, and is characterized by a rapid progression of renal failure with a 100% increase in creatinine in less than 2 weeks. This form usually occurs in acute liver failure. In type 2, renal failure progresses over weeks to months. Dopamine, diuretics, and octreotide have all been used to remove excess volume and optimize renal perfusion; however orthotopic liver transplantation remains the definitive therapy because renal failure is reversible if the liver is replaced [54]. Combined liver–kidney transplantation is an option for children with both liver and renal disease.

Hematological abnormalities occur with liver disease because the synthesis of fibrinogen and factors II, V, VII, IX, and X decreases [55]. Because of the decreased synthesis of these factors, the prothrombin time (PT) and the partial thromboplastin time (PTT) are increased. Thrombocytopenia is common when patients develop hypersplenism in response to portal hypertension. Also, anticoagulant factors (protein C and S, antithrombin III) are reduced in patients with end-stage liver disease. The altered hemostasis increases the risk of inserting vascular catheters and nasogastric tubes, and increases the potential for excessive bleeding from surgical wounds. Antifibrinolytics such as aprotinin and aminocaproic acid have been reported to reduce blood loss; however, there are insufficient data to recommend their use.

Electrolytes and acid–base balance often are altered in chronic liver disease by renal dysfunction and/or the use of diuretics. Acid–base changes may be due to renal dysfunction or to changes in ventilation. The intravascular volume status may be difficult to assess in patients with liver disease due to the presence of ascites, peripheral edema, and anasarca. The effective plasma volume is often inadequate. Consequently, intraoperative measurement of central filling pressures is required during transplantation.

Extracorporeal liver support

In recent years, extracorporeal liver support has been utilized in pediatric patients with acute severe liver failure as a bridge to transplant. One of the commonly used systems is the Molecular Adsorbent Recirculating System (MARS®, Gambro, Inc., Lakewood, CO, USA), utilizing albumin dialysis, which was introduced in the 1990s in adult patients [56].

A large-bore, double-lumen catheter similar to a hemodialysis catheter is placed in a large central vein; and via a circuit primed with human albumin and two special filters, the patient's blood is circulated through the MARS machine, removing protein-bound and water-soluble toxins that have accumulated as a result of liver failure. The water-soluble substances are subsequently removed from the albumin dialysate via a conventional hemodialysis filter. Albumin-bound substances are adsorbed onto a charcoal filter and an anion exchanger placed in series in the albumin dialysate circuit. Adult and pediatric (<25 kg) sized filters are available. MARS dialysis can be performed continuously, or once daily for 8–10 h sessions.

Indications for MARS therapy include acute liver failure with significant hepatic encephalopathy, high indirect bilirubin, coagulopathy, hemodynamic instability, hepatorenal and hepatopulmonary syndromes, and plasma ammonia >200 mMol/L [56]. In a series of 20 pediatric patients averaging 7 years of age and awaiting liver transplant, or suffering from acute graft failure after transplant, all were mechanically ventilated and 19 or 20 required vasopressors [57]. Thrombocytopenia and significant bleeding were frequent, and death occurred before transplant in four patients – two from cerebellar herniation and two from cardiorespiratory failure. The 3-month survival for MARS-treated patients was

65%. This therapy is likely to be used more commonly in the future for pediatric liver transplant patients with acute liver failure.

KEY POINTS: INDICATIONS FOR LIVER TRANSPLANT AND PATHOPHYSIOLOGY

- Biliary atresia is the most common indication for liver transplant in children
- Portal hypertension, coagulopathy, hepatic encephalopathy, hyperdynamic circulation, ascites, hyperbilirubinemia, and renal dysfunction are all common in hepatic failure
- Extracorporeal liver support (MARS) is increasingly used for "liver dialysis" as a bridge to liver transplantation

Anesthetic management

Preoperative evaluation

Most transplant centers utilize a multidisciplinary approach for the evaluation of patients for liver transplantation. Typical laboratory studies include blood typing, blood chemistries, liver and renal function tests, coagulation profiles, and viral serologies. Cardiac and pulmonary systems are assessed through electrocardiogram (ECG), chest x-ray, and echocardiography. A careful neurological examination should be performed to detect any problems present in the preoperative period. Anatomical assessment of the native liver typically includes abdominal ultrasound and/or CT or magnetic resonance imaging (MRI). A liver biopsy may be indicated to confirm the diagnosis or severity of the liver disease. Also, an assessment of the psychosocial and financial situation of the child's family is performed. Following the initial evaluation, the patient's history and data are presented to a selection committee, which decides if the patient is a candidate for transplantation. Patients approved for transplantation are then activated on the transplant center's recipient list. In situations of acute hepatic failure or rapid decompensation of chronic liver disease, the evaluation process can be condensed to a few hours. Contraindications to liver transplantation are listed in Box 30.1 [58].

Referral to the transplant center and acceptance of the child as a transplant candidate allows the transplant center physicians the opportunity to optimize the patient's medical condition while the child awaits transplantation. Medical therapy to control ascites, infection, and encephalopathy is initiated. Nutritional assessment and diet modification are frequently performed. Endoscopy and sclerotherapy may be performed to treat gastrointestinal bleeding. If the patient has cardiopulmonary disease, additional studies, including arterial blood gases, response to inhaled oxygen, and cardiac catheterization may be indicated. Vitamin K may be administered to improve hemostatic function. Prophylactic dental work or dental extraction and tonsillectomy and adenoidectomy are performed if required prior to transplantation and initiation of immunosuppression. A summary of the preoperative evaluation is presented in Box 30.2 [58].

Perioperative period

In general, patients are admitted from home when a potential donor is identified. Because of the logistic complications associated with scheduling, performing donor surgery, and transporting the donor organ to the transplant center, often only 8–12 h notice is provided to the patient, family, and transplant team members. Upon admission to the hospital, interval history and physical examination are performed to seek evidence of new changes and complications since the original pretransplant evaluation. Whenever possible, the child is made NPO prior to surgery. In addition to routine blood tests, multiple additional blood samples are obtained for serologic studies, and specialized immunotesting is undertaken. A peripheral intravenous line is usually started and maintenance fluids administered. Disease-specific anesthetic considerations are listed in Table 30.5 [58].

Following arrival of the donor organ at the hospital, final inspection and possible biopsy and frozen section of the liver are performed. Following notification from the transplant surgeon that the liver is appropriate for transplantation, the child is transported to a warm operating room. In some children, especially those who are older, premedication may be required with either intravenous or oral midazolam. Children with hepatic encephalopathy should not receive premedication because midazolam may produce significantly greater central nervous system depression among these patients and may potentially increase ICP. Routine monitors (pulse oximetry, ECG, arterial blood pressure) are applied prior to induction of anesthesia. One hundred percent oxygen is administered by

Box 30.1: Contraindications to pediatric liver transplantation

- Rapidly progressing hepatocellular carcinoma with metastasis
- Extrahepatic malignancy
- Uncontrolled systemic infection
- Severe multisystem mitochondrial disease
- Niemann–Pick type C
- Severe portopulmonary hypertension not responsive to medical therapy
- Mean pulmonary artery pressure (MPAP) greater than 35 mmHg despite therapy

facemask. Because of concerns that these patients have a full stomach and may aspirate gastric contents, cricoid pressure is applied and a rapid sequence induction of anesthesia is performed for most patients. Those who present for elective transplant to correct a metabolic disease may undergo inhalational induction. Since patients with significant ascites are likely to have a reduced functional residual capacity, adequate preoxygenation is required. Once the airway is secure, mechanical ventilation with an increased inspired concentration of oxygen and positive end-expiratory pressure is initiated. Cuffed endotracheal tubes are favored because they make a reliable seal between the tracheal tube and the tracheal mucosa and reduce the risk of inadequate ventilation and monitoring of ventilation from a leak around the endotracheal tube.

Following tracheal intubation, vascular access is obtained and monitoring catheters are inserted. Ideally, two large-bore intravenous lines are placed in the upper extremities (20–22 gauge for infants, 18–20 gauge for a young child, and larger for older children). Adequate venous access is critical during any liver transplant procedure because the anesthesia team must be able to respond rapidly to surgical hemorrhage. The fluid delivery system must allow for sufficient control over the volume and rate of fluid and blood product administration in small children to prevent overhydration. An arterial catheter is inserted, preferably in a radial artery, because the aorta may be cross-clamped during reconstruction of hepatic arterial inflow. A multi-lumen central venous catheter is inserted after induction. One lumen is used for central venous pressure monitoring, and the other lumens used for infusion of medications and/or volume. The surgical team may decide to insert a tunneled central line if long-term access is likely to be needed in the postoperative period. Measuring pulmonary artery pressures may facilitate the perioperative management of patients with cardiac disease or associated pulmonary hypertension. Except for these rare cases, central venous pressure monitoring is sufficient in infants and children for liver transplant. See Chapter 19 for more detail about vascular access procedures. Many adult centers use transesophageal echocardiography to monitor cardiac function and filling during liver transplantation; however, this is much less common in the pediatric setting [59].

Particular attention is paid to maintaining normal body temperature during pediatric liver transplantation. Numerous factors facilitate development of unintentional hypothermia: exposure of the abdominal contents to air, duration of surgery, rapid administration of cool intravenous fluids and blood products, and implantation of the cold liver graft and washout of the cold storage solution during reperfusion of the organ. Rigorous attention is paid to warming the operating room and to the use of insulated wrapping of exposed extremities, forced-air warming blankets, humidified anesthesia circuit, and warming of all intravenous fluids.

No particular anesthetic regimen has proven superior in liver transplantation. A combination of potent inhaled anesthetic, bolus doses of opioids or an infusion, provides a relatively stable intraoperative course during liver transplantation. Higher concentrations of inhaled anesthetics reduce splanchnic blood flow and should probably be avoided. Sevoflurane, isoflurane, and desflurane are commonly used with success when added to a balanced anesthetic technique with opioids. Nitrous oxide should not be used in order to avoid bowel distension. A comparison of right ventricular function in adult patients undergoing liver transplantation found no difference between propofol and isoflurane [60]. Even though the primary metabolic pathway for propofol is hepatic, there appears to be extrahepatic metabolism in the lung, kidney, and intestine [61,62].

Intravenous opioids have been used extensively in the anesthetic management of adult and pediatric patients undergoing liver transplant. Although end-stage liver disease is likely to affect the distribution and plasma clearance of opioids, the functioning newly transplanted liver graft will improve opioid clearance. Opioid analgesics undergo hepatic biotransformation via mixed function oxidase (e.g. fentanyl) and glucuronosyltransferase (e.g. morphine). Because the hepatic extraction of morphine and fentanyl is high, plasma clearance is less affected by alterations in hepatic function than by alterations in hepatic blood flow. Morphine, fentanyl, and sufentanil appear to have unchanged plasma clearance and volumes of distribution in patients with end-stage liver disease, which may reflect the ability of the large volume of distribution to buffer any decrease in drug metabolism. In contrast, alfentanil, with its volume of distribution approximately 25% that of the other opioids, has a decreased plasma clearance and an increased free fraction of drug in patients with cirrhosis. The impact of large changes in and replacement of intravascular volume during the course of a lengthy liver transplant procedure is not known.

Liver disease affects the duration of action of non-depolarizing muscle relaxants. The action of pancuronium is prolonged in patients with liver disease. The duration of action of vecuronium depends on the extent of liver disease and on the dose of vecuronium. Vecuronium in a bolus of 0.1 mg/kg has the same pharmacokinetics in both patients with normal livers and those with liver disease [63]. In more advanced liver disease, a dose of 0.2 mg/kg of vecuronium may have a prolonged duration of action [64,65]. Similarly, rocuronium will have prolonged duration of action after repeated doses despite a normal onset of action for the first dose [66]. Redistribution of the drug within the body may be important for the termination of the drug's effect in patients with liver disease, but when larger doses of drug are administered, reduced hepatic clearance becomes more evident. Studies suggest that the liver graft with normal function rapidly resumes its role of drug metabolism.[67,68]. Despite the overall uncertainty of anesthetic drug metabolism in the

perioperative period following liver transplantation, delayed recovery from anesthetic drugs and neuromuscular blockade rarely poses a clinical problem. The timing of extubation of the trachea varies among centers; however, immediate postoperative extubation has gained acceptance and is practiced more commonly. In the authors' institutions, tracheal extubation in the operating room is performed in over 50% of patients. Most commonly, the decision to extubate the patient early is based on the presence or absence of co-morbidities.

Because of the duration of the procedure and the potential for hypoperfusion of the skin and extremities, positioning is critical to prevent injuries. All extremities should be padded, and all cables and wires need to be wrapped and protected from the skin. The head should be turned and repositioned periodically to prevent pressure sores and alopecia.

KEY POINTS: PREOPERATIVE EVALUATION AND PERIOPERATIVE PERIOD FOR LIVER TRANSPLANTATION

- Careful physical exam, lab studies, echocardiography, radiography, and ultrasound/CT/MRI are necessary before transplant listing
- Arterial and central venous access are required for liver transplant surgery
- A variety of anesthetic regimens can be used; avoiding drugs with extensive hepatic metabolism is important

Surgical procedure

Liver transplantation is usually divided into four stages: dissection (preanhepatic), anhepatic, reperfusion, and biliary anastamosis. During the dissection period, the liver is mobilized via a large bilateral subcostal incision (Fig. 30.3) [69]. All perihepatic adhesions are lysed; the suprahepatic vena cava, infrahepatic vena cava, and structures in the porta hepatis (portal vein, hepatic artery, and common bile duct) are identified and mobilized. Lysis of dense adhesions following a Kasai portoenterostomy or other previous surgery usually prolongs the dissection time and increases blood loss during this period. Adequate replacement of blood components during this time is essential. Common problems and goals of the preanhepatic phase are summarized in Table 30.6 and Box 30.3 [58].

Prior to implantation, the donor organ is stored in preservation solution, most commonly University of Wisconsin solution. Because of the high potassium content (120 mEq/L), the donor organ is perfused with a cold crystalloid or colloid solution to remove the preservation solution from the liver before the liver is implanted. In the case of reduced-size liver transplants, the partial hepatectomy of the donor liver is performed on the back table prior to implantation. When the dissection phase is complete in the recipient, the preservation solution is flushed out of the donor liver, and it is brought onto the operative field. However, flushing the donor liver with large volumes of fluid does not always remove all of the potassium, air, and particulate matter. Consequently, when the donor organ is reperfused, the recipient will be subjected to a bolus of hypothermic solution, and may be subjected to hyperkalemia and thrombotic and air emboli. Bradycardia and increases in pulmonary artery pressure are common, and, occasionally, there is a hyperkalemic cardiac arrest at the time the donor organ is reperfused.

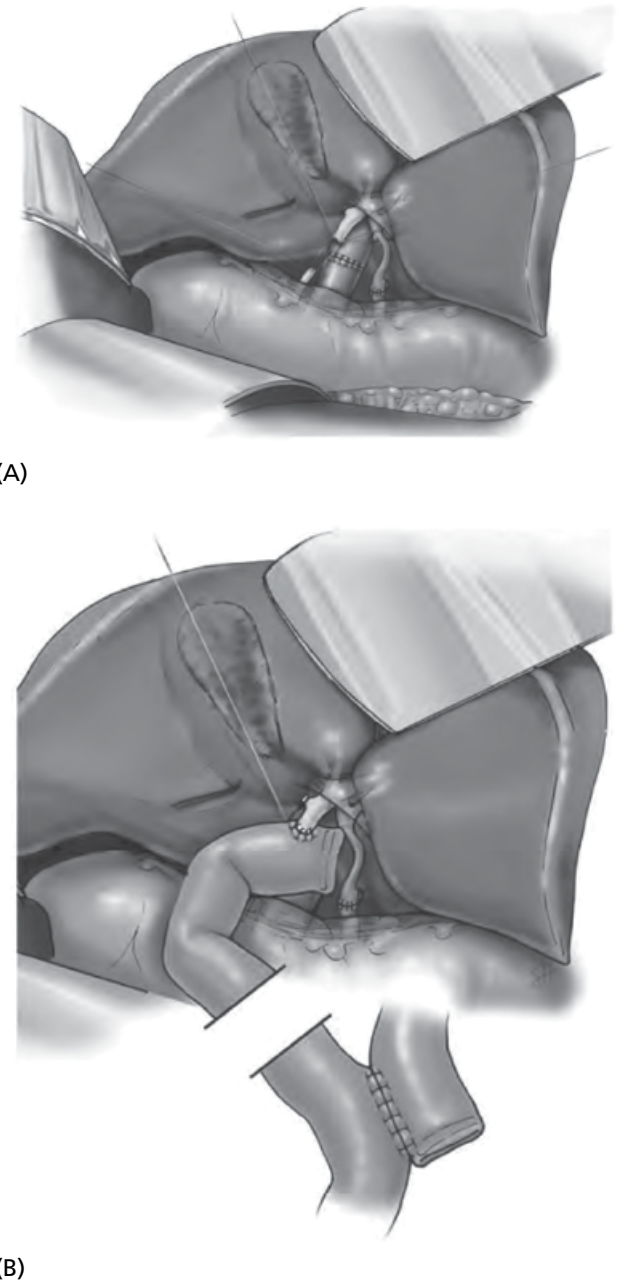

Figure 30.3 Surgical technique for liver transplantation. (A) Whole allograft with choledocholedochostomy showing completed portal venous (central) and hepatic arterial (right) anastomoses. The donor and recipient bile ducts have been aligned with the corner sutures in place for anastomosis. (B) Whole allograft with completed hepaticojejunostomy. Biliary anastomosis is in the foreground, whereas the portal venous and hepatic arterial anastomoses are in the background. Caval anastomoses are not seen. *Source*: Reproduced from Cotton et al [69] with permission of Wolters Kluwer.

The anhepatic stage begins with cross-clamping the suprahepatic vena cava, infrahepatic vena cava, portal vein, and hepatic artery. This surgical approach will significantly reduce preload from cross-clamping the inferior vena cava. However, patients with chronic cirrhosis develop collateral circulation, and an inferior vena cross-clamp is generally well tolerated.

Table 30.6 Common complications during the preanhepatic (dissection) period

Problem	Risk factors	Treatment
Massive hemorrhage Hypotension	Impaired synthetic function Prior abdominal surgery Bleeding Large-volume ascites drained Acidosis	Transfuse as necessary Vasopressors 5% albumin for ascites May need vasopressor infusions

Source: Reproduced from Wasson et al [58] with permission of Elsevier.

Box 30.3: Anesthetic goals during the preanhepatic (dissection) period

- Maintenance of hemodynamic stability
- Replacement blood or volume losses
- Avoidance of significant acidosis
- Avoid electrolyte derangements (K^+ or Ca^{2+})
- Normothermia and normoglycemia

Source: Reproduced from Wasson et al [58] with permission of Elsevier.

Table 30.7 Anesthetic goals during the anhepatic period

Goal	Target or treatment
Maintenance of intravascular volume and hemodynamic stability	Hematocrit 24–27% (hemoglobin 8–9 g/dL) CVP 6–10 mmHg Use vasopressor infusions as necessary
Maintain normoglycemia	May need dextrose bolus or infusion
Maintain normothermia	Bair Hugger™, warmed fluids, heat–moisture exchanger, low-flow anesthesia
Maintenance of acid–base balance	Hyperventilation Sodium bicarbonate boluses (1–2 mEq/kg)
Maintain normal calcium and low–normal potassium levels	Replace Ca^{2+} as necessary Treat any hyperkalemia

Source: Reproduced from Wasson et al [58] with permission of Elsevier.

Partial clamping of the inferior vena cava is used for reduced size grafts, or when inferior vena cava cross-clamping produces cardiovascular instability. Using the piggy-back technique [70], the liver is dissected away from the inferior vena cava, the short hepatic veins, portal vein, and left, right, and middle hepatic veins. The infrahepatic vena cava of the donor is oversewn, and the suprahepatic vena cava is anastomosed to the native hepatic veins. In addition, a portocaval shunt can be established for children who do not tolerate clamping of the portal vein. Typically, these recipients have not developed collateral flow secondary to portal hypertension (e.g. metabolic liver disease and acute fulminant hepatic failure). During the anhepatic period, the native liver is completely excised, bleeding is controlled in the retrohepatic area, and the donor liver is sutured in place. The liver is most commonly reperfused with venous inflow, which accounts for approximately 80% of liver blood flow. The anhepatic period ends with restoration of blood flow to the new liver. A summary of anesthetic goals during the anhepatic phase is presented in Table 30.7 [58].

Following restoration of blood flow into the new liver, the final stage of the operation, reperfusion, has started. The surgical goals during this time include completion or revision of the hepatic artery anastomoses and establishment of biliary drainage. In infants and children, reconstruction of the hepatic arterial inflow may be more difficult and frequently includes reconstruction via a patch graft from the recipient aorta, or donor saphenous vein graft to the celiac trunk, hepatic artery, or aorta. Biliary drainage may occur via a direct choledochocholedochostomy, or more commonly in children, via a Roux-en-Y choledochojejunostomy. A major goal during the early reperfusion period is the control of bleeding. This period requires close communication between surgeons and anesthesiologists to determine the presence of a coagulopathy (common in the early reperfusion period) as opposed to defined surgical bleeding (common following total hepatectomy of the native liver and multiple vascular anastomoses and following previous abdominal surgery). The operating team uses a variety of clinical observations (color, texture, bile production) and laboratory measurements (prothrombin time, metabolic acidosis, ionized calcium, glucose concentration) to document the status and quality of liver graft function. The anesthetic goals of the reperfusion phase are presented in Table 30.8 [58].

Occasionally, infants who have cardiac anomalies and intracardiac shunts require liver transplantation. This is especially dangerous because when the graft is reperfused there is the likelihood of air, clot, and other debris entering the systemic circulation. If this occurs, there is the danger of coronary artery or cerebral artery embolism. One method used to reduce this risk is to leave the vena cava above the liver clamped and to open the vena cava below to allow the initial blood entering the liver from the portal vein to exit the vena cava into the abdomen. This often means that one-fourth to one-third of the blood volume is lost via this route. This period of phlebotomy requires rapid replacement of blood, but is effective in reducing the risk of systemic embolization.

Table 30.8 Anesthetic goals during the reperfusion period

Goal	Treatment
Correct calcium	Calcium chloride (central) 10–20 mg/kg IV
Prevent or treat hyperkalemia: low–normal (K^+ 3.5–4.0)	Hyperventilation Calcium chloride boluses Sodium bicarbonate Insulin or dextrose Inhaled albuterol Furosemide Epinephrine
Normothermia: expect ~1°C drop	Warm room Bair Hugger™ Warm fluids
Normotensive	Vasoactive infusions ready as needed Dopamine and/or epinephrine
Normal heart rhythm	Treat as above Defibrillation pads attached to defibrillator

Source: Reproduced from Wasson et al [58] with permission of Elsevier.

KEY POINTS: SURGICAL PROCEDURE FOR LIVER TRANSPLANTATION

- Surgery is divided into four stages: pre-anhepatic, anhepatic, reperfusion, and biliary anastomosis
- The anhepatic phase reduces preload from inferior vena cava cross-clamping; this is generally well tolerated because of collateral venous return
- Reperfusion can introduce acidemic blood or perfusate with air or particulate material entering the circulation

Intraoperative management issues

Hemodynamics

Periods of hemodynamic instability are common during liver transplantation. In the earlier portions of the anesthetic (e.g. during line placement, preparing and draping the skin), the general debilitating effects of end-stage liver disease and the reduced blood volume induced by diuresis may limit the patient's ability to compensate for the hypotensive effects of anesthetics. In response to abdominal incision and dissection around the native liver, surgical stimulation may overcome light levels of anesthesia and produce hypertension and tachycardia.

A more common scenario is the development of hypotension at various points during the operation. Massive blood loss must always be entertained in the differential diagnosis for hypotension. Given the site of surgery, the presence of extensive abdominal and retroperitoneal collateral vessels, and scar tissue from previous surgeries, bleeding may be significant during the dissection phase of surgery. It should always be kept in mind that splenic bleeding is a possibility. The changes in hemodynamics during the anhepatic period are frequently the most complicated to understand. With application of the venous clamps to the portal vein and to the infrahepatic and suprahepatic vena cava, there is an abrupt decrease in venous return to the right side of the heart and subsequently to the left side of the heart. Although there may be a brief period of hypotension in response to application of the clamp, infants and children appear to tolerate moderate hypovolemia and maintain normal systemic arterial pressures. Stimulation may produce hypertension and tachycardia if the anesthesia level is light. Reflex tachycardia, reduction in central venous pressure (CVP), dampening of the arterial waveform during positive pressure ventilation, and development of a metabolic acidosis are all consistent with significant hypovolemia. In addition, this same hemodynamic picture may develop from surgical manipulation resulting in compression of the inferior vena cava or right ventricle.

In adult patients, the cardiac index may decrease 30–50% when the venous clamps are applied, but systemic arterial pressure is only slightly decreased because there is a compensatory increase in systemic vascular resistance. Volume administration during the anhepatic period is guided by CVP, systemic arterial pressure, and by the arterial pressure waveform. While surgical attention is focused on the vascular anastomoses during the anhepatic period, significant bleeding may continue from areas behind the liver and at other sites of collateral flow. In rare situations, vasopressin (0.1–0.3 units/min IV) may be required to decrease splanchnic blood flow while the anastomoses are being completed. Fluid administration may include crystalloid, colloid, or blood products, depending upon the hemoglobin, PT, and preference of the surgeon and anesthesiologist. Colloid solutions may have particular benefit during the anhepatic period and at the end of the dissection period. Care should be taken not to administer excessive fluid during the anhepatic phase because when the blood is returned to the central circulation with unclamping of the inferior vena cava, a high CVP will impair hepatic venous drainage. Typically a CVP of 8–10 mmHg is adequate to maintain arterial pressure at the time of reperfusion with little need for vasopressors.

Because the portal vein is clamped during the anhepatic period, portal venous hypertension develops. Because of the increased venous pressure, there is a tendency toward fluid translocation and bowel edema during the anhepatic period. Administration of colloid solutions during the dissection and anhepatic period may reduce the amount of bowel edema that develops and facilitate closure of the abdomen at the end of the operation. In addition, the extent of bowel edema may influence the duration of impaired intestinal motility following the operation. Because large volumes of hydroxyethyl starch are associated with coagulopathy, albumin solutions are routinely utilized for colloid administration. Patients with persistent hypotension may require cardiovascular support with dopamine or epinephrine during this time.

Infants and children commonly have normal urine outputs during the anhepatic period, apparently because there are other pathways by which venous blood can return to the central circulation. However, low urine output during the anhepatic phase is not an indication for fluid administration because of the potential adverse effects of high CVP, and the routine recovery of urine output after removal of the venous cross-clamp. The CVP is a better indicator of hydration status.

Completion of the anhepatic period restores venous return from the lower extremities and splanchnic bed. Despite adequate intravascular volume, hypotension is a common finding following graft reperfusion. Numerous factors are felt to contribute to the hemodynamic changes associated with reperfusion. Immediately upon reperfusion, a combination of hypotension, bradycardia, and supraventricular and ventricular dysrhythmias may develop. Prior to reperfusion, a small bolus of fluids may be administered to optimize ventricular filling. Acid–base status is checked approximately 5–10 min before reperfusion. Sodium bicarbonate and calcium are administered to achieve a high–normal pH and calcium levels prior to cross-clamp release. At the moment of reperfusion, attention must be divided between the cardiac monitor and the surgical field. Evidence of life-threatening hemorrhage requires the immediate infusion of blood products while the surgeons control the bleeding. Inspection of the cardiac monitor will detect ECG changes consistent with profound bradycardia and/or hyperkalemia. Bradycardia may result from the sudden atrial stretch occurring with restoration of normal venous return and/or influx of cold storage flush solution, with profound alterations in pH and electrolyte content. If the heart rate decreases by 30–40%, atropine should be administered, and warm solutions should be instilled into the abdominal cavity.

ECG evidence of hyperkalemia includes development of peaked T waves (rare in babies), QRS widening, and

sine-wave formation. Inspection of the arterial waveform trace will confirm the loss of mechanical activity. The occurrence of hyperkalemia at the time of reperfusion represents systemic toxicity of organ preservation solution that was not removed when the organ was flushed. Acute interventions for hyperkalemia include administration of calcium and bicarbonate, and circulatory support with closed chest cardiac massage and epinephrine. Because the surge in serum potassium is transient, treatment is directed towards decreasing the concentration of serum potassium and restoring the cardiac rhythm. The potassium concentration increases 0.5–1.5 mEq/L at the time of reperfusion in almost all patients. Because this increase in potassium is expected during reperfusion, care should be taken to prevent increases in potassium concentrations during the dissection and anhepatic periods. Forced diuresis (renal dose dopamine, fenoldepam, diuretic administration) can help lower the potassium level. In addition, insulin and glucose administration effectively decreases the serum potassium concentration during the anhepatic period. Following the abrupt increase at reperfusion, potassium concentrations tend to decrease during the remainder of the operation. Urinary losses of potassium account for some of the decrease, while potassium uptake by muscle cells and allograft liver cells also contribute to the decreases in serum potassium. Potassium administration is indicated if the serum potassium concentration decreases and the urine output remains adequate in the post-reperfusion period.

Other factors, including transient hypocalcemia, acidosis and hypothermia, contribute to hypotension following graft reperfusion. Studies in adult transplant patients suggest that approximately 30–40% of patients develop a "post-reperfusion" syndrome consisting of decreased arterial blood pressure and profound vasodilation. A study utilizing transesophageal echocardiography (TEE) found right ventricular dysfunction (paradoxical motion of interventricular septum, right atrial enlargement, right-to-left interatrial deviation) following reperfusion [70]. In addition, the pulmonary circulation is known to be sensitive to acute alterations in temperature and pH. Perfusion of the lungs with ice-cold, hyperkalemic, acidic blood may increase pulmonary vascular resistance and cause right ventricular dysfunction. Embolization of air, clot, and cellular debris can occur at the time of graft reperfusion, as was shown by the TEE study just mentioned.

Perturbations of hemodynamics at reperfusion can affect other organs and systems. The liver graft is sensitive to increased levels of central venous and pulmonary artery pressure. Vascular engorgement of the liver is common following reperfusion of the liver, especially if the CVP was greater than 10 mmHg before the liver was reperfused. Because the arterial blood supply to the liver may still be compromised (e.g. during the hepatic arterial reconstruction), excessive passive engorgement of the liver may deprive some areas of the liver of oxygen and cause poor restoration of graft function. Anesthetic management must attempt to prevent liver graft engorgement. If the systemic arterial pressure is adequate, infusion of nitroglycerin may reduce elevated central blood volumes and graft swelling or engorgement. Specific treatment for pulmonary hypertension includes increased ventilation, correction of acid–base status, and normalizing body temperature.

Hemostasis

Intraoperative hemostasis is a complex issue during orthotopic liver transplantation [55,68]. The hemostatic system is often impaired as a result of intrinsic liver disease and as a result of the transplant procedure. Based upon preoperative diagnosis and coagulation testing, several groups have attempted to predict the risk of intraoperative bleeding during liver transplantation [72]. However, a predictive score that indicates a low likelihood of bleeding is not a reason to decrease the level of preparedness. Blood products should be immediately available for transfusion. Low potassium units of blood should be used (less than 2 weeks since collection) or it is prudent to wash units of packed red blood cells to remove the excess potassium. Once the initial extent of dissection and coagulopathy is determined, the need for additional crossmatching of blood and/or preparation of fresh frozen plasma (FFP), cryoprecipitate, and platelets can be determined. In the event of significant hemorrhage, the blood bank must be notified of anticipated increased requirements for blood products.

The anesthesia team is responsible for maintaining adequate hemostasis during liver transplant procedures. Central to this role is the ability to rapidly monitor coagulation status intraoperatively. For the monitoring system to be effective, the anesthesiologist must have rapid access to the results of these tests so that the abnormalities can be corrected immediately. Routine coagulation testing should include measurement of PT, activated PTT, platelet count, hemoglobin concentration, and fibrinogen concentration. Thromboelastography (TEG) and thromboelastometry, specific types of whole blood viscoelastic coagulation monitoring, have been used successfully by some clinicians during liver transplantation [73]. TEG is a test of clot strength, and requires a 30–60 min recording of clot formation and lysis. It gives an indication of clotting factor activity, platelet function, and fibrinolysis. Since significant fibrinolysis is less common in children, TEG monitoring is not routinely utilized in most centers [59].

Intraoperative management of coagulopathy during liver transplantation includes the administration of blood products and potential pharmacological interventions. The principal blood product administered is FFP, which will correct clotting factor deficiencies. Because hepatic artery thrombosis is one of the most common causes of graft failure in pediatric patients, FFP is administered to correct and maintain at values for PT and PTT close to 1.5 times prolonged from normal, depending on the amount and severity of intraoperative bleeding. Cryoprecipitate is administered when the infusing FFP does not correct a low fibrinogen concentration (<80–100 mg/dL). In the post-reperfusion period, intravascular filling pressures may be elevated. Consequently, the decreased volume of cryoprecipitate is better tolerated.

Thrombocytopenia is a common finding during liver transplantation. Many patients have decreased platelet counts because portal hypertension has induced hypersplenism. Intraoperative thrombocytopenia may develop or worsen due to replacement of blood loss during the dissection phase with non-platelet-containing solutions. Platelet counts decrease slightly during the anhepatic period and decrease significantly upon reperfusion of the graft. Platelet entrapment within the grafted liver has been demonstrated in a porcine model of liver transplantation; in addition, platelet activation and consumption increase following reperfusion of the graft.

Platelet counts of 50,000–100,000/L commonly develop and are not an indication for platelet transfusion in the absence of excess bleeding. Over transfusion of platelets may also increase the risk of hepatic artery thrombosis. Platelet transfusion is indicated if thrombocytopenia is present and there is a clinical impression of abnormal hemostatic function.

Severe post-reperfusion coagulopathy occurs in some patients who undergo liver transplantation, possibly because of the reperfusion-initiated disseminated intravascular coagulation. Studies indicate that primary fibrinolysis may develop during liver transplantation due to changes in the circulating concentration of tissue-type plasminogen activator. Both ε-aminocaproic acid (EACA) and aprotinin have been utilized to pharmacologically reduce the severity of fibrinolysis during orthotopic liver transplantation. EACA improves the TEG findings of fibrinolysis during liver transplantation; however, prophylactic use of EACA has not been demonstrated to be of value. Administration of aprotinin, a protease inhibitor of kallikrein, decreases the laboratory abnormalities associated with fibrinolysis and reduces transfusion requirements during liver transplantation [74]. The worldwide marketing of this agent was suspended in 2008 due to complications in the adult cardiac surgery population – including thrombosis, stroke, and renal failure – and it is not available in the USA. Children are hypercoagulable after liver transplantation because of a decrease in protein C and antithrombin III [75], and they may be more likely to develop hepatic artery thrombosis or emboli [76–78]. Therefore, antifibrinolytics are not routinely used in most pediatric transplant centers.

Hepatic artery thrombosis may result from disorders of the coagulation system and/or technical factors in hepatic arterial reconstruction. Intraoperative and postoperative Doppler ultrasound examinations of the hepatic arterial and portal vein anastomoses are commonly used to assess patency of the anastomoses. Because of the potential for graft loss with vessel thrombosis, a slightly anticoagulated state is maintained in infants and small children following liver transplantation. This includes avoiding fully correcting the heparin effect in the operating room, maintaining a slightly higher PT, and early administration of aspirin. At the Texas Children's Hospital, our practice is to start a heparin infusion in the operating room once hemostasis has been achieved after reperfusion and to continue this infusion for the first few days postoperatively. In addition, hyperviscosity from overtransfusion of red cells should be avoided. Maintaining the hemoglobin between 8 and 10 mg/dL provides adequate oxygen-carrying capacity.

Metabolic control (K^+, Ca^{2+}, acid–base, glucose)

Acute changes in acid–base status, potassium concentration, ionized calcium, and glucose are common, both before and during liver transplantation. Concomitant renal dysfunction promotes acid–base changes and exacerbates electrolyte problems. Diuretic therapy can cause electrolyte imbalance (hyponatremia, hypokalemia, hypocalcemia) and prerenal azotemia. A common pattern of electrolyte changes develops in most patients. Consequently, an anticipated treatment plan can be developed. Routine intraoperative monitoring of arterial blood gases, electrolytes, and glucose concentrations will define the need for and further refine intraoperative electrolyte therapy. Because of the multiple factors contributing to hemodynamic instability in these patients, these parameters are more tightly controlled than in other operations.

Many patients who present for surgery have hyponatremia due to prerenal azotemia and the use of diuretics. Care should be taken to avoid a rapid rise in sodium concentrations during surgery from the use of salt-containing solutions, sodium bicarbonate, and blood products. Also, both hypo- and hyperkalemia are frequently encountered during surgery (see earlier discussion).

Patients undergoing liver transplantation are particularly susceptible to the development of ionized hypocalcemia. Although total calcium concentrations are decreased in patients with chronic liver disease, ionized calcium concentrations are normal. Intraoperative administration of blood products decreases ionized calcium and magnesium concentrations because citrate-based anticoagulant solutions used in collection and storage of blood products bind these ions. Citrate usually is metabolized rapidly by the liver. In normal patients, low ionized calcium concentrations only occur following massive and rapid administration of blood products. Patients with end-stage liver disease are particularly sensitive to the administration of citrate-containing blood products, and the administration of moderate amounts of FFP can significantly decrease ionized calcium concentrations. Profoundly low ionized calcium concentrations, particularly during the anhepatic period, may cause myocardial depression and hypotension. Given the potential for dramatic changes in the ionized calcium concentration, direct measurement of ionized calcium is particularly useful during liver transplantation. Calcium replacement therapy during the dissection and anhepatic phases can be achieved with either bolus administration or constant infusion of calcium. Calcium chloride and calcium gluconate are equally effective in increasing the ionized calcium concentration during the anhepatic period [79]. Calcium requirements are expected to increase (often markedly) during the anhepatic period and to quickly decrease following reperfusion of the hepatic allograft. With restoration of blood flow to the liver graft, metabolism of citrate proceeds at a much faster rate than that which occurred with the native liver or during the anhepatic phases. A reduction in calcium requirement following reperfusion is consistent with adequate hepatic allograft function. As mentioned earlier, normal ionized calcium concentrations at the end of the anhepatic period may protect against the cardiovascular effect of abrupt increases in potassium from the reperfused liver. Measurement of ionized calcium 5 min before graft reperfusion and administration of calcium prior to reperfusion is suggested.

Metabolic acidosis is extremely common during orthotopic liver transplantation. Numerous factors contribute to its development, including tissue hypoperfusion; decreased or absent metabolism of lactate, citrate, and other metabolic acids by the liver; rapid administration of acidic blood products; associated renal impairment; and acidic effluent from the liver allograft. During the dissection period, a development of acidosis most commonly reflects global tissue hypoperfusion. The administration of additional intravascular volume and restoration of adequate blood pressure and cardiac output often corrects the acidosis. The anhepatic period in particular is associated with rapid development of acidemia. The contribution of decreased tissue perfusion (caused

by the abnormal hemodynamics associated with vena cava and portal vein occlusion) and the absence of hepatic function are unknown. Sodium bicarbonate is used to treat metabolic acidosis during the anhepatic period, and the amount of bicarbonate administered is based on the rapidity and severity of changes in the acid–base balance. In general, with base deficits greater than 5–8 mEq/L, or pH less than 7.35 ($PaCO_2$ <40 mm Hg), bicarbonate should be administered to create a relatively normal pH immediately prior to reperfusion of the graft. Arterial blood gases and pH measurements obtained approximately 5 min prior to reperfusion will determine the amount of bicarbonate required.

Following reperfusion of the liver graft, metabolic acidosis frequently recurs. Treatment of severe metabolic acidosis at this point is indicated when there is concomitant myocardial depression and/or there are signs of persistent hyperkalemia. Normally, the exacerbation of metabolic acidosis quickly abates during the post-reperfusion period; this abatement is one of the early signs that the graft is functioning. The liver allograft usually resumes metabolic function rapidly, and hepatic metabolism of lactate and citrate frequently leads to the development of a metabolic alkalosis in the later portions of the operation and in the postoperative period. Resolution of metabolic acidosis (and development of alkalosis) is indicative of adequate allograft function, although the sensitivity and specificity of these findings are not known. The extent of the metabolic alkalosis is related to the amount of intraoperative transfusion, and not to the amount of bicarbonate administered.

Glucose balance is complicated by liver transplantation. Hypoglycemia may be present in patients with fulminant liver failure or severe chronic liver disease and may necessitate preoperative administration of dextrose-containing fluids. It usually is necessary to administer glucose to these patients before the graft is reperfused. In theory, the anhepatic period should pose a greater risk of hypoglycemia because there is no liver in the circulation. Numerous factors are present that help maintain a relatively normal glucose concentration in the blood during the anhepatic period: stress response to surgery, steroid administration, dextrose-containing blood products, and reduced glucose utilization due to hypothermia. Since organ preservation solutions and flush solutions frequently contain dextrose, glucose concentrations commonly increase after reperfusion of the graft. Hyperglycemia in the reperfusion period also has been suggested as a marker for allograft function. Small infants may have markedly decreased glycogen stores when presenting for liver transplantation and are frequently at increased risk for developing hypoglycemia. Preoperative and frequent intraoperative glucose determinations are the best methods of detecting abnormal glucose levels. Dextrose should be administered if hypoglycemia is present. Persistent hyperglycemia, glucose greater than 250 mg/dL, is treated with insulin administration.

Temperature maintenance

Hypothermia is common during liver transplantation, despite utilization of multiple methods to conserve body heat. The long intra-abdominal operation, massive fluid and blood product administration, and implantation of a graft that has a temperature near zero, all contribute to the development of hypothermia. There is usually a 1–2°C decrease in body temperature when the ice-cold donor liver is placed in the abdomen. There also may be an abrupt decrease in core temperature of 1–2°C with reperfusion when cold flush solution is infused into the systemic circulation. Profound hypothermia carries significant risk, including cardiac depression, arrhythmias, abnormalities in clotting function, and decreased renal function. Because of these risks, specific efforts are directed at maintaining core temperature. Heating the operating room is imperative for infants and small children. A forced-air warming blanket is placed beneath the child, and the exposed extremities are wrapped. Forced-air warming is useful over the legs and/or upper extremities in larger patients. Intravenous fluids and blood products are warmed prior to their administration. Lowering of fresh gas flows and using a humidifier will reduce the heat loss caused by the use of cold dry inspired gases.

KEY POINTS: INTRAOPERATIVE MANAGEMENT DURING LIVER TRANSPLANTATION

- Hemodynamics are often unstable due to massive blood loss, reperfusion, hyperdynamic circulation, or occasional pulmonary hypertension
- Hemostasis is challenging because of poor liver synthetic function and massive blood loss; care should be taken not to overcorrect coagulopathy because of the risk of hepatic artery thrombosis
- Metabolic control can be challenging, and particular attention must be paid to potassium, calcium, and glucose concentrations, and acid–base status

Special techniques

Three advances in surgical technique have improved the number of available grafts for children: using a reduced-size graft (pare-down), dividing the liver allowing two grafts for two recipients, and living donor transplantation. The surgical technique most commonly used to split the liver is performed while still *in vivo* (in the heart-beating donor) as compared with *ex vivo* (splitting performed after the graft is removed from the donor) (Fig. 30.4) [69]. This decreases cold ischemia time and facilitates hemostasis of the liver edge. This technique results in improved child and graft survivals [80,81]. The Studies in Pediatric Liver Transplantation (SPLIT) group is an excellent source of data regarding pediatric liver transplantation in North America. This group represents 46 pediatric liver transplant centers across America and Canada and reflects the results of programs with a strong pediatric emphasis. A review of the SPLIT database reveals patient survival rates of 91.4% and 86.5%, at 1 and 5 years following liver transplantation, respectively [82].

Living related transplantation has greatly benefited the pediatric transplant population, particularly in countries in which there is limited availability of deceased donor grafts for cultural or even legal reasons [83]. In this procedure a left lateral segmentectomy (segments 2 and 3) is performed in the donor and transplanted in a similar fashion to a whole-organ transplant. Approximately 300 living donor liver transplants

are performed annually and 20% of these are in child recipients. Despite the success of this technique for the recipients there is considerable risk to the donor. Complications include exposure to blood products, peripheral nerve injuries, biliary leakage, abdominal wall defects, pleural effusions, pneumonia, pulmonary emboli, and death [84,85].

Retransplantation

Hepatic retransplantation is performed to treat primary nonfunction of the allograft, allograft dysfunction resulting from thrombosis of the hepatic artery or portal vein, rejection unresponsive to aggressive medical therapy, or recurrent or primary disease in the transplanted liver. Retransplantation rates are currently at 10–20%. Because of the dense adhesions around the transplanted liver, significant hemorrhage may occur during the dissection phase. In addition, if the liver has sustained an ischemic insult, disruption of the vascular anastomoses may occur and produce catastrophic hemorrhage. There must be adequate vascular access to allow massive volume resuscitation. Sufficient blood products must be available in the operating room to rapidly instill one blood volume in the patient. Most reports indicate that patient survival following retransplantation of the liver is worse than it is following the primary transplant. However, a 2010 study found graft and patient survival after retransplantation to be similar to that of primary liver transplantation [86].

Renal transplantation

Indications

Renal transplantation is the optimal therapy for children with chronic renal insufficiency and end-stage renal disease (ESRD). Despite the availability of dialysis for children, transplantation is the preferred long-term management for children with ESRD to allow the best chance for normal growth, activity, and development. Also, the risk for death is more than four times higher with dialysis than with renal transplantation [87]. The incidence of ESRD in children 0–19 years of age is between 5 and 12 per million. The incidence increases with age and males are more likely to develop ESRD than females secondary to the higher rate of congenital urological anomalies. The etiologies of ESRD, and therefore the disease processes leading to transplant, differ depending on the age of the patient. For children under 5 years of age, congenital lesions (renal dysplasia/aplasia, obstructive uropathy, complex urogenital malformations, congenital nephrosis) are responsible for the majority of pediatric transplants. Over 5

years of age, glomerulonephritis (e.g. focal glomerulosclerosis, membranoproliferative glomerulonephritis) and recurrent pyelonephritis are major causes of ESRD (Fig. 30.5). The North America Pediatric Renal Trials and Collaborative Studies registry reported that from 1987 to 2013, in 12,189 transplants, 47.2% were over 12 years of age, 32.6% were 6–12 years of age, 14.7% percent were 2–5 years, and only 5.4% were under 2 years of age [88].

The improving outcome of renal transplantation in children and overall graft survival rate is encouraging (Table 30.9) [88]. In recent years, survival after a living donor graft is over 93%, and after a deceased donor graft is over 90%, at 3 years. Of note, 64 ABO-incompatible pediatric renal transplants (0.6% of total) have been reported, with a current 3-year graft survival of 78.2%, which is not different from ABO-compatible transplants; 50.3% of transplants were from living donors, with 80% from a parent; and 2.6% were from unrelated donors.

Pathophysiology

A patient's fluid and electrolyte balance is dramatically altered by renal failure. Hypervolemia, hypovolemia (after dialysis), hyponatremia, hyperkalemia, hypocalcemia, hyperphosphatemia, and metabolic acidosis are common. Because the failing kidney may not excrete adequate free water, hypervolemia is frequent and is a cause of hypertension. Hypovolemia can occur after aggressive dialysis. Hyponatremia occurs when water retention exceeds sodium retention, or when there is salt wasting plus an inability to concentrate urine. Hyperkalemia may be a major problem due to its effects on the cardiac conduction system, and it may require treatment before general anesthesia can be safely induced. Hypocalcemia is secondary to the hyperphosphatemia that results from the kidney's inability to excrete phosphates. Metabolic acidosis develops because the failing kidney cannot excrete the body's daily production of metabolic acids.

Many organ systems are affected by ESRD. Hypertension, increased cardiac output, pericarditis, arrhythmias, and cardiomyopathy are manifestations of the altered cardiovascular system. Hypertension occurs secondary to fluid overload or to alterations in the renin–angiotensin–aldosterone system. Patients with anemia compensate for their decreased oxygen-carrying capacity by increasing their cardiac output. The use of recombinant erythropoietin has decreased the incidence of severe anemia in ESRD patients. Congestive heart failure due to hypertension and volume overload, a uremia-induced cardiomyopathy, and pericardial disease may complicate the management of children with ESRD. Pulmonary edema can develop as a result of fluid overload, hypoproteinemia, and altered pulmonary capillary permeability.

Anemia develops due to decreased erythropoietin production and decreased erythrocyte lifespan, despite normal reticulocyte counts. Uremic toxins decrease red blood cell lifespan and suppress bone marrow function. The anemia is normocytic and normochromic, despite renal failure-induced deficiencies in folate and vitamin B12. There is an increased concentration of 2,3-diphosphoglycerate, which, in conjunction with the metabolic acidosis, shifts the oxygen–hemoglobin dissociation curve to the right. This shift and an increased cardiac output partially compensate for the decreased oxygen-carrying content caused by the anemia. Coagulation is often altered in uremic patients by residual heparinization following dialysis and by abnormal platelet function. Platelets are usually normal in number and lifespan but have a reversible functional defect secondary to accumulation of guanidinosuccinic

Table 30.9 Graft survival rates for pediatric renal transplantation by cohort year, and living versus deceased donor

	Graft survival rates					
	Living donor			Deceased donor		
Cohort group	1 year	3 years	5 years	1 year	3 years	5 years
1987–1991	90.3	82.4	76.3	76.4	65.3	56.9
1992–1996	92.1	87.0	81.6	87.0	77.9	70.9
1997–2001	95.4	91.4	86.3	93.1	84.5	78.3
2002–2006	96.3	92.0	86.4	94.4	84.1	79.2
2007–2013	96.4	93.4	–	95.8	90.4	–

acid, which inhibits adenosine diphosphate-induced activation, of platelet factor III, which is needed for normal platelet adhesion [89].

Renal failure induces numerous neurological effects. Uremic encephalopathy manifests as a global depression that is reversible with dialysis. Uncontrolled hypertension may lead to either focal neurological deficits or seizures, so hypertension must be controlled. Seizures may also occur with rapid electrolyte changes (e.g. hyponatremia). Peripheral neuropathies are common in patients with renal failure and usually consist of axonal degeneration with segmental demyelination. The median and common peroneal nerves are frequently involved. Autonomic dysfunction develops in children with ESRD. Baroreceptor activity may be abnormal and lead to hypotension that is unresponsive to intraoperative volume administration.

Nutrition is generally poor in ESRD. Uremia causes anorexia, leading to poor calorie intake and growth retardation. Despite the need for protein and calories, protein intake must be carefully controlled to prevent worsening metabolic acidosis. Renal osteodystrophy, aluminum toxicity, altered somatomedin activity, and insulin and growth hormone resistance are all associated with the growth failure [90]. Delayed gastric emptying is common in children with renal failure. Therefore, patients undergoing a renal transplant may have an increased risk of aspiration of gastric contents regardless of the NPO interval.

KEY POINTS: INDICATIONS AND PATHOPHYSIOLOGY OF RENAL TRANSPLANTATION

- In young children, congenital malformations and lesions are the most common indication for renal transplant; in older children glomerulosclerosis and glomerulonephritis are most common
- Dramatic alterations in fluid balance, potassium, sodium, and calcium balance and levels, and in renin–angiotensin–aldosterone systems are seen in ESRD
- Transplantation offers better growth, survival, and quality of life than long-term dialysis

Preoperative assessment and preparation

There are two sources for kidneys for transplantation into children: cadaver and living donors. Because living donor transplants are elective operations, there is adequate time to optimize the nutritional, hydration, and metabolic status of the patient.

Evaluation of the fluid and electrolyte status of the patient is of primary importance. If the patient has been recently dialyzed, a review of the dialysis records is often helpful. Changes in weight, blood pressure, and electrolyte concentrations before and after dialysis should be noted. The patient's dry weight is the minimum weight not associated with hypotension or cardiovascular instability; the current weight compared to the dry weight will indicate the volume status of the patient. Because there are significant changes in electrolytes (e.g. Na^+, K^+) after dialysis, serum electrolytes should be determined after dialysis. Hypertension in patients with ESRD is common and frequently indicates hypervolemia. However, many patients also require antihypertensive medications, which should be continued until the time of surgery to avoid intraoperative rebound hypertension.

The physical examination should assess the airway and cardiopulmonary status of the patient and determine if a functioning arteriovenous shunt is present. If so, it must be protected during the operation. Patients with nephrotic syndrome or those who have been on steroids may be edematous, which could make tracheal intubation more challenging. Due to the delayed gastric emptying of patients with ESRD, the use of an antacid or anti-H_2 agent and metoclopramide may be useful before anesthesia induction.

Surgical technique

Pediatric renal transplantation employs more than one surgical technique. In older children (weighing >20 kg), the standard surgical approach is similar to that of adults, that is, a lower abdominal incision with extraperitoneal placement of the donor kidney in the iliac fossa. Vascular anastomoses are usually to the iliac vein (end-to-side) and iliac or hypogastric arteries (end-to-side or end-to-end). For infants and small children (weighing <20 kg), a midline incision is made and the kidney placed intra-abdominally, although extraperitoneal placement is also possible (Fig. 30.6) [91]. The vascular anastomoses are made to the inferior vena cava and the lower abdominal aorta. The aorta and vena cava are cross-clamped while the anastomoses are being completed. In addition, the donor organs for most small children are from older children or adults with obvious size implications.

Anesthetic management

Premedication with midazolam is usually safe and may allay anxiety if needed. Standard American Society of Anesthesiologists (ASA) monitors are used, and because of the potential for acute blood loss, large-bore peripheral intravenous access and a blood warmer are indicated. Because the patient's volume status is difficult to determine and may vary considerably during the operation, measurement of the CVP helps guide appropriate fluid management. The CVP catheter can also be used to obtain blood samples for laboratory tests and to administer vasoactive medications into the central circulation. However, preservation of sites for long-term vascular access in patients who may need hemodialysis in the future should be considered, and the subclavian veins are generally avoided for this reason. Larger, older children can usually be adequately managed with peripheral IV access alone. Also, an indwelling arterial catheter is not routinely used for adults or older children, but it may be quite helpful for smaller children, especially if the aorta is to be cross-clamped. One must be careful not to risk the patency of an existing arteriovenous shunt or to compromise future placement of such a shunt.

Anesthesia for renal transplantation is usually induced with intravenous drugs because the patients frequently have an IV catheter already in place. For patients without an IV catheter, inhaled induction of anesthesia is a viable alternative.

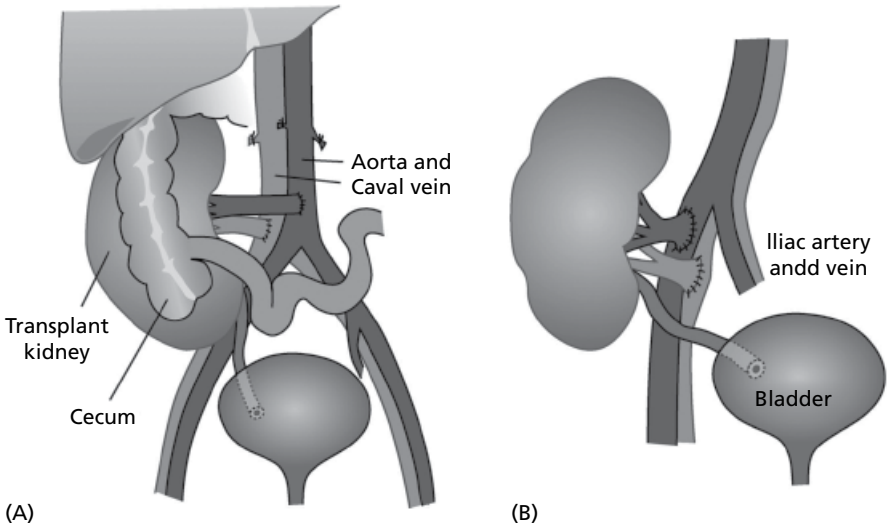

Figure 30.6 Renal transplantation in infants. The kidney is placed intra-abdominally instead of in the iliac fossa because of size considerations. In infants, the kidney graft can be placed intraperitoneally (A) or extraperitoneally (B). *Source*: Reproduced from Jalanko [91] with permission of Springer Nature.

The pharmacokinetics and pharmacodynamics of anesthetic drugs are altered in patients with ESRD, and this must be taken into account when administering drugs to induce anesthesia. Propofol will produce vasodilation and potentially hypotension in patients who are hypovolemic. Ketamine can also be used as an IV induction agent for patients with ESRD, but its sympathomimetic effects may exacerbate pre-existing hypertension. To blunt the autonomic response to laryngoscopy and tracheal intubation, opioids or lidocaine can be given intravenously. As with all sick children, careful titration of anesthetic drugs to the desired effect is always the safest approach.

The choice of muscle relaxant for tracheal intubation continues to generate discussion. Because delayed gastric emptying is common in patients with renal failure, patients undergoing renal transplantation may be at increased risk for regurgitation and possible aspiration of gastric contents. This situation makes a rapid-sequence intravenous induction of anesthesia with an intravenous induction agent, cricoid pressure, and succinylcholine theoretically advantageous. However, the administration of succinylcholine may cause serum potassium concentrations to rise 0.5–0.75 mEq/L in normal patients [92]. A number of conditions can lead to an exaggerated rise of serum potassium and subsequent hyperkalemic cardiac arrest. Patients with ESRD are at risk for hyperkalemia if they have uremic neuropathy or if they have not been dialyzed recently [93]. An alternative to succinylcholine is to perform a modified rapid-sequence intravenous induction of anesthesia using an intravenous agent, a non-depolarizing muscle relaxant, cricoid pressure, and controlled ventilation. The non-depolarizing muscle relaxant used should not depend on renal pathways of elimination. Two categories that fit this requirement are the atracurium/*cis*-atracurium family, whose elimination is by Hoffman degradation and ester hydrolysis, and the steroid-based muscle relaxants that are predominantly metabolized by the liver. The steroid-based muscle relaxants vecuronium and rocuronium have some dependence on renal excretion, perhaps 10–25%, that will lead to some prolongation of onset and duration of action of the drugs when used in patients with ESRD.

Maintenance of general anesthesia during renal transplantation is usually provided by a combination of potent inhaled anesthetic agents and opioids. Nitrous oxide can be used, but it may distend the intestines and make it more difficult to close the abdomen at the end of the operation. Sevoflurane has the theoretical problem of producing a metabolite, compound A, that has been associated with renal concentrating defects, and although useful for inhaled induction of anesthesia, should probably not be the first choice for maintenance of anesthesia [94]. If sevoflurane is used, fresh gas flows should be maintained above 2 L/min. Fentanyl is the most widely used opioid for renal transplantation; no active metabolites are excreted by the kidneys, and there is extensive experience with its use in children without significant complication. The metabolites of morphine are excreted by the kidney so probably should not be the first choice for intraoperative analgesia.

If the patient has an arteriovenous shunt, the extremity with the shunt must be positioned so that the shunt is protected and available to allow the anesthesiologist to periodically determine that the shunt is functional. A blood pressure cuff should not be used on that extremity. At the very least, the shunt should be checked both at the beginning and the end of the operation for a thrill or bruit and the presence of either or both documented on the anesthetic record.

Fluid management during renal transplantation is challenging owing to reduced preoperative renal function and to blood loss and third space fluid losses during the operation. Preoperative fluid status is discussed earlier. Interstitial fluid losses (third space) and blood losses are determined in the usual fashion (see Chapters 11 and 19). Fluid administration should be based on estimates of need and clinical criteria, including vital signs and CVP when utilized. It should be recognized that hypovolemia should be avoided, and fluid administered to produce normovolemia to hypervolemia with adequate blood pressure to the new organ. An isotonic crystalloid solution is a suitable choice of fluid. Theoretically, lactated Ringer solution should be avoided due to the potassium (4 mEq/L) that it contains. On the other hand, normal saline is hypernatremic (154 mEq/L) and can lead to a

hypernatremic metabolic acidosis if given in large quantities. Intermittent measurements of the serum electrolyte and glucose concentrations should be done to follow the metabolic status of the patient. If a blood transfusion is required, washed or fresh packed red blood cells are preferred due to the small volume and the minimal amount of potassium present after washing. The blood should also be irradiated to minimize graft-versus-host reactions in an immunocompromised host.

The surgeons may request a higher than normal mean arterial pressure to ensure adequate perfusion of the new kidney. Whenever a new kidney is placed into a small recipient (<20 kg), it is possible that the aorta will be cross-clamped to perform the arterial anastomosis. When the aorta is subsequently unclamped, the blood pressure may decrease dramatically secondary to reduced afterload and the return of acidotic blood from the lower extremities. Furthermore, a large quantity of blood is diverted to the renal allograft, which will decrease the arterial blood pressure if the intravascular volume is inadequate. The anesthesiologist must be prepared to treat abrupt changes in arterial pressure with fluid and vasopressors. It must be remembered that these changes occur with patients who usually have baseline hypertension. Vascular thrombosis is a potential cause of graft failure in the smallest of recipients so the outcome may depend on the reperfusion management. After completion of the vascular anastomosis, mannitol and furosemide may be administered to facilitate diuresis.

The anesthesiologist will also be involved with the administration of immunosuppressant medications, antibiotics, diuretics, and other drugs during the operation. The surgeon or nephrologist should notify the anesthesiologist of the doses and timing of these medications. It is helpful to find out common side-effects of these drugs that may impact anesthetic management. Antilymphocyte antibodies include muromonab-CD3 (OKT3), alemtuzumab (Campath), antithymocyte globulin (Atgam), and antithymocyte globulin (thymoglobulin) (see Table 30.1). The infusion of these agents causes a cytokine response. This cytokine response can include fever, chills, rigors, and malaise that should be pretreated with acetaminophen, corticosteroids, and diphenhydramine [95,96]. Anti-interleukin-2 antibodies include basiliximab, and daclizumab. These medications do not cause a cytokine response. Side-effects from anti-interleukin-2 antibodies are comparable to placebo except for an acute hypersensitivity reaction that can occur with basiliximab [95].

At the end of the operation, a determination should be made whether the patient's trachea will be extubated. If so, residual neuromuscular blockade should be antagonized. Prolongation of the action of neuromuscular blockers is matched by prolongation of action of the reversal agents. The patient should be awake when the trachea is extubated. If there is evidence of pulmonary edema, or a relatively large kidney is placed into the abdomen of a small child, tracheal extubation can be delayed and the patient transported to a pediatric intensive care unit (ICU) and the patient's condition allowed to stabilize.

Postoperative pain control is most commonly achieved by the administration of intravenous opioids. Epidural analgesia can be used, but the association with possible hypotension has tended to limit its widespread use as well as the alterations in coagulation status of patients with ESRD.

KEY POINTS: ANESTHETIC MANAGEMENT DURING RENAL TRANSPLANTATION

- Close attention to the most recent dialysis and lab studies is crucially important
- Vascular access in older children usually can be accomplished with large-bore IV lines, while central and arterial access are reserved for special situations
- Avoiding drugs with extensive renal metabolism, maintaining high blood pressure and volume status for the transplanted kidney, and keeping current with immunosuppressant and antibiotic regimens are all important

Follow-up

Follow-up protocols vary by age and institution; techniques include renal ultrasound, MRI including diffusion-weighted imaging, creatinine clearance, and experimental urinary and blood biomarkers [97]. Ultrasound-guided renal biopsy is not routine in transplantation surveillance and is undertaken only if graft dysfunction is indicated. Rejection episodes are treated with increased doses of corticosteroids and other immunosuppressants. Surveillance for opportunistic infection and secondary malignancies including post-transplant lymphoproliferative disorder is important in renal transplant patients [58].

Heart transplantation

History

On 6 December 1967, just 3 days after Christian Barnard stunned the world with the first human heart transplant, the first pediatric heart transplant was performed in Brooklyn, New York, by Adrian Kantrowitz and associates [98]. The recipient was 17 days old with Ebstein's anomaly and the donor an anencephalic infant. The recipient only survived a few hours and died of apparent acute graft dysfunction [99]. Cyclosporine became available in 1978 and the first successful infant cardiac transplant was subsequently completed by Cooley and associates at the Texas Children's Hospital in 1984 [99,100]. The number of pediatric heart transplants worldwide increased throughout the 1980s and early 1990s to approximately 400 transplants annually and remained relatively constant up until 2009 [101]. The last decade, however, has seen a progressive increase in the number of transplants performed annually, with 684 reported in 2015 compared with 442 in 2004 [102].

Indications

Evidence-based indications for heart transplantation

The most recent evidence-based review of indications for pediatric heart transplant were published in 2007 following a working group assessment from the American Heart Association [103]. These indications incorporated the A–D pediatric heart failure staging system (Table 30.10) and are based mainly on consensus clinical opinions of experts (level C evidence) [103]. Class I indications (general agreement of usefulness and efficacy) include stage D heart failure in

Table 30.10 Heart failure staging in pediatric cardiac disease

Stage	Interpretation	Clinical example
A	At risk for developing heart failure	Congenital heart defects Family history of cardiomyopathy
B	Abnormal cardiac structure and/or function No symptoms of heart failure	Anthracycline exposure Univenticular hearts Asymptomatic cardiomyopathy Repaired congenital heart defects
C	Abnormal cardiac structure and/or function	Repaired and unrepaired congenital heart diseases
D	Past or present symptoms of heart failure Abnormal cardiac structure and/or function Continuous infusion of intravenous inotropes or prostaglandin E1 to maintain patency of a ductus arteriosus Mechanical ventilatory and/or mechanical circulatory support	Cardiomyopathies Same as stage C

Table 30.11 Evidence-based indications for pediatric heart transplantation

Indications	Level of evidence
Class I	
Stage D heart failure associated with systemic ventricular dysfunction in pediatric patients with cardiomyopathies or previously repaired/palliated CHD	B
Stage C heart failure associated with severe limitation of exercise and activity. If measurable, such patients would have a peak maximum oxygen consumption <50% predicted for age and sex	C
Stage C heart failure associated with systemic ventricular dysfunction in patients with cardiomyopathies or previously repaired/palliated CHD when heart failure is associated with significant growth failure attributable to the heart disease	B
Stage C heart failure in pediatric heart disease with associated near sudden death and/or life-threatening arrhythmias untreatable with medications or an implantable defibrillator	C
Stage C heart failure in pediatric restrictive cardiomyopathy disease associated with reactive pulmonary hypertension	C
Class IIA	
Stage C heart failure in pediatric heart disease associated with reactive pulmonary hypertension and a potential risk of developing fixed, irreversible elevation of pulmonary vascular resistance that could preclude orthotopic heart transplantation in the future	C
Certain anatomical and physiological conditions likely to worsen the natural history of CHD in infant patients with a functional single ventricle, which can lead to use of heart transplantation as primary therapy, including: (1) severe stenosis (stenoses) or atresia in proximal coronary arteries; (2) moderate to severe stenosis and/or insufficiency of the AV and/or systemic semilunar valve(s); and (3) severe ventricular dysfunction	C
Several anatomical and physiological conditions likely to worsen the natural history of previously repaired or palliated CHD in pediatric patients with stage C heart failure that may lead to consideration for heart transplantation without severe systemic ventricular dysfunction, including: (1) pulmonary hypertension and a potential risk of developing fixed, irreversible elevation of pulmonary vascular resistance that could preclude orthotopic heart transplantation in the future; (2) severe aortic or systemic AV valve insufficiency that is not considered amenable to surgical correction; (3) severe arterial oxygen desaturation (cyanosis) that is not considered amenable to surgical correction; and (4) persistent protein-losing enteropathy despite optimal medical/surgical therapy	C

patients with cardiomyopathies or congenital heart disease (CHD), stage C heart failure with severe growth/activity limitation or refractory life-threatening arrhythmias or restrictive cardiomyopathy with reversible pulmonary hypertension (Table 30.11) [104].

Contraindications to pediatric heart transplant (class III: risks outweigh the benefits) include previous infection with hepatitis B/C or human immunodeficiency virus (HIV), history of substance abuse, significant behavioral or cognitive disorders, history of non-compliance, poor family support structure, irreversible multisystem disease, fixed severely elevated pulmonary vascular resistance (PVR), or severe hypoplasia of the central branch pulmonary arteries or veins.

Indications for cardiac retransplantation (Table 30.12) in pediatrics are mainly based on non-randomized studies and registries (level B evidence) [104]. Contraindications for retransplantation include primary transplant within 6 months and ongoing acute allograft rejection.

Diagnostic indications for heart transplantation

Primary diagnosis is an important factor affecting post-transplant survival [102]. Diagnostic indications for pediatric heart transplantation (<18 years of age) are categorized into four major groups: congenital heart disease, dilated cardiomyopathy, retransplantation, and "other" (Table 30.13). CHD and dilated cardiomyopathy (DCM) are the most prevalent indications, contributing to over 80% of pediatric heart transplants [102]. Although the distribution of diagnoses has remained relatively constant over time, there are significant differences with age (Fig. 30.7) and geographical location (Fig. 30.8) [102]. In infants <1 year of age the most common indication for transplant is CHD (55%), whereas in the 11–17-year age group the most common diagnosis is DCM (54%). CHD is a more common indication in North America (42%) than in Europe (23%), whereas cardiomyopathies represent the majority of cases in Europe (59%) and other areas (71%). Figure 30.9 illustrates the frequency of transplant by age [102].

Dilated cardiomyopathies

Dilated cardiomyopathy accounts for over 50% of pediatric cardiomyopathies in the USA, with the majority being idiopathic in nature [104]. Other causes of pediatric cardiomyopathy include viral myocarditis, neuromuscular

Table 30.12 Evidence-based indications for pediatric heart retransplantation

Indications	Level of evidence
Class I	
In children with abnormal ventricular function and at least moderate graft vasculopathy	B
Class IIA	
Indicated in children with normal ventricular function and at least moderate graft vasculopathy	B

Table 30.13 Categorization of diagnosis for pediatric heart transplants

Category	Diagnoses in category
Congenital heart disease (CHD)	Congenital heart defect, HLHS uncorrected, with surgery, without surgery, previous surgery unknown, or valvular heart disease
Dilated cardiomyopathy (DCM)	Dilated myopathy due to adriamycin, alcohol, familial, idiopathic, myocarditis, post-partum, viral, or other reasons
Retransplant (RETX)	Retransplant due to acute rejection, chronic rejection, coronary artery diseases, hyperacute rejection, non-specific, primary failure, restrictive/constrictive causes, or other reasons
Other	Arrhythmogenic right ventricular dysplasia, cancer, coronary artery disease, myopathy-ischemia, hypertrophic cardiomyopathy, muscular dystrophy, reactive cardiomyopathy (any reason), or other cardiac disease

HLHS, hyperplastic left heart syndrome.

disease, and genetic causes. The overall unadjusted survival is better after transplant for DCM patients when compared with CHD or retransplant patients [102] and the post-transplant outcomes are reported to be better than for other forms of cardiomyopathies [102,104,105]. Patients with DCM have a relatively low wait-list mortality (11%) but mechanical ventilation and arrhythmias increases the risk of death whilst waiting [106].

Congenital heart disease

The CHD group represents a diverse group of diseases (Table 30.14) that may affect the perioperative and post-transplant course in different ways. Suitability for transplant takes into account degree of allosensitization, PVR, and hepatic reserves [107]. Approximately one-third of these patients are palliated single-ventricle patients [105] who may not have "heart failure" in the traditional sense of systolic dysfunction, and may be listed for transplant due to severe diastolic dysfunction or high PVR leading to high Fontan pressures, cyanosis, protein-losing enteropathy, ascites, and plastic bronchitis. There are emerging data to suggest that failing Fontan patients with preserved ventricular systolic function have more perturbed Fontan physiology and a higher cardiac transplant mortality than those with systolic dysfunction [108]. General indications for transplant in patients with CHD are listed in Box 30.4.

Retransplantation

Coronary artery vasculopathy is a chronic low-grade rejection phenomenon that results in gradual vascular occlusion and occurs in 11% and 17% of recipients at 5 years and 10 years, respectively, after transplant [90]. Coronary artery vasculopathy results in listing for retransplantation if ventricular function deteriorates, or significant dysrhythmias or heart block ensue. These patients usually do not experience angina because of the denervated state of the transplanted heart and are at risk for sudden death. Although cardiac retransplantation is uncommon, it is associated with increased mortality and morbidity [101,102].

Other

This group includes restrictive cardiomyopathies, hypertrophic cardiomyopathies, and arrhythmogenic right ventricular dysplasia. Hypertrophic cardiomyopathy only accounts for 5–6% of pediatric heart transplants and has a diverse spectrum of etiologies, including idiopathic, familial, and inborn errors of metabolism. Restrictive cardiomyopathies are uncommon, and are characterized by diastolic dysfunction with normal ventricular size and wall thickness and biatrial enlargement. These patients account for approximately 5% of cardiomyopathy transplants [103]. Historically, restrictive cardiomyopathy patients have a poor prognosis with a high incidence of pulmonary hypertension and sudden death, and are not amenable to other surgical or medical therapy. Given the natural progression of restrictive cardiomyopathy, early listing for heart transplant is recommended [104].

KEY POINTS: DIAGNOSTIC INDICATIONS FOR HEART TRANSPLANTATION

- CHD and DCM are the two main indications for pediatric heart transplant
- Primary diagnosis is an important factor affecting post-transplant survival
- Survival is better for DCM patients than for CHD, other forms of cardiomyopathies, and retransplantation

Box 30.4: General indications for heart transplanation in patients with congenital heart disease

- Patients with stage D heart failure refractory to medical therapy, who will not benefit significantly from surgical, interventional, or electrophysiological intervention
- Patients having congenital heart disease (CHD) with associated near-sudden death or life-threatening arrhythmias refractory to all therapeutic modalities
- Patients with stage C heart failure associated with reactive pulmonary hypertension and a potential risk of developing fixed, irreversible elevation of pulmonary vascular resistance that could preclude orthotopic heart transplantation in the future
- Stage C heart failure associated with systemic ventricular dysfunction in pediatrie patients with previously repaired or palliated CHD when heart failure is associated with significant growth failure attributable to the heart disease
- Pediatric patients with CHD with normal ventricular function when the following anatomical and physiological conditions are present and not amenable to surgical intervention:
  - Severe stenosis (stenoses) or atresia in proximal coronary arteries
  - Moderate to severe stenosis or insufficiency of the atrioventricular or systemic semilunar valve(s)
  - Symptomatic arterial oxygen desaturation (cyanosis) that is not considered amenable to surgical correction
  - Persistent protein-losing enteropathy despite optimal medical and surgical therapy

Pretransplant recipient selection and optimization

The decision to list a patient for cardiac transplant is made by a multidisciplinary group led by the medical transplant team, the patient's primary cardiologist, and the surgical transplant team. A formal structured evaluation focuses on four main areas [103]:

- Cardiovascular anatomy and hemodynamics
- Dysfunction in other organ systems
- Human leukocyte antigen (HLA) sensitization
- Psychosocial assessment of patient and family.

Cardiovascular anatomy and hemodynamics

Cardiac catheterization, often in conjunction with CT or MRI, is used to accurately delineate the patient's cardiac anatomy, an important consideration in patients who have been palliated for CHD. A critical hemodynamic parameter that needs to be assessed pretransplant listing is PVR. All patients with elevated PVR (>3 Woods unit (Wu) in biventricular patients or 2 Wu in single-ventricle patients) should have their PVR measured during cardiac catheterization at baseline and after administration of oxygen, inhaled nitric oxide, or other pulmonary vasodilators. Ideally PVR should be <6 Wu prior to transplant listing. More experienced centers may accept higher PVR values if it is reactive to vasodilator therapy. Patients with irreversibly elevated PVR may need to be considered for heterotopic heart transplant, or heart–lung transplant.

Dysfunction in other organ systems

The severity of dysfunction in other organ systems has an impact on post-transplant survival and outcomes, e.g. a need for renal dialysis at the time of transplant is a risk factor for 1-year mortality [102,109] and estimated glomerular filtration rate is a continuous risk factor for 1-, 5-, and 10-year mortality [102]. There is an increasing trend to treat irreversible moderate–severe renal dysfunction and end-stage heart failure with a combined heart–kidney transplant. Similar strategies of combined heart–liver transplant are being used in the presence of irreversible hepatic dysfunction.

HLA sensitization
